Chapter 127
Neuroendocrine Mechanisms of Change in Food Intake During Pregnancy

Alison J. Douglas

Keywords Hyperphagia • Hypothalamic resistance • Opioids • Oxytocin • Progesterone • Prolactin

Abbreviations

AgRP	Agouti-related protein
BNST	Bed nucleus of the stria terminalis
CART	Cocaine and Amphetamine-Related Transcript
CCK	Cholecystokinin
CG	Chorionic gonadotrophin
CL	Corpus luteum
CRH	Corticotrophin-releasing hormone
GABA	Gamma amino butyric acid
HPA	Hypothalamo-pituitary-adrenal
GI	Gastrointestinal
Icv	Intracerebroventricular
IGF-1	Insulin-like growth factor 1
Ip	Intraperitoneal
Iv	Intravenous
MC4R	Melanocortin receptor 4
MCH	Melanin concentrating hormone
αMSH	Alpha melanocyte stimulating hormone
mRNA	Messenger ribonucleic acid
NA	Not available
NTS	Nucleus of the solitary tract
NPY	Neuropeptide Y
POMC	Proopiomelanocortin
PVN	Paraventricular nucleus
PYY3-36	Pancreatic Peptide 3–36
SON	Supraoptic nucleus
VMN	Ventromedial nucleus of the hypothalamus

127.1 Introduction

Over the last 80 years, there appears to have been a biphasic research interest in control of food intake during pregnancy. Between the 1930s and 1960s, Edinburgh-based physiologists and biochemists Newton, Marrian, and Dewar asked questions about what controls weight gain during pregnancy (Dewar 2001). Then, after the explosion of research that identified a raft of interconnecting and integrating hypothalamic factors in the 1980s and 1990s, followed by the discovery of new gut and adipose hormones in the 1990s, as described in detail in other chapters, various laboratories worldwide, have pursued the questions in a new light. Pregnancy is a time of emerging and profound physiological and psychological change in the mother accompanied by high nutritional demand by the developing offspring, necessitating extensive maternal adaptations to provide the required sustenance. The earliest and most visible adaptation is hyperphagia. To this end, plasticity occurs body-wide throughout pregnancy, including in the synthesis and effects of brain, gut, and adipose peptides. Despite this, the initial conclusion – that progesterone, the main steroid hormone of pregnancy, plays a key role – remains valid. This chapter highlights the relationship between maternal weight and food intake, gives an overview of the changes in and roles of the key anorexic and orexigenic hypothalamic, gut and adipose peptides in driving the hyperphagia, considers how progesterone might drive increased appetite and addresses the consequences of under- and over-nutrition during pregnancy on the mother and her offspring.

127.2 Maternal Weight and Food Intake Relationship

Pregnancy precipitates a state of reversible hyperphagia, increased body weight and adiposity (Shirley 1984; Rocha et al. 2003). These changes provide for the metabolic demands of the developing young and their uterine environment, as well as other supporting maternal organs such as the heart, lungs, and kidneys. Equally importantly, preparations are made during pregnancy for birth and beyond. This includes extensive mammary gland remodeling and development in anticipation of milk production and, associated with this, huge increases in energy storage (fat deposition, positive energy balance), to provide the reserves required later in lactation (Hervey et al. 1967; Asarian and Geary 2006) which, contrary to pregnancy, is a state of negative energy balance.

The extent of increase in food intake usually depends upon the number of offspring gestating (Morgan and Winick 1981) and the species and is apparent through most of pregnancy. In women, food intake typically increases by only 10–15%, whereas in laboratory rats, it increased by as much as 60% in mid-late gestation according to some studies (overview in Douglas et al. 2007). However, the amount of food eaten does not simply mirror the body weight increase; intake per unit body weight is high in early-mid pregnancy but then declines in the last trimester pregnancy, even though the uterine contents still rapidly gain weight (fetus + placenta weight increases by more than tenfold at this time). This state of positive energy balance facilitates the deposition of energy stores into adipose tissue in anticipation of need not just in response to some signal relating to fetal size or demand. Therefore, it is important to analyze the hormonal and neuronal mechanisms underlying the dynamic regulation in food intake. Since rodent models have typically been used to investigate the adaptations underlying these overt behavior patterns, the evidence discussed below derives mostly from studies in rats and mice.

127.3 Hormonal Signals Mediating Increased Food Intake

As mentioned above, it has long been recognized that the increased secretion of progesterone correlates with and is ultimately responsible for increased food intake during pregnancy (Hervey et al. 1967; Asarian and Geary 2006). Progesterone secretion dramatically increases very early in pregnancy, firstly from the ovarian corpus luteum and then in some species the placenta takes over secretion partially or wholly. How progesterone causes increased food intake is not completely understood but several progesterone targets are likely to be involved, including the cells that are sensitive to peripheral appetite-regulating peptides (e.g., leptin and ghrelin), the hypothalamic neurons that make orexigenic and anorexigenic peptides, such as NPY/AGRP, alpha (α)MSH/CART, orexin A, and melanocortin, and other less obvious but equally important emerging factors such as oxytocin (see Chap. 20) and corticotrophin-releasing hormone (CRH). Firstly, the review will consider adaptations in these potential targets that may underlie the increased food intake in pregnancy before addressing the likely role of progesterone.

127.3.1 Peripheral Signals Regulating Food Intake in Pregnancy

Since food intake is regulated by the balance between hunger and satiety, it is useful to initially consider signaling factors from the periphery that mediate these opposite phagic states. The acute hunger signal mediated by ghrelin has not yet been well studied in pregnancy. Despite increased growth-hormone secretion in pregnancy, which might indicate increase ghrelin secretion and/or action, none of the published studies show major changes in ghrelin secretion. Therefore, ghrelin probably cannot account for the hyperphagia of pregnancy (Douglas et al. 2007; Messini et al. 2008). To date, no effect of progesterone on ghrelin has been reported, although, interestingly, ghrelin may influence progesterone secretion by directly inhibiting steroid biosynthesis (Viani et al. 2008). However, hypothalamic sensitivity to ghrelin is strongly influenced by nutritional status and hence some change in sensitivity is to be expected (Douglas et al. 2007; Fulglsang 2008).

More is understood about the gestational changes in the main satiety signal, leptin, and the consequences of its secretion. This is due to research that addressed the theory that pregnancy (a naturally reversible state of hyperphagia and adiposity) could provide a model for understanding onset and control of obesity and perhaps provide therapies. Leptin concentrations are robustly elevated throughout pregnancy, as in obesity. Therefore, since production is not suppressed, and leptin inhibits appetite, a change in leptin secretion does not account for increased food intake in pregnancy. Leptin receptor expression does not change (Rocha et al. 2003), but resistance to leptin at the hypothalamic level could explain increased appetite. Leptin resistance only develops during mid-late pregnancy (Douglas et al. 2007), so we have also argued that this cannot cause the initial increase in food intake, and primarily reflects the elevated leptin secretion of pregnancy that is a consequence of increased adiposity. Insulin is another important satiety signal from peripheral energy stores but, as for leptin, resistance develops during pregnancy, probably due to sex steroid effects via adiponectin secretion, which is also from adipose tissue (Leung et al. 2009). So, like leptin, there is no reason to believe that the emerging insulin resistance could be a cause of early hyperphagia (Douglas et al. 2007), although they could both be part of the elevated food intake patterns that are sustained in mid-late gestation. Thus, two key phases of hyperphagia in pregnancy should be recognized: initiation of increased food intake early in gestation, followed by an elevated appetite

through mid-late gestation. Most available evidence relates only to mechanisms in mid-late gestation, with sparse information on the induction of hyperphagia. Therefore, after discussion of mechanisms sustaining the elevated appetite, potential mechanisms emerging in the initial peri-implantation period will be addressed only briefly. Also, it is now recognized that pregnancy is not a good model for understanding obesity as it encompasses a much wider range of physiological changes that impact on feeding behavior, e.g., in sex steroid and novel placental hormones, and pregnancy hyperphagia arises with demand from specific reproduction-related signals that have a relatively short, defined natural lifespan.

127.3.2 Peripheral Signals Affecting Hypothalamic Appetite Control Centers

Ghrelin, leptin, and insulin all modulate neuronal activity, either directly or indirectly, depending upon multiple facets including access to the brain, receptiveness of neurons, and interaction with receptors/intracellular signaling mechanisms. As detailed in other chapters, the arcuate nucleus is considered the primary target for peripheral appetite signals, and comprises a complex network of phenotypically different but integrated neurons. These first order neurons express receptors for, and are profoundly influenced by all the above mentioned hormones. Little is known of changes in ghrelin or insulin effects in the arcuate hypothalamus in pregnancy, but leptin has been more extensively investigated. Leptin typically directly inhibits NPY orexigenic neurons and directly excites anorexigenic proopiomelanocortin (POMC)/αMSH neurons of the arcuate nucleus but, as indicated above, these first-order neurons develop leptin resistance in mid-pregnancy. Interestingly, it is not leptin alone that induces this, but the parallel increase in prolactin and placental lactogen (chorionic somatomammotrophin) secretion in pregnancy (Garcia et al. 2003; Douglas et al. 2007; Augustine et al. 2008) seems to be partly responsible. Other important peripheral factors include cholecystokinin (CCK) and PYY3-36 derived from the gastrointestinal tract. CCK acts via the gastric vagal nerve to stimulate brainstem noradrenergic, prolactin-releasing peptide, NPY, and POMC projections to the hypothalamus. It is thought they activate arcuate αMSH neurons and inhibit NPY neurons, leading to meal termination. Adaptations in CCK and PYY3-36 signaling in pregnancy are not well investigated but CCK signals are mediated in part by noradrenaline release and noradrenaline inputs to the hypothalamus are inhibited in the latter half of gestation, indicating that reduced satiety signals contribute to increased food intake at this time. Together these findings indicate a complex cascade of hormonal and neuronal adaptations that need to be considered together in relation to the sustained gestational hyperphagia (Fig. 127.1).

127.4 Adaptations in Orexigenic and Anorexigenic Neuropeptides During Pregnancy

Although there is a lack of evidence that altered peripheral hunger or satiety signals directly underlie increased appetite in pregnancy, changes in central neuronal mechanisms are emerging that enable a picture of responsible mechanisms to be constructed. These are reported for both first-order arcuate neurons as well as second-order hypothalamic neurons in the lateral hypothalamus and elsewhere.
Fig. 127.1 Peripheral factors changing through pregnancy that potentially impact on the maternal hypothalamic neurons to influence hyperphagia. Peripheral factors changing through pregnancy that potentially impact the arcuate nucleus, lateral hypothalamus, paraventricular nucleus, supraoptic nucleus, ventromedial nucleus, and dorsomedial nucleus in the maternal brain cause complex interconnected adaptations that lead to increased appetite. Key hormones are indicated from each source organ/tissue that change during pregnancy and could potentially impact on the hypothalamic control of food intake. *CL* corpus luteum, *GI* gastrointestinal, *CG* chorionic gonadotrophin, *CCK* cholecystokinin, *PYY* peptide YY3-36

127.4.1 First-Order Arcuate Nucleus Neurons

127.4.1.1 Orexigenic Neuropeptides

The best described orexigenic neuropeptide is NPY, but reports vary as to whether NPY expression in the arcuate nucleus or action within the appetite centers changes during pregnancy (Widmaier et al. 1997; Ajala et al. 2001; Garcia et al. 2003; Oberto et al. 2003; Rocha et al. 2003). Even if expression is increased, it may not relate to enhanced food intake since in the pregnant rat feeding responses to central NPY administration are similar to those in virgin females (Brunton et al. 2006). On the other hand, the expression of AgRP, a more long-acting orexigenic neuropeptide, is enhanced in pregnancy (Rocha et al. 2003), indicating a possible primary change underlying the prolonged adaptation in food intake. Since AgRP is co-expressed in NPY neurons that are inhibited by leptin,

Table 127.1 Reported changes in hypothalamic appetite peptides in mid-late pregnancy

+ melanocortin resistance

* POMC & Proenkephalin A in late pregnancy

** POMC in mid pregnancy

Summary of available data from the literature reporting mRNA and protein expression for appetite neuropeptides in the hypothalamus in mid-late pregnancy and any information about activity and/or effects of these neuropeptides in the context of feeding behavior or energy balance. Taken from the following references: Widmaier et al. (1997); Ajala et al. (2001); Garcia et al. (2003); Rocha et al. (2003); Oberta et al. (2003); Russell et al. (2003); Brunton et al. (2006); Sun et al. (2006); Douglas et al. (2007); Brunton et al. (2008); Augustine et al. (2008)

its increasing expression is possibly due to the emerging leptin resistance. Although neither this nor other functional aspects of AgRP in pregnancy have yet been reported, it could be that AgRP, as a first order neuropeptide, is important in maternal hyperphagia (Table 127.1).

127.4.1.2 Anorexigenic Neuropeptides

The contribution of one arcuate anorexigenic neuropeptide, CART, during pregnancy is unknown. However, expression of the αMSH precursor, POMC decreases in mid pregnancy, though it later increases again prior to birth (Russell et al. 2003), but only in a subset of POMC neurons. The synthesis and release of αMSH itself are not reported in pregnancy and may not parallel POMC expression since posttranslational processing is also sensitive to leptin. Interestingly, just as leptin and insulin resistance, melanocortin resistance also emerges (Ladyman et al. 2009), suggesting additional disruption of satiety signaling in second-order neurons. AgRP is an endogenous antagonist to αMSH, via the melanocortin 4 (MC4) receptor, so the increasing AgRP could explain melanocortin resistance and sustained hyperphagia in mid-late pregnancy. Although the identity of the likely αMSH/AgRP targets in pregnancy is unknown, they may be typical second-order neurons in the lateral hypothalamus and paraventricular nucleus (PVN), or in the supraoptic nucleus (SON), and

Table 127.2 Key features of paraventricular nucleus and supraoptic nucleus neurons in the hypothalamus

1. These groups of neurons are hypothalamic nuclei receiving innervation from multiple brain regions including the brainstem, mediating peripheral signals, the limbic system mediating emotions, and other hypothalamic nuclei that regulate multiple body functions such as reproduction, metabolism, and stress
2. The two regions are interconnected for some physiological functions, synchronization of neuron activity in the two nuclei is crucially important, e.g., birth, milk ejection

PVN

3. The PVN is an integrating nucleus, mediating converging inputs and coordinating outputs
4. The PVN encompasses subregions with distinct neuronal phenotypes – key neuropeptides include CRH, oxytocin, and vasopressin
5. CRH responds to the perception of stress from inputs from other brain regions and mediates a hormonal response that facilitates stress coping, mobilization of energy stores to enable the body to respond, and helps the return of homeostasis (i.e., to the nonstress state)
6. Oxytocin is synthesized in two populations of neurons, parvocellular and magnocellular in different subregions of the PVN. Parvocellular neurons project centrally to control physiological responses, e.g., appetite and sympathetic responses Magnocellular neurons project to the posterior pituitary and secrete hormone into the blood to control physiological functions like birth
7. Oxytocin is also released from magnocellular cell bodies into the extracellular space within the brain
8. Vasopressin is also synthesized in both parvocellular and magnocellular neurons of the PVN. Magnocellular neurons release vasopressin at the posterior pituitary into the blood to control body water balance and blood pressure. In the brain, vasopressin from parvocellular neurons helps to control daily rhythms and stress responses. It is also released from cell bodies into the extracellular space like oxytocin
9. At least part of the appetite function of arcuate nucleus peptides is via the PVN neurons

SON

10. The SON contains magnocellular neurons, ~50% are oxytocin neurons and ~50% vasopressin; they have similar functions to magnocellular neurons in the PVN
11. Despite similarities, the neurons in the PVN and SON can act differentially
12. SON neurons respond to many of the other brain appetite signals and may be important in mediating satiety/hunger effects on other behaviors

This table lists key facts of neuroendocrine neurons in the paraventricular nucleus (PVN) and supraoptic nucleus (SON); CRH- corticotrophin releasing hormone

Table 127.3 Key features of orexigenic and anorexigenic neuropeptides in increasing food intake in pregnancy

1. Although many brain factors increase food intake (are orexigens), only one called AgRP actually increases in pregnancy and might contribute to increased eating in pregnancy
2. Some brain factors that inhibit food intake (are anorexigens) are attenuated in pregnancy and so might contribute to increasing appetite
3. Oxytocin is a brain factor important for birth and lactation – it also typically inhibits food intake. Control of oxytocin adapts in pregnancy to decrease its function during gestation but increase its function at birth
4. The typical effect of oxytocin to inhibit food intake is lost in mid pregnancy
5. Brain factors stimulating oxytocin are inhibited in pregnancy – this includes other anorexigenic factors like alpha MSH – its effects in inhibiting food intake also become lost in pregnancy
6. Brain factors inhibiting oxytocin are increased in pregnancy – this includes AgRP
7. Evidence shows that increased appetite in pregnancy may be due to decreases in brain signals that usually inhibit eating

This table explains how changes in known adaptations of orexigenic and anorexigenic neuropeptides contribute to increased eating in pregnancy in rodent models

adaptations in some of these neurons have been extensively reported in the literature (Tables 127.2 and 127.3). POMC products also include βendorphin, an opioid peptide that, converse to αMSH, is orexigenic. βendorphin expression also increases in mid-late pregnancy in the arcuate nucleus, and is implicated in the adaptations of the PVN/SON neurons (Russell et al. 2003), so may be part of the network sustaining hyperphagia (Table 127.1).

127.4.2 Second-Order Hypothalamic Neurons

127.4.2.1 Lateral Hypothalamic Neurons

The orexigenic neuropeptides (melanin concentrating hormone (MCH) and orexin A) in neurons of the lateral hypothalamus are not well investigated during pregnancy. Reports indicate decreased rather than increased expression perinatally (Garcia et al. 2003; Sun et al. 2006) and, central administration of orexin A has the same effect on feeding behavior in virgin and pregnant rats (Brunton et al. 2008). So, these neuropeptides are not obvious candidates for increasing food intake. Therefore, other second-order neurons are potentially important. Indeed, pregnancy-related adaptations of PVN and SON neurons, particularly in CRH and oxytocin, are extensively reported (Russell et al. 2003; Table 127.1).

127.4.2.2 PVN and SON Neurons

The PVN and SON are extensively innervated by arcuate and lateral hypothalamus neurons, making them part of the hypothalamic appetite control network. CRH neurons in the PVN and oxytocin neurons in the PVN and SON play key roles in pregnancy and birth. CRH neurons mediate hypothalamo-pituitary-adrenal (HPA) axis responses to stress and anxiety and, to control stress coping and fetal glucocorticoid exposure, their responsiveness is strongly attenuated during mid-late gestation. Likewise, oxytocin neurons that drive birth and maternal behavior are powerfully restrained during pregnancy to preserve oxytocin stores and prepare neurons in advance for their new and unique patterns of activity then. These extensive adaptations throughout pregnancy might also contribute to maternal hyperphagia and some evidence supports this hypothesis. Although little is known about their role in feeding behaviors compared to the arcuate and lateral hypothalamic factors, these neuropeptides are anorexigenic. In early-mid pregnancy, CRH expression does not change or increases slightly, but by late pregnancy it decreases substantially (Brunton et al. 2008). This accompanies the profoundly attenuated responses to stress and is mediated in part by inhibition from opioids, which block signals from brainstem noradrenergic pathways. Interestingly, while feeding responses to administration of NPY or orexin A in late pregnancy are retained and not different from virgins, CRH and HPA axis responses to these appetite peptides in the same mothers are attenuated (Brunton et al. 2006, 2008). Also CRH responses to CCK are attenuated (Russell et al. 2003; Douglas 2005), overall indicating that CRH neurons no longer respond normally to central or peripheral hunger signals. If central CRH release and actions in the feeding circuit are similarly attenuated, it could be argued that lack of restraint by CRH would increase eating. However, direct effects of CRH on feeding behavior are generally poorly reported, let alone in pregnancy, so at present it is not easy to extrapolate to whether the inhibition of CRH neurons plays a role in the pregnancy hyperphagia.

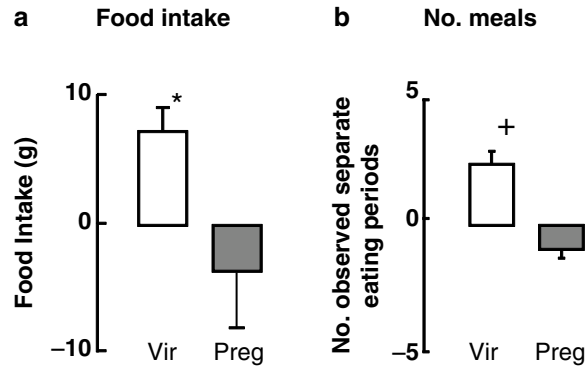
In parallel with CRH neurons, oxytocin neurons are also inhibited in mid-late pregnancy, and their responses to a variety of stimuli, including stress and feeding signals are attenuated. Such adaptations are extensively reviewed (e.g., Russell et al. 2003; Douglas et al. 2007) in the light of oxytocin's role in parturition and lactation, and include strong inhibition by opioids (Russell et al. 2003; Brunton et al. 2006), and GABA (Brussaard et al. 2000). Oxytocin is typically anorectic; the parvocellular oxytocin neurons acting via the brainstem nucleus tractus solitarius (NTS) are involved in the regulation of gastric reflexes and, in particular, parvocellular oxytocin neurons innervate NTS neurons that are activated by CCK during feeding. In late pregnancy, oxytocin responses to CCK are attenuated (Douglas 2005; Brunton et al. 2008) and brainstem noradrenergic pathways to the


Fig. 127.2 The anorexigenic effect of central oxytocin is lost in mid-late pregnancy. Effect of central oxytocin antagonist administration on food intake and eating behaviors. Rats were fitted with an icv cannula into the lateral cerebral ventricle under halothane anesthesia. Food was removed from the cages 24 h before experiment. On the day of experiment, during the light phase, virgin and 16-day pregnant rats were injected icv with either vehicle (artificial cerebrospinal fluid; 4 μL) or oxytocin antagonist (OTA; 10mg), and then given pre-weighed food. The food remaining was weighed after 24 h (a) and eating behavior was recorded every 1 min for 2 h (b). Data are from OTA–treated rats and represent the difference from vehicle-treated rats (mean ± SEM, n = 5–14). Oxytocin antagonist increases food intake and number of meals in virgin but not in pregnant rats. (**a**) Food intake in 24 h: 2-way ANOVA $p < 0.001$, *$p < 0.05$ versus vehicle. (**b**) Number of meals in 2 h: 2 way ANOVA across group for $p < 0.01$; +$p< = 0.05$ versus vehicle (Adapted from information in Douglas et al. 2007 review)

hypothalamus are inhibited (Douglas 2005). Direct actions by NPY are also possible: SON and PVN neurons express NPY receptors, and NPY increases oxytocin neuron activity and secretion (Broberger et al. 1999; Yokosuka et al. 2001; Brunton et al. 2006; Goldstone 2006; Morin and Gehlert 2006). However, oxytocin neurons respond less to NPY in late pregnancy (Brunton et al. 2006) so, like CRH, lack of oxytocin could partly underlie maternal hyperphagia. Recently it has been shown that αMSH also stimulates oxytocin neurons and they densely express MC4 receptors (see also Chap. 20; Douglas et al. 2007) – if resistance to this anorexigen is present in oxytocin neurons it probably also contributes to hyperphagia mechanisms at this time. AgRP inhibits oxytocin neuron responses to ingestive behavior (Wirth et al. 2002), supporting the notion that increased AgRP promotes melanocortin resistance in oxytocin neurons in mid-late pregnancy. Oxytocin also plays a role in the ventromedial nucleus in controlling food intake, and the leptin resistance described above is at least partly located within this nucleus (Ladyman et al. 2009). The role of oxytocin in feeding in mid pregnancy has been investigated using a pharmacological approach (Fig. 127.2; Douglas et al. 2007), and shows that the expected increase in feeding after central oxytocin receptor antagonist administration is lost compared to virgins. This strongly indicates that anorexigenic neuropeptides, including oxytocin, play an attenuated role in the control of feeding in gestation. Other hunger signals such as leptin and prolactin are also likely components since oxytocin neurons express leptin and prolactin receptors and prolactin inhibits oxytocin neurons (Grattan and Kokay 2008); but their combined role in pregnancy is not yet investigated in terms of feeding behavior (Table 127.1).

127.4.2.3 The Potential Role of Opioids

As mentioned above, hypothalamic opioids increase appetite. Since opioid expression is increased in various brain regions and opioids strongly inhibit CRH and oxytocin in the second half of gestation, the question of whether they play a role in the maternal hyperphagia has also been asked. However,

using the general opioid antagonist, naloxone, a similar decrease in food intake in mid-pregnant and virgin rats was observed (Douglas et al. 2007). Accordingly, the strong opioid inhibition of oxytocin and CRH neurons seems not to play a role and another factor must be the key. As AgRP seems to act in parallel with opioids (Wirth et al. 2002), perhaps adaptations in AgRP/αMSH control of oxytocin neurons are responsible for appetite changes while opioid control of oxytocin neurons is responsible for control of birth-related changes. Which neuronal subpopulations these might encompass is not clear since both the parvocellular and magnocellular neurons respond to multiple and overlapping factors.

127.5 The Role of Progesterone

During pregnancy, there is a close relationship between progesterone secretion, food intake, and extra-uterine body weight. Pseudopregnancy induces the same steroid secretory patterns as pregnancy and gives rise to the same hyperphagia. Progesterone treatment induces similar changes in virgin rodents, and upon cessation of progesterone treatment, and there is a rapid rebound decrease in food intake and body weight (Hervey et al. 1967; Dewar 2001; Asarian and Geary 2006). So, how can progesterone interact with the appetite control system to effect such important adaptations? Progesterone readily crosses the blood brain barrier and can act either via its cognate receptor or by conversion to its neuroactive steroid metabolite, allopregnanolone. Clearly, hypothalamic areas that express progesterone receptors are prime candidates as causal mediators of physiological adaptations to pregnancy, and it is noteworthy that arcuate neurons expresses them in abundance. Progesterone receptor expression in the arcuate nucleus decreases mid-gestation, before increasing again toward birth (Steyn et al. 2007), possibly indicating a shift in the subpopulation phenotype susceptible to progesterone. While both NPY (Dufourny et al. 2005) and βendorphin neurons are reported to express progesterone receptors (Fox et al. 1990), their co-localization with AgRP, αMSH, or CART is uncertain from the literature. Whether progesterone has positive effects on NPY synthesis or secretion, or the co-expressed AgRP is not reported to our knowledge. Progesterone is a recognized driver of POMC expression (Hammer et al. 1994), which changes through the estrous cycle and pregnancy (Russell et al. 2003) so, potentially, the rising progesterone secretion through gestation could impact on βendorphin effects. However, if opioids are not responsible for increased food intake in mid-pregnancy (as argued above), then progesterone effects might be via αMSH or CART. As well as possible direct effects on arcuate neurons, progesterone could influence their function indirectly by altering dopamine, and therefore prolactin, secretion (Steyn et al. 2007), which mediates the leptin and melanocortin resistance described above.

Some of the second-order appetite neurons do not robustly express progesterone receptor, notably CRH and oxytocin neurons in the PVN and SON (Fox et al. 1990; Russell et al. 2003), and expression is not induced during gestation (Francis et al. 2002). Nevertheless, these neurons are strongly influenced by sex steroids; for example, oxytocin neurons are strongly inhibited by progesterone, probably via induction of inhibitory opioid tone (Russell et al. 2003). Much evidence now indicates that progesterone effects on CRH and oxytocin neurons are indirect via allopregnanolone. This neurosteroid is generated in the liver and brain during pregnancy and is a primary cause of the attenuated HPA axis responses to stress (Brunton et al. 2008, 2009). Allopregnanolone acts by binding to membrane receptors: when it binds to $GABA_A$ receptors it enhances GABA signaling, and could affect GABA input to CRH neurons from peri-PVN, NTS, or bed nucleus of the stria terminalis (BNST) neurons. Allopregnanolone also increases opioid expression in this model (Brunton et al. 2009) so may additionally act directly on arcuate or brainstem opioid neurons.

Similarly, allopregnanolone directly enhances GABA inhibition of oxytocin neurons, and contributes to their adaptations during gestation (Brussaard et al. 2000), as well as being partly responsible
Fig. 127.3 Relationship between progesterone, food intake, and inhibition of oxytocin neurons. As progesterone (and allopregnanolone) concentration—increases so does food intake ⋯⋯ and body weight in the pregnant rat. Progesterone and allopregnanolone inhibit oxytocin neurons strongly from ~mid-gestation (*shading*), probably via GABA signalling and opioids, which then declines toward birth as progesterone secretion reduces (Interpretation and integration of information from Brussaard et al. 2000; Russell et al. 2003; Brunton et al. 2006; Douglas et al. 2007)

for the attenuation of oxytocin responses to stress perinatally (Russell and Brunton 2006). This may be important also in the context of maternal hyperphagia, so could inhibit oxytocin anorexigenic effects by controlling the activity of oxytocin neurons and the amount of oxytocin release and action at its target regions. Such an action on oxytocin neurons is more likely than on oxytocin targets, since oxytocin receptor expression is evidently not dependent on progesterone in pregnancy (Young et al. 1997; Bealer et al. 2006). Toward the end of gestation, the allopregnanolone influence on oxytocin neurons decreases in parallel with the decreasing progesterone secretion and decreasing food intake just prior to birth, and enabling the neurons to respond appropriately to the relevant birth stimuli (Russell et al. 2003). Progesterone control of oxytocin neurons is further illustrated by studies revealing that progesterone administration pre-birth maintains the inhibition of oxytocin neurons and delays delivery (Russell et al. 2003). Therefore, progesterone action via allopregnanolone is a prime candidate mechanism by which food intake increases and is maintained throughout the pregnancy period (Fig. 127.3).

Whether a neurosteroid mechanism contributes to the control of arcuate neurons in addition to direct progesterone receptor-mediated effects in pregnancy is unclear. Also direct investigation of the role of allopregnanolone in maternal hyperphagia has not been reported. There is a limited amount of information that can explain the precise role of progesterone in controlling food intake in pregnancy, but some potential mechanisms are emerging to add to the complex picture.

127.6 Initiation of Increased Food Intake in Early Pregnancy

At this stage, it is not clear what, if anything, can be specifically said about the mechanisms underlying the induction of maternal hyperphagia. All the above systems seem to adapt later, in mid-late pregnancy after food intake has already increased, including peripheral signals, increased orexigenic and decreased anorexigenic factors. Certainly progesterone and prolactin/placental lactogen secretion increase immediately, but what their early brain targets are is not known. Data from the late estrous cycle (or pseudopregnancy), when food intake also increases in parallel with increasing progesterone secretion, might be informative. Factors such as serotonin (Steffens et al. 2008), IGF-1

(Todd et al. 2007), and nitric oxide (Otukonyong et al. 2000) are all candidates as rapid responders to sex steroids. However, responses to other immediate pregnancy factors, including from the decidua and developing placenta such as cytokines and chorionic gonadotrophins, remain to be investigated.

127.7 Applications to Other Areas of Health and Disease

As mentioned above, there was initially some speculation that understanding the mechanisms behind changes in food intake during pregnancy, and particularly their reversibility after pregnancy, would give insight into mechanisms and treatment of obesity. This is not likely to transpire due to the entirely different physiological paradigms, but better understanding of the mechanisms of maternal hyperphagia may impact on other areas of health and disease. Gestational diabetes is one maternal condition that can emerge in pregnancy and have an impact on future maternal and offspring health due to over-nutrition and macrosomia. This can be a consequence of maternal overnutrition and potentially leads to the serious condition of preeclampsia later in gestation. Additionally, overnutrition in pregnancy correlates with offspring obesity later in life (Beall et al. 2004; Muhlhausler 2007; Grattan and Kokay 2008; Kirk et al. 2009). This is related to the topical issue of fetal/neonatal programming, whereby conditions experienced in the womb or early in life negatively impact on health in later life. Thus, maternal obesity provides some type of metabolic programming to the child and increases the likelihood of their obesity.

Importantly, under-nutrition during pregnancy also negatively affects offspring development and health. Under-nutrition decreases litter size and weights (Wade and Schneider 1992; Langley-Evans et al. 2005; Martin-Gronert and Ozanne 2006), and low birth weight is correlated to neurological disorders and cardiovascular disease risk later in life (El Haddad et al. 2003; Franke et al. 2005; Seckl and Meaney 2006). This may occur via developmental anomalies since, for example, a low protein diet in the early stages of gestation, peri-implantation, leads to altered microanatomy (Watkins and Fleming 2009). Furthermore, such programming increases likelihood of other adverse conditions such as decreased somatic growth, and increased risk of diabetes, cardiovascular disease, depression, and anxiety (Leonhardt et al. 2002; Lesage et al. 2004). Evidently, more research is required to further clarify the underlying mechanisms of maternal eating behavior in early pregnancy and how is it affected by conditions such as infection, stress, and obesity. Only then will there be enough knowledge to provide a valid basis for effective advice to the mother (or for women planning a pregnancy) on their optimal eating patterns to avoid a range of adverse maternal and fetal/offspring consequences.

Summary Points

- Progesterone, from the corpus luteum and subsequently the placenta, underlies the increased food intake in gestation, but there is no clear evidence about what mechanisms progesterone acts through to increase food intake.
- The brain mechanisms that mediate the induction of increased food intake in early gestation are not known.
- In mid-late pregnancy hyperphagia is maintained via a cascade of complex, interacting, peripheral and central factors controlling appetite.
- Hypothalamic leptin resistance emerges, located at least partly in the ventromedial hypothalamus but also in the arcuate nucleus.

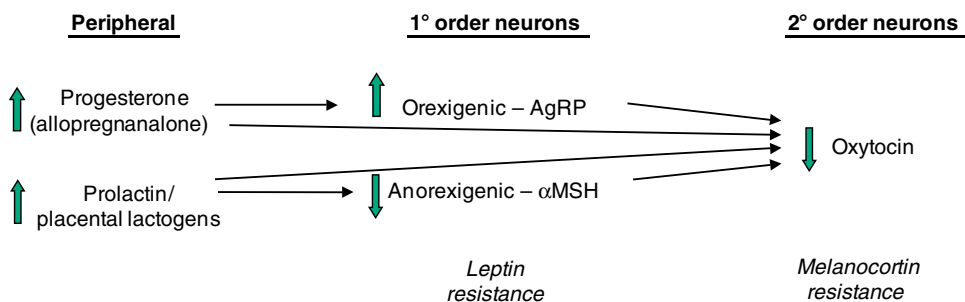
- Arcuate orexigenic neuropeptides may increase, including NPY and AgRP.
- In second-order neurons, anorexigenic neuropeptides are inhibited, e.g., CRH and oxytocin.
- The anorexigenic responses to central oxytocin are lost in pregnancy.
- We suggest a model explaining sustained maternal hyperphagia: progesterone (and/or) prolactin (placental lactogen) induce melanocortin resistance on oxytocin neurons, via AgRP inhibition, leading to loss of oxytocin-mediated satiety signaling, which may increase meal size/number and contribute to increased food intake in mid-late gestation. (Fig. 127.4).


Fig. 127.4 Model for potential pathways sustaining increased food intake in mid-late gestation. Based on evidence in the literature we can suggest a model for neuroendocrine adaptations that explains sustained maternal hyperphagia. (1) Progesterone acts on NPY/AgRP neurons to increase AgRP expression and on POMC neurons to decrease αMSH expression. (2) AgRP inhibits oxytocin neurons and also antagonizes αMSH effects at MC4 receptors, which are expressed in oxytocin neurons; this may induce melanocortin resistance in oxytocin neurons. (3) Simultaneously (and possibly in synergy with progesterone), prolactin/placental lactogens induce leptin resistance and melanocortin resistance which is located in arcuate, oxytocin and/or ventromedial hypothalamus (VMH) neurons. (4) Progesterone also inhibits oxytocin neurons via allopregnanolone enhancement of GABA and opioid signalling. (5) Prolactin further inhibits oxytocin neurons directly. (6) Oxytocin neurons are robustly inhibited over mid-late gestation and anorexigenic effects of oxytocin are strongly attenuated. Thus, this integrated cascade of adaptations in neuroendocrine systems could help explain maternal hyperphagia

---

Definitions

Adipose: It is a tissue making fat, located mainly under the skin and in the abdomen – adiposity = fatness.

Anterior pituitary gland: It is a gland at the base of the brain containing multiple cell types secreting multiple hormones under the control of neuroendocrine factors from the hypothalamus.

Central: It refers to the location of neurons or targets within the central nervous system, and may signify the exogenous administration of drugs, e.g., by the intracerebroventricular route.

Decidua: It refers to the modified region of the maternal uterine endometrium that is the immediate region opposing the placenta and provides part of the barrier between mother and offspring, and also secretes local and circulating hormonal factors.

Hypothalamus: It refers to a complex brain area that regulates many important homeostatic neuroendocrine functions; different regions of the hypothalamus regulate, among many things: hunger, reproduction, stress responses, metabolism, growth, and release of hormones from many glands, especially the pituitary gland.

Hypothalamo-pituitary-adrenal axis: It is a system comprising three anatomical elements that respond to and drive responses to stress, ultimately secreting glucocorticoid hormones that aid stress coping and return of homeostasis.

Magnocellular neuron: It is a large neuroendocrine neuron of the supraoptic nuclei and para-ventricular nuclei of the hypothalamus that projects to the posterior pituitary gland.

Maternal hyperphagia: It refers to sustained increase in food intake throughout gestation.

Negative energy balance: It refers to the condition when the mother utilizes more energy than she is consuming, e.g., in lactation, due to transfer of energy store to offspring in milk.

Neuroendocrine hormones: These are hormones produced by neurons that either: (1) are secreted from the posterior pituitary into the peripheral blood circulation to directly target organs or into the hypophysial portal blood to control the secretion of anterior pituitary hormones, or (2) are released from centrally projecting axon terminals to influence neurons in other central nervous system subregions.

Neuronal network: It is a group of interconnecting and integrating neurons that communicate by physical connections via their axons or by nonphysical connections by responding as a group to an autocrine or paracrine signal, and coordinate a behavior or physiological outcome.

Neurosteroid: It refers to a steroid metabolite with distinct physiological actions that is generated within the brain from other steroids.

Parvocellular neuron: It is a centrally projecting neuron of the paraventricular nucleus.

Pharmacological experiments: It refers to the exogenous administration of drugs to test endogenous mechanisms.

Placenta: It is a fetal–maternal interface constructed from fetal membranes and/or trophoblast, which provides a barrier between mother and offspring but also is the means to provide nutrition and waste disposal as well as hormonal communication.

Positive energy balance: It is a condition when the mother consumes more energy than she is expending, e.g., in pregnancy, even though the developing embryo/fetus has high energy demands.

Chapter 128
Effect of Pregnancy and Consciousness Factors on Food-Related Behavior

J. K. Chun, S. W. Lim, and W. I. Cho

Abbreviations

5-CL	5th consciousness layer, numerical number refers to relevant consciousness layer: 6-CL, 7-CL, and 8-CL, 6th, 7th, and 8th consciousness layer, respectively
CS-Q	Cognitive sensory questionnaire
EG	Emesis gravidarum
FRL	Food-related lifestyles
MDS	Multidimensional scaling
PN	Women who had never been pregnant
PY	Women who had been pregnant
3-WBT	Three-way branch transformation

128.1 Introduction

One noticeable change in the food habits of pregnant women is loss of appetite, often referred to as morning sickness, emesis gravidarum (EG), experienced by a majority of pregnant women (Bowen 1992; Ortega 2001; Lim et al. 2008). This particular food behavior of pregnant women has been accepted as physiological phenomenon that occurs in the early stages of pregnancy and disappears as the pregnancy advances. However, the change in food habits and appetite are not merely a physiological one but also involves a significant change in the food evaluation process, which occurs in individual mind system and affects food choice motivation and food consumption.

The decision-making process underlying food choices, including perceptions about food products, has been studied for decades (Glanz et al. 1992; Shepherd and Raats 2006). Food evaluations have been conducted by panelists with respect to the sense of taste, the odor, and the kinesthetic experience of fresh and processed foods. Because the sensory judgment is subjective, the variability of the sensory data among panelists is an inherent problem.

Since Fechner (1866) noted the importance of the mind for sensory science, and Thurstone (1927) proposed a psychometric function involving psychological magnitude or perception, and his

e-mail: wanilcho@gmail.com

proposal has played a major role in the theoretical development of sensory science (Ennis 1998). Although studies have focused on establishing a scale for perceptual intensity, to establish the relationship between sensory response and external stimuli, the perception mechanism is not yet fully understood (Wells 1998; Eliasmith and Thargard 2001).

Determinants of food choices have been categorized into food and nonfood factors (Rozin and Tuorila 1993, Eertmans et al. 2001). Nonfood factors include personal preferences such as dislikes and preferences, demographic variables, food-centeredness, and psychological and physiological needs and traits. The relationship between food choice and cognitive and motivational factors has been investigated by many researchers and has been related to biological, psychological, cultural, economic, and social factors (Cosper and Wakefield 1975; Bell et al. 1981; Lau et al. 1984; Michela and Contento 1986; Rappoport et al. 1992; Furst et al. 1996: Meiselman 1996).

Glassman (2000) and Kunde et al. (2003) insisted that unconscious factors play important roles in perceptions and frames of reference related to food choices. Ashby and Lee (1991), and Ennis (1998) demonstrated that human consciousness factors and nonsensory components were closely related to the process by which food is evaluated. Accordingly, food choice has been recognized as a process involving the events and experiences that occur throughout life (Furst et al. 1996). Because food choice is a particular human behavior, general behavioral theory has been applied to food-related behavior (Ajzen and Fishbein 1975) in that behavior is closely associated with lifestyle.

The lifestyle concept is rooted in models of cognition and behavior regulations that derive from psychology (Cohen 2000), and research on food-related lifestyles (FRL) has been widely conducted (Brunsø and Grunert 1995).

The FRL questionnaire is comprised of 69 items measuring 23 dimensions of lifestyle in five major domains of life, including: shopping, cooking, issues of quality, consumption situations, and purchasing motivations. This instrument was based on a hierarchical formulation of cognitive structure (Grunert and Grunert 1995). At the highest level of the hierarchy, personal values are defined as abstract and trans-situationally aggregated cognitive categories. At the lowest level, product perceptions are defined as situation-specific input into a categorization process. Scholderer et al. (2002) and Brunsø et al. (2003) have elaborated this basic theory in a dual-process framework.

128.2 A Consciousness-Oriented Approach to Food-Related Behavior

128.2.1 Vasubandhu's Consciousness-Only Structure

A similar hierarchical structure to that of Scholderer (2002) had been developed by Vasubandhu (ad 400), an Indian Buddhist scholar–monk. This structure has been popularized in non-Western contexts as a consciousness-only theory (Anacker 1984). Vasubandhu described the human mind in greater detail than did Western scholars and his classification system includes relevant causes of numerous mind states such as desire, attachment, like, dislike, and so on. He argued that humans operate within a multilayered hierarchical structure of consciousness consisting of eight layers of consciousness; three layers operate at higher levels and five sensual layers operate at lower levels. This structure is characterized by dual top-bottom consciousness streams, as schematically presented in Fig. 128.1.

People in Asian countries including India, Thailand, Vietnam, Cambodia, China, Korea, and Japan have been influenced by this conceptual framework. If appetite represents an actual desire for food, loss of appetite is based in consciousness. In this context, Chun (2002) proposed a concept
Fig. 128.1 Vasubandhu's multilayer consciousness structure (Cited in Chun 2002. With permission)

related to cognitive sensory evaluation that defined the multilayered hierarchy such that the fifth layer of consciousness (5-CL) represented the process by which the attributes of observable or sensate objects are known via the five organs of sensorial consciousness (eye, nose, tongue, ear, and skin). This framework is essentially the same as the five sensory or lower levels of the hierarchy presented in the Western conceptualization of cognitive structure (Brunsø and Grunert 1995; Cohen 2000).

The sixth consciousness layer (6-CL) is a post-sensory manager controlling the process by which meaningful information is perceived and classified; it is also comparable to the structure proposed by Rosch et al. (1976) in that it belongs to a superordinate level that organizes memories into packets that function as the basic units for categorization.

The characteristics of the multilayered structure can be understood in terms of two layers, the seventh layer of consciousness (7-CL) and the eighth layer of consciousness (8-CL), which can be considered to constitute unconsciousness in general.

The 7-CL, defined as egocentric or Manas consciousness (Anacker 1984), evaluates objects subjectively on the basis of accumulated information stored in memory. It is relevant to Karma (Anacker 1984) and represents the individual personality acting and making decisions based on personal experiences that are referenced from long-term memory (Lim et al. 2008). Personal values derive from 7-CL, which can be considered to be equivalent to the highest level in the Western conceptualization of a cognitive hierarchical structure. Egotism, including ego-image, ego-esteem, and ego-threat are developed in this layer.

The 8-CL, the ultimate level, controls the overall mental process by which homeostasis is maintained and stores abstract information, functioning as a back-up file that can be transmitted to the next generation. Thus, no thought is directly associated with this layer; rather, it represents a seed associated with the genetic code known as Karma, the habitual tendencies produced by past actions (Anacker 1984).

In short, the mind is considered to be a special type of sense, which suggests that humans have additional senses inside the mind.

128.2.2 Perception in the Consciousness

The perspective that the mind is composed of multilayered consciousness or multiple senses suggests the existence of multiple stages of perception or interperception. Chun (2002) claimed that incoming stimuli sensed by 5-CL from objects in the external world are transferred into 6-CL via passive acquisition. Thereafter, active transformations across 6-CL and 7-CL occur. As long as the egoistic 7-CL is involved, every perception process follows a three-way branch transformation (3-WBT) logic to one of three options: good, bad, or neutral, as defined by the point of view of the perceiver. After repeated

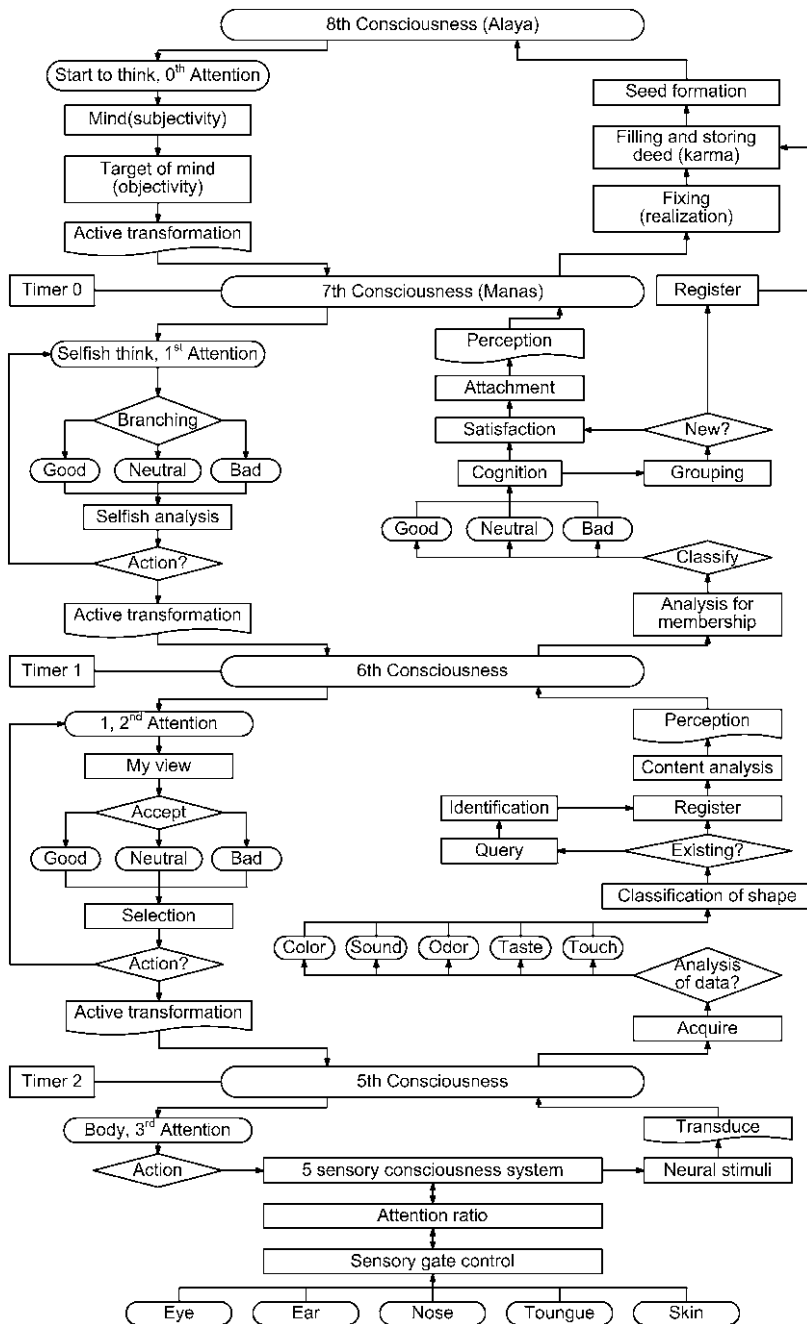
transformations, the good option will be recognized as the best when interperception among the internal mental layers or senses favor this option. Therefore, any judgment about the taste of food results from data processing or conditioning occurring across the multilayered structure, while memories of food and associated images are stored and used as the references for the next session of 3-WBT.


Fig. 128.2 Dual path flow according to the multilayered consciousness concept. Timer 0 through 3 refers to the time units undergoing consciousness processes in 7-CL, 6-CL, and 5-CL, respectively (Cited and revised in Chun 2002)

Key Points

Key points in the consciousness flow chart

1. Consciousness flow refers to human mental activity working across conscious and unconscious states.
2. Consciousness is considered to be a multilayered componential structure.
3. The 5th consciousness layer (5-CL) is the lowest or bottom layer, and 8-CL is considered to be the highest or top level of the mind.
4. The stimuli sensed from external objects are acquired and perceived by upper CLs and interpreted in favor of the self or 7-CL.
5. Food-related behaviors, such as food choices and rates of consumption, are determined by the ego-centric consciousness, 7-CL.

Chun (2002) schematically illustrated how the system of consciousness interfaces with the external world and generates motivation in the internal world using different time units for action (see Fig. 128.2).

Many studies have demonstrated that people automatically evaluate all stimuli (social and nonsocial objects and events) as either good or bad (Fazio et al. 1986; Bargh et al. 1996). Thus, any food-related behavior might be regarded as the outcome of the flow of consciousness through 7-CL as transformed by 3-WBT.

128.3 A Consciousness-Oriented Approach to Pregnancy

128.3.1 Two Subjects in One Food Supplier

Pregnant women experience various phenomenal changes with regard to food appetite caused by underlying psychological changes as well as changes in the environment, including such external and internal phenomena as physiological programming. Thus, anything that occurs in 5-CL and 6-CL might represent an environment for the self or 7-CL.

Key Points

Key points of the two-ego consciousness system

1. Pregnancy is a typical state of consciousness in which two selves, mother and fetus, reside in one physical food-supply system.
2. Loss of appetite might be caused by conflict between the different food habits of the two egos.
3. EG decreases or disappears as pregnancy advances due to negotiation and compromise between the two selves.
4. EG can be understood as a valuable insight into the world of consciousness, which is the origin of various food-related behaviors.

There is no doubt that pregnancy represents the beginning of the emergence of life, starting with a single cell that grows into an entire body characterized by an increasingly complex neuronal system for controlling this body. During this period, nutrients are supplied through the mother's digestion system for two purposes: to support the mother and fetus; and to support the construction of the new neural network, which progresses outside of the consciousness of the mother. In the absence of an adequate neuronal system, the fetus may share the mother's communications network.

This situation of "two subjects in one food supplier" strongly implies that a mind resides in the fertilized cell and participates in controlling the entire life course, including food consumption. Indeed, it would be difficult to assert that mother and fetus have identical minds; thus, the newcomer must have arrived with its own genetic codes, containing its history or Karma, encoded in 8-CL. That the genetic record emerging from previous generations affects the mother's food-related behaviors, including those involved in EG during pregnancy, is strongly suggested.

128.3.2 Intersubjective Communication

As long as two egoistic subjects (two 7-CLs) reside in one physical body, it is important to understand how they communicate with each other, particularly in a physical context in which only one food consumption system operates. In this framework, ultimate consciousness, 8-CL, emerges as an intersubjective capability enabling communication between the minds.

Without this assumption, we would confront questions such as: Do the two selves relate as master and slave? If so, food choice and acceptance would be decided by the mother and problems such as EG would not occur. If not, conflict deriving from the situations of the egoistic selves would ensue. Does each self have an independent consciousness? If so, how do they communicate without a terminal device to reach agreement and compromise during the early phase of neural networking? Food choice constitutes good example of how the thinking and communication of the two subjects develop.

Two contradictory facts are generally acknowledged: that the food-related behaviors of children are affected by their parents, and that the food preferences of brothers and sisters are different. These phenomena imply that genetic and familial factors contribute to attitudes toward food during pregnancy but questions about causation remain. Along these lines, pregnancy may be considered to constitute an important, particular, or boundary condition for the purpose of developing a general understanding of how the relevant components of consciousness are activated in the process of forming an ego. It might be presumed that a certain component or layer of consciousness remains latent until a critical moment arrives, and pregnancy might constitute one such critical moment.

128.4 Methodological Considerations

128.4.1 Categorization of Food and Nonfood Issues

The involvement of factors related to consciousness in food choices means that evaluations of the process by which food is selected should address conscious and unconscious issues, as previously described. In order to apply the concept of multilayered consciousness to the evaluation process, Chun (2002) classified food and nonfood issues into two categories: objective and subjective issues that pertain to the elements of consciousness as defined in Table 128.1.

Table 128.1 Food- and nonfood-related issues in the cognitive sensory evaluation of food(Cited in Chun 2002. With permission)

Issues	Component	Contents
Objective issue	Environment	Brightness, temperature, humidity, audio-factor, visual-factor
	Product property	Taste, flavor, shape, color, chewing sound, texture
Subjective issue	5-CL	Gender, age, weight, height, hunger, health (eye, ear, nose, tongue, mouth, stomach), sensitivity of sense organs, smoking, and preference associated with five senses
	6-CL	Schema, effect of schema, knowledge of product information, family education, education, concentration
	7-CL	Age of first eat, frequency of eating, cooking experience, ability of association, direction of association, preference of family, hobby, first impression, demand of unconsciousness state, ideology, feeling after eating, faith, rationality, religious teaching, frequency of dreaming, similarity of eating habit
	8-CL	Eating while pregnant, given digestibility, willingness, awareness of mind, frequency of meditation

The objective category primarily includes those attributes of food addressed by food sensory science (Meilgaard et al. 2006); the subjective category also includes certain data that can be measured with conventional sensory tests as well as lifestyle, personality, and other issues outside the domain of sensory scientists and within 7-CL and 8-CL. In order to clarify the psychological reactions that affect food choice and acceptance, it is necessary to understand how food-related stimuli are cognitively merged into the stream of consciousness.

128.4.2 Cognitive Sensory Evaluation Using the CS-Q Questionnaire

In this context, a novel methodology is necessary to account for multiple stimuli entering via the five senses, for the internal world, or layers of consciousness, as well as for a concept of time. The content and methodology of the cognitive sensory questionnaire (CS-Q) were developed by Chun (2002), and the response of the survey was presented by cognitive sensory barcodes and cognitive sensory frequencies to be described later in the Application section.

The CS-Q was designed to address all items defined in Table 128.1 (Shine and Chun 2004). It consisted of questions in the subjective category, including questions for information on subject components, about health and lifestyle, about food attitude and behavior, regarding pregnancy experience, and questions in the objective category regarding foods. It also included questions about feeling, satisfaction for each component, and overall satisfaction after consumption of food. The CS-Q test does not restrict environmental conditions because the internal environment is too complex to control; for instance, 5-CL and 6-CL can be the environments for the egocentric 7-CL.

128.4.3 Design Considerations in the CS-Q

The following are illustrative of the questions and answers are shown in brackets at the end of the questions.

- **Objective Category Referred to 5-CL**: What is the color of potato chips? (white, white-yellowish, yellow, brownish-yellow, brown); Did you have any change in appetite? Was there any change in the quantity of your meal? (not at all, slightly, quite, much, very much).
- **Subjective category, referred to 6-CL, 7-CL, and 8-CL**: How much do you know about potato chips? (nothing at all, little, fair, much, and very much) for 6-CL; How responsive are you toward a new food? (not at all, little, fair, much, and very much), What does eating potato chips cause you to imagine? (nothing at all, potato or fruit, bear, friends, event or business) for 7-CL; How often have you eaten potato chips while pregnant? (not at all, quite seldom, seldom, often, very often); Do you have any dreams particularly associated with pregnancy? (not at all, quite seldom, seldom, often, very often) for 8-CL.
- **Componential and overall satisfaction**: Do you like the color of the potato chip? (extremely dislike, dislike, slightly dislike, neutral, slightly like, extremely like).

128.4.4 Subjects and Food Items for the CS-Q

The subjects and food items included in the CS-Q should be selected in consideration of consciousness issues for two subjects groups who had experienced pregnancy and those who had not, focusing on a typical food item, potato chips on which subjects have a wide range of age with different exposure periods.

128.5 Influence of Pregnancy on Food-Related Behaviors

128.5.1 Changes in Dietary Behavior Upon Pregnancy

Lim et al. (2008) reported that in the PY group, 86% (161/188, very much 8%, much 20%, moderate 20%, low 38%) of the women experienced a change in food-related behavior such as food taste, tasting sensitivity, appetite, quantity and frequency of daily meal during pregnancy (see Fig. 128.3). About a quarter of the group showed a high degree of dietary change, and about half of the group showed a noticeable degree of dietary change. The most frequent changes were severe loss of appetite and a remarkable change in food preference, accompanied by EG.

The number of births affected the food consumption in the PY group with respect to three response categories as shown in Fig. 128.4. No remarkable changes in any category during EG, as observed in Fig. 128.4a. In contrast, after EG, the number of previous births of the PY group markedly influenced two response categories: increased food consumption and no change in food consumption, as shown in Fig. 128.4b. The percentage of respondents with increased food consumption dropped from 72% (for first-birth subject) to 38% (for third-birth subject), while the percentage with no change in food consumption increased from 25% (for first-birth subject) to 60% (for third-birth subject).

The distinct changes in food consumption in PY group after EG periods suggest that accumulated pregnancy experiences cultivate the ability to control the digestive organ, which is operated by the unconscious, or parasympathetic, nervous system. Considering the remarkable effect of EG on dietary behavior and, in particular, on food consumption during pregnancy, psychological changes accompanying the physiological changes should be considered one of the variables in the food acceptance process, such that a judgment is made as to whether a food should be accepted or rejected. Subjective memories of particular foods, as part of a woman's consciousness or psychological background, may play a role in this judgment. Thus, the experience of pregnancy may occupy an important position in

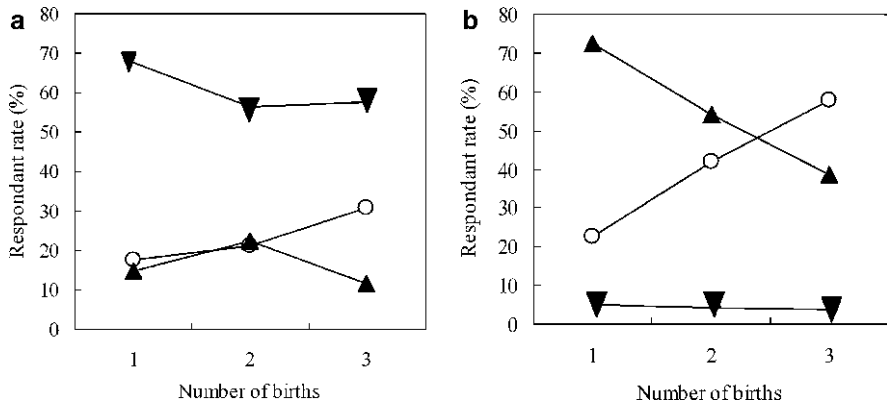
Fig. 128.3 The percentage of respondents who exhibited changes in food-related behavior during pregnancy. Data resulted from PY group (*n* = 188, mean age 43.2) (Cited in Lim et al. 2008. With permission)


Fig. 128.4 Percentage of subject in PY group who experienced changes in dietary behavior: (**a**) During EG and (**b**) After EG. Data resulted from PY group (*n* = 188, mean age 43.2); ▲, increased food consumption; ○, no change in food consumption; ▼, decreased food consumption during and after EG according to the number of previous births (Cited in Lim et al. 2008. With permission)

a woman's reference memory, influencing dietary behaviors such as food preferences and satisfaction. This strongly suggests that the content and factors of the food evaluation process can differentiate between women who have been pregnant and those who have not. Thus, it appears that the latent consciousness layer governing the sensorial organ was activated during pregnancy.

128.5.2 Relationship Between Componential and Overall Satisfaction

The differences between PN and PY groups in dietary behavior might derive from the perceptual stage of food consumption. A comparative study on perceptions of potato chips by PN and PY groups (Lim et al. 2008) revealed that the satisfaction derived via the five sense organs and the overall

Fig. 128.5 Spider web plot of the correlations between componental satisfaction and overall satisfaction in the PN and PY groups for potato chips. Data evaluated with PN and PY groups for potato chip. ○, PN ($n = 111$, mean age 22.8); ▲, PY ($n = 188$, mean age 43.2) (Cited in Lim et al. 2008. With permission)
satisfaction were highly correlated, with a correlation coefficient greater than 0.4 for all components with the exception of the environmental component (0.195).

The taste (0.662) and texture (0.651) components were more closely related to overall satisfaction than were the other components, suggesting that taste and texture are critical in the process of evaluating potato chips. The spider web plot (Fig. 128.5) demonstrates clear differences in all of the components, except color and shape, between the PN and PY groups.

The asymptotic significance values were significantly higher for two components (0.939 for texture, and 0.294 for color and shape) and 0.879 for overall satisfaction, indicating similarities between the two groups of women. In contrast, the other four components (sound 0.013, odor 0.002, taste 0.018 and environment 0.057) showed significant differences between the groups but the highest similarity was observed for overall satisfaction. This suggests that food preference, defined as a subjective choice of food based on satisfaction, is not determined by satisfaction of individual relevant componental features but by satisfaction of multiple integrated components.

128.5.3 Factors Affecting Overall Food Satisfaction in the Two Groups of Women

Multidimensional scaling (MDS) analysis for all componental elements of the relevant component set is shown in Fig. 128.6.

In this map, the elements of the sensorial components did not group, in accordance with the componental classification, but instead showed scattering in all componental categories. The degree of scattering and the distance from overall satisfaction were greater in the PY group than in the PN group. The locus of overall satisfaction was in the midst of the components in the PN group but was at the outer rim in the PY group. However, the two groups showed a common consistent trend for close association or binding with the taste component. These results further confirm that a clear change in the food satisfaction process occurs during pregnancy and that taste is an important factor for either group.
Fig. 128.6 MDS plots of stimuli score of componential elements and overall satisfaction for the PN and PY groups. Data evaluated with PN ($n = 111$, mean age 22.8) and PY ($n = 188$, mean age 43.2) groups for potato chip. ◊, environmental condition; ▲, color and shape; △, sound; □, odor; ○, taste; ♦, texture; ⊗, overall satisfaction (Cited in Lim et al. 2008. With permission)

128.5.4 Influence of Sensorial Stimulus on Overall Satisfaction

According to Chun's hierarchical consciousness framework, sensorial stimuli are acquired at bottom layer or 5-CL and perceived by the higher layer. Thus the preference and overall satisfaction are outcomes from decision made at higher level in 6-CL and 7-CL.

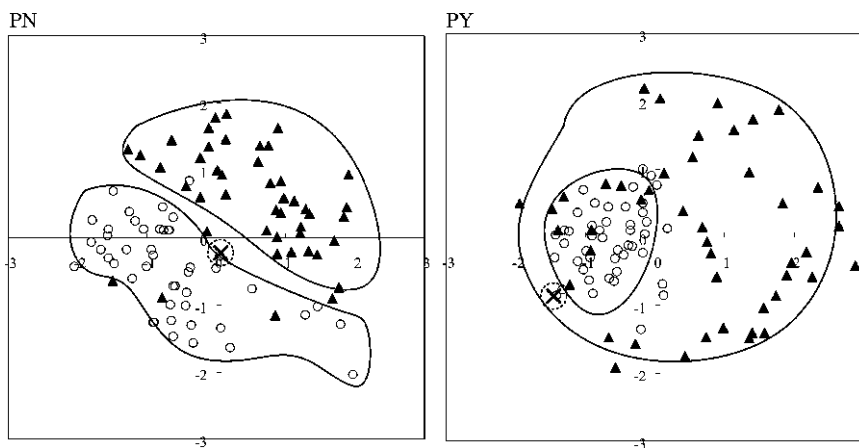
The positioning maps of MDS analysis shown in Fig. 128.7 indicates how influential the sensorial signal and the preference are. The sensorial stimulus, a single common symbol (▲) represents all sensorial signals (environmental condition; color and shape; sound; odor; taste; texture), and the preference is similarly indicated with a common symbol (○). In the PN group, the strength of the


Fig. 128.7 MDS plots of strength of sensorial stimulus, preference of componential elements, and overall satisfaction. Data evaluated with PN ($n = 111$, mean age 22.8) and PY ($n = 188$, mean age 43.2) groups for potato chip. ▲, sensorial stimulus; ○, preference of componential elements; ⊗, overall satisfaction (Cited in Lim et al. 2008. With permission)

sensorial stimulus and preference of componential elements are distributed evenly around overall satisfaction (⊗). The PY group showed greater scattering than the PN group, and overall satisfaction is located at the outer edge of the plotted zone, close to the positions of preference.

Lim et al. (2008) claimed that the pregnancy experience could account for the consciousness feature of satisfaction, and that the consciousness components have as much influence on overall satisfaction as the sensorial features.

128.6 Effect Consciousness Factors on Food Consumption

128.6.1 Relationship of Consciousness Components and the Preference of Componential Elements

Figure 128.8 compares the relationship of consciousness components, represented by a common symbol (●), and preference with (○) in the MDS plot. As compared with the patterns for strength of sensorial stimulus, preference of componential elements, and overall satisfaction in Fig. 128.7, the distribution patterns of consciousness component in the positioning maps (Fig. 128.8) are very similar between the PY and PN groups with respect to both the aggregating format and the locus of overall satisfaction.

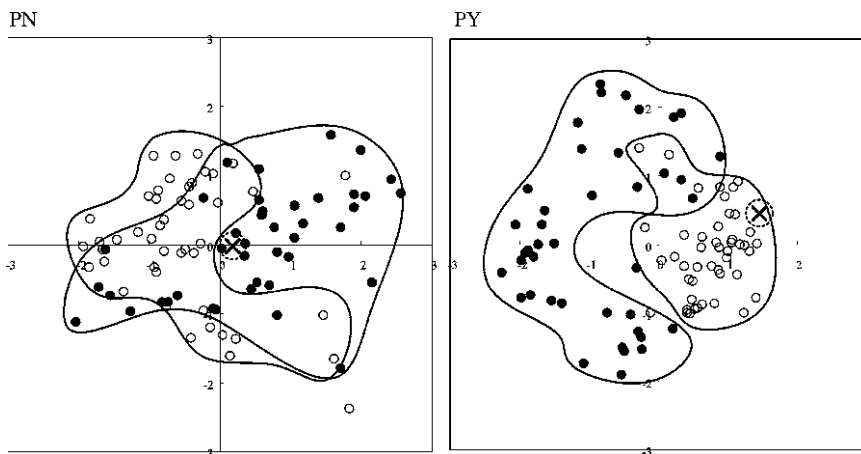
As these two results make clear, the consciousness components had as much influence on overall satisfaction as the sensorial features. Although consciousness components are not directly measurable, as are sensorial stimuli, their roles in overall satisfaction are remarkable.


Fig. 128.8 MDS plots of consciousness component, preference of componential elements, and overall satisfaction. Data evaluated with PN (*n* = 111, mean age 22.8) and PY (*n* = 188, mean age 43.2) groups for potato chip. ●, consciousness component; ○, preference of componential elements; ⊗, overall satisfaction (Cited in Lim et al. 2008. With permission)

128.6.2 Relationship Between Consciousness and Sensorial Stimuli

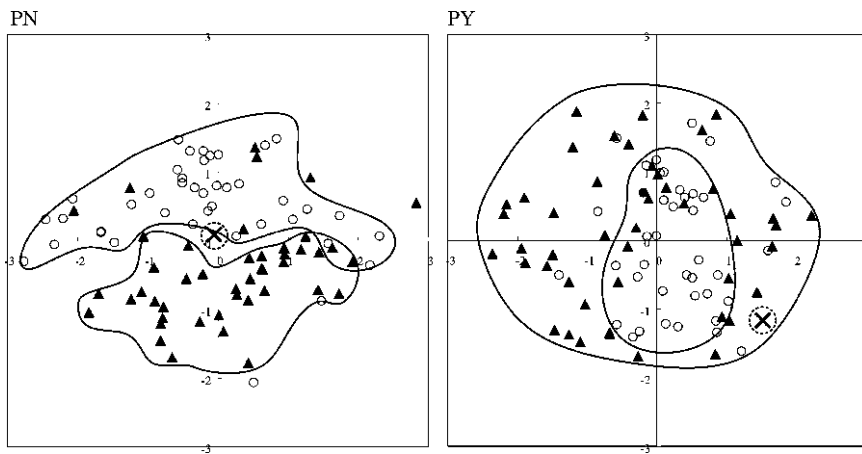
Given the importance of consciousness factors, it is necessary to examine the relationship between sensorial stimuli and consciousness as related to judgments of the stimuli sensed by the sensorial organs. As above, the consciousness components were represented by common symbols shown in Fig. 128.9, the pattern of the consciousness loci (○) was similar to that seen in the consciousness vs. preference and sensorial stimulus vs. preference plots, but the aggregating format and positioning were remarkably different. Aggregation was low in both the PY and PN groups. In the PY group in particular, the aggregating phenomenon disappeared completely, suggesting that consciousness factors may be as important as sensorial factors.


Fig. 128.9 MDS plots of consciousness for the PN and PY groups. Data evaluated with PN ($n = 111$, mean age 22.8) and PY ($n = 188$, mean age 43.2) groups for potato chip. ▲, sensorial stimulus; ○, consciousness component; ⊗, overall satisfaction (Cited in Lim et al. 2008. With permission)

128.6.3 Overall Satisfaction With Food at Various Levels of EG

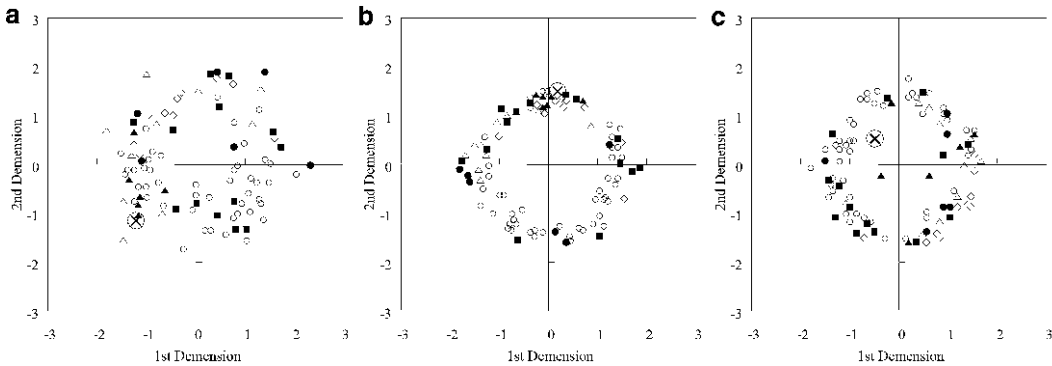
When food preferences were involved in the MDS analysis, the locus of overall satisfaction emerged in the context of other subjective issues on the positioning map. This indicated that overall satisfaction was one of the states resulting from consciousness activities and that it might vary according to the consciousness of the individual. Lim and Chun (2005) reported that the locus of overall satisfaction varied according to the level of EG, as shown in Fig. 128.10. They also claimed that the number of births affected food preferences in the PY group.


Fig. 128.10 Locus of overall satisfaction at various states of EG in the MDS plots: (**a**) No EG (**b**) Mild EG (**c**) Severe EG. Data evaluated with PN (n = 111, mean age 22.8) and PY (n = 188, mean age 43.2) groups for potato chip. ⊗, overall satisfaction; ▲, componental satisfaction; ◊, 5-CL component; ●, 6-CL component; ■, 7-CL component; Δ, 8-CL component; ○, Sensorial stimuli (Cited in Lim 2005)

128.6.4 FRL Differences Between PY and PN Groups

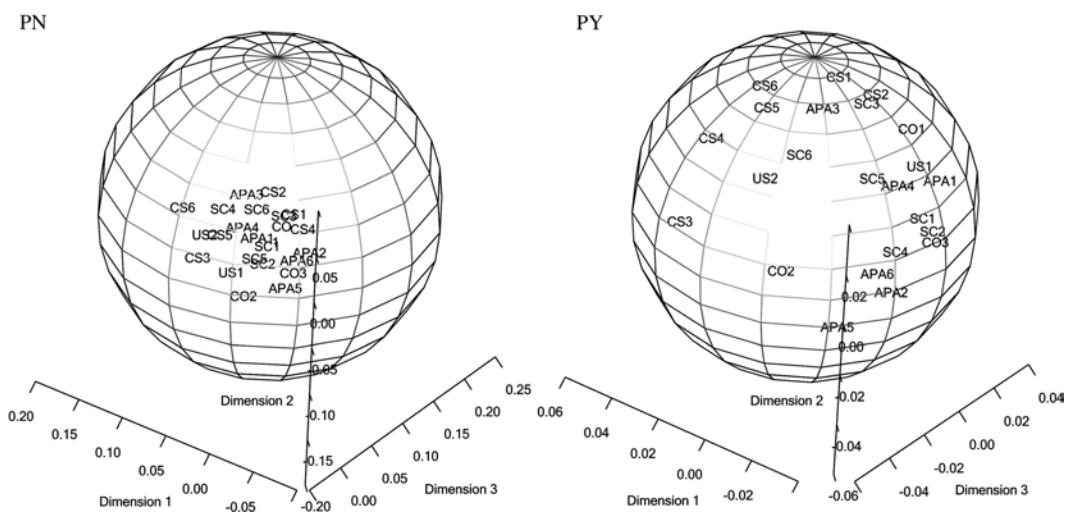
The MDS positioning plot differences was also found in the results obtained from the FRL questionnaire, widely accepted tool as noticed in Fig. 128.11 which depicts responses to the 23 dimensions of the questionnaire (Scholderer et al. 2004). It shows that the behaviors of those in the PY and PN groups are remarkably different in terms of their individual positioning and their responses to the 23 dimensions addressed by the questions. The responses of PN subjects are densely aggregated in a narrow zone of the sphere. In contrast, those of PY subjects are widely scattered.


Fig. 128.11 MDS plots of the 23 dimensions of the FRL for the PN and PY groups. PN, college students, aged 20–29, n = 98; PY, housewives with at least one child, aged 30–49, n = 65 (Cited in Cho and Chun 2009. Refer to Scholderer et al. (2004) for abbreviations)

128.6.5 Differences Between PY and PN Groups With Regard to Food Acceptance and Frequency of Food Consumption

The MDS positional plots (Fig. 128.12) of food consumption and acceptance of 21 categories of Korean food, including vegetables, meats, and beverages resembled those obtained with the FRL (Fig. 128.11).

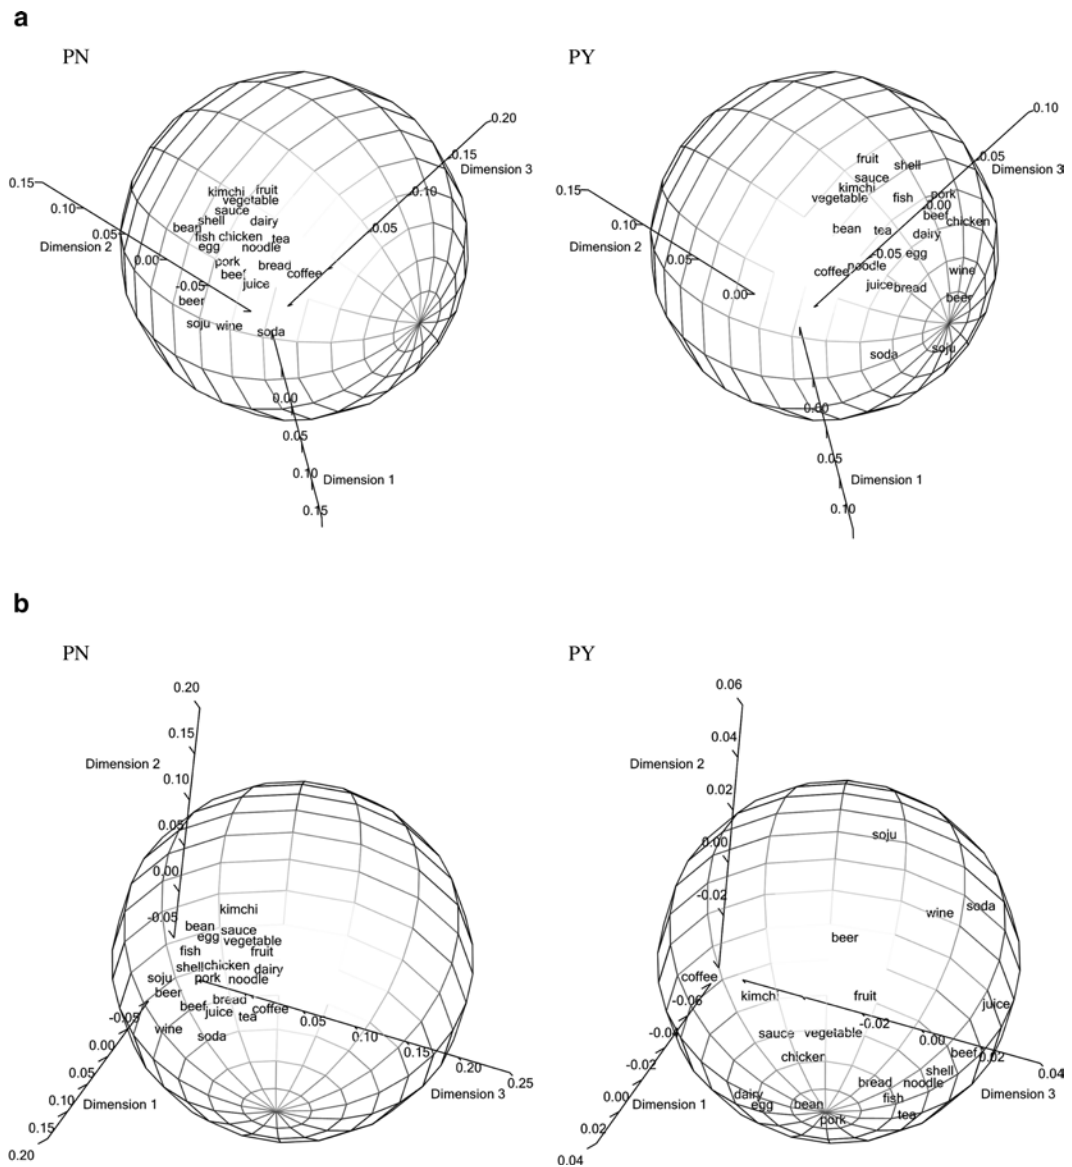
In 3D sphere MDS plots, the differences between two groups were clarified in the positional area regarding acceptance and consumption of food. The PY group showed greater scattering than the PN group. In this connection, the scattering is more remarkable in food consumption than food acceptance.


Fig. 128.12 MDS plots of food acceptance (**a**) and food consumption (**b**) among PN and PY groups (Cited in Cho and Chun 2009)

These differences between food acceptance and food consumption suggest that the experience of pregnancy shifts attitudes about food toward broader food acceptance because the motivations behind food-related decisions become more focused on the entire family

128.6.6 Comparison of FRL and Multilayered Consciousness Approaches

Using a survey based on Chun's concept of causal consciousness and the FRL instrument (Scholderer et al. 2004), which is based on actual behaviors, it could be confirmed that the experience of pregnancy affected food-related attitudes and behaviors including food preferences, choices, consumption, and satisfaction. In particular, nonfood-related psychological factors were as influential as were food-related factors. This finding needed a cross-checking of the FRL questionnaire from the perspective of Chun's layered consciousness theory. The cross-checking showed that almost all the issues covered by the FRL were related to behaviors caused by combined states of layers 5-CL, 6-CL, 7-CL, and 8-CL. Accordingly, the FRL framework using the means–ends approach to consumer behavior (Olson and Reynolds 1983) is consistent with the causal role played by consciousness of self, which includes personal values at the top level of the hierarchy.

In addition, 5-CL and 6-CL are similar to the bottom level that uses product perceptions as situation-specific input to a higher-level process. Lifestyle is considered to be an outcome of a process of conscious interperception controlled by individual egoistic personal values at 7-CL. Therefore, approaches using concepts of multiple layers will be useful for analyzing the typical food-related behaviors of pregnant women.

128.7 Applications of the Multilayer Concept

Because the concept of multilayered consciousness was developed under the assumption that anything occurring in the external world can be addressed by the internal world operating according to relative time (see Fig. 128.2), this concept can integrate all senses into one mental path. The cognitive sensory frequency curve constitutes one method for representing the outcome of this integration of our sensory system with the internal world of the mind during food consumption. Thus, this model is versatile and can be applied to areas such as sensory evaluations of food, analysis of food consumers, control of obesity, dynamic expressions of food satisfaction, and so on.

128.7.1 Construction of the Cognitive Sensory Frequency Curve

The cognitive sensory evaluation method (Chun 2002) presents all stimuli as barcodes that are integrated into a single barcode pattern. Figure 128.13a illustrates this method but converts it into multistory barcode, to avoid overlapping bars, and into frequency curves, as illustrated in Fig. 128.13b.
Fig. 128.13 Cognitive sensory output of 38 individual subjects: (**a**) a cognitive sensory barcode of an individual subject, and (**b**) cognitive sensory curves. Data resulted from university students ($n = 38$, mean age 22) for potato chip (Cited in Shine and Chun 2004. With permission)

The cognitive sensory frequency curve patterns (Fig. 128.13b) show that several common peaks reflect cognitive bases constructed through common cultural backgrounds, or Karma, that can be perceived across the egoistic boundaries of subjects. The conventional sensory score represents a small part of the sensory information; it lacks data about most of the real image of the food because it misses the gestalt. Yet, the scores of individual subjects can be summed to provide the basis for defining consumer groups.

128.7.2 Musical Expression of Cognitively-Expressed Food Preferences

The multilayered approach was applied to convert the cognitive expression of food preferences into a musical format, because taste is similar to the process by which an orchestra harmonizes multiple sounds. Kim et al. (2005) developed a method for musical composition and performing to dynamically express the taste of food and to replace the static expression obtained from methods relying on numerical sensory scores and linguistics. And they transformed the taste of potato chips for an individual subject into a musical format as shown in Fig. 128.14. The length of the note in the first line reflects the state of physical health of the sensorial organs in the perception of external stimuli.

The scores of lines 3 through 4 were the dynamic displays of the cognition of internal stimuli constructed in 7-CL through 8-CL where the consciousness undergoing several processes with different
Fig. 128.14 Musical score composed on the basis of the cognitive sensory evaluation method: (**a**) Musical score note for an individual subject, (**b**) Acoustic curve obtained by performing musical score and (**c**) Acoustic curves of normal and deaf individual subjects. The musical score was composed using cognitive food sensory data gathered while eating potato chips via a computer system; Cakewalk 9.0 (for composing), Goldwave 5.0 (for recording), and Windows Media Player (for playing). (Cited in Kim et al. 2005. With permission)

time unit as described above in Fig. 128.2. Thus, the different internal processes were expressed by employing different repetition cycles in the musical score.

As the number of repetition cycles increases, the increased density of notes in the low range makes a low frequency resembling a background humming or a drum. This sound reflects a conscious background governed by the 7-CL and 8-CL.

The comparative study of the acoustical frequency curve of a handicapped subject showed a difference in the pattern (Fig. 128.14c), suggesting that the handicapped subject was also enjoying the sound of biting into a potato chip (Jin and Chun 2005; Kim et al. 2005).

128.7.3 Virtual Food Control for Obesity

The boundary model of hunger and satiation addressed the impact of physiological and cognitive factors on dietary behavior (Herman and Polivy 1975). Chun (2003) also noted that mental hunger and satiety might account for problematic obesity, in that virtual food remains in the mind, as illustrated in Fig. 128.15. As long as the satiety is followed by the satisfaction on food which resides in

Fig. 128.15 Comparison of
satiety and virtual satiety
one's consciousness as virtual foods, virtual food in consciousness might serve to shift the boundary of satiety or virtual satiety.

Our interpretation of obesity in terms of virtual food indicates that a novel approach might be required, insofar as this phenomenon is closely associated with the conscious decision-making process of individuals.

128.8 The Consciousness Approach in Dietary Studies

128.8.1 Food as a Mediator for Understanding Pregnancy

The review of the comparative study involving two groups of women, PY and PN, showed two distinct findings: EG significantly affected food consumption, and the influence of EG was attenuated in a second or later pregnancy. Considering the remarkable effect of EG on dietary behavior in general, and on food consumption during pregnancy in particular, changes in consciousness should be considered as important variables operating in the process whereby food is accepted. Thus, the experience of pregnancy might occupy a principal position in the reference memory of pregnant women, influencing dietary behaviors such as food preferences and satisfaction. This strongly suggests that the content and factors contributing to the process of food evaluation can be used to differentiate between women who have and have not been pregnant. Thus, latent factors in the layer of consciousness governing sensory organs might be activated during pregnancy in favor of the fetus. This phenomenon can be illuminated by a metaphor referencing the dual operating system installed in a personal computer. At the same time that a pregnant woman wants to maintain her dietary habits, the fetus must feed itself according to the guidelines encoded in its genes and passing it to the next generation. Therefore, it might be defined as one body, two-ego system. Along these lines, 8-CL is responsible for storing the genetic code and passing it to the next generation.

The influence of EG on food consumption signals a notable change in judgments about food during and after pregnancy, and begs questions about the cause and effect of pregnancy with regard to

dietary habits. First, what is the nature of pregnancy from the perspective of consciousness? Is it the growth of a new consciousness system within an existing life, a configuration of two selves, or the establishment of a two-ego system in one physical body? Second, what does EG mean? It might represent a phase involving self-discipline or a transitional state in which the two egos refer to 7-CL to adopt a new dual system whereby compromise between the different needs for food emanating from the two selves is achieved. In this context, virtual food (Chun 2003), constructed in the background of consciousness and from memories stored in either 7-CL or 8-CL, as well as different food experiences might serve as references for the judgments underlying food consumption. Third, is it possible for the two subjects to communicate with each other in order to reach a compromise, thus avoiding critical damage to both selves using a mechanism resembling a hotline that spans dual neural networks? Because the neural networking of the fetus is not sufficiently developed to consider the operation of neural signaling, should serious consideration be given to a form of wireless communication via the consciousness channel? In this way, 8-CL, the highest level, might play a role as a communications tower in the intersubjective realm of 7-CL and 8-CL.

Therefore, the painful EG experience might be understood as a novel aspect of mutual communication between baby and mother insofar as the mother hopes for the health of her baby. It provides a valuable opportunity for insight into the real nature of two selves and the meaning of pregnancy, transforming an often physiologically painful experience into a joyful experience involving the development of competence in the process of advancing to motherhood.

128.8.2 Perception Processing and Multiple Timer Concepts

The main cause of the differences in typical food-related behaviors derives from interperception among the layers of consciousness, as described above with regard to 3-WBT. In this way, previous experiences of reacting in a selfish way due to ego-esteem and ego-threats serve as reference points. In this context, 7-CL is responsible for the selfish and egoistic aspects of the subjective decision-making process (Chun 2002, 2004; Jin and Chun 2005). Indeed, Churchland (1988), and Cohen (2000) have reported that cognitive states significantly influence the perception and observation of an object in a top-down way.

Assuming the operation of interperception and dual-flow processes in streams of consciousness, a flow chart must consider sequence and relevant time units for the internal top-level domain of consciousness as well as for the bottom-level domain that interfaces with the external world. Chun (2002) insisted that the time unit for accessing 8-CL must be reduced to nearly zero because thought necessarily travels at an unlimited speed to manage the universe of the mind. Furthermore, this account logically matches modern digital data processing with respect to compositional structure, efficacy, and economics. More specifically, consciousness has been considered as operational software for the hardware of the brain in the context of the multiple streams for data acquisition and perception, the logistics governing feedback loops, the retrieval of references, the output signals for motor neurons, and the mechanisms governing the performance of multiple tasks and record storage. Thus, the incorporation of a multiple timer concept would be helpful for approaching the world of the mind (Chun 2002).

128.8.3 Simplification of Variables Structural Equation Modeling

As described in the text, the multivariate nature of food-related behaviors was interpreted using statistical tools such as ANOVA, structural equation modeling, and MDS plotting. Factor analysis is

widely used to reduce the number of variables. Our ultimate goal of approaching consciousness did not aim to add variables but rather to reduce these into a fundamental mental framework.

Within this framework, factors such as the education and age of subjects could be neglected because education belongs to a domain of data that is classified prior to decision-making, and the concept of time is constructed in a relative manner in the internal world. Consequently, approaches focusing on consciousness might contribute to simplifying the multivariate nature of food-related behaviors.

128.9 Issues of Part and Whole

Application of Vasubandhu's theory dividing the mind into a multilayered structure of consciousness leads to arguments about the divided mind as based in irrationality (Tuske 1999) and about tastes sensed by the tongue as derived not from 5-CL but rather from a system-wide process yielding a decision. We support the latter account but the division into several subsystems aids in understanding how the system works as a whole.

In this context, the validity of the proposed path model (Cho and Chun 2009), constructed by combining subjective (nonfood memories) and objective factors (food-related memories), was investigated with respect to routes based on the hypothesis that causal routes represent a main routine of the "software" governing this path. It was hypothesized that this path was triggered by unconscious factors, but that the effective route was regulated consciously. The role of cause and effect reactions in shaping expectations and rewards entails that memories of historical experiences will serve as important references for decision-making (Wansink 2003). An egocentric unconscious process serving as the decision-maker manages the path across the limitations of time and space. This implies that future, present, and past are integrated into the path (Raftopoulos 2001) via conscious and unconscious processes (Dehaene and Naccache 2001). Because imagination enables the observation of virtual objects by the ego-self during decision-making, many researchers have investigated the notion that vision is dominant with regard to the general issues of daily life. Food products, however, are judged by taste, smell, visual appearance and sound (Kim et al. 2005). The virtual satiety may help to prolong satiety, lower hunger and desire to eat (Isaksson et al. 2008).

Summary Points

- A multilayer hierarchical structure of consciousness was applied to the food-related behaviors of pregnant women.
- Comparative studies on pregnant and nonpregnant women showed differences in their food-related behaviors, including preferences, consumption, and satisfaction with food.
- A method for cognitive sensory evaluation was described using the multilayer concept and addressing conventional sensory and unconscious factors.
- The concept of interperception was introduced using three-way-branch transformations into the path formed by the stream of consciousness.
- The method of cognitive sensory evaluation can accommodate the concept of multiple timers and can express food-related perceptions in various ways, including barcodes, frequency curves, and musical notes.

Definitions and Explanations of Key Terms

3-Way branching transformation (3-WBT): When interperception occurs among the mental layers, transformation occurs according to three options: the good, the bad, and the neutral are understood according to the perspective of the perceiver in an egoistic way. After repeated transformations or experiences with the good outcome, the latter will be recognized as the best option.

Cognitive sensory evaluation: The cognitive sensory evaluation method integrates all food and nonfood stimuli within human consciousness.

Componential satisfaction: Satisfaction based on sensory preference scores for such factors as appearance, sound, odor, flavor, texture, and environment.

Emesis gravidarum: Often referred to as morning sickness, this is a physiological phenomenon experienced by the majority of pregnant women which occurs during the early stages of pregnancy; it disappears as the pregnancy advances.

Interperception: The external stimuli sensed by sensory organs are perceived by the mind or consciousness. In multilayer theory, several perceptions occur across the layers.

Multilayered consciousness: A conception of the mind, based on the consciousness-only theory proposed by Vasubandhu, stating that the human mind is comprised of multiple functional layers or modules. The layers are hierarchically arranged and referred to as 5th consciousness, 6th consciousness, 7th consciousness, and 8th consciousness, abbreviated herein as 5-CL, 6-CL, 7-CL, and 8-CL.

Overall satisfaction: Satisfaction based on overall preference scores.

Preferences for componential elements: Preferences for each sensory attribute of food.

Sensorial stimuli: Perceived intensity of each sensory attribute of food.

Top-bottom or top-down: The terminology is used to describe the direction of the flow of consciousness because consciousness was defined as similar to a bloodstream. Therefore, top-bottom logic indicates that human behaviors are outcomes of the flow of consciousness proceeding from 8th consciousness toward 5th consciousness.

Top and bottom minds: The top mind is the ultimate or deepest mind, controlling mental activity in its entirety, and the down or bottom mind refers to the consciousness that manages the sensory organs.

Two selves concept: The pregnancy of women is considered as a typical of a stage in which two lives live together within one physical system for consuming food; thus, this is referred to as a two-ego system.

Vasubandhu: Indian monk and scholar who lived in ad 400 and insisted that everything is constructed by the mind.

Chapter 129
Diet in the Aetiology and Management of Postpartum Depression: Knowing the Facts

Vassiliki Costarelli

Keywords Postpartum depression • Diet • Fish oils

Abbreviations

PPD	Postpartum depression
EPDS	Edinburgh postnatal depression scale
PUFA	Polyunsaturated fatty acids
EPA	Eicosapentaenoic acid
DHA	Docosahexaenoic acid
RCT	Randomized Controlled Trial
BDI	Beck depression inventory
FFQ	Food frequency questionnaire

129.1 Introduction

Postpartum depression (PPD) is a condition that affects women who have recently delivered a baby, with most cases occurring in the first 6 months after delivery. It is a serious mental health problem characterized by a prolonged period of emotional disturbance, occurring at a time of major life change and increased responsibilities (Almond 2009).

Prevalence of postpartum depression worldwide is approximately 13–20%; however, these are probably conservative estimates because the condition is often underreported or underdiagnosed (Halbreich and Karkun 2006). It is important to note that a study conducted in the UK found that the incidence of PPD is approximately 27% in minority ethnic women (black, Asian and other) compared to 15% in white women (Onozawa et al. 2003) which indicates that women from ethnic minorities are probably a high-risk group for depression in the postpartum.

Symptoms of depression in the postpartum period may persist for any length of time after birth and range from postpartum blues to severe depression. Postpartum blues can be defined as short episodes of depressive symptoms, such as anxiety, disturbed sleeping patterns, decreased appetite

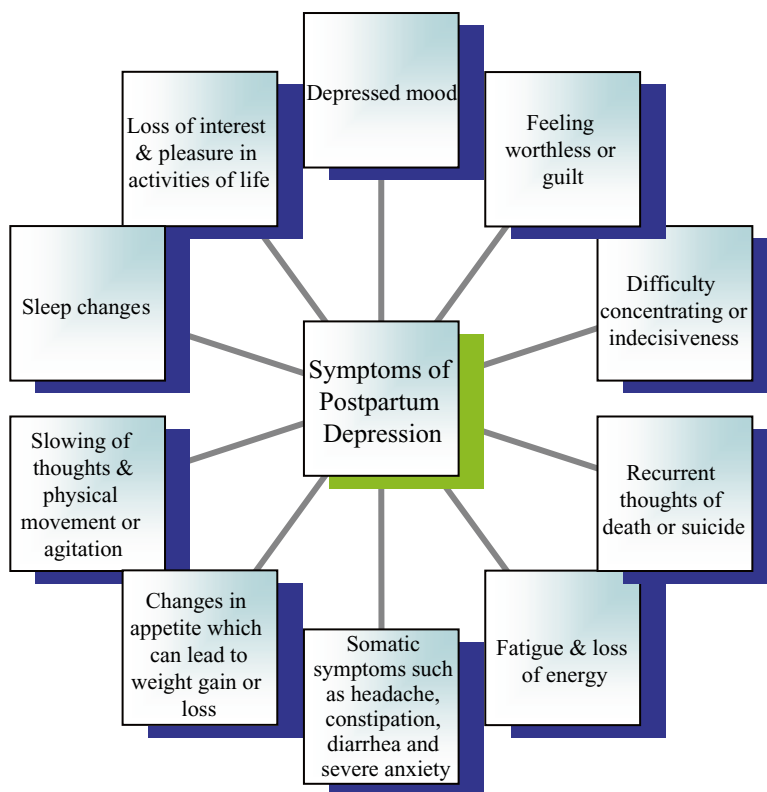

Fig. 129.1 Main symptoms of postpartum depression

and irritability, normally taking place on day 4 after delivery but may commence up to 2 weeks after delivery (Gurel and Gurel 2000). However, the symptoms of PPD which are described in detail in Fig. 129.1, are usually more severe and could include feelings of suicide, obsessive thoughts and extreme petulance (Wisner et al. 2002; Hatton et al. 2005). Postpartum psychosis, on the other hand, is the most severe form of postpartum psychiatric illness and will not be discussed in the current chapter.

The consequences of PPD can be significant for both the new mother and the child. It is important to stress that, higher rates of emotional, behavioural and cognitive problems have been reported in the children of mothers with PPD (O'Brien et al. 2004; Stewart 2007). Table 129.1 summarizes the main adverse effects reported in infants and children of mothers with PPD.

The causes of PPD remain unclear, with research suggesting a multifactorial aetiology (Verkerk et al. 2003). More specifically, evidence suggests that the key risk factors for PPD include genetic predisposition and environmental factors, together with a number of social, psychological and biological factors (Craddock and Forty 2006; Almond 2009; Leung and Kaplan 2009). The main risk factors of PPD are described in Table 129.2. The strongest predictors of postpartum depression seem to be the personal and family history of depression, antenatal depression and anxiety and most importantly the lack of social support. Two metaanalyses also found a higher risk of postpartum depression among socially disadvantaged women (O'Hara and Swain 1996; Beck 2002).

The biological risk factors linked with PPD are more difficult to determine. Biological factors that play a part to the pathophysiology of the condition include hormonal influences (Bloch et al. 2000; Murakami et al. 2008), neurotransmitter function (Dunlop and Nemeroff 2007) and nutrient deficiencies because of malnutrition or poor diet quality (Bodnar and Wisner 2005).

Table 129.1 Postulated adverse effects on children of mothers with postpartum depression (Stein et al. 2009)

Impairment in mother-infant interaction
Infants and toddlers became withdrawn, irritable and inconsolable
Higher rates of emotional and behavioural problems as children approach school age
Poorer cognitive development
Higher risk of mood and anxiety disorders in adolescence

This table lists the main negative effects on children of mothers with postpartum depression

Table 129.2 Main risk factors implicated in the aetiology of postpartum depression

Hormonal changes after childbirth
Previous experience of depression or anxiety
Family history of depression or mental illness
Stress involved in caring for a newborn and managing new life changes
Having a challenging baby who cries more than usual, is hard to comfort, or whose sleep and hunger needs are irregular and hard to predict
Having a baby with special needs (premature birth, medical complications, illness)
First-time motherhood, very young motherhood, or older motherhood
Other emotional stressors, such as the death of a loved one or family problems
Financial & employment problems
Isolation and lack of social support

Source: American Psychiatric Association (APA)

The main risk factors in the aetiology of postpartum are described in this table

Evidence suggests that inadequate intake of specific nutrients might be a substantial contributor to the development of depression in women in the postpartum period (Bodnar and Wisner 2005). Plausible associations between nutrient inadequate intake and mood have been reported for folate, vitamin B$_{12}$, calcium, iron, selenium, zinc and omega-3 fatty acids (Alpert et al. 2000; De Vriese et al. 2003). In the case of maternal and postpartum depression, the nutrient that has received the most attention has been the omega-3 essential fatty acids (Chiu et al. 2004). Finally, it is important to underline that one of the symptoms of PPD is changed appetite (increased or decreased), which would contribute to the poor dietary intake and nutritional status of women in the postpartum and hence deteriorate the management of the condition.

The purpose of the current short chapter is to present and discuss the main dietary factors implicated in the aetiology and management of PPD based on a thorough review of the scientific literature to date.

129.2 Diet and Postpartum Depression

Research on the relationship between nutrition and brain function is very large. However, while specific nutrients have been associated with depression in the general population, little is known about low nutrient levels in the aetiology and management of postpartum depression (Derbyshire and Costarelli 2008). It is well documented that pregnant women are especially susceptible to the effects of low nutrient intakes (Bodnar and Wisner 2005; Derbyshire et al. 2009) as during pregnancy and lactation, nutritional requirements are increased (Picciano 2003). In addition, there is evidence that nutrient inadequacies in pregnant women who consume a typical western diet might be

much more common than researchers and clinicians anticipated. A number of studies have reported inadequate intakes of omega-3 fatty acids, folate, B vitamins, iron and calcium in pregnant women (Giddens et al. 2000; Derbyshire et al. 2009). A British study found a significant percentage of pregnant women did not meet the estimated average requirement for folate (69%), for calcium (40%) and iron (67%) (Mouratidou et al. 2006). Similarly, a study of pregnant adolescents and adults living in the USA found mean intake for energy, iron, zinc, calcium, magnesium, folate and vitamins D and E to be below recommended standards (Giddens et al. 2000). Depletion of nutrient reserves throughout pregnancy could increase a woman's risk for maternal and postpartum depression. It is likely that the Mediterranean Dietary Pattern could be protective of PPD. More specifically, adherence to a Mediterranean Dietary Pattern ensures an adequate intake of fruits, nuts, vegetables, cereals, legumes or fish, important sources of nutrients linked to depression prevention (Sanchez-Villegas et al. 2006). A recent study investigating depression in the elderly has found that lower intake of seed oils and higher intake of olive oil prospectively predict a healthier affective state in the elderly. Most importantly, olive oil intake, in particular, predicts a lower chance of scoring in the highest part of the geriatric depression scale (Kyrozis et al. 2009). However, no studies have been found investigating the possible role of the Mediterranean style diet in PPD so far.

Finally, recent studies have also showed that insulin affects the secretion of serotonin in the brain. It is likely that PPD might be linked to the sudden fall in insulin levels occurring after delivery. A diet with a high-glycemic index, which would stimulate the secretion of insulin and thereby facilitate the transport of tryptophan, the precursor of serotonin, in the brain, would alleviate the above condition (Chen et al. 2006). However, a recent study investigating the link between glycemic load and PPD failed to substantiate a clear inverse relationship between them (Murakami et al. 2008). This hypothesis warrants further investigation given the plausibility of the above mechanism.

129.2.1 Omega-3 Fatty Acids and PPD

The nutrient that has received the most attention from nutrition researchers with respect to depression in pregnancy and the postpartum period has been the n-3 essential fatty acids. (Hibbeln 2002; Freeman et al. 2006a; Miyake et al. 2006b). Several studies, such as cohort studies, randomized controlled trials as well as ecological studies, have found mainly positive links between low n-3 levels and a higher incidence of maternal depression. Oily fish are a rich source of omega-3 fatty acids in particular eicosapentaenoic acid (EPA) and docohexaenoic acid (DHA) which are very important for brain development and function (Browne et al. 2006). It is known that omega-3 fatty acids are essential for receptor function, neurotransmitter uptake and signal transmission. More specifically, evidence indicates that adequate levels of the above fatty acids may help to regulate neurotransmitter levels, which are thought to be reduced in cases with depressive symptoms (Sapolsky 2000). In addition, it has been proposed that high concentrations of DHA located in non-myelin cell membranes of the central nervous system may help support synaptic transmissions (Holman et al. 1991).

The intake of n-3 fatty acids in the modern diet has declined with the decreased intake of sources of omega-3 fatty acids (particularly those coming from marine sources). The latest National Diet and Nutrition Survey undertaken in the United Kingdom identified that 53 g of oily fish was consumed per week, the equivalent to just 0.35 weekly servings (Henderson et al. 2002). In addition, studies suggest that there has been an increase in the amount of n-6 fatty acids in the modern diet, which can interfere with the metabolism and synthesis of DHA and EPA (Meyer et al. 2003). In addition, it has been shown that omega-3 fatty acids are transferred from the mother to fetus and baby, throughout gestation and while breastfeeding, which may result in their depletion (Browne et al. 2006).

Fish oils supplements high in omega-3 fatty acids, has been used as psychotropic medications for the treatment of major depression with conflicting results (van Strater and Bouvy 2007; Freeman et al. 2008). Other studies however, seem to support the theory that dietary and supplemental sources of omega-3 fatty acids are associated with fewer PPD symptoms (Hibbeln 2002; Freeman et al. 2006a; Miyake et al. 2006b). In addition, other studies revealed that women, with lower levels of plasma DHA in late pregnancy and the early postpartum period, may be more likely to experience postpartum depressive symptoms (Otto et al. 2003). De Vriese and colleagues also found that n-3 blood levels were considerably lower in women who developed PPD than in women who did not (De Vriese et al. 2003).

One of the largest investigations to date, the Osaka Maternal and Child Health Study carried out a prospective cohort in 865 Japanese women. Fourteen percent of Japanese women were diagnosed with PPD and omega-3 and DHA intakes were inversely associated with PND (Miyake et al. 2006b).

An analysis of ecological studies from 23 countries revealed that high DHA levels in breast milk and higher seafood consumption were positively predictive of lower rates of postpartum depression (Hibbeln 2002). A review of epidemiological evidence and intervention studies reported an association between low n-3 intake and depression (Rees et al. 2005), however, another review found inconsistent results in clinical trials with EPA and/or DHA (Freeman et al. 2006b). Similarly, Hosli and colleagues in another review, found mixed results also; clinical studies contradicted observational studies and findings from a meta-analysis were inconsistent (Hosli et al. 2007). Recent studies investigating the association between omega-3 fatty acids with both maternal depression and PPD and their results are summarized in Table 129.3.

It is important to underline that the sample size and duration of follow-up and methodologies used were problematic in some of the studies. It is also important to consider that occasionally different diagnostic criteria for depression were used in many of these studies. Although most studies utilized the Edinburgh Postnatal Depression Scale (EPDS), different cutoff points have been used, which could explain partly, the above conflicting results.

129.2.2   Other Nutrients and PPD

The research on vitamins and minerals dietary intake and postnatal depression is limited (Abou-Saleh et al. 1999; Miyake et al. 2006a). The few studies examining the effect of specific nutrients in relation to mood disorder in women in pregnancy and the postpartum period, summarized in Table 129.4, produce varying results, possibly due to the limitations on the study designs and methodologies used (e.g. examining a single nutrient, small number of subjects, different methods assessing depression).

129.2.2.1   Calcium

Calcium seems to act as an intracellular messenger and stimulates the release of neurotransmitters from the cerebral vesicles (calcium influx into a cell acts as a trigger, releasing neurotransmitters from their storage vesicles) (Llinas 1977). In a randomized controlled trial, participants were divided into two groups, one consuming 2,000 mg calcium per day, or a placebo (between 11 and 21 weeks of gestation, $n = 293$). Depression was evaluated in the puerperium using the EPDS. Results indicated that symptoms of depression were significantly reduced in subjects consuming calcium carbonate tablets ($P = 0.07$) (Harrison-Hohner et al. 2001).

In another study, 4,589 women received either 1,000 mg of calcium or placebo tablets with their morning and evening meals and a daily prenatal supplement (50 mg calcium, 30 mg iron, 400 IU

Table 129.3 Studies investigating the association between omega-3 fatty acids with both maternal depression and PPD

Author, year	Design and sample size	Main findings
Strøm et al. (2009)	Data from a large prospective cohort linked with high-quality registers, $n = 54{,}202$ women. Intake of fish and omega-3 PUFAs was assessed in midpregnancy with a food-frequency questionnaire	Weak evidence to support an association between intake of fish or omega-3 PUFAs and PPD.
Su et al. (2008)	Randomized controlled 8-week trial, $n = 36$ pregnant women, comparing omega-3 PUFAs (3.4 g/day) with placebo in pregnant women with major depressive disorder	Omega-3 PUFAs may have therapeutic benefits in depression during pregnancy
Browne et al. (2006)	Prospective cohort, $n = 80$ postnatal women, 41 diagnosed with depression and 39 controls. EPDS and BDI were used and an FFQ during pregnancy	Both postnatal ω-3 status and fish consumption in pregnancy were not associated between PPD
Freeman et al. (2006a)	Randomised controlled trial, $n = 16$ with PPD who consumed a 0.5 g/day, 1.4 g/day or 2.8 g/day ω-3 supplement daily for 8-weeks. Both the EPDS and Hamilton Rating scale were used	Omega-3 fatty acids may play a role in the treatment of PPD
Miyake et al. (2006a)	Prospective cohort, $n = 865$ women who completed a diet history questionnaire during pregnancy alongside the EPDS	No significant association found between dietary fish and fat intake with PPD
Otto et al. (2003)	Prospective cohort, $n = 112$ pregnant women. Venous blood samples were collected at week 36 of pregnancy, after delivery and 32 weeks after delivery, use of EPDS	DHA levels were significantly lower in women with depressive symptoms in comparison to women without depressive symptomatology
De Vriese et al. (2003)	Cross-sectional study, $n = 48$, 10 with PPD and 38 without. Blood samples taken after delivery analyzed for serum phospholipids and cholesteryl esters.	Fatty acids concentration was lower in women with depression in comparison to women without depression
Llorente et al. (2003)	Randomized control trial in breast feeding women. DHA (200 mg/day) $n = 44$ or placebo ($n = 45$) for a 4 month period. Plasma phospholipid fatty acids were measured and depression was assessed with a self-rating questionnaire and interview	No difference between the two groups on diagnosed or self-rated depression. The levels of DHA were significantly higher in the treatment group
Makrides et al. (2003)	Cross-sectional cohort, $n = 380$ postpartum women who completed the EPDS and iron, zinc and DHA status were measured	For every 1% elevation in plasma DHA there was a significant 59% reduction in symptoms of depression
Hibbeln (2002)	Published prevalence data for postpartum depression were included that used the EPDS ($n = 14532$ subjects in 41 studies) and measured the DHA, EPA and AA content of breast milk (studies across 23 countries)	Higher concentrations of DHA in mothers' milk and greater seafood consumption both predicted lower prevalence rates of postpartum depression
Peet et al. (1998)	Cross-sectional study, $n = 30$, 15 depressed and 15 without	Women with depression had significantly lower levels of omega-3 fatty acids and DHA

There is also good evidence that increasing the dietary omega-3 intake in late pregnancy or following delivery may reduce the risk of PPD

Table 129.4 Studies investigating the association between of selected mineral and vitamins and PPD

Author, year	Design and sample size	Nutrient	Main findings
Wojcik et al. (2006)	Observational, intervention study, $n = 66$. Women received standard vitamin, zinc and magnesium supplementation. Women completed EPDS 3 days and 30 days postpartum. Serum zinc and magnesium levels were also determined	Zinc (Zn) and Magnesium (Mg)	The severity of postpartum depression may be associated with lower serum zinc concentrations but not magnesium
Miyake et al. (2006b)	Cross-sectional ecological study, $n = 865$ Japanese women, diet history questionnaire during pregnancy alongside the EPDS	Riboflavin (B$_2$)	Riboflavin intake (3rd quartile) was inversely associated with a decreased risk of postpartum depression
Beard et al. (2005)	Prospective, randomized, controlled, intervention trial was conducted in South Africa nonanemic controls and anemic mothers, $n = 95$. Mothers of full-term normal birth weight babies were followed from 10 weeks to 9 months postpartum	Iron (Fe)	Strong relationship between maternal iron status and depression
Harrison-Hohner et al. (2001)	Randomized intervention study, $n = 247$. Women consumed either a placebo or a 2,000 mg calcium supplement daily for 6 weeks. At 6 weeks postpartum women completed the EPDS	Calcium (Ca)	Women in the calcium interventions group had significantly fewer symptoms of depression
Abou-Saleh et al. (1999)	Case-control study, 23 pregnant and 38 non pregnant controls. The EPDS was completed 7 days after birth. Plasma concentrations of tryptophan, B$_{12}$ and folate were measured	Folate and B$_{12}$	Women with depressive symptoms consumed significantly lower levels of folate compared to the controls.

The studies examining the effect of specific nutrients in relation to mood disorder in women in pregnancy and the postpartum period, summarized in this table, produce varying results

vitamin D) beginning before 22 weeks of gestation until delivery. Six weeks postpartum, the mean EPDS scores were similar between treatment groups, however at 12 weeks, a significantly larger proportion of women in the placebo group (15.3%) had EPDS scores >14 compared with the calcium treated group (5.7%) ($P = 0.014$) (Levine et al. 1997).

It is possible that calcium supplementation may serve to stabilize calcium regulation at the intracellular level in individuals with low calcium diets, which in turn would help to alleviate PPD; however, this is yet to be investigated.

129.2.2.2 Zinc

Another nutrient associated to mood is zinc, mainly through its possible influence on serotonin uptake (Levenson 2006). There is also evidence that intervention with zinc has possible antidepressant effects. In addition, studies have reported an association between low zinc status and depression (Nowak et al. 2005; Levenson 2006). A relationship between decreased serum zinc concentration and higher scores on the EPDS have been reported by Wójcik and colleagues. More specifically,

serum zinc concentrations 30 days postpartum were associated with alleviated symptoms of depression. In the same study, no statistically significant findings were reported with regard to serum magnesium concentrations and depressive symptoms (Wojcik et al. 2006).

129.2.2.3 Iron

It is documented that iron deficiency can lead to reduced memory and learning ability, impaired mood and cognition or behavioural abnormalities. As far as PPD is concerned, Beard and colleagues reported a strong relationship between maternal iron status and depression in a study that followed mothers of full-term normal-birth-weight babies from 10 weeks to 9 months postpartum (Beard et al. 2005). However, more studies are needed to confirm the above findings.

129.2.2.4 Folate and Other Vitamins

Folate is needed for the biosynthesis of the neurotransmitters: serotonin, dopamine and norepinephrine. In addition, it has been shown that the active metabolite of folate, 5-methyltetrahydrofolate, is required for remethylation of homocysteine in the production of methionine, which is involved in a number of biochemical processes involving the above neurotransmitters (Miller 2008). As a result, it is likely that a deficiency in folate would affect the production and function of these important neurotransmitters. Vitamin B_6 is also involved in neurotransmitter pathways as a cofactor in the production of serotonin from tryptophan. Low plasma levels of the B_6 derivative, pyridoxal phosphate, have been associated with symptoms of depression (Hvas et al. 2004). In addition, vitamin B_{12} plays an important role in the neurological function as a cofactor in the formation of Sadenosylmethionine, an intermediate for production of the neurotransmitters (Coppen and Bolander-Gouaille 2005).

A very small number of studies were set out to examine the effects of folate and other B vitamin consumption in relation to the development of PPD (Abou-Saleh et al. 1999; Miyake et al. 2006a). In a large recent epidemiological study conducted by Miyake et al. (2006b), 865 Japanese women were asked to complete a diet history questionnaire and the EPDS at 2–9 months postpartum. No associations were identified in this investigation between dietary intakes of vitamin B_6, B_{12} or dietary folate in relation to the onset of postnatal depression with the exception of riboflavin (mean intake 1.4 mg/day) which was inversely associated with symptoms of PPD (Miyake et al. 2006a). In another study, Abou-Saleh et a.l (1999) monitored plasma folate and vitamin B_{12} concentrations and screened women ($n = 62$) for depression using the EPDS in the puerperium. Cases with PPD had lower folate levels when compared with controls ($P < 0.01$), whereas, multiple regression analysis revealed that high vitamin B_{12} concentrations were associated with increased EPDS scores ($P < 0.01$) (Abou-Saleh et al. 1999).

Further studies are needed in this field in order to elucidate the possible role of folate and other B vitamins in the prevention and management of PPD.

129.3 Conclusions

Proper nutrition during pregnancy is vital as evidence suggests that nutrient intake can be a key factor in a woman's vulnerability to postpartum depression. It has been proposed that depletion of nutrient reserves throughout pregnancy and a lack of recovery postpartum may increase a woman's risk for

postpartum depression. Research indicates that an inadequate intake of omega 3 during pregnancy and the perinatal period may be strongly associated with the onset of PND. It is possible that omega-3 and other fatty acids may protect against the onset of PND; however, much larger investigations using prospective methodologies and larger sample sizes are now required to reinforce the findings of these investigations. Further research is also needed to evaluate the safety and recommended levels of fish oil consumption since methlymercury and additional contaminants may be present in larger oily fish.

Weaker relationships have been identified between symptoms of PND and folate, B_{12}, calcium and zinc intake. More studies are needed to investigate the role of diet and nutrition in the aetiology and management of PPD so that specific dietary recommendations can be formed.

129.4 Applications to Other Areas of Health and Disease

Midwifery and nursing: It would be useful to educate midwifes and nurses on the role of diet on the aetiology and management of PPD, so that they can better inform women in pregnancy and in the postpartum.

Social work and counseling: A higher risk of postpartum depression has been reported among socially disadvantaged women and women of ethnic minority groups; as a result, alerting social workers and counsellors on the important of nutrition on PPD would be beneficial.

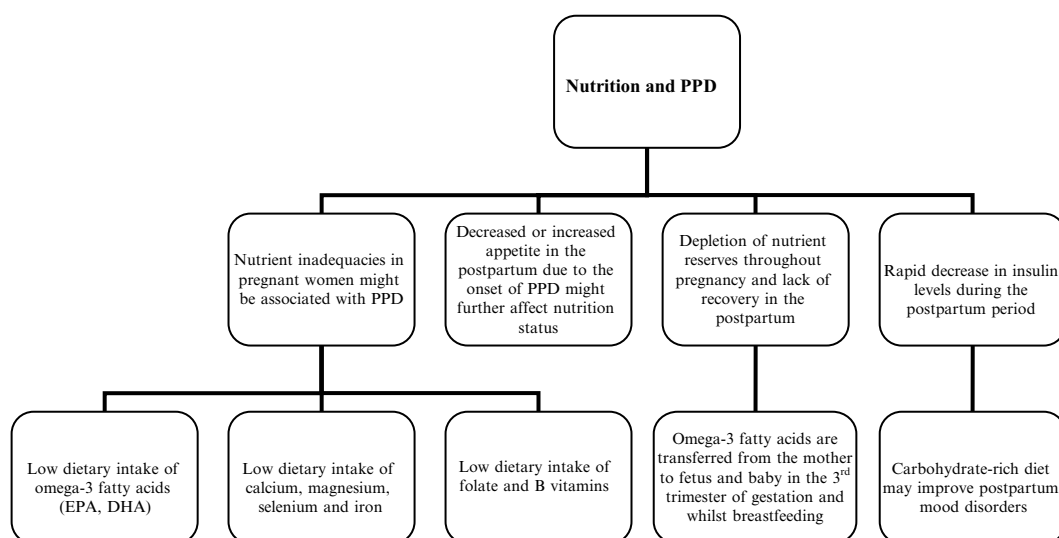
Nutrigenomics: It would be interesting to investigate in the future the possible provision of tailor-made nutritional advice to women with a specific genome, predisposing them to PPD.


Fig. 129.2 Keys points linking nutrition with PPD. Evidence suggests that depletion of nutrient reserves throughout pregnancy can increase the risk of PPD. There is also good evidence that increasing the dietary omega-3 intake in late pregnancy or following delivery may reduce the risk of PPD. The role of the inadequate intake of folate, calcium, zinc and iron intake on the onset of PPD has also been investigated

Summary Points

- Prevalence of postpartum depression (PPD) is increasing worldwide and has potentially detrimental effects on both the mother and the offspring.
- Depletion of nutrient reserves throughout pregnancy can increase a woman's risk for PPD.
- Evidence suggests that inadequate intake of specific nutrients might be a substantial contributor to the development of depression in women in the postpartum period.
- The role of the inadequate intake of folate, calcium, zinc and iron intake on the onset of PPD has been investigated, with conflicting results.
- There is good evidence that increasing the dietary omega-3 intake in late pregnancy or following delivery may reduce the risk of PPD.

Definitions of Key Terms

Postpartum (or postnatal) depression: It is a condition that affects women who have recently had a baby, with most cases occurring in the first 6 months after delivery. It is a serious mental health problem characterized by a prolonged period of emotional disturbance.

Perinatal (or maternal) depression: This refers to major and minor episodes of depression during pregnancy.

Postpartum blues: This is defined as short lived episodes of depressive symptoms such as anxiety, disturbed sleeping patterns, decreased appetite and irritability, normally taking place on day 4 after delivery but may commence up to 2 weeks after delivery.

Postpartum psychosis: This is the most severe form of postpartum psychiatric illness. It is a rare event that occurs in approximately 1–2 per 1,000 women after childbirth. Its presentation is often dramatic, with onset of symptoms as early as the first 48–72 h after delivery.

Edinburgh postnatal depression scale: This is a 10-item questionnaire that may be used to identify women who have PPD. Usually a score of 12 or greater or an affirmative answer on question 10 (presence of suicidal thoughts) raise concern and indicate a need for more thorough evaluation.

Key facts of Postpartum Depression

- Postpartum depression (PPD), also called postnatal depression, is a form of clinical depression which can affect women after childbirth and has significant consequences for both the new mother and family.
- Prevalence of postpartum depression worldwide is approximately 13% to 20%; however, these are probably conservative estimates because the condition is often underreported or underdiagnosed.
- Main symptoms of PPD include sadness, anxiety, fatigue, insomnia, appetite changes, crying episodes, and irritability.
- The causes of PPD remain unclear, with research suggesting a multifactorial aetiology. The strongest predictors of postpartum depression seem to be the personal and family history of depression, depression and anxiety during pregnancy and most importantly the lack of social support.
- It has been suggested that postpartum depression can partly be attributed to depletion of omega-3 fatty acids from the mother's brain to support development of the brain of the fetus or breast-fed infant. Ensuring a sufficient supply of omega 3 fatty acids in the mother's diet is very important.

Prenatal Diet and Stress Responsiveness

Susanne R. de Rooij

Abbreviations

ACTH	AdrenoCorticoTropic Hormone
ANS	Autonomic Nervous System
AVP	Arginine VasoPressin
CRH	Corticotropin-Releasing Hormone
Dex	Dexamethasone
FR	Food Restricted
GR	Glucocorticoid Receptor
HPA-axis	Hypothalamic–Pituitary–Adrenal axis
PVN	ParaVentricular Nucleus
TSST	Trier Social Stress Test
11β-HSD	11 Beta-Hydroxy Steroid Dehydrogenase

130.1 Introduction

The notion that early life events may affect the course of life has been part of common beliefs for a very long time. One of the first records of this thought is found four centuries BC in Plato's work. In Plato's philosophy, suffering in life is the result of the evil experience before birth. It has only been during the last few decades, however, that this notion has gained a scientific basis. Experimental and observational evidence strongly suggests that prenatal conditions play a role in determining health and behavior in later life. One of the prenatal factors, which seem to be of great importance to postnatal health and behavior, is prenatal nutrition.

130.2 Fetal Programming

In 1977, Anders Forsdahl found a geographical association between past infant mortality and subsequent arteriosclerotic heart disease in Norway (Forsdahl 1977). Based upon this observation, he was the first to suggest that a poor standard of living in early life was a risk factor for heart disease. Geographical studies were also the basis for the suggestion made by David Barker and Clive Osmond that coronary heart disease might be linked to impaired fetal growth (Barker and Osmond 1986). They observed that in different parts of England differences in neonatal mortality rates in the early part of the twentieth century correlated with death rates from coronary heart disease in the same generation decades later. Both mortality rates showed a similar distribution with a clear difference between the poor northern part of the country and the richer southern part. This close geographical similarity led them to the hypothesis that adverse environmental conditions in utero and during infancy increase the susceptibility to disease in later life. Detailed birth records from Hertfordshire, UK allowed them to validate this hypothesis. It appeared from thousands of records kept by midwives that a decrease in birth weight was associated with an increased risk of death from coronary heart disease. Barker went on to suggest that when faced with poor nutrition and health of the mother, the fetus has to adapt to a limited supply of nutrients, which permanently changes the body's structure, physiology, and metabolism, a process known as fetal programming or developmental plasticity. These adaptations may subsequently predispose to disease in adult life (Barker 1998) (Fig. 130.1). It has been put forward that the adaptation process is beneficial from an evolutionary point of perspective because it provides the organism with an opportunity to adapt itself to the expected environment within a single generation (Gluckman and Hanson 2004). This is in contrast to genetic adaptation, which would take much longer than a single generation to be effective. Not all responses are supposed to be adaptive though. When faced with a lack of resources, the organism may need to make trade-offs in order to simply survive. By sacrificing the development of less essential organs, more energy becomes available for essential processes.

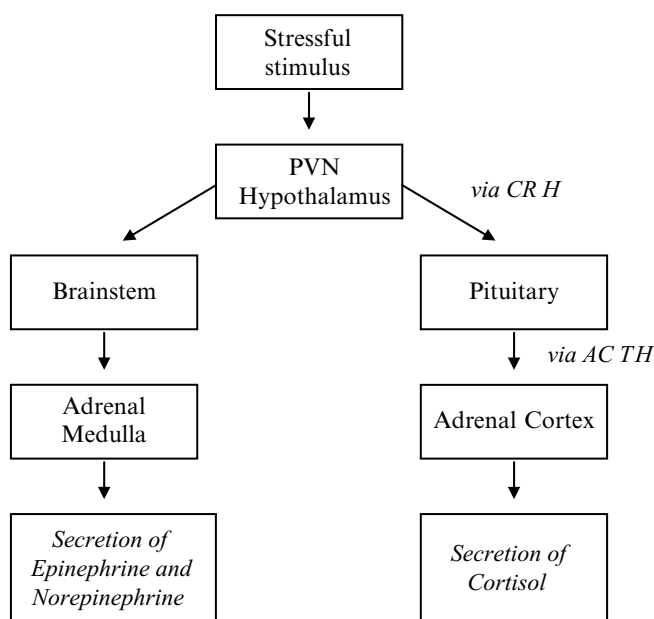
Evidence for the "fetal origins of disease" hypothesis has mainly come from animal experimental studies and from studies investigating the consequences of low birth weight, a marker for an adverse prenatal environment. A wide range of physiological and psychological diseases have been suggested to be susceptible to fetal programming. The stress response is a logical fetal programming candidate not only because glucocorticoids (stress hormones) play an important role in fetal growth but also because altered functioning of the response to stress could be an important mechanism in the fetal origins of type 2 diabetes, hypertension, and cardiovascular disease.
Fig. 130.1 (**a**) Fetal origins of disease hypothesis. (**b**) Schematic overview of the different steps incorporated in the fetal origins of disease hypothesis

130.3 The Stress Response

The biobehavioral response to stress has two key components: the Autonomic Nervous System (ANS) response and the Hypothalamic–Pituitary–Adrenal (HPA)-axis response (Fig. 130.2). These responses are turned on when a person is confronted with a stressful situation. The ANS reacts fast, within seconds, and the HPA-axis reacts somewhat slower, within minutes to hours. Both systems are set in motion by receiving messages from the hypothalamus, which can receive messages from several parts of the brain, including the prefrontal cortex, the amygdala, and the hippocampus. The ANS response starts in the paraventricular nucleus (PVN) from the hypothalamus, travels through sympathetic nerves originating in the brainstem, and ends in the adrenal medulla, which is stimulated to secrete epinephrine and norepinephrine into the circulation. The joined effects of this response are activation of the sympathetic part of the ANS and shutting down of the parasympathetic part of the ANS resulting in an increase in heart rate, blood pressure as well as a range of other changes in cardiovascular, gastrointestinal, renal, and endocrine function. The HPA-axis response also starts in the PVN from the hypothalamus. Here, corticotrophin-releasing hormone (CRH) is excreted, which stimulates the pituitary to secrete adrenocorticotropic hormone (ACTH), which in its turn stimulates the adrenal cortex to secrete cortisol. Cortisol has an important function in mobilizing energy during stress. It also reinforces the actions of the ANS and plays an important role in the negative feedback of the stress response eventually causing the stress response to be terminated.

130.3.1 Fetal Programming of the Stress Response

Both systems responsible for the stress response, the ANS as well as the HPA-axis have been suggested to be susceptible to fetal programming resulting in altered functioning of the stress response in later life. Exactly how this works mechanistically is largely unknown, but several hypotheses have been

Fig. 130.2 (**a**) The stress response. (**b**) Schematic overview of the physiology of the stress response PVN = ParaVentricular Nucleus; CRH = Corticotropin-Releasing Hormone; ACTH = AdrenoCorticoTropic Hormone


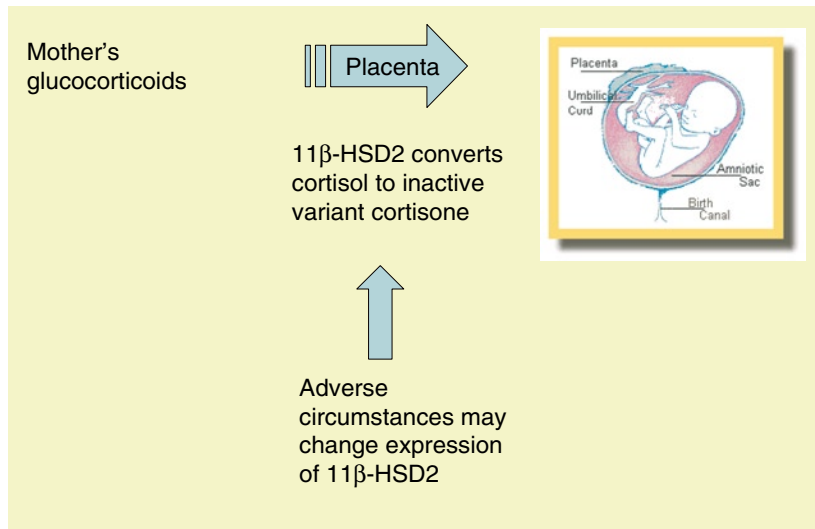


Fig. 130.3 (**a**) The fetus and cortisol. (**b**) Overview of the pathway from high levels of maternal stress hormones to fetal overexposure to stress hormones

put forward. First of all, maternal undernutrition or unbalanced nutrition could directly turn on the fetal stress response as a reaction to the shortage of nutrients supplied to the fetus. Second, the fetal stress response could also be set off indirectly by exposure to maternal glucocorticoids. Normally, maternal cortisol is converted to the inactive variant cortisone by the placental enzyme 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2). However, when maternal cortisol levels are high in response to the metabolic stress in her body, some cortisol may pass the placental barrier by changing the expression of 11β-HSD2. The cortisol that reaches the fetus could stimulate the fetal stress response or could directly affect the fetus (Fig. 130.3).

The increased cortisol and possibly also noradrenaline concentrations resulting from activation of the fetal stress response or directly passed through from the mother could have several effects on the developing fetus: they could change the set points of the stress systems, possibly by altering expression of genes important to the stress response, or directly affect the growth of organs implicated in the stress response, such as the adrenal gland.

130.3.2 Consequences of Fetal Programming of the Stress Response

If proven to be valid, the hypothesis that the fetal environment alters the stress response has important consequences for health in later life. Altered functioning of the HPA-axis and the ANS has been implicated in a range of physical as well as psychiatric diseases. Hyperactivity of the HPA-axis in the form of increased cortisol levels has been associated with increased risk of hypertension, obesity, dyslipidemia, hyperinsulinemia, hyperglycemia, and insulin resistance: all major contributors to the development of cardiovascular disease. High cortisol levels have also been found in depression patients and in patients suffering from post-traumatic stress disorder (PTSD). However, both these diseases have also been shown to be associated with very low levels of cortisol as have a number of

other abnormalities including chronic fatigue syndrome, fibromyalgia, irritable bowel syndrome, and burnout. Alterations in the ANS stress response have been linked with elevated risk for cardiovascular disease via several pathways: hypertension, ventricular arrhythmias, cardiac hypertrophy, carotid atherosclerosis, and endothelial dysfunction. Besides cardiovascular disease, ANS abnormalities have also been associated with a range of other clinical disorders including: insulin resistance, kidney disease, asthma, and depression.

130.3.3 Studying the Stress Response

The two physiological systems involved in the stress response, the HPA-axis and the ANS, can be studied in a basal condition as well as in a stressed condition. Fasting cortisol after awakening is often used as a measure of the HPA-axis in a stressful situation, because waking up highly activates the HPA-axis.

There are two ways in which the stressed HPA-axis and ANS can be measured: in response to physiological stimulation and in response to psychological stress. In physiological stress tests, the stress system is either directly activated by administering a hormone that is part of the HPA-axis or indirectly by creating a physiological stressful situation, which activates the stress response. The CRH stimulation test, the ACTH stimulation test, and the dexamethasone (dex) suppression test fit in the first category, while tests as the cold pressor test fit in the second category. In the CRH test CRH is injected, which stimulates the pituitary to produce ACTH, which subsequently stimulates the adrenals to produce cortisol. Sometimes arginine vasopressin (AVP) is simultaneously injected to maximize responses. In the ACTH test, ACTH is injected which stimulates the adrenals to produce cortisol. In the dex suppression test dex, which is a synthetic glucocorticoid, is administered. Administration leads to a lowering of cortisol levels because of the negative feedback loop that exists in the HPA-axis. In the cold pressor test, the hand of the participant is put in a container with ice water. This activates the sympathetical stress response as well as the HPA-axis.

A drawback of physiological stress tests is that they trigger the stress response at the lower levels of the stress system. Higher order brain systems that can activate the stress response, as the limbic structures and the prefrontal cortex, remain uninvolved. Psychological stress tests, though, are able to activate the stress response at the highest levels. Several different tasks are used for this ranging from mental challenges to the performing of a presentation. These tests require intense mental effort and/or stimulate several emotional responses thereby activating stress responses via the higher order brain systems. A well-established psychological stress protocol is the Trier Social Stress Test (TSST) (Kirschbaum et al. 1993). The TSST consists of a simulated job interview and a mental arithmetic task. First, the participant has to perform a speech about why he or she is a good candidate for a certain job. The speech has to be performed in front of an interview panel and is taped on camera. After the speech, the participant is asked to count down from a large prime number in increments of 13 as quickly and accurately as possible. The TSST combines two elements that have been shown to be capable of inducing quite robust physiological stress responses: uncontrollability and social evaluative threat.

The characteristics of a stress test are crucial for determining the stress response. Not only the level of activation, but also the balance between autonomic and endocrine activation depends on the sort of test. Some characteristics mainly lead to activation of the ANS while other characteristics primarily activate the HPA-axis. The choice of a test should thus be based on what the interest of the study is.

130.4.1 Evidence from Animal Experiments

Several animal models have been developed in which the consequences of dietary restriction during pregnancy have been studied. Emphasis has mostly been on effects on the HPA-axis. The majority of animal experiments aimed at studying fetal programming of the stress response have been performed in three different sorts of animals: rats, guinea pigs, and sheep. A review of the literature is given per species.

130.4.1.1 Rats

Rats have been extensively used as an animal model for studying fetal programming. An advantage of the rat model is the short gestational period of the rat, which allows studying long-term effects over a relatively short time span. A series of rat studies performed at the University of Lille (France) introduced a diet in which the daily intake of the pregnant and/or lactating rats was reduced to half the normal size. Feeding rat mothers this 50% food restricted (50% FR) diet during the last week of gestation led to an elevated level of corticosterone and a decreased level of placental 11β-HSD in the mother (Lesage et al. 2001). The newborn rat offspring had decreased body and adrenal weight and showed several alterations in the HPA-axis compared to rats born to normally fed mothers. Rat pups that were 50% FR during both the last week of gestation and during lactation showed similar changes. Additionally, when the rat pups were stressed by letting them inhale ether, they had a weaker ACTH response than control pups, providing evidence for altered HPA-axis reactivity to stress (Leonhardt et al. 2002). In young adult male rats subjected to stress by severely restraining their movement possibilities, the prenatal 50% FR diet was associated with an increased response of plasma-free corticosterone and a decreased response of adrenalin (Lesage et al. 2002). In older adult male rats subjected to stress induced by dehydration, the prenatal 50% FR diet was associated with a failure of total and free corticosterone levels to react, while basal levels of total and free corticosterone were elevated (Sebaai et al. 2004).

In summary, maternal food restriction induced intrauterine growth retardation and an overexposure of fetuses to maternal corticosterone. This led to several alterations in the development of the HPA-axis which appeared to be expressed differently with increasing age. Some alterations in the sympathoadrenal system responsiveness were also observed.

130.4.1.2 Guinea Pigs

Guinea pigs have been used in a series of experiments on fetal programming of the HPA-axis stress response. Guinea pigs are suitable animals to investigate programming, especially because they give birth to relatively mature offspring, which makes them more comparable to humans. A model in which pregnant guinea pigs were deprived of food during days 50 and 51 of gestation, which is the period of maximal fetal brain growth, showed growth restriction in the offspring (Lingas et al. 1999). Also, cortisol concentrations were increased in the mothers as well as in the offspring while expression of the glucocorticoid receptor (GR) in the fetal brain was decreased. CRH expression in the fetal brain also appeared to be decreased (Go et al. 2001). Studies on functioning of the HPA-axis in these offspring at the time when they were adults showed highly sex-specific results (Lingas and Matthews 2001). Male offspring showed lower ACTH and cortisol concentrations in a basic condition as well as in response to a number of stress challenges compared to male offspring normally fed in utero.

Female offspring, however, showed higher ACTH and cortisol concentrations basically and under stress. Interestingly, effects of prenatal nutrient restriction on the HPA-axis in guinea pigs have been shown to even pass to the next generation (Bertram et al. 2008). Offspring of guinea pigs of which the mothers received a 70% food-restricted diet during either early or late gestation had increased basal cortisol concentrations and increased cortisol response to a stress challenge. In conclusion, prenatal undernutrition has profound effects on HPA-axis functioning in the guinea pig that seem to be sex specific.

130.4.1.3 Sheep

The most extensively studied animal model on fetal programming of the stress response is the sheep model. The sheep model offers the advantage of being able to frequently sample on both sides of the placenta. Also, a lot is known on what constitutes a normal diet for sheep. In a number of experiments performed by the University College London, food intake of pregnant sheep was reduced by 15% during the first 70 days of gestation. During late gestation, the fetuses showed decreased ACTH and cortisol responses to administration of CHP+AVP (Hawkins et al. 1999). Also, CRH and GR expression in the brain were reduced (Hawkins et al. 2001). In contrast, when measured postnatally, HPA-axis response to the CHP+AVP challenge was increased (Hawkins et al. 2000). Also, heart rate was reduced and femoral artery vascular resistance in response to hypoxemia was increased. All seems to depend on the timing and degree of undernutrition though. A study that investigated the consequences of a 70% reduction in maternal nutrient intake during early gestation showed that during late gestation fetuses had increased ACTH levels (Edwards et al. 2002). Ten days of severe undernourishment of the mother during late gestation increased the HPA-axis stress response in the offspring, while 20 days did not (Bloomfield et al. 2003). A study on the effects of periconceptual undernutrition additionally revealed sex differences in functioning of the HPA-axis in the offspring. Female offspring had higher basal cortisol concentrations compared to controls, while male offspring showed no differences (Gardner et al. 2006). Increasing age also seems to matter. While a 50% FR diet during mid-gestation increased the HPA-axis response to stress in offspring at the age of 2 months, the effect had disappeared at the age of 5 and 10 months (Chadio et al. 2007). The sheep model has also been used to investigate the role of activity of the placental enzyme 11β-HSD in fetal programming of the HPA-axis. Interestingly, it was shown that 30% chronic nutrient restriction throughout gestation was associated with a decrease in placental 11β-HSD activity (McMullen et al. 2004). However, while it was expected that 11β-HSD level dictates the level of cortisol delivered to the fetus from the maternal circulation and thus fetal cortisol concentrations, the fetal cortisol concentrations were unchanged.

In summary, the sheep model provides considerable evidence that prenatal diet affects the stress response. However, data are difficult to interpret and many factors seem to be of importance in determining what the exact effects of the prenatal diet on stress responsiveness are.

130.4.2 Evidence in Humans

Due to obvious ethical restrictions to manipulate maternal diet in humans, birth weight and other anthropometric measurements performed at birth have been used as proxies for an adverse fetal environment. Clearly, there are limitations to this approach which we will come back to later.

The majority of the studies that have examined stress responsiveness in relation to birth measurements have looked at the HPA-axis and cortisol concentrations. However, recently, quite a lot of work has also been done on the ANS stress response.

At birth, fetal growth restriction was found to be associated with an increase in a number of HPA hormones in the umbilical cord blood. A first study reported elevated cortisol levels in umbilical cord blood in babies who were born small for gestational age as compared to babies who were born appropriate for gestational age (Economides et al. 1988). A second study showed that concentrations of CRH, ACTH, and cortisol concentrations in umbilical cord plasma were all higher in babies who were growth retarded (below the 10th percentile for gestational age) compared to the concentrations in normal babies (Goland et al. 1993). The first indication of a long-term association between fetal growth and HPA-axis activity was found in a cohort of 9-year-old boys and girls who were all born in Birmingham (UK) (Clark et al. 1996). In a total of 190 children, glucocorticoid metabolites were measured in a 24-h urine sample. Results showed a U-shaped association between birth weight and glucocorticoid metabolites: the highest average urinary glucocorticoid metabolite excretion was found in children who had been either light or heavy at birth. Thereafter, associations between birth weight and cortisol also began to be found in adult men and women. A series of studies performed in several cohorts reported an inverse association between birth weight and fasting cortisol concentrations. Among men and women born in Hertfordshire (UK) with a mean age of 64 years, born in Adelaide (Australia) with a mean age of 21 years, and born in Preston (UK) with a mean age of 51 years, higher fasting cortisol concentrations were found in those with lower birth weights (Phillips et al. 1998, 2000). In 2005, a meta-analysis was performed on 11 studies that investigated the association between birth weight and cortisol (van Montfoort et al. 2005). The meta-analysis revealed an inverse association between birth weight and circulating cortisol concentrations.

From the year 2000 onward, several studies have been performed in which the HPA-axis as well as the ANS has been measured in a stressed state, either provoked physiologically or psychologically. A number of studies have stimulated the HPA-axis by intravenously injecting Synacthen, which is a synthetic ACTH. One of these studies, which was performed in South Africa, observed that young men who had been born in the lowest 10th percentile of the birth-weight range had higher basal cortisol levels as well as higher cortisol responses to ACTH stimulation (Levitt et al. 2000). The other studies showed that older men and women who were born small also had increased cortisol concentrations in response to administration of Synacthen (Reynolds et al. 2001, 2005). Surprisingly, in a combined dex suppression/CRH stimulation test it was found that cortisol and ACTH levels were not higher but lower among men with low birth weight (Ward et al. 2004a). Cortisol reactivity appeared to be somewhat higher again, though, in African-American students with low birth weight who participated in a cold pressor test (McCormick 2006).

The TSST was used in a number of studies in children and adults who were small at birth and produced several sex-specific results. Boys in the age group of 7–9 years had higher cortisol responses to the psychological stress protocol when they had low birth weights, while girls of same age did not show any differences (Jones et al. 2006). On the other hand, girls who were small at birth had higher morning peak cortisol levels, whereas there was no difference in boys. Regarding the cardiovascular stress responses, in boys an association was found of lower birth weight and higher arterial pressure and vascular resistance, while in girls an association was found of lower birth weight with higher cardiac sympathetic nervous system activation (Jones et al. 2008). The authors interpreted the data as evidence for boys who were small at birth having an increased HPA-axis stress response and girls who were small at birth having an increased ANS stress response. Evidence for an enhanced autonomic response in women with low birth weight was also found in a study performed in the Adelaide

Family Heart Study cohort. Women, but not men, with low birth weights had higher blood pressure and heart rate reactivity to the psychological stress protocol than women with normal birth weights (Ward et al. 2004b). This seemed to be due to reduced baroreflex sensitivity and reduced low-frequency blood pressure variability (Jones et al. 2007).

Other studies that investigated the cortisol response to the TSST were performed in a cohort of male twins and in a Finnish cohort of men and women in their late adulthood, the Helsinki Birth Cohort. The first study confirmed the negative association between birth weight and cortisol responses to psychological stress (Wust et al. 2005). The second study found an inverse U-shaped association: increased cortisol responses to the TSST were found in men and women who were either small or large at birth (Kajantie et al. 2007).

A final interesting study was based on data from an assessment of psychological function during evaluation for military service in Sweden (Nilsson et al. 2001). It was found that stress susceptibility, as measured by a structured interview with a psychologist, decreased with increasing birth weight.

With regards to all the studies that have examined birth weight in relation to stress responsiveness it can be concluded that there are definitely associations between restricted fetal growth and HPA as well as ANS stress responsiveness. Most research seems to point at increased responsiveness of both systems in those who were small at birth, although associations are not uniform and seem to depend on gender.

As already indicated above, there are limitations to studying the effects of birth weight. Birth weight is only a surrogate marker for the prenatal environment. Other factors besides maternal nutrition contribute to birth weight. Also, the fact that organs develop during specific periods of gestation suggests that there may be a critical window for circumstances to affect the development. Looking at birth weight does not allow studying the effects of prenatal adversity during these so-called critical periods. Very few studies have looked at the direct effects of nutrition during pregnancy on stress responsiveness in later life. A first study that did look at these effects is the Dutch Famine Birth Cohort Study, which will be described in detail below. A second study that looked at these effects is the Motherwell Study (Herrick et al. 2003). The Motherwell Study included men and women who were born as term singletons in Motherwell, Scotland during 1967–1968, whose mothers were advised to eat a high-meat, low-carbohydrate diet. At the time, pregnant women attending the maternity hospital were advised to consume 1 lb (0.45 kg) of red meat per day and to restrict the intake of carbohydrate rich foods, such as potatoes or bread. Moderate consumption of fish, eggs, and cheese was encouraged together with green vegetables twice daily. The diet was intended to prevent preeclampsia, which was then thought to result from nutritional deficiency. The women's actual nutritional intake was recorded each week showing a doubling of protein intake between early and late pregnancy but a reduction in total energy intake.

At the age of 28–32 years, the sons and daughters of the Motherwell mothers were invited to the clinic to participate in glucose tolerance testing on which occasion fasting cortisol levels were also assessed. A total of 323 of them participated. The results showed that those exposed to increased meat and fish intake and lower green vegetable consumption during the second half of pregnancy had increased fasting cortisol concentrations. Cortisol concentrations increased by 5.4% per portion of maternal meat/fish consumption per day. To further understand these results, a subgroup of 70 men and women were asked to participate in TSST (Reynolds et al. 2007). Cortisol responsiveness to the TSST was again greater in those prenatally exposed to the unbalanced high-protein maternal diet. Compared with the offspring of mothers who had reported eating no more than 13 portions of meat/fish per week, the average cortisol concentrations were raised by 22% and 46% in the offspring of mothers eating 14–16 and at least 17 portions per week. Thus it appeared that an unbalanced high-protein maternal diet clearly affected stress responsiveness in adult life.

130.4.3 The Dutch Famine Birth Cohort Study

130.4.3.1 The Dutch Famine

The Dutch famine or Hungerwinter was a period of 5 months in 1944–1945, during the last winter of World War II. During this period, the urban western part of the Netherlands ran out of food as a consequence of a number of cascading events. While the southern part of the Netherlands was already liberated by the allied forces, advance of the Allies to the north of the Netherlands came to a halt when Operation Market Garden, aimed at gaining control of the bridge across the Rhine at Arnhem, failed. In order to support the Allied offensive, the Dutch government in exile called for a strike of the Dutch railways to hamper movement of the German troops. As a reprisal for the strike, the German administration banned all food transports. This embargo on food transports was partially lifted in early November 1944 by allowing transport of food across water. By then, however, it had become impossible to bring in food across water because most canals and waterways were frozen due to the extremely severe winter, which had started unusually early. Food stocks in the large cities of the western Netherlands ran out within a matter of weeks. Rations soon fell below 1,000 cal per person a day in late November 1944. At the height of the famine from December 1944 to April 1945 the official daily rations varied between 400 and 800 cal: less than a quarter of the prefamine rations (Fig. 130.4). Children younger than 1 year were relatively protected, as their official daily rations never fell below 1,000 cal. Pregnant and lactating women were entitled to an extra amount of food, but at the peak of the famine these extra supplies could not be provided anymore. The famine ended after the liberation of the Netherlands in early May 1945. The food situation improved swiftly. In June 1945, rations had risen to more than 2,000 cal a day (Burger et al. 1948). The famine had a profound effect on the general health of the population. In Amsterdam, the mortality rate in 1945 had more than doubled compared to 1939, and it is very likely that most of this increase in mortality was attributable to malnutrition (Banning 1946).
Fig. 130.4 (**a**) Rations during the Dutch famine. (**b**) Macronutrient content of rations provided to adults in Amsterdam between April 1941 and April 1947

130.4.3.2 The Dutch Famine Birth Cohort Study

The Dutch famine was a humanitarian disaster. But even during these extremely harsh circumstances, women conceived and gave birth to babies, and it is in these babies that the effects of prenatal malnutrition can be studied (Fig. 130.5). Usually, studying effects of prenatal famine in humans is difficult, because the period of undernutrition lasts longer than gestation. The Dutch famine, however, struck a population that was well fed before and after the famine. The period of undernutrition was thus restricted to 5 months, also allowing the study of gestation-specific effects of undernutrition. Furthermore, detailed information on the weekly rations of people living in Amsterdam is available. Birth records were kept on babies born in the Wilhelmina Gasthuis in Amsterdam and these men and women could be retrieved using the Dutch population registry. A total of 2,414 of them comprise the Dutch Famine Birth Cohort. People were included in the cohort when they were born as a term singleton between 1 November 1943 and 28 February 1947. The official daily food-rations for the general population of 21 years and older were used to define exposure to famine (Trienekens 1985). A person was considered to be prenatally exposed to famine if the average daily food-ration of the mother during any 13-week period of gestation contained less than 1,000 cal. Based on this definition, babies born between 7 January 1945 and 8 December 1945 had been exposed in utero. Periods of 16 weeks each were delineated to differentiate between those exposed in late gestation (born between 7 January and 28 April 1945), in mid-gestation (born between 29 April and 18 August 1945), and in early gestation (born between 19 August and 8 December 1945). People born before 7 January 1945 and conceived and born after 8 December 1945 were considered as unexposed to famine in utero and acted as control groups (Fig. 130.6).

A first round of data collection in the Dutch Famine Birth Cohort at the age of 50 years yielded remarkable results (Painter et al. 2005). Exposure to famine in early gestation appeared to be associated with an excess in dyslipidemia, altered clotting, more obesity in women, a higher prevalence of coronary heart disease, and an increased proportion of people reporting poor health. Exposure to famine in mid-gestation was associated with more obstructive airways disease and microalbuminuria. Exposure to famine during any stage of gestation was associated with impaired glucose tolerance. A second round of data collection at age 58 years showed among others that exposure to famine in mid-gestation was associated with impaired insulin secretion and exposure to famine in early gestation with an increased prevalence of breast cancer in women (Roseboom et al. 2006).

130.4.3.3 Stress Response in Men and Women Prenatally Exposed to the Dutch Famine

To investigate whether exposure to undernutrition in utero alters the stress response, functioning of both HPA-axis and cardiovascular responses to stress in men and women prenatally exposed to the Dutch famine were investigated. Therefore, a combined dex suppression and ACTH stimulation test was performed to measure HPA-axis response to physiological stress and a psychological stress protocol was performed to measure HPA-axis and cardiovascular responses to psychological stress. The combined dex suppression and ACTH stimulation test was performed in a subsample of the cohort consisting of 97 men and women with a mean age of 58 years, of whom 57 had been prenatally exposed to famine (de Rooij et al. 2006a). Results of the dex suppression test showed no differences in cortisol concentrations between participants exposed and participants unexposed to famine in utero. The ACTH stimulation test also did not reveal different cortisol concentrations between the exposed and the unexposed groups.

The psychological stress protocol was also performed at age 58 years but in a much larger group of 694 cohort members (de Rooij et al. 2006b; Painter et al. 2006). The protocol consisted of three 5-min stress tasks: a Stroop test (a color-word conflict challenge), a mirror-tracing test (a star had to be traced that could only be seen in mirror image), and a speech test (a speech had to be given in front of a video camera). Cortisol concentrations were measured seven times and blood pressure and heart rate were measured continuously during the protocol. There was no effect of prenatal exposure to the Dutch famine on cortisol reactivity to the stress tests. However, men and women exposed to famine during early gestation showed larger systolic blood pressure responses to the stress protocol compared to men and women unexposed to famine in utero. Diastolic blood pressure responses were also higher, but this difference did not reach statistical significance.

Key Points of Stress Responsiveness Research in the Dutch Famine Birth Cohort

Test performed	Response measured	Number of participants	Exposure	Result
Dexamethasone-suppression test	Plasma cortisol	98	21 born before the famine 20 exposed in late gestation 20 exposed in mid-gestation 17 exposed in early gestation 20 conceived after famine	No differences found between exposed and unexposed subjects
ACTH stimulation test	"	98	"	"
Psychological stress protocol	Salivary cortisol	725	215 born before the famine 120 exposed in late gestation 100 exposed in mid-gestation 62 exposed in early gestation 197 conceived after famine	"
Psychological stress protocol	Systolic blood pressure	725	"	Subjects exposed to famine in early gestation had higher SBP stress responsiveness.
Psychological stress protocol	Diastolic blood pressure	725	"	Subjects exposed to famine in early gestation tended to higher DBP stress responsiveness
Psychological stress protocol	Heart rate	725	"	No differences found between exposed and unexposed subjects

130.4.3.4 Conclusions from the Dutch Famine Birth Cohort Study

Results from stress responsiveness studies in the Dutch Famine Birth Cohort showed that at the age of 58 years, individuals conceived in famine were more stress responsive in terms of systolic blood pressure compared with individuals who were unexposed to famine in utero. No differences were found in cortisol responsiveness to stress. It could be concluded that prenatal exposure to undernutrition programs the ANS response to stress and not so much the HPA-axis response. However, caution should be taken in interpreting the results. Cortisol responses induced by the stress protocol were not very large. They may not have been robust enough to detect any effects of prenatal famine exposure.

130.5 Conclusions

Evidence from animal studies shows that there are definitely effects of prenatal diet on functioning of the stress response in adult life. Human evidence seems to point in the same direction. Indirect evidence based on studies of the consequences of low birth weight as well as direct evidence based on the Motherwell study and the Dutch Famine Birth Cohort Study suggest a role for prenatal diet in programming the stress response. However, inconsistencies have been found. Birth-weight studies and the Motherwell study both found evidence for fetal programming of the HPA-axis, while the Dutch Famine Birth Cohort study did not. The Dutch Famine Birth Cohort study did find an association between prenatal undernutrition and the ANS response to stress, which is confirmed by a

number of birth-weight studies. Hyper- as well as hypoactivity of the stress response has been found and several factors seem to influence the direction and magnitude of the stress response as well as which parts of the response are affected. Future studies are needed to provide more clarity on the subject.

130.6 Applications to Others Areas of Health and Disease

The output of the several studies described in the present chapter is of importance to a wide range of health and disease areas because of the wide spread effects in the body of a dysfunctional stress response, as referred to in the first part of the chapter.

It also offers opportunities for public health strategies. Although most studies performed so far have mainly investigated the consequences of a restricted prenatal diet, results of the Motherwell Study suggest that an unbalanced diet in utero can equally affect the stress response in later life.

Recent research in women who were planning a pregnancy showed that only a very small proportion of these women followed the recommendations for nutrition, which include taking 400 μg or more of folic acid supplements a day, drinking four or fewer units of alcohol a week, and eating a healthy diet (Inskip et al. 2009). Remarkably, these are women who are trying to get pregnant. Of young women in general, almost one in four women in Europe were attempting to lose weight in 2001; only one-third ate fresh fruit or vegetables daily. At the other end, it is well known that the prevalence of obesity is still rising worldwide, also among pregnant women! It appears that young women are still largely unaware of the importance of a healthy diet during pregnancy. The fact that mothers can improve the health of their babies by consuming a balanced diet needs to be communicated to the greater public.

Summary Points

- Prenatal undernutrition has been shown to affect susceptibility for several diseases in later life, including type 2 diabetes and cardiovascular disease.
- Fetal programming of the stress response is one of the candidates that have been suggested to mediate the association between prenatal diet and disease in later life.
- Experiments in rats have shown that maternal food restriction induced growth retardation and overexposure of fetuses to maternal corticosterone. Several alterations in the development of the HPA-axis in the offspring have been observed, as well as some changes in responsiveness of the sympathoadrenal system.
- Studies performed in guinea pigs revealed that prenatal undernutrition had some profound effects on HPA-axis functioning in the offspring. A number of these effects seemed to depend on the gender of the guinea pig.
- Sheep have frequently been used as a model for fetal programming of the stress response. Results of these models have provided considerable evidence for a role of prenatal diet in functioning of the HPA-axis in later life. Timing and severity of undernutrition seem to be important factors.
- In human studies, birth weight has extensively been used as a marker for the fetal environment. The many studies that have been performed investigating the association between birth weight

and stress responsiveness seem to lend support to the hypothesis of fetal programming of the stress response.

- The Motherwell Study directly measured the effects of prenatal diet on stress responsiveness in later life. Fasting cortisol and cortisol responses to a psychological stress protocol were elevated in men and women whose mothers consumed a diet consisting of high meat and fish intake and low green vegetables intake.
- The Dutch Famine Birth Cohort Study examined the effects of prenatal exposure to undernutrition on stress responsiveness in later life. No effects on the HPA-axis were found, but men and women who had been exposed to famine during early gestation had increased blood pressure responses to psychological stress.
- It can be concluded that prenatal diet shapes the response to stress in later life. Exactly how this happens, to what extent and which factors are of importance remains to be clarified.
- Young women are largely unaware of the importance of a healthy diet during pregnancy. From a public health point of view, it would be wise to communicate to the greater public that a balanced diet during gestation can improve health outcomes in offspring.

Definitions and Explanations of Key Terms or Words

Autonomic Nervous System (ANS): One of the two physiological systems involved in the biobehavorial stress response. The ANS is part of the peripheral nervous system, which together with the central nervous system constitutes the nervous system. The ANS controls homeostasis in the body and can be divided in two parts: the sympathetic and the parasympathetic nervous system. The sympathetic part is mainly concerned with activation of several bodily systems and functions, while the parasympathetic part mediates calming and vegetative functions.

Biobehavorial stress response: The response set in motion by a stressful stimulus (or stimulus that is interpreted as stressful), which involves activation of the HPA-axis and the ANS resulting in the secretion of noradrenalin, adrenaline, and cortisol. For a schematic overview of the stress response, see Fig. 130.2.

Birth weight: Weight of a child at birth, which has frequently been used as a summary measure of the fetal environment. Birth weight is the end result of interplay between several factors, including gestational age, genetic factors, maternal nutrition, maternal health, and placental functioning.

Dutch famine: Period of severe undernutrition in the western urban cities of the Netherlands, which happened at the end of World War II. The famine started in November 1944 and lasted 5 months until the liberation of the northern part of the Netherlands on 5 May 1945. Daily energy intake was as low as 400–800 cal a day at the peak of the famine.

Fetal programming hypothesis: Undernutrition in utero permanently changes the body's structure, physiology and metabolism conferring a predisposition to disease in later life.

Hypothalamic–Pituitary–Adrenal (HPA)-axis: One of the two physiological systems involved in the biobehavorial stress response. The HPA-axis is part of the neuroendocrine system and consists of the interaction between the hypothalamus, the pituitary gland located below the hypothalamus, and the adrenal cortex located on top of the kidneys.

Trier Social Stress Test (TSST) (Kirschbaum et al. 1993): The TSST is a psychological stress protocol designed to provoke a stress response in the laboratory, which is subsequently being measured by means of hormone sampling or cardiovascular recording. It consists of two tasks: a public speaking task and a mental arithmetic task.

131.1 Introduction

Many reports and meta-analyses of reports on the cognitive development of very preterm or low birth weight infants in childhood have concluded that their Intelligence Quotients (IQ) are usually within the normal range, but approximately 0.5–1.0 SD below the mean of term infants at a similar age. Preterm infants may also show many specific developmental deficits in educational areas such as

R.W.I. Cooke (✉)

Crown Street, Liverpool, L8 7SS, UK
e-mail: mc19@liv.ac.uk

reading, mathematics, writing, and speech, and show significant discrepancies between verbal and performance scores on IQ tests (Wolke and Meyer 1999). These deficits are seen most often in those children born preterm who are of lower weight and height and with a smaller head circumference. Most preterms with smaller heads in childhood were born with an OFC within the normal range, but have suffered postnatal growth failure. This growth failure is associated with the severity of neonatal illness, but is probably of nutritional origin. The human brain undergoes a growth spurt from about 25 weeks gestation to 18 months postnatally, and is particularly vulnerable to growth restriction at this time. Brief periods of restriction may be compensated for by catch-up growth, but longer periods may result in permanent deficits. Modern imaging techniques such as volumetric magnetic resonance imaging (MRI) have shown which parts of the brain are affected as the results of perinatal growth restriction. Improvements in nutritional management of the sick preterm infant are needed to prevent postnatal growth failure and its developmental consequences.

131.2 Developmental Outcomes in the Preterm Infant

With the improved survival of preterm infants following the introduction of neonatal intensive care several decades ago, came the increasing realization that their neurodevelopmental outcomes were often poorer than those of term infants, especially if they had suffered neonatal illness. Large controlled studies of preterm infants in later childhood have shown that at school age they experience a number of minor motor, cognitive, behavioral, and learning difficulties (Powls et al. 1995; Botting et al. 1997, 1998; Foulder-Hughes and Cooke 2003). Table 131.1 shows some of the differences in test scores between preterm infants and term controls at 7 years. These are often seen in conjunction with lower weight, height, and head circumference (Powls et al. 1996; Cooke and Foulder-Hughes 2003). These problems continue into adult life (Cooke 2004).

131.3 Tests Used to Assess Preterm Children at School Age

A wide range of tests are used to assess abilities in studies of preterm infants and for clinical purposes. Intelligence tests consist of a battery of timed subtests, roughly divided into two groups referred to as verbal and performance. The verbal tests involve understanding and memory tasks and together

Table 131.1 Comparative test results for preterm infants and term controls at 7 years (Foulder-Hughes and Cooke 2003)

Test	Preterm $n = 280$	Term controls $n = 210$	$p <$
M-ABC (<5%)	30.7%	6.7%	0.001
VMI (<85)	24.3%	8.1%	0.001
ADHD (Connors' >70)	8.9%	2.1%	0.001
VIQ (mean)	92.9	101.2	0.001
PIQ (mean)	87.8	99.6	0.001

This table shows the relative performance of 280 preterm infants and 210 term controls tested at the age of 7 years. The preterm infants perform significantly less well on all the tests, and show lower mean IQ scores

M-ABC Movement Assessment Battery for Children, *VMI* Berry test of visual motor integration, *ADHD* Connors' questionnaire for attention-deficit disorder, *VIQ* verbal intelligence quotient, *PIQ* performance intelligence quotient

give the verbal intelligence quotient (VIQ). The performance subtests involve pattern recognition and timed fine motor tasks, and as a group give the performance intelligence quotient (PIQ). All the subtest scores combined give the full intelligence quotient (FIQ). To derive the final score, the raw scores are adjusted for the subject's age and standardized to a mean of 100. Before the age of about 5–6 years, tests such as the Bayley Scales of Infant Development provide a similar sort of assessment with subtests for language or prelanguage and performance using simple tasks and puzzles. These when adjusted for age are standardized in a similar way to provide a mental and psychomotor developmental index. These are similar to VIQ and PIQ, but rather less language dependent for younger infants. To test for other aspects of development, motor skills are often tested using a test such as the M-ABC. This scores the child's performance on paper, ball, and balance skills and gives an impairment score, which is higher the less skilled the child is. A raw score of an age-standardized score can be given. The performance on the M-ABC overlaps some of the skills tested in the PIQ and PDI subtests.

131.4 Postnatal Growth Failure in the Preterm Infant

While the majority of preterm infants are born with a weight and head circumference appropriate for their gestation, it has long been recognized that early postnatal growth failure is a significant problem. Berry et al. (1997) described postnatal growth in a cohort of 109 infants with birth weights below 1,000 g. At birth, the cohort's mean weight was 94% of the mean intrauterine weight, but only 73% at 14 and 56 days. When initial clinical variables were examined, a positive correlation between energy intake over the first 56 days and protein intake over the first fortnight was seen. Duration of respiratory support and use of postnatal dexamethasone were negatively associated with postnatal growth rates. Using intensive feeding methods, they were able to improve growth from 14 to 56 days, but the infants had lost ground during the first 14 days. Clark, Thomas and Peabody (2003) also showed the extent of postnatal growth failure in a cohort of over 20,000 preterm infants from 124 US centers (Table 131.2).

Embleton et al. (2001) similarly showed the extent of growth failure in a group of 105 preterm infant of less than 34 weeks gestation. For the least mature infants (≤30 weeks), the energy deficits were 406 kcal/kg at 7 days and 813 kcal/kg at 5 weeks. Significant protein deficits were also shown and the mean weights at 5 weeks were −1.1 SD below the expected mean.

At the limits of viability, growth failure after birth becomes more marked and neurodisability more frequent. The Epicure study (Wood et al. 2000) reported on a large national cohort of infants at 23–25 weeks gestation. Half the cohort had a disability. Bayley-II scales gave mean scores of 84 on the MDI and 87 on the PDI, respectively, at 30 months. The mean OFC was 1.6 cm below the mean for the corrected age, and OFC was lower in those with disability. Even in those children without disability, 24% had an OFC more than 2 SD below the mean.

In a more recent NICHD Neonatal Research Network study, early growth was examined in a large cohort of infants with birth weights between 500 and 1,000 g (Ehrenkranz et al. 2006). The infants

Table 131.2 Percentage of infants by gestation with an OFC less than the 10th percentile for age at discharge from hospital

Gestation	23	24	25	26	27	28	29	30	31
OFC <10%	46	47	41	32	26	21	19	15	14

This table shows the marked effect of low gestational age at birth on the proportion of preterm infants having a very small head at discharge near term

OFC occipital-frontal head circumference

were divided into four quartiles based on weight gain velocity during initial hospitalization and by OFC growth velocity during the same period. The quartiles did not differ significantly by mean birth weight, gestation, intrauterine growth restriction, or sex. Weight gain in the highest quartile was 21 g/kg/day compared to 12 g/kg/day in the lowest. Although the proportion of those failing to regain their birth weight by 18 days was significantly higher in the lowest quartile, proven NEC, late onset sepsis, bronchopulmonary dysplasia (BPD), and postnatal steroid therapy were significantly more frequent in the lower quartiles, although only postnatal steroids remained significant in logistic regression analysis. Similar results were found for the four OFC velocity quartiles, with mean growth rate being 1.17 cm/week in the highest quartile and 0.67 cm/week in the lowest. At discharge 35% of the infants in the lowest quartile had an OFC less than the 10th percentile, compared to 16% in the highest. At between 18 and 22 months corrected age, survivors were assessed using the Bayley-II scales. Forty-four percent infants with an OFC in the lowest quartile had an MDI <70, compared with 22% in the highest. Similar results were shown for the PDI scores.

Other investigators have also reported the association between illness severity, postnatal head growth and subsequent neurodevelopmental outcome (Georgieff et al. 1985; Gross et al. 1983; Hack et al. 1989). While growth rates in hospital appear to be an independent risk factor for subsequent neurodisability, it remains unclear as to whether management practices or the illnesses themselves are responsible for undernutrition and growth failure.

131.5 Growth Restriction of the Developing Brain

The brain of the developing infant is highly vulnerable to the effects of growth restriction (Dobbing 1981). This is quite unlike the adult brain, which is almost immune to damage from even severe nutritional deficits. Growth restriction to the developing brain does not produce visible lesions as such, but has its effects in quantitative terms. Vulnerable periods are not the same as critical periods in brain growth, and the structures and processes affected are those developing at the time of the insult. Vulnerability is greatest at the time of the fastest growth, i.e. the time of the maximum growth spurt. Many developmental events in the brain may only have the opportunity to occur at defined times, and if they do not occur at the right time, that opportunity may be lost for ever. There is little opportunity for subsequent compensation.

Adult neuronal cell numbers are achieved early in brain development, when growth moves to glial multiplication (mainly oligodendroglial) in the first half of the growth spurt, and then myelination dominates in the second half. Myelination then continues at a slower rate for many years, with completion only in early adulthood. There are approximately eight times as many glial cells as neurons, but each neuron may have as many as 20,000 synapses. The first part of the growth spurt is concerned largely with dendritic growth and synaptic connectivity on which normal function depends.

Dobbing and Sands (1970, 1979) were able to use qualitative methods in animal and human brain to time the growth spurt. They used measurements of DNA, brain weight, and cholesterol as surrogates for neuronal tissue, brain size, and myelination. In human, the growth spurt begins at about 25 weeks gestation and continues until around 18 months post-term, with a peak velocity at term (40 weeks gestation). Only about one-sixth or less of the period of the human growth spurt is spent as a fetus, which may explain the relatively small effect of late fetal growth restriction on later development. If growth is restricted during the growth spurt for more than a short period, no catch-up is seen after the growth spurt is over, unlike the case with somatic growth where catch-up usually occurs. Undernutrition at this time does not alter the timing of cell multiplication, but only the height of the peak, producing a smaller brain. Some parts of the brain, e.g. the cerebellum, are particularly

vulnerable. In rats, it could be shown that smaller parts of the brain were associated with loss of cortical neurons and lipids (greater than that expected for brain size) and a marked reduction in synapse formation. During the human growth spurt of the brain, cellularity falls in the forebrain toward term but increases to beyond term in the cerebellum. Cell numbers continue to increase in the brain stem and cerebellum to around 2 years of age, while cholesterol (an indicator of myelination) continues to increase to 4 years and beyond.

At 10–18 weeks of fetal life, neuroblasts are forming neurons. Some loss of number of neurons may not be as important as loss of connectivity and synapse formation later. Neuronal multiplication is also not affected by maternal nutrition but only by later fetal growth restriction. Growth restriction in the neuronal multiplication stage does not allow catch-up growth, although this does tend to occur if the restriction happens later. Although the stages of brain growth are spoken of as if they occur serially, there is a great deal of overlap in their timing. Specific nutrient deficiencies have been suggested to be important, but the evidence for these is poor. An overall lack of fetal or neonatal nutrition generally is more likely to be responsible.

131.6 Magnetic Resonance Imaging Studies

Although the occipitofrontal head circumference is a good guide to brain weight in infants (Cooke et al. 1977), the availability of MRI in the last 2 decades has facilitated more detailed studies of poor brain growth in children born preterm. When overall brain size is considered, a study of 87 Very Low Birth-Weight (VLBW) children at 15–17 years showed an average reduction in coronal cross-sectional area of 7%, and of transverse section 12% (Cooke and Abernethy 1999). A similar study using volumetric analysis in 72 very preterm 15-year-old children showed broadly similar findings, with an average reduction in total brain volumes of 6%, but of 12% for the cortical gray matter volumes (Nosarti et al. 2002). Interestingly, the sex of the child appears to influence the degree of reduction in brain size. When gray and white matter volumes were estimated at 8 years in 65 very preterm children and compared with term controls, reduction in both were seen, but only statistically significant in males (Reiss et al. 2004). This may indicate that the sex of a preterm infant influences its response to perinatal adversity.

Improvements in quantitation of regional brain volumes have allowed more detailed studies to be made. Peterson et al. (2000) have published values for 25 preterm infants at 8 years compared with term controls. Reductions of 11–12% were seen in the premotor region, 14% for the sensorimotor and 7–10% for the mid-temporal region. Reductions in volume on the left and right sides of the brain were not symmetrical. Another study was able to separate gray and white matter volumes in different regions (Kesler et al. 2004). A total of 73 preterm and 33 term controls were examined at 7–11 years. MRI showed disproportionately enlarged parietal and frontal gray matter, but reduced temporal and subcortical gray matter volumes. Although statistically significant, the differences were small, ranging from 2% to 4%. The authors concluded that preterm birth may be associated with disorganized cortical development, possibly involving disrupted synaptic pruning and neural migration. Cerebral asymmetry has long been recognized, and may be seen as early as 20-week gestation. It has been associated with conditions such as autism and schizophrenia. It might be expected to be seen in preterm children with poor postnatal brain growth, but in a large study of 61 14-year-olds born at less than 30-week gestation, no significant differences were observed after controlling for confounding variables (Lancefield et al. 2006).

Although the cerebellum is important in motor coordination, often a problem in preterm children, it has been little studied with MRI until recently. In preterm children, reductions of 6–8% in volume

have been reported (Peterson et al.2000; Allin et al. 2001). A longitudinal MRI study with serial measurements of cerebellar volume of infants from 28 weeks to term showed a mean increase in cerebellar volume of 177% compared with 107% for total brain volume (Limperopoulos et al. 2005). This growth rate was seriously impaired by preterm birth even in the absence of cerebellar injury. At 15 years of age, Allin et al. (2005) showed a reduction in cerebellar volume in preterms compared with controls even after controlling for reduced overall brain volume. These reductions in lateral cerebellar volumes were associated with deficits in executive, visuospatial, and language function, while reductions in volume of the vermis were related to cognitive deficits.

The corpus callosum is responsible for most interhemispheric communication, and often shows lesions in preterms in the neonatal period and later. Most of these lesions relate to periventricular leucomalacia (PVL), and are seen as thinning, mainly of the posterior part (Stewart et al. 1999; Cooke and Abernethy 1999). Generalized reductions in cross-sectional area of different parts of the corpus callosum of 16–19% were also seen (Cooke and Abernethy 1999). A study using diffusion tensor imaging in 10-year-old preterms with attention deficit, looking at white matter integrity compared to that of term control children, showed changes that had not been compensated for by 10 years after birth (Nagy et al. 2003) (Figs. 131.1, 131.2, and 131.3).

The caudate nuclei are thought to be important in higher order motor control, learning, and memory, and many studies have shown associations between caudate volume and learning difficulties in children of school age. In preterms at 15–17 years, caudate volumes were 16–17% lower than in term controls (Abernethy et al. 2002). The reduction in volume though was of the same order as the reduction in overall brain size.

The hippocampus is important in memory and spatial navigation, and may change in size with time, increasing with use or decreasing in size with adverse experiences. A number of studies have

Fig. 131.1 A normal saggital cranial MRI scan at 15 years. The broad white c-shaped structure of the corpus callosum is easily seen

Fig. 131.2 A saggital cranial MRI of a preterm at 15 years with marked thinning of the corpus callosum. The structure of the corpus callosum can be seen to be markedly thinned at its middle and posterior part

tried to measure reductions in mean hippocampal volume in preterm children (Peterson et al. 2000; Isaacs et al. 2000, 2003; Nosarti et al. 2002; Abernethy et al. 2002). Because of its complex shape, volume measurements are difficult to make. Differences in these studies in hippocampal volumes between preterm children and controls mostly exceeded 10%.

The differences in brain size found on MRI are associated with the many neurodevelopmental deficits seen in preterm children, but caution is needed in their interpretation, as these associations may not always be causal. Major motor deficits are not uncommon in these high-risk children, and are mostly associated with PVL, although cerebral palsy may also be seen in the absence of gliosis and PVL, and simply decreased white matter volume.

Although cognitive deficits are often seen in association with cerebral palsy, they are also seen in preterms without motor deficit, and most commonly with the lowest gestation survivors. Characteristically the verbal IQ is less affected than the performance IQ. Peterson et al. (2000) showed correlations between full IQ and regional brain volumes ranging from 0.40 to 0.62 in children born very preterm. Similar significant correlations between IQ and cerebellar volumes in preterm children have been demonstrated (Allin et al. 2001). Hippocampal and caudate volumes are also seen to be reduced significantly in preterm children with low full IQ (Abernethy et al. 2002, 2004).

IQ is thought to be relatively stable over time in older children and adults, but a decline in preterm children has been described (Isaacs et al. 2004). Visible MRI abnormalities did not seem to relate to IQ, but voxel-based morphometry showed the full IQ scores to be related to areas in the parietal and temporal lobes. Decline in verbal IQ over time was associated with frontal and temporal lobe measurements, and performance IQ with the occipital and temporal lobes (including the hippocampus).

Fig. 131.3 An axial cranial
MRI of a preterm at 15 years
with ventriculomegally. The
enlargement of the cerebral
ventricles is due to cerebral
atrophy, and is strongly
associated with poorer motor
and cognitive performance in
later life
Table 131.3 Correlation between test scores and OFC at birth, OFC at 7 years and change in OFC from birth to 7 years (Foulder-Hughes and Cooke 2003)

	VMI	M-ABC	VIQ	PIQ	FIQ
OFC at birth (sds)	0.029	−0.075	0.046	−0.056	0.009
Change in OFC (sds)	0.096	−0.020	0.139	0.190[*]	0.184[*]
OFC at 7 years (sds)	0.232[**]	0.218[**]	0.252[**]	0.157[**]	0.236[**]

This table shows data on 280 preterm infants tested at 7 years, and shows that the head size at 7 is strongly correlated with all test results, but that head size at birth is not. Postnatal head growth rather than fetal head growth is a greater determinant of later high test scores

OFC occipitofrontal head circumference, *sds* standard deviation score, *VMI* Beery test of visual motor integration, *M-ABC* Movement Assessment Battery for Children, *VIQ* verbal intelligence quotient, *PIQ* performance intelligence quotient, *FIQ* full intelligence quotient

[*]$p < 0.05$, [**]$p < 0.001$

Minor motor impairments are common in preterm children and often called dyspraxia or developmental coordination disorder (Foulder-Hughes and Cooke 2003). Table 131.3 shows the correlations between impairment scores and IQ and OFC at birth, 7 years and as change in OFC between the two times. The most significant relationships are shown with current OFC. Many MRI findings have been associated with the condition, but probably not all causally. Interestingly enough cerebellar abnormalities and volumes do not seem to be associated (Allin et al. 2001). The most striking associations appear to be with reductions in the thickness of the corpus callosum. Using the Movement ABC (an impairment score), those preterm children with obvious corpus callosum thinning had an mean score of

20 compared to 7.75 for those without (Abernethy et al. 2004). Cross-sectional data confirm this association (Rademaker et al. 2004).

Preterm dyspraxia is associated with, and often complicated by other spatial and visuoperceptual problems (Foulder-Hughes and Cooke 2003). In a recent study involving preterm adolescents without visible lesions on MRI, a test was used to rate the subject's ability to judge angles, and this was compared with voxel-based morphometry of the cortical MRI. The test selected those with good and poor angular judgment. A highly significant difference was seen in the gray matter volume in the area of the right ventral extrastriate cortex, an area previously identified as associated with this skill (Isaacs et al. 2003). Rademaker et al. (2004) showed that the standardized results from the Beery Developmental Test of Visual Motor Integration (VMI) in a cohort of 7–8 year olds were associated with the cross-sectional area of the corpus callosum. The same test was used by Cooke and Foulder-Hughes (2003) when scores for preterm children were shown to be highly significantly correlated with OFC at 7 years, but not with the OFC at birth. Full IQ was similarly related.

131.7 Improving Nutrition and Effect on Outcomes

Over the years there have been very many reports of the effects of different feeding strategies on growth in the preterm newborn. Many of these have been small studies, concentrating mainly on short-term weight gain, and not considering head growth or long-term cognitive outcomes. Over 2 decades Lucas et al. (1984, 1989, 1990, 1998) have described both the early improvements in growth, and later cognitive outcome assessments in two major controlled feeding trials.

In the first of these (Lucas et al. 1984, 1989), preterm infants were randomized to be fed a special preterm formula or banked breast milk. If their own mother was providing breast milk, then the infant was randomized to be supplemented if required with preterm formula or banked breast milk. Although the formula had an energy content of 80 kcal/100 mL, the banked breast milk had an average energy content of 46 kcal/100 mL. Feeds were given at up to 180 mL/kg/day for formula and 200 mL/kg/day for banked breast milk. The intervention was continued until the infant was discharged or reached 2 kg in weight. Infants fed the special formula were the fastest to regain their birth weight, showed the fastest early growth rate (mean 18 g/kg/day), the greatest length gain (mean 1.4 mm/day), and the greatest gain in head circumference (1.6 mm/day).

The trial was extended, and a further report (Lucas et al. 1989) described the effects of type of feeding on early cognitive outcomes. The Knobloch Developmental Screening Test and a standardized neurological examination were performed at 9 months of age. No significant differences were seen in scores of infants fed formula or banked breast milk alone. In those where the formula or banked breast milk were given as a supplement to mother's own milk, a mean 4.9 point advantage for formula was seen, particularly when the formula made up more than 50% of the daily intake. One standard deviation (SD) for the score was 10 points.

Extensive use of banked breast milk for feeding preterm infants decreased as the effects of its low energy content became apparent. In a further study and follow-up study, Lucas et al. (1990, 1998) compared the effects of feeding a standard term formula and a special preterm formula to preterm infants. Infants whose mothers were supplying breast milk had term or preterm formula supplements if required. At 18 months, blind evaluation showed clear advantages to the special formula fed infants. The effects were seen mainly in motor performance, with a mean score 15 points higher, and 23 points higher in the subgroup who were small for dates. The SD for the score was 15. Significantly more infants fed the term formula had a developmental index below 85.

The participants in this trial were followed-up at 7–8 years, with a short form of the Wechsler intelligence scale for children. A major sex difference was seen in the effects of early diet on cognition. Preterm boys fed the term formula as sole diet had a mean 12-point disadvantage in verbal IQ. 47% of boys fed term formula had an IQ less than 85 compared to 13% for the preterm formula. There was also a significant excess of cases of cerebral palsy in the term formula fed infants. The latter finding suggested that suboptimal nutrition at a period of rapid brain growth may impair the ability to withstand the effects of early brain insult. It showed too that even a short period of suboptimal nutrition can have far reaching consequences, especially in males.

Wilson et al. (1997) conducted a randomized–controlled trial of early hyperalimentation in sick preterm infants with the main objective of reducing pulmonary morbidity. Both daily energy and nitrogen intake were increased in the intervention group between day 3 and 42. No differences were found in pulmonary or other neonatal morbidities, despite improvements in early growth parameters. Of interest was that the incidence of head circumference below the 3 rd percentile was 5% in the intervention group as against 16% in the standard fed controls.

In a secondary analysis of a large randomized trial of glutamine supplementation, Poindexter et al. (2006) examined the effect of early (before 5 days) or later amino acid administration in extremely low birth-weight infants. At 36 weeks postmenstrual age, there were significant differences in weight, length, and head circumference in favor of early amino acid administration. At 18 months corrected age, there were no differences in weight, length, or Bayley developmental test scores, although significantly more infants had a head circumference below the 10th or 5th percentile. Later assessments have not been reported, and the authors comment that the Bayley scales at 18 months may not reliably predict later cognitive ability.

In another study of early amino acid administration, a cohort of 117 VLBW hyperalimented infants were compared with 67 conservatively fed controls (Dinerstein et al. 2006). Significantly higher energy and nitrogen intakes were achieved during each of the first 4 weeks after birth. The intensively fed group had significantly higher weight, length, and head circumferences at term. Both groups still showed some infants with poor growth at term, and both groups had mean energy and nitrogen deficits in the first 4 weeks. No follow-up data were presented.

Although 150 mL/kg/day of a preterm formula has been said to be sufficient for normal growth in very preterm infants, in many clearly it is not. A trial comparing infants below 30-week gestation on target intakes of 150 against 200 mL/kg/day, showed higher weights and arm circumferences at 35 weeks postmenstrual age, but no differences in length or head circumference (Kuschel et al. 2000). At 1 year of age, there were no differences in any growth parameter. The study infants were not allocated to the different feeding amounts until they were already fully enterally fed, and also target feed volumes could be adjusted by the clinicians according to poor growth or intolerance. It is probable that the first 2–3 weeks after preterm birth are when postnatal growth failure becomes established.

Tan and Cooke (2008) conducted a randomized–controlled trial of hyperalimentation in 142 infants of less than 29-week gestation. The intervention group commenced parenteral nutrition with 20% more energy than standard, and 25% more protein. Eighty percent of the babies in the intervention group were still in deficit for energy and/or protein at the end of 4 weeks. In the study as a whole, 24% of those in deficit at 4 weeks had a head circumference of more than 2 sd below the mean at 36 weeks postmenstrual age, as opposed to none of those not in deficit. Surviving infants were followed-up with an MRI head at near term, and a Bayley developmental assessment at 3 and 9 months post-term (Tan et al. 2008). The total brain volume measured by MRI and the Bayley MDI and PDI at 3 months post-term were significantly correlated with energy deficit at 4 weeks. Head circumference and total brain volume were significantly correlated with MDI and PDI at 3 and 9 months. Thus, optimal nutrition in the first weeks after birth, if achievable, can be demonstrated to improve long-term cognitive ability in preterm infants.

131.8 Applications to Other Areas of Health and Disease

The area of nutrition and cognitive development in the preterm is a narrow one, but some of the principles may apply at other times in life. Although early nutritional deficits seem to have the most deleterious effects, the development of full cognitive ability occurs over many years. Nutritional deficits in later childhood may also play a role in later ability, but the deficits then may be more qualitative than quantitative. There is evidence that while older children are rarely underfed in developed countries, the quality of the food in nutritional terms may be inappropriate. The behavior as well as learning ability may be altered by quite subtle dietary manipulation.

Summary Points

- Preterm infants, particularly those born before 32 weeks of gestation, are likely to show behavioral, motor, and cognitive difficulties in later life.
- Poorer neurodevelopmental outcomes are often associated with poor postnatal growth, especially in the early weeks after birth.
- Poor postnatal growth may be due to a variety of perinatal factors and these include inadequate nutrition.
- The human brain undergoes a growth spurt in the weeks coming up to full term, which makes it more vulnerable than usual to injury from outside influences.
- MRI brain scans have been used to investigate poor brain growth in children born preterm, and have shown not only overall smaller brains but a variety of specific areas of poor growth, which in turn are associated with poor cognitive performance in childhood.
- Improving early nutrition in preterm infants has been shown to improve their brain growth.
- There is some evidence from controlled trials that intervening to improve nutrition and early brain growth improves cognitive outcomes in childhood, but these studies are quite old now and may not reflect current practice.
- There is an urgent need for further well-designed trials to investigate the value of improved early nutrition for very preterm infants.

Definitions and Explanations

Bronchopulmonary dysplasia: also known as chronic lung disease of prematurity, is a lung condition in preterm survivors, which follows mechanical ventilation for early respiratory distress. It results in these children requiring prolonged low-level oxygen supplementation, and in later wheezing. There is also often poor early growth related to increased needs and feeding difficulties.
Necrotizing enterocolitis: is a bowel disorder in preterm infants, which results in death of small areas in the intestine and frequent subsequent perforation of the gut. Its exact cause is unknown, but its importance is in that it occurs soon after preterm birth and results in major feeding difficulties and poor early growth.
Periventricular leukomalacia: is a lesion of the brain seen in very preterm infants as the result of previous brain injury. It is essentially a form of scar tissue, and is associated with later neurodevelopmental problems in most cases. It can be diagnosed in life using ultrasound or MRI scanning.

Growth spurt: is a term used to describe the period of maximum brain growth velocity in humans and animals. It occurs around term and is associated with increased vulnerability to insults such as poor nutrition.

The corpus callosum: is the largest white matter tract in the human brain and connects the right and left cerebral hemispheres. It is often affected in preterm infants by leukomalacia or generalized poor myelination in early infancy.

The caudate nuclei and the hippocampal nuclei: are often studied in children as there many functions include memory and spatial orientation, which are very important in learning. They are vulnerable to poor growth in sick preterm infants.

Dyspraxia: is a term used to describe clumsy, awkward, or inefficient motor movements in children. It is very common in children who were born preterm.

Visual motor integration: is the description of a test often used in children born preterm. It looks at their ability to copy by drawing a series of increasingly complex shapes. The score is standardized by age to a mean of 100.

Movement ABC: is a test for impairment of gross and fine motor movements in children. Eight simple tasks such as pencil and paper and ball skills are scored from 0 to 5 on the child's ability, high scores being for the poorest performance.

Key Points of Postnatal Brain Growth and Later Development in Preterms

The human brain is growing at its maximum velocity in the weeks coming up to full term, and as a result is at its most vulnerable at this time. If brain growth is restricted during this period, changes may occur, which are irreversible, and which may have lasting consequences for later cognition. There are many factors that may impair brain growth in preterm infants after birth, and these include chronic lung disease, cerebral hemorrhage and infarction, treatment with steroids, and poor nutrition. Attempts to improve nutrition in the weeks after preterm birth have resulted in better brain growth, but the evidence that this has improved later ability is still controversial.

132.1 Introduction

Several data indicate that perinatal restriction of nutrients can modify morphological and functional maturation of the central nervous system (CNS). The short- and long-term consequences of this undernutrition are dependent upon specific time-windows that usually occur during the period of rapid brain growth that largely differs among species. As shown in Fig. 132.1, the major brain growth period in humans extends from the second trimester of gestation through the first 18–24 months of postnatal life. In rodents, it begins prenatally and peaks during the first 3 weeks after birth. It has been shown that in mice the first 3 weeks of postnatal life are crucial for the development of hypothalamic neuronal circuits regulating energy balance (for a review, see Bouret and Simerly 2006). Similarly, we have shown recently that a 50% decrease in maternal perinatal undernutrition (MPU) decreased the proopiomelanocortin (POMC, the precursor to α-MSH, a crucial anorexigenic neuropeptide) gene expression in the hypothalamus as well as in the nerve fiber projections from the arcuate nucleus-POMC neurons to the paraventricular nucleus in developing rats (Delahaye et al. 2008), indicating that MPU affects the development of hypothalamic neuronal circuitry. However, as specific brain regions have their own developmental "timetables," undernutrition could affect developmental events differently in the various parts of the brain before, and maybe after, the period of rapid brain growth. It is noteworthy that disturbances of the chronology of cellular and molecular events during this critical period may induce irreversible and long-lasting dysfunctions.

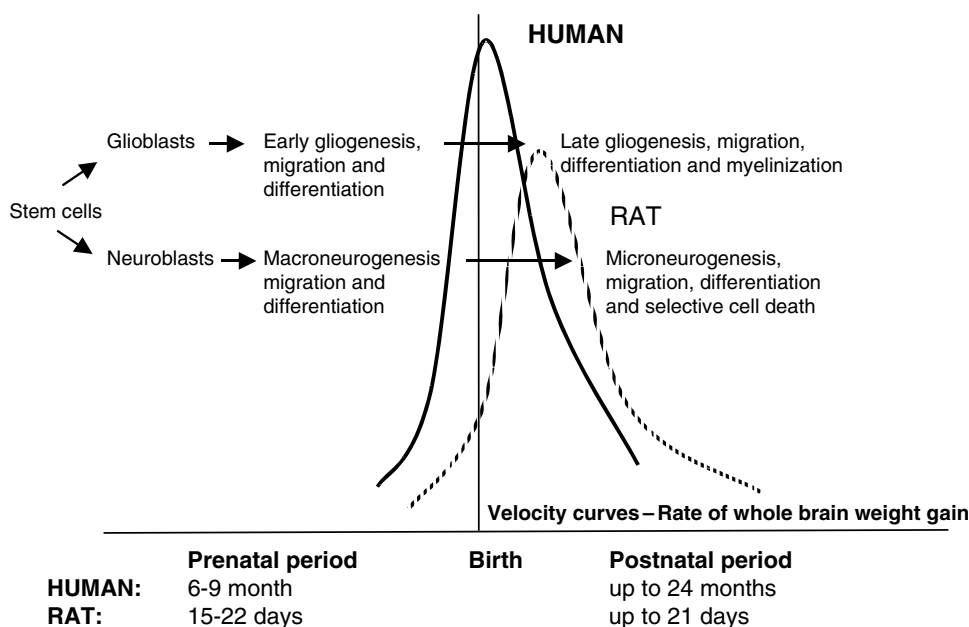
The pathophysiological mechanisms as well as molecules involved in the so-called "perinatal programming of adult diseases," or "developmental origin of health and adult diseases (DOHAD)" are still to be elucidated. However, there is compelling evidence showing that early undernutrition is frequently associated with altered perinatal growth and hypothalamo-pituitary-adrenal (HPA) axis


Fig. 132.1 Comparison of the periods of brain growth development in human and rat.
The velocity curves of the growth of human and rat CNS are indicated during the perinatal period. The major developmental cellular processes in man are also shown. Note the shift of events to early postnatal period in rats (Adapted from Lesage et al. 2006)

perturbations throughout a person's lifespan. Recent data have also shown that MPU alters the development of the sympatho-adrenal system (SAS) leading particularly to both morphological and functional disturbances of adrenal chromaffin cell. Together, these results suggest that MPU may program neuroendocrine stress systems whose regulation involves several CNS areas (for a review, see Lesage et al. 2006). The perinatal development and maturation of the CNS require numerous factors such as growth factors, i.e., neurotrophins. Among these latter molecules, brain-derived neurotrophic factor (BDNF) that has been originally isolated from porcine brain exhibits its highest concentration in the hippocampus and hypothalamus throughout the lifespan in rats (for review see Tapia-Arancibia et al. 2004). During early life, it influences almost all aspects of CNS development while, in adulthood, it is involved in several processes such as cellular proliferation, neuronal migration and survival, neuritogenesis, axonal and dendritic plasticity, synapse formation and efficacy, modulation of neurotransmitter, or neuropeptide synthesis and release (for review see Tapia-Arancibia et al. 2004). Interestingly, a close relationship between the nutritional status and BDNF level has been described. Conditional deletion of BDNF in the postnatal brain leads to obesity and disturbances of hypothalamic POMC gene expression (Rios et al. 2001). In addition, a selective depletion of BDNF in hypothalamic ventromedial (VMH) and dorsomedial (DMH) nuclei of adult mice leads to hyperphagia and obesity in adult mice (Unger et al. 2007). In humans, the functional loss of one copy of BDNF has been associated with severe obesity and impaired cognitive function, while a de novo mutation of tyrosine kinase receptor B (TrkB), the functional BDNF receptor, is associated with severe obesity and developmental delay (Yeo et al. 2004). Taken together, these data demonstrate that BDNF is an essential component of central mechanisms mediating development, satiety, and energetic status control. Although several studies have demonstrated that BDNF is very sensitive to diverse perinatal manipulations such as early ethanol exposure (Caldwell et al. 2008), fetal-neonatal iron deficiency (Tran et al. 2008), prenatal restraint stress (Burton et al. 2007), and opiate exposure (Schrott et al. 2008), little is known about the effects of maternal undernutrition on BDNF system in the offspring. The present chapter aims to explore the ways in which BDNF might participate in the programming of chronic adult diseases frequently observed in the offspring from undernourished mothers.

132.1.1 BDNF and Its Receptors

132.1.1.1 Biosynthesis, Structure, and Activity

Mature BDNF is a 14.5 kDa peptide that is generated by the proteolysis of a 32-kDa precursor molecule (pro-BDNF) within the regulated secretory pathway. Several lines of evidence indicate that the cleavage leading to mature BDNF is realized by enzymes belonging to the proprotein convertases (PCs) family such as furin or PC1 (Mowla et al. 2001). However, it has been shown that pro-BDNF is able to promote TrkB autophosphorylation suggesting that pro-BDNF is also biologically active (Mowla et al. 2001).

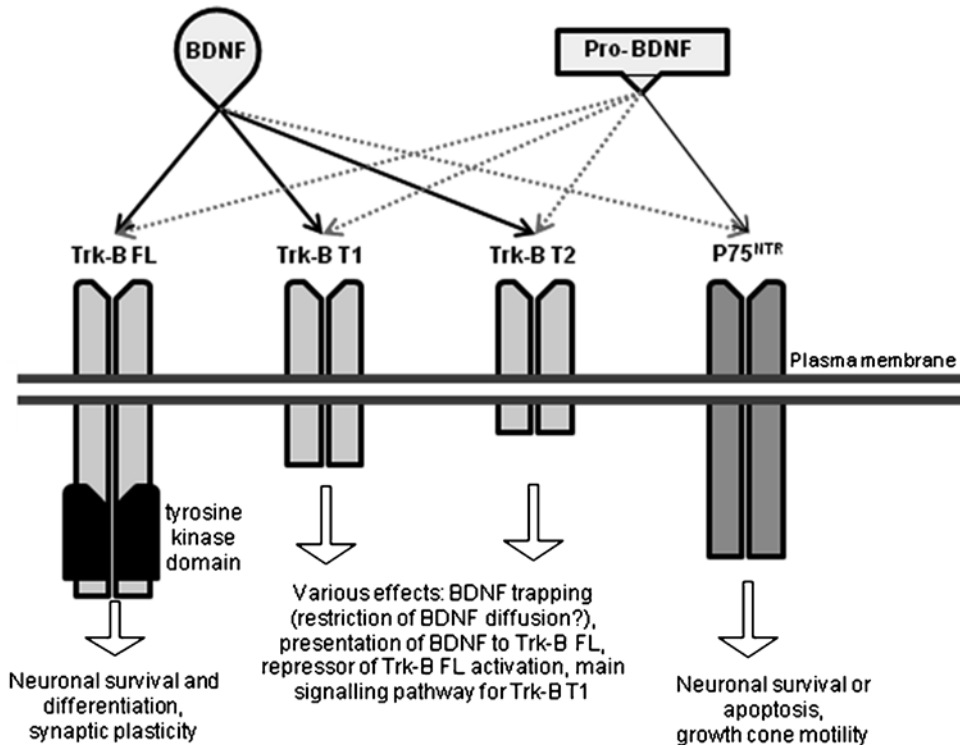
Most characterized biological effects of BDNF are mediated through the TrkB receptor (Fig. 132.2). BDNF binding to TrkB induces receptor dimerization, phosphorylation, and activation of the intracellular tyrosine kinase domain. These events initiate several complex intracellular signal transduction cascades, which subsequently induce biological responses. In addition to the full-length catalytic receptor (TrkB.FL), two truncated isoforms (TrkB.T1 and TrkB.T2) that are produced by alternative splicing of TrkB mRNA have been described in mammals (for review see Tapia-Arancibia et al. 2004) (Fig. 132.2). Although lacking the intracellular tyrosine kinase activity, the TrkB.T1 and TrkB.T2 forms are also biologically active since they trigger transduction signals that necessitate the


Fig. 132.2 Schematic representation of the major interactions of Pro-BDNF/BDNF with its receptors. Are illustrated the full-length (TrkB.FL), truncated (TrkB.T1 and TrkB.T2) TrkB and P75^NTR receptors in rodents. The binding capacity is indicated by solid (high) and dotted (low) lines, respectively. As indicated, Pro-BDNF is able to bind P75^NTR and TrkB receptors to a lesser extent. In contrast, BDNF binds preferentially TrkB receptors than P75^NTR. Other mature neurotrophins such as NT4 and NT3, in particular conditions, also recognize TrkB receptors. Major functions and cellular effects of receptors activation are indicated. For better clarity, interactions between P75^NTR and TrkB receptor isoforms are not indicated

presence of their short isoform-specific intracellular sequences. However, the physiological roles of TrkB.T1 and TrkB.T2 receptors remain unclear. It has been suggested that they may have at least two main functions, i.e., acting as ligand trapping molecules to regulate the local availability of neurotrophins or functioning as dominant negative receptors of neurotrophin responsiveness by heterodimerization. In addition, the p75 neurotrophin receptor (P75^NTR, Fig. 132.2) adds a new layer of complexity since it is able to bind pro-BDNF and to a lesser extent BDNF, to dimerize with TrkB isoforms and to exert specific biological activity such as cell death and functional impairment (Hennigan et al. 2007).

132.1.1.2 Tissue Distribution

In rat, BDNF mRNA is detected in numerous brain areas and in spinal cord, but also in several peripheral non-neuronal tissues such as the cardiorespiratory system, stomach, pituitary, skeletal muscle, and utero-feto-placental unit (Fig. 132.3). In human, a high gene expression has also been observed in spleen (Yamamoto et al. 1996).

The TrkB.FL and TrkB.T2 receptors display a similar tissue distribution in rat. Their mRNAs are restricted to CNS and to a limited number of peripheral organs such as adipose tissue or testis
Fig. 132.3 Tissue distribution of BDNF and its receptors mRNAs in rat tissues. Tissue distribution of BDNF, full-length (TrkB.FL) and truncated (TrkB.T1 and TrkB.T2) TrkB, and P75^{NTR} receptors mRNAs determined by RT-PCR analysis in adult and feto-placental (at embryonic day 21, E21) rat tissues. Cyclophilin B (cyclo) was used as an internal control. *Extraemb. Mb*. Extraembryonic membranes. The size of the amplified products is 442 bp (BDNF), 557 bp (TrkB.FL), 563 bp (TrkB.T1), 550 bp (TrkB.T2), 106 bp (P75^{NTR}), and 456 bp (cyclo), respectively

(Fig. 132.3). In contrast, the TrkB.T1 isoform is widely distributed in both rat and human (Yamamoto et al. 1996; Fig. 132.3), with a lower synthesis in the digestive system. Although, it seems to be expressed at a lower level, the p75^{NTR} mRNA is detected in most of the tissues investigated (Fig. 132.3). These data indicate that BDNF should be implicated in many more physiological functions than initially suspected, in particular in peripheral tissues that have not all been demonstrated to be sensitive to this neurotrophin, so far.

132.1.2 Physiological Roles of BDNF

132.1.2.1 BDNF and Perinatal CNS Maturation

The so-called "neurotrophins hypothesis" states that some neuronal populations depend on exogenous neurotrophic factors for their survival, and that these factors are present in insufficient amounts to maintain all the neurons that have been initially generated during development. During early development, BDNF has been shown to influence almost all aspects of CNS maturation and neuronal functions (for review see Tapia-Arancibia et al. 2004). The ontogenesis of BDNF production has been studied in several brain areas of rat fetuses and neonates. For example, in the neocortex, it has been shown that BDNF protein progressively increased from embryonic day 21 (E21) until postnatal day (P) 14, and then progressively decreased (Das et al. 2001). Interestingly, the time-window of increased BDNF production corresponds to the period of maximal synaptogenesis that occurs between P11 and P20 in rat cortex. In the hippocampus, it has been reported that maximal BDNF immunoreactivity is observed between P7 and P21, with subtle discordances depending on the rat strain studied (Das et al. 2001; Silhol et al. 2005; Coupé et al. 2009; Fig. 132.4). We have recently published that the cellular proliferation level was dramatically increased from E21 to P15 in the hippocampal dentate gyrus indicating that BDNF may contribute to this phenomenon in this brain region (Coupé et al. 2009). In this line, it has been shown that early-weaned male mice (separated from their mothers at P14) showed decreased BDNF protein levels in the hippocampus associated with reduced cell proliferation in the dentate gyrus in adulthood (Kikusui and Mori 2009). In the

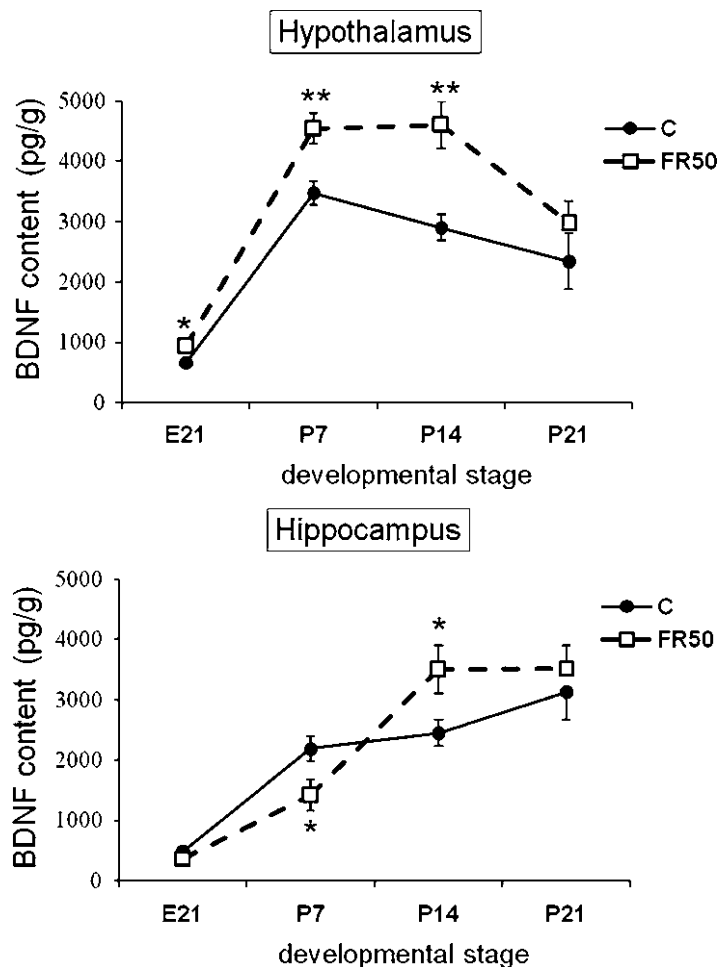
control (Adapted from Coupé
et al. 2009)


hypothalamus, it has also been demonstrated that BDNF protein levels are maximal during early lactation reaching a maximal value as soon as P7 (Silhol et al. 2005; Coupé et al. 2009; Fig. 132.4). Finally, a peak of BDNF mRNA was described in the VMH of P4 rats suggesting that this neurotrophin may contribute to the neuronal organization and functional development of this hypothalamic nucleus involved in the regulation of satiety (Sugiyama et al. 2003). Altogether, these data indicate that, in rodent, CNS BDNF protein concentration is maximal during lactation, which corresponds to the period of rapid brain growth (Fig. 132.1), to the settle of several nervous and neuroendocrine axes, and to the modification of plasma levels of hormones involved in the regulation of metabolism such as leptin, insulin, and glucocorticoids.

132.1.2.2 Role in Adult CNS

BDNF plays a major role in regulating the survival, growth, and differentiation of new neurons during early neural development, as well as maintaining neuronal populations and connections later in life in many different species. This neurotrophin and its receptor TrkB are indeed present in the adult mammalian cerebellum, cortex, hippocampus, hypothalamus (Fig. 132.3), midbrain, and spinal cord,

areas that exert numerous vital functions, in neurons as well as in glial cells. For example, BDNF infusion into the rat lateral ventricle leads to cell proliferation in the adult brain parenchyma (Pencea et al. 2001), demonstrating that BDNF is involved in the recruitment and/or generation of new cells to replace others, lost after injury or diseases.

BDNF has been proposed as a key regulator and mediator of long-term synaptic modifications related to learning and memory maintenance. The neurotrophin is involved in translating the activity signal into synaptic plasticity changes. BDNF is necessary and sufficient to induce long-lasting structural changes at the dendritic spines whose enlargement could be blocked by inhibiting protein synthesis. In addition to its classical long-lasting effects, BDNF has also been shown to exert acute effects both on synaptic transmission, possibly involved in the induction of long-term potentiation, and on membrane conductance influencing neuronal excitability and synaptic plasticity (Bouvier et al. 2006).

Data suggest a link between BDNF and respiratory control (Bouvier et al. 2006). Genetic inactivation of BDNF has been shown to induce severe respiratory disturbances and alterations in central respiration-related structures, leading to the death of mutant mice by 3 weeks of age. These animals also exhibited a significant reduction of the central respiratory frequency and an increase in the respiratory cycle variability. BDNF indeed enhances glutamatergic synaptic strength between respiratory neurons, which is in line with the fact that generation of the respiratory rhythm mainly relies on excitatory glutamatergic connections.

BDNF and its receptors are expressed in several hypothalamic and hindbrain nuclei involved in regulating energy homeostasis, in the developing and mature rat brain. In adult mice, selective deletion of BDNF in the VMH and DMH results in hyperphagic behavior and obesity (Unger et al. 2007). By contrast, infusion of BDNF into the brain of mature rats significantly reduces food intake (Lapchak and Hefti 1992). Central BDNF acts as downstream effector through which melanocortin receptor 4 (MC4R) signaling regulates energy balance. Thus, these data indicate that BDNF is a pivotal element in the regulation of energy homeostasis in the adult brain and that its secretion from the VMH and/or the DMH is required for normal appetite control.

In adult rat, BDNF has also been reported to play a role in plasticity processes related to the stress response (Rage et al. 2002), as well as in the specific guidance cue for dopaminergic neurons from the periventricular nucleus to the pars intermedia of the pituitary (Nakakura et al. 2007), suggesting that it could participate to the modulation of neuroendocrine systems.

132.1.2.3 Peripheral Functions

As indicated by the mRNA expression of pro-BDNF and its receptors outside CNS (Fig. 132.3), BDNF exerts several roles in peripheral tissues. It is involved in the activity of the peripheral nervous system (PNS) and is a key mediator of mechanisms regulating activity-dependent synaptic maturation and plasticity. Recently, BDNF has been shown to be expressed by first-order baroreceptor neurons (Martin et al. 2009). It is thus a likely mediator of both developmental and postdevelopmental modifications associated to functional characteristics of the arterial baroreceptor reflex changes throughout ontogenesis, including perinatal adjustments of the reflex gain and adult resetting during hypertension.

BDNF has been shown to be implicated in the control of peripheral respiration-related structures, since in BDNF-deficient mice the peripheral chemoafferent pathway is affected. BDNF is indeed required for survival of chemoafferent sensory neurons in petrosal and nodose ganglia that innervate the chemoreceptors in the carotid body which in turn provides chemosensory inputs on central respiratory circuits in the hindbrain (Bouvier et al. 2006).

There is growing evidence that BDNF also plays a role in gut function. BDNF, TrkB, and p75[NTR] receptors are expressed in the enteric nervous system and gut mucosa of a variety of species, including

man. For example, BDNF has been shown to be involved in the peristaltic reflex of the rat colon by increasing the release of serotonin and calcitonin gene-related peptide in response to mucosal stroking. Recent data reported that BDNF enhanced neuronal responsiveness to neurotransmitters such as serotonin and substance P suggesting that the promotion of motility by BDNF could result from its potent modulating role on enteric neuronal activity and synaptic communication (Boesmans et al. 2008).

BDNF ameliorates and normalizes glucose metabolism in obese diabetic C57BL/KsJ db/db mice (Nagakawa et al. 2000). It also enhances glucose utilization in muscle and in brown adipose tissue (Yamanaka et al. 2007a). The antidiabetic effect of BDNF, which is dependent on plasma insulin levels, modifies insulin signaling in peripheral tissues (Yamanaka et al. 2007b).

The wide expression of BDNF and/or its receptors in non-neuronal tissues (Fig. 132.3) suggests that it could exert numerous physiological functions remaining to be discovered. In this line, recent data have suggested putative roles for neurotrophins in the regulation of proliferation and survival of testicular germ cells and peritubular cells (Robinson et al. 2009).

132.1.3 BDNF and Maternal Perinatal Undernutrition

132.1.3.1 Short-Term Defects

Although it has been demonstrated that maternal stress decreased BDNF content in the olfactory bulb and hippocampus of both P1 and P5 male rat neonates (Van den Hove et al. 2006), few studies have explored the short-term consequences of maternal nutritional challenges on BDNF levels in the offspring. It has been shown that a 70% protein restriction from day eight of pregnancy until 4 weeks after birth reduced both body and brain weight as well as BDNF concentration in the hippocampus of P28 rats and was associated with impaired learning and memory ability (Wang and Xu 2007). However, this study did not provide a detailed kinetic analysis of maternal protein restriction on BDNF concentration in the offspring during the critical developmental windows corresponding to the period of maximal CNS growth velocity (Fig. 132.1). Given the critical role that BDNF plays during CNS development, we speculated that a 50% maternal food restriction (FR50) performed from E14 to P21, would modify the time course production of hippocampal and hypothalamic BDNF levels in E21, P7, P14, and P21 developing rats.

We showed that MPU modulates BDNF expression differentially in both hippocampus and hypothalamus in an age-specific manner, demonstrating that BDNF level in offspring is very sensitive to the maternal nutritional status (Coupé et al. 2009). Indeed, whereas FR50 rats displayed an augmented hypothalamic BDNF content during 2 weeks, i.e., from E21 to P14, BDNF concentration in the hippocampus, was firstly reduced at P7 and then increased at P14 (Fig. 132.4). We also observed that the hypothalamic gene expression of the truncated neuronal BDNF receptor (TrkB.T2) was augmented in FR50 rats at P14 suggesting that MPU, through both altered neuronal receptor availability and BDNF level, may compromise the neurotrophic BDNF/TrkB pathway during the perinatal life. In this study, we also analyzed the effects of MPU on the hippocampal and hypothalamic cell proliferation in the offspring, using bromodeoxyuridine (BrdU) incorporation. Interestingly, the increased concentration of BDNF observed in the FR50 hypothalamus at P7 and in the hippocampus at P14, respectively, was correlated to an augmented BrdU incorporation when compared to controls (Fig. 132.5). Together, our results reinforce the idea that BDNF plays a crucial role during the critical time-windows of rat CNS development. In addition, since MPU increases both BDNF concentration as well as cell proliferation during these stages, one could speculate that these mechanisms are part of a physiological compensatory system to maintain the CNS maturation and development even

Fig. 132.5 Effect of maternal undernutrition on cell proliferation in hippocampus and hypothalamus of rat neonates. Quantification of the amount of cell proliferation (revealed by BrdU immunoreactivity and expressed as percent of cells versus controls) in several regions of the hypothalamus (at P8) and of the hippocampus (at P15) in developing rats from mothers fed ad libitum (C) or subjected to a 50% food restriction during the last week of gestation and during lactation (FR50). *E21* embryonic day 21; *P* postnatal day; *CA* cornu ammon, *DG* dentate gyrus, *PVN* paraventricular nucleus, *VMH* ventromedial hypothalamic nucleus, *Arc* arcuate nucleus, *SE* subependymal area, *ME* median eminence. *P < 0.05; **P < 0.01; ***P < 0.001 FR50 vs. C (Adapted from Coupé et al. 2009)
under subnutritional conditions. However, our data indicate that the time course of BDNF production and cell proliferation is modified by MPU, at a time during which an intense establishment of hypothalamic neural circuits occurs (for review see Bouret and Simerly 2006), suggesting that these perturbations may have long-lasting consequences.

132.1.3.2 Long-Term Consequences

Several studies performed both in humans and in animals have demonstrated that maternal malnutrition alters various maturational events in the brain resulting in modifications of behavior, cognition, learning, and memory that extend into the postnatal period and continue into adulthood. Surprisingly, to our knowledge, only one paper has reported the effects of a 70% maternal protein restriction throughout pregnancy on brain BDNF concentration in the adult male rat. In this recent study, it has been shown that 55- to 60-day-old animals from malnourished mothers exhibited impaired long-term

synaptic potentiation associated with a decreased expression of BDNF in the entorhinal cortex (Hernandez et al. 2008). Interestingly, perinatal undernutrition has been shown to alter several physiological functions that may be mediated by the BDNF/TrkB pathway. For example, perinatal malnutrition exposure reduces hippocampal and cognitive functions (Gomez-Pinilla and Vaynman 2005) has long-term effects on hypothalamic neural circuits regulating energy expenditure (Breton et al. 2009) and promotes the development of metabolic dysfunctions such as intolerance to glucose, altered feeding behavior, or obesity (Vickers et al. 2000; Breton et al. 2009). Accordingly, it has been reported that heterozygous BDNF$^{+/-}$ mice exhibit increased locomotor activity, hyperphagia, obesity, and disturbed insulin levels (Lyons et al. 1999; Rios et al. 2001). In this line, it has been reported recently that adult male rat from mothers that have been prenatally stressed present alterations of hippocampal BDNF levels, increased anxiety-like behavior (Zuena et al. 2008) as well as hyperphagia, glucose intolerance, and hyperglycemia when they get older (Lesage et al. 2004). Taken together, these data strongly suggest that MPU could induce long-term modifications of the BDNF/TrkB system in the offspring, which may in turn participate to the programming of chronic adult diseases frequently observed in children from undernourished mothers (for review see Barker 2006).

132.1.4 BDNF and Programming of Adult Diseases

132.1.4.1 BDNF Alterations in Adult Diseases

As already mentioned, BDNF signaling is a key factor in the regulation of energy balance, body weight, and glucose metabolism. In humans, the decreased brain levels of BDNF detected in Alzheimer's disease (AD), dementia such as schizophrenia, and depression were often associated with metabolic syndrome features such as type 2 diabetes (Krabbe et al. 2007). In addition, variation of BDNF plasma level, whose source remains to be established, as well as genetic alterations in the genes encoding BDNF or TrkB have been correlated to eating disorders. On the one hand, it has been shown that BDNF plasma concentration is significantly reduced in female patients with anorexia nervosa (AN) or bulimia nervosa (BN) and significantly increased in obese women, suggesting that its circulating level is indeed positively correlated with the subject's body mass index (Monteleone et al. 2005). On the other hand, several mutations of the BDNF and TrkB encoding genes have been described in human patients with AN or BN as well as obesity (Ribasés et al. 2003). In addition, high level of circulating BDNF has been associated with impaired glucose metabolism in obese type 2 diabetic patients whereas the serum BDNF concentration was found to significantly decrease in diabetic patients independently of obesity, thus being a potential marker of type 2 diabetes (Krabbe et al. 2007).

As previously noted, central BDNF signaling plays an important role in neuronal differentiation, growth, survival, neurotransmission modulation, and synaptic plasticity. This neurotrophin has recently emerged as one of the most important molecule for the impaired nervous system diseases exhibiting severe motor control deficiencies. Indeed, neurological diseases are highly correlated with dysregulation of BDNF signaling pathways leading to long-term gene transcription modifications. In addition, genetic studies have shown potential association of most of the neurodegenerative diseases with polymorphisms in the BDNF and/or their receptor genes (Hu et al. 2008). First, reduced mRNA expression of BDNF and increased truncated form of TrkB mRNAs and proteins were observed in the brain of AD patients. Recently, it has been shown that BDNF may prevent and reverse AD (Nagahara et al. 2009). Second, reduced BDNF production has been observed in the dopaminergic neurons of the substantia nigra that are the neuronal group most severely degenerated in the Parkinson's disease. Third, reduced BDNF and TrkB levels have been observed in the striatum of

Huntington's disease (HD) and in neural cell models of HD (Ginés et al. 2006). In addition, decreased expression of BDNF mRNAs and hippocampal volumes are observed in several rat models of depression. Although mechanisms of action are far from clear, BDNF downregulation can be prevented by treatment with antidepressants and increase in BDNF levels or TrkB signaling produces an antidepressive effect. Finally, BDNF upregulation is associated with seizure activity suggesting that it may play a role in epileptogenesis (Hu et al. 2008). Together, these data strongly suggest that BDNF could constitute a missing link between metabolic and neurodegenerative diseases that could, at least in part, both originate from perinatal alterations.

132.1.4.2 Putative Perinatal Mechanisms

Several lines of evidence indicate that embryonic and early postnatal stages are critical for the adequate development of the offspring and that deleterious exposure to several environmental factors, during these critical periods, could lead to severe physiological and metabolic alterations in adulthood. Since BDNF is very sensitive to diverse perinatal manipulations, it is suspected to be associated with increased risk for neurodevelopmental disorders that provoke learning and/or behavioral deficits. In addition, BDNF acts as an anorexigenic factor, and there is a close relationship between nutritional status and BDNF plasma concentration. It is therefore not surprising that maternal BDNF plasma levels decrease dramatically during pregnancy in order to fulfill both maternal and fetal nutrient needs (Lommatzsch et al. 2006). However, the long-term consequences of BDNF perinatal variations on the development of adult diseases remain unexplained. Interestingly, it has been reported recently that injection of recombinant BDNF protein into wild-type pregnant mice carrying E14.5 embryos leads to a dose-dependent elevation of BDNF protein levels in fetal brains (Kodomari et al. 2009). In addition, the authors also demonstrated that around E14, BDNF concentrations in the fetal brain of BDNF homozygous null mutant were comparable to the levels detected in wild-type fetuses. These findings suggest that maternal BDNF reaches the fetal brain through utero-placental barrier and thus could contribute to its development. Since, placenta and extraembryonic membranes also express the BDNF gene (Fig. 132.3) one could speculate that modifications of maternal and/or placental BDNF production might play an important role on the development of brain and other BDNF-sensitive peripheral tissues in the fetus (Fig. 132.6). In this line, prenatal environmental perturbations such as maternal undernutrition might impede BDNF plasma levels in mothers and/or in placenta, and thus could participate to the programming of adult diseases (cognitive and neurodegenerative diseases, metabolic syndrome) usually observed in offspring from prenatally stressed mothers (Fig. 132.6). We cannot exclude that perturbations of fetal BDNF production could also participate to the development of adult diseases since several fetal tissues also express the BDNF gene (Fig. 132.3).

132.2 Conclusion and Perspectives

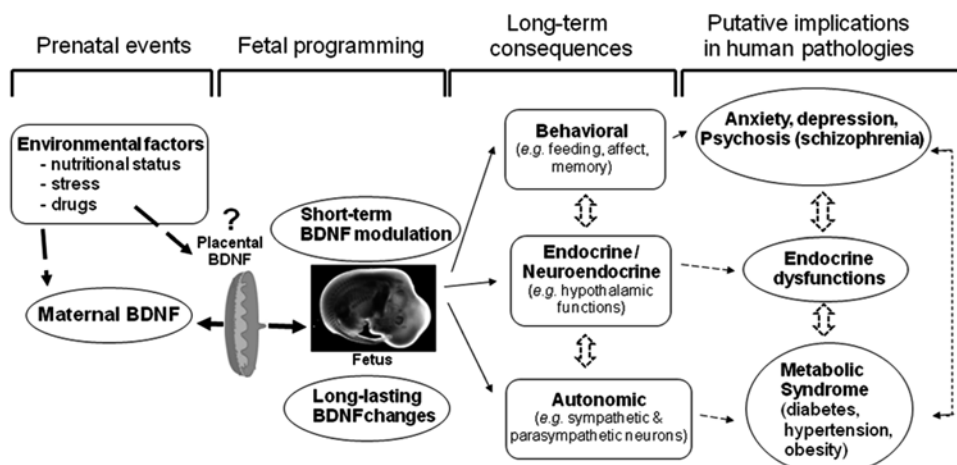
BDNF is very sensitive to diverse environmental perturbations during critical windows of the fetal development. It participates to the development and the maturation of the CNS and exerts several metabolic functions, constituting thus a putative missing link between neurodegenerative diseases and metabolic syndrome that could result from insults during perinatal life. In addition, BDNF and its receptors mRNAs are widely expressed in adult and fetal tissues suggesting that BDNF system dysfunctions during early development might have more consequences than initially suspected. Future studies will be necessary to unravel to what extent modifications of this system, using for


Fig. 132.6 Perinatal BDNF and programming of adult diseases. Hypothetical mechanism showing how early BDNF dysfunctions might participate in the development of chronic adult diseases. A modulation of maternal and/or placental and fetal BDNF production induced by the maternal nutritional status (or other perinatal environmental factors) could modify the development of several tissues during critical time-windows

example mutant mice, might compromise the development of several tissues and physiological functions. Finally, since it has been shown that BDNF is able to cross the utero-placental barrier, interventions such as nutritional diet or moderate exercise that have been shown to increase BDNF plasma levels (Chang et al. 2008) may constitute an alternate therapeutic option for preventing "programmed" diseases.

Summary Points

- Maternal perinatal undernutrition (MPU) sensitizes the offspring to the development of chronic adult diseases such as the metabolic syndrome (type 2 diabetes, hypertension, and obesity).
- Brain structures such as hippocampus and hypothalamus are very sensitive to environmental perturbations during the perinatal life.
- BDNF plays an important role in the functional maturation of both hippocampus and hypothalamus.
- MPU modifies the time-course production of BDNF in the brain of rat neonates.
- MPU affects the development of hypothalamic circuitry involved in the regulation of energy homeostasis in the male rat neonate.

Key Facts of BDNF

1. BDNF has been originally isolated from brain, which constitutes its principal site of production.
2. In the brain, BDNF is involved in several processes such as maturation of the CNS, cellular proliferation, neuronal migration and survival, synapse formation, axonal and dendritic plasticity.
3. BDNF also modulates the synthesis and secretion of several neurotransmitters and neuropeptides and exerts a marked anorexigenic effect.

---

4. BDNF and its receptors are also present in several peripheral tissues where they should exert diverse physiological functions.
5. BDNF concentration is very sensitive to perinatal environment.
6. BDNF levels are altered in patients suffering from brain pathologies (Alzheimer and Parkinson diseases, schizophrenia) that are frequently associated with metabolic syndrome features (obesity, hypertension, type 2 diabetes).
7. BDNF protein is able to cross the utero-placental unit.

Key Terms

Perinatal: Refers to a period of time covering both fetal (prenatal) and early postnatal life.
Programming of adult diseases: Hypothesis speculating that perinatal environmental perturbations, such as undernutrition, infection, psychological stress, gestational diabetes, or other insults, may sensitize the individual to the development of several diseases (including diabetes, obesity, hypertension, depression, and schizophrenia) in adulthood.
Hippocampus: Brain region that is a part of the limbic system, playing a major role in learning and memory processes.
Hypothalamus: Brain region that is involved in the control of almost all the neuroendocrine axes, playing a crucial role in the energy homeostasis since it contains several orexigenic and anorexigenic peptides.
Bromodeoxyuridine: Synthetic nucleoside that is an analogue of thymidine. It is a substitute to thymidine during DNA replication and thus allows the detection of proliferating cells in living tissues.

Chapter 133
The Developing Brain and Dietary Omega-3 Fatty Acids

Sheila M. Innis

Abbreviations

ALA   Alpha Linolenic Acid, 18:3ω-3
ARA   Arachidonic Acid, 20:4 ω-6
DHA   Docosahexaenoic Acid 22:6 ω-3
EPA   Eicosapentaenoic Acid 20:5 ω-3
EPG   Ethanolamine Phosphoglycerides Including Diacyl and Plasmalogen
FAD   Fatty Acid Desaturases
LA   Linoleic Acid, 18:2 ω-6
PC   Phosphatidylcholine
PI   Phosphatidylinositol
PS   Phosphatidylserine
TG   Triacylglycerols

133.1 Introduction

The omega (ω)-3 polyunsaturated fatty acids are a family of fatty acids which humans, as other animals are unable to synthesize due to the absence of a Δ-15 desaturase, the enzyme necessary to insert a double bond at the ω-3 position of a fatty acid carboxyl chain (Fig. 133.1). Three major forms of ω-3 fatty acids are present in usual human diets: the 18-carbon chain α-linolenic acid (ALA, 18:3ω-3), and its elongation and desaturation products eicosapentaenoic acid (EPA, 20:5ω-3) and docosahexaenoic acid (DHA, 22:6ω-3) (Fig. 133.2). In the body, the ω-3 fatty acids are found esterified in membrane glycerophospholipids where they impact membrane functions and from which they are released to participate directly or indirectly in regulation of metabolic and physiological processes. However, the ω-3 fatty acids are distributed with definitive tissue, membrane and glycerolipid specificity, and this likely underlies their contribution to normal yet diverse cell functions. DHA, but not ALA or EPA is highly enriched in mammalian brain grey matter, particularly phosphatidylserine (PS) and the ethanolamine-containing glycerophospholipids (EPG). DHA is also high in the

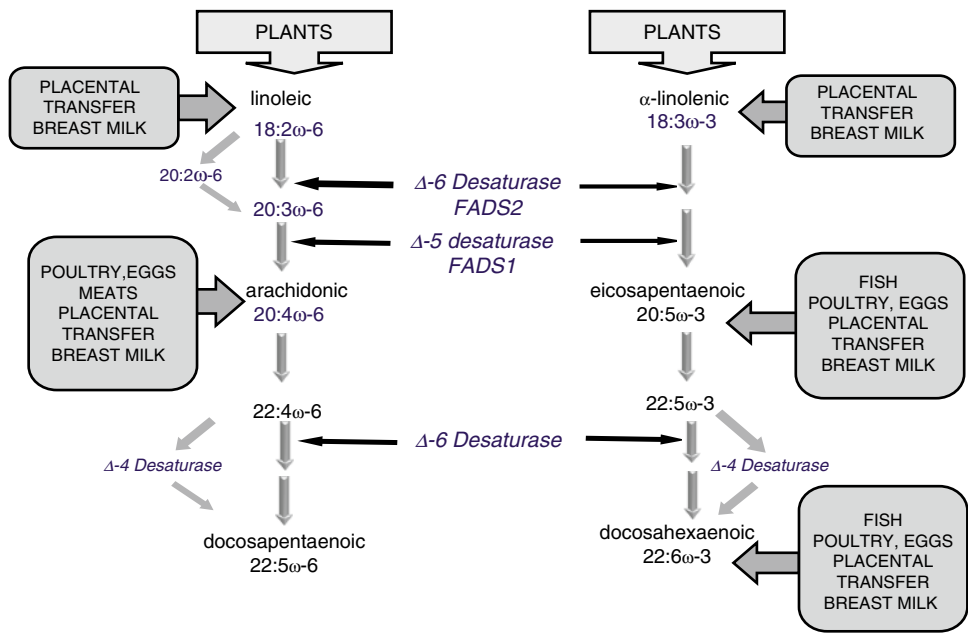
Fig. 133.1 Schematic to illustrate the major fatty acids, and use of ω and Δ nomenclature. The schematic illustrates a fatty acid carbon chain showing the methyl (CH$_3$) and carboxyl (COOH) ends and the position of the double bonds in the ω-9, ω-6 and ω-3 fatty acids. The carboxyl terminus is designated as Δ and the methyl terminus is designated ω. Humans lack a Δ-12 and Δ-15 desaturase


Fig. 133.2 Schematic of major steps of fatty acid desaturation and elongation and their dietary sources. The major steps of fatty acid desaturation and elongation, and the major dietary sources of ω-3 and ω-6 fatty acids at differences before and after birth, and in the diet are illustrated. Δ-6D, Δ-5D are 6 and 5 desaturases, respectively, are encoded by FADS2 and FADS1, respectively

glycerophospholipids that make up the membrane discs that comprise the highly specialized outer segments of the rods and cones in the retina. Dietary restriction of ω-3 fatty acids leads to loss of DHA and an increase in ω-6 fatty acids in the brain with effects that span from impaired neurogenesis to altered activities of proteins, ion channels, signal pathways, and gene expression, ultimately

influencing behavior and learning. During pre- and early post-natal development, DHA is provided by the mother by placental transfer and in breast milk, respectively, placing the emphasis of dietary ω-3 fatty acid adequacy on the maternal diet. With weaning, the metabolic demand for ω-3 fatty acids shifts from the mother to offspring, and thus the amounts and types of ω-3 fatty acids in diet of the child is of central importance. Pivotal questions relating dietary ω-3 fatty acids to brain development are the functional roles of and needs for ω-3 fatty acids at different stages of brain development, and whether ω-6 fatty acids modify ω-3 fatty acid requirements and function. This chapter provides a review of current knowledge on dietary ω-3 fatty acids and brain development, focusing primarily on human nutrition with information drawn from studies in other species to address mechanistic and dietary variables difficult to study in humans.

133.2 Omega-3 Fatty Acids and Lipids in the Developing Brain

The lipid composition of the mammalian brain is markedly different from other organs, notable for the unusually high levels of ether-linked glycerophospholipids and high amounts of the ω-3 DHA and the carbon chain 20 and 22 ω-6 fatty acids arachidonic acid (ARA, 20:4ω-6) and adrenic acid (22:4ω-6) (Sastry 1985; Siegel et al. 2006) (Tables 133.1 and 133.2). In contrast to plasma, liver, and other organs, brain glycerophospholipids are low in the 18-carbon chain ω-6 linoleic acid (LA, 18:2ω-6) and triacylglycerols (TG). Also unlike the liver, ethanolamine plasmalogens (1-alkenyl 2-acyl ethanolamine phosphoglyceride) are major glycerophospholipids, representing 30–50% of the EPG in grey matter and 80% or more of the myelin EPG. DHA is highest in EPG (both 1-alkenyl 2-acyl and diacyl) and PS of brain grey matter, although the same lipids in mature myelin contain low amounts of DHA; EPG but not PS is also high in ARA and 22:4ω-6, and other major classes including PC, PI and sphingomyelin are low in DHA (Svennerholm 1968; Sastry 1985; Siegel et al. 2006). EPG and PS together comprise 20–25% of brain lipid, and these glycerophospholipids are preferentially oriented on the inner leaflet of the plasma and internal membrane bilayers. DHA represents about 10% of total fatty acids in human brain grey matter, with lower amounts in white

Table 133.1 Lipid composition of adult human brain

	Grey matter (%)			White matter (%)		
	Fresh wt.	Dry wt.	Lipid	Fresh wt.	Dry wt.	Lipid
Water	81.9			71.6		
Total lipid	5.9	32.7	100	15.6	54.9	100
Cholesterol	1.3	7.2	22.0	4.3	15.1	27.5
Phospholipid, total	4.1	22.7	69.5	7.2	25.2	45.9
P'Ethanolamine	1.7	9.2	27.1	3.7	13.2	23.9
P'Choline	1.9	10.7	30.1	2.4	8.4	15.0
Sphingomyelin	0.4	2.3	6.9	1.2	4.2	7.7
P'Inositides	0.16	0.9	2.7	0.14	0.5	0.9
P'Serine	0.5	2.8	8.7	1.2	4.3	7.9
Galactocerebroside	0.3	1.8	5.4	3.1	10.9	19.8
Galactocerebroside sulfate	0.1	0.6	1.7	0.9	3.0	5.4
Ganglioside, total	0.3	1.7	–	0.05	0.18	–

This table gives the percentage of different lipids in brain grey matter and brain white matter based on fresh weight and dry weight. The major phospholipids are phosphatidylethanolamine (includes all EPG), phosphatidylcholine, sphingomyelin, phosphatidylinositol, and phosphatidylserine. The information is adapted from Siegel et al. (2006)

Table 133.2 Major ω-3 and ω-6 fatty acids in human adult cerebral grey and white matter glycerophosphoglycerides

	EPG	PS	PC	PI
Grey matter				
22:6ω-3	28.6	30.7	2.6	4.0
20:4ω-6	13.2	2.0	5.5	28.2
22:4ω-6	8.3	5.0	0.8	1.5
22:5ω-6	1.5	1.8	0.1	Trace
White matter				
22:6ω-3	3.0	0.9	0.4	1.1
20:4ω-6	7.9	1.4	2.0	17.3
22:4ω-6	13.4	2.0	0.9	2.4
22:5ω-6	0.5	0.1	0.1	Trace

This table shows the amounts of the major ω-3 and ω-6 fatty acids in the major glycerophospholipids EPG, ethanolamine phosphoglycerides; PS, phosphatidylserine; PC, phosphatidylcholine; PI, phosphatidylinositol of the adult human brain. The ethanolamine phosphoglycerides include both diacyl and plasmalogen. This shows that 22:6ω-3 (also called docosahexaenoic acid) is highest in grey matter EPG and PS, and that the same lipids differ in composition between grey and white matter. This information is adapted from Svennerholm (1968)

matter giving an average of about 7% DHA in total fatty acids of the human brain. In the rod outer segments, diacyl PE, PS, and PC are high in DHA; PE and PS are enriched on the outer monolayer, PC is enriched on the inner monolayer and plasmalogens are usually undetectable (Giusto et al. 2000). About 20% of the fatty acids in the human retina are DHA, with much higher concentrations in the rod outer segment membranes. Much remains to be discovered regarding the functional basis for the enrichment of DHA in specific brain glycerophospholipids, including the high levels of plasmalogens, and their membrane distributions.

The fatty acid composition of brain at different stages of development has been reported in animals and from analysis of human autopsy tissue. In general, these studies show a progressive increase in DHA in the brain, accompanied by an increase in ARA and 22:4ω-6 with development. The increase in DHA in the human brain is particularly robust from the beginning of the third trimester of gestation and continues to at least 4 years-of-age (Svennerholm 1968; Clandinin et al. 1981; Martinez and Mougan 1998). The increase in DHA, ARA, and 22:4ω-6 in the diacyl and plasmalogen fractions of EPG, and in PS and PC of the human forebrain from 30 week gestation to 4 years-of-age extrapolated from Martinez and Mougan (1998) is illustrated in Fig. 133.3. The increase in DHA is in part explained by brain growth; when expressed as a percent of cerebral grey matter fatty acids, DHA increases, while ARA and 22:4ω-6 decrease in EPG, and all 3 fatty acids decrease in cerebral white matter EPG with increasing age and thus maturation (Table 133.3). Autopsy analysis have been extrapolated to estimate that the human fetus accumulates about 60 mg/day DHA during the last trimester of gestation, of which 2.1–2.85 mg/day DHA is accumulated in the brain (Clandinin et al. 1981). Other analyses show accretion of DHA is linear in the human forebrain from the beginning of the third trimester of gestation continuing at a similar rate throughout at least the first one to two years after birth (Martinez 1992). However, while these data illustrate the quantitative increase in DHA in the brain during growth, changes associated with individual membranes, such as the increasing synaptic density that continues until about 5–6 years-of-age, are not reflected (Levitt 2003).

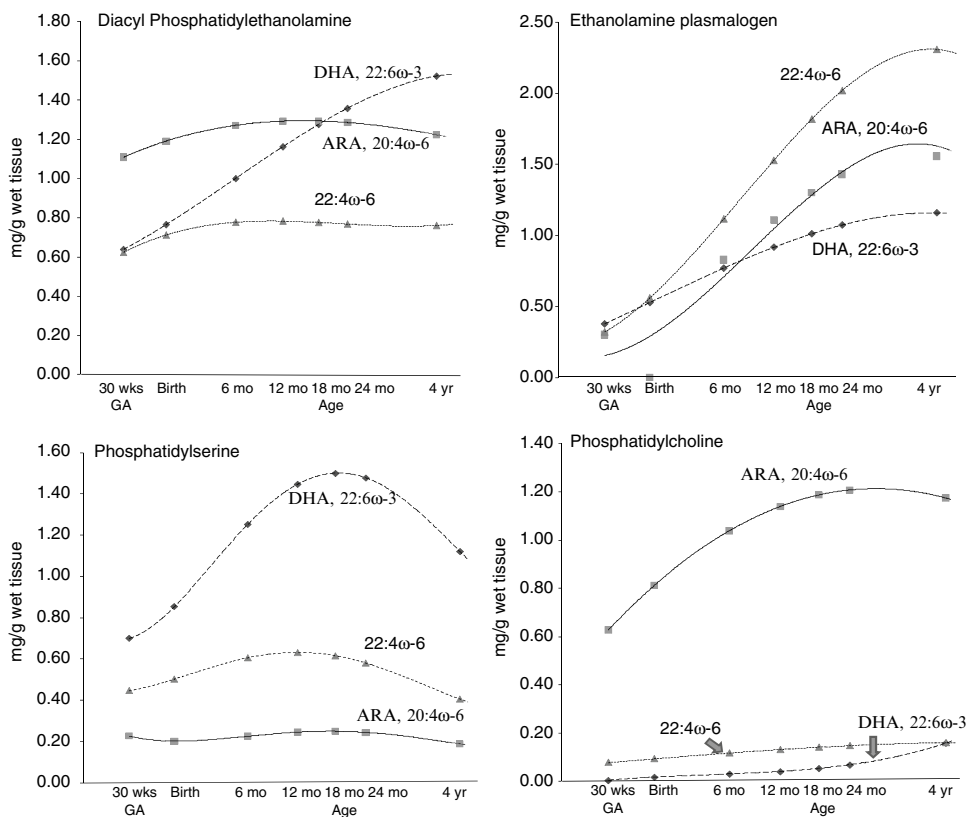
The effects of dietary ω-3 fatty acid deficiency on the composition of brain fatty acids have been extensively described in animals, with some data available from autopsy analysis of infants who had


Fig. 133.3 Increase in DHA, ARA and 22:4ω-6 in the human forebrain to 4 years-of-age. Increase in DHA, ARA and 22:4ω-6 in the human forebrain from 30 weeks gestation to 4 years-of-age extrapolated from the equations of Martinez and Mougan (1998). Note that the scale of the y axis differs in the four plots

Table 133.3 Changes in docosahexaenoic acid and major long chain ω-6 fatty acids in human cerebral grey and white matter ethanolamine phosphoglycerides with increasing age

	12 week gest'n	38 week gest'n	7 months	4 years	26 years
Grey matter					
22:6ω-3	10.8	17.1	16.9	22.3	28.6
20:4ω-6	17.3	14.9	16.4	16.7	13.2
22:4ω-6	9.5	10.6	11.7	9.9	8.3
22:5ω-6	2.8	4.4	5.0	2.4	1.5
White matter					
22:6ω-3	–	17.7	8.7	5.7	3.0
20:4ω-6	–	16.2	13.4	9.5	7.9
22:4ω-6	–	13.3	19.6	18.0	13.4
22:5ω-6	–	4.8	3.5	1.4	0.5

This table shows the percentage of the major ω-3 and ω-6 fatty acids in human brain grey matter and white matter at different stages of development. The table shows that 22:6ω-3 (also called docosahexaenoic acid) increases in brain grey matter from 12 weeks of gestation throughout development to adulthood. In white matter, DHA decreases with age and 22:4ω-6 is a major polyunsaturated fatty acid. This information is adapted from Svennerholm (1968)

been breast-fed or fed formula prior to death. In animals, there is no doubt that a diet deficient in ALA leads to decreased DHA in the brain and retina and that this is accompanied by a characteristic increase in 22:4ω-6 and particularly 22:5ω-6 (Innis 1991). Clear evidence has been published to show that the in utero environment does not protect the embryonic and fetal brain during maternal dietary ω-3 fatty acid deficiency (Innis 2005, 2007). Similarly, inadequate, unbalanced, or excessive intakes of ω-3 fatty acids during the milk feeding period can also cause marked alterations in accretion of ω-3 and ω-6 fatty acids in the infant brain (Innis 2008; Novak et al. 2008). The increase in carbon chain 22ω-6 fatty acids in the brain of fetal, infant and adult animals given ω-3 fatty acid deficient diets is likely a compensatory mechanism to maintain brain membrane glycerophospholipid fatty acid homeostasis as close to normal as possible, similar to the increase in 20:3ω-9 and 22:3ω-9 in the brain that occurs when a diet lacking both ω-6 and ω-3 fatty acids is fed (Innis 1991).

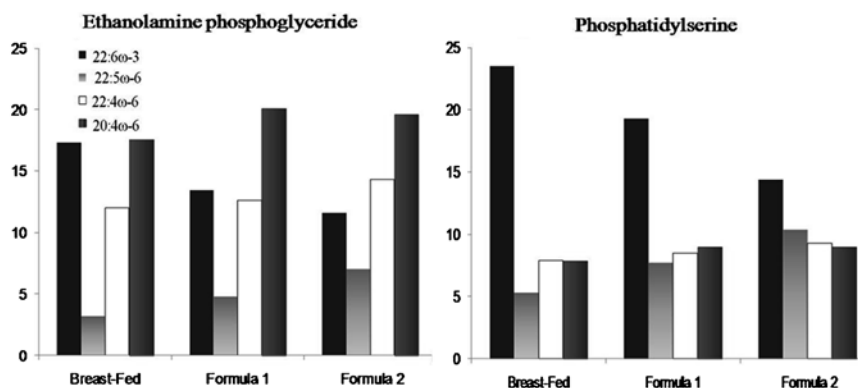
In human infants, brain cortex DHA increased from birth to about 40 weeks postnatal in 15 infants who had been breast-fed, but not in 20 infants who had been fed formula before death (Makrides et al. 1994). As in animals fed a ω-3 fatty acid deficient diet, 22:4ω-6 and 22:5ω-6 were higher in the cortex of the formula-fed infants, with an inverse relationship between DHA and 22:5ω-6. Similar studies of infants in Scotland who before death had been fed formula with fat containing 16.0% LA and 1.5% ω-3 α-linolenic acid (ALA, 18:3 ω-3) or 14.5% LA and 0.4% ALA found reduced DHA and increased carbon chain 22 ω-6 fatty acids, particularly 22:5ω-6 in cerebral cortex EPG and PS, as illustrated in Fig. 133.4 (Farquharson et al. 1995). The increase in 22:5ω-6 to levels as high as 7.0% and 10.4% in cerebral cortex EPG and PS, respectively, of infants fed formula with 7% energy as LA and 0.2% as ALA mirrors the changes in the brain of animals fed milk diets with inadequate ω-3 fatty acids, or high LA/ALA ratios (Innis 1991; Novak et al. 2008; Innis 2008). These studies establish that the developing human brain is vulnerable to diet-dependent changes in DHA and ω-6 fatty acids. However, the elevation of ω-6 fatty acids, and particularly the increase in 22:5ω-6 in infants fed with formulas with no carbon chain 20 or 22 ω-6 fatty acids (Makrides et al. 1994; Farquharson et al. 1995) is not consistent with a simple conclusion that low desaturases enzyme activities limits the capacity for carbon chain 20 or 22 polyunsaturated fatty acid synthesis, unless specific to synthesis of DHA. Regardless, the changes are important since the ω-6 fatty acids do not substitute for DHA in supporting neurogenesis or neurite outgrowth, dopaminergic and


Fig. 133.4 Cerebral cortex fatty acids of breast-fed infants and infants fed formula with no DHA. Levels of fatty acids as a percentage of total fatty acids in cerebral cortex of infants who before death had been breast-fed or fed infant formula, adapted from Farquharson et al. (1995). The fat blends had for formula 1: 16.0% 18:2ω-6 (LA) and 1.5% 18:3ω-3 (ALA); formula 2: 14.5% (LA) and 0.4% (ALA), giving about 8% and 0.75% energy LA and ALA, and 7.25% and 0.2% LA and ALA in formulas 1 and 2, respectively

serotinergic neurotransmission, synthesis of neuroprotective metabolites of DHA, or learning and visual functions (Chalon 2006; Coti-Bertrand et al. 2006; Innis 2007, 2008; Dagai et al. 2009; Katakura et al. 2009; Niemoller and Bazan 2009).

133.3 Essential Fatty Acids and Their Metabolism

Humans can synthesize saturated and monounsaturated fatty acids using carbons from degradation of carbohydrates, proteins or fats, with the major products being the saturated fatty acids palmitic acid (16:0),stearic acid (18:0), and their Δ-9 desaturase products palmitoleic acid (16:1n-7) and oleic acid (18:1n-9) (Innis and Davidson 2008). Synthesis of ω-3 and ω-6 fatty acids requires insertion of a double bond at the third or sixth carbon, respectively, from the carboxyl terminus of an 18-carbon chain fatty acid in reactions that require Δ-15 and Δ-12 desaturase, respectively (Fig. 133.1). The absence of Δ-15 and Δ-12 desaturase in animals means that all animals require a dietary source of both ω-3 and ω-6 fatty acids (Innis 1991). DHA for synthesis of new membrane lipids and to replace DHA irreplaceably lost during membrane lipid turnover has two potential sources: synthesis from ALA provided in the diet or from DHA consumed in the tissues of other animals. Synthesis of DHA from EPA or chain shortening of DHA to EPA is also possible, but since foods providing EPA also provide DHA, this may be of limited relevance to normal fatty acid biochemistry. The central issue relating dietary ω-3 fatty acids to brain development and function can be summarized as to whether the desaturase enzymes for synthesis of DHA from ALA are constitutionally low or for some reason inhibited at different stages of development, thus necessitating an appropriate supply of preformed EPA and DHA. Although DHA has held centrestage because of its high concentrations in the brain and retinal membranes, ALA and EPA may also have important functions, for example, as metabolic regulators of the conversion of LA to ARA, or as a source of acetyl and malonyl CoA for brain cholesterol and fatty acid synthesis (Cunnane et al. 2006; Novak et al. 2008; Chen et al. 2009), with additional roles of EPA in modulating neuroinflammatory and eicosanoid pathways, and perhaps in synaptic plasticity and neuro-extension (Adibhatla and Hatcher 2008; Kawashima et al. 2008; Liu et al. 2008).

There is no doubt that as a species, hominins evolved consuming diets with meats, fish and plants that provided EPA, DHA, and ALA, all three ω-3 fatty acids are transported across the placenta, are present in human milk, and are taken up by the brain (Simpolous 1999; Innis 2004, 2005, 2008; Cordain et al. 2005; Eaton 2006). However, among the ω-3 fatty acids, DHA is uniquely enriched in the brain, with the far-reaching hypothesis that the changing diet during early human evolution to include rich sources of DHA and ARA in foods gathered from the land/water interface was pivotal in the evolution of the large human brain (Crawford et al. 1999). On the other hand, humans including infants can form DHA and EPA from ALA, albeit in apparently low amounts (Hussein et al. 2005; Burdge 2006; Carnielli et al. 2007), and 22:5ω-6 accumulates in high amounts in brain glycerophospholipids of infants fed formulas lacking DHA (Makrides et al. 1994; Farquharson et al. 1995). The evidence favors the physiological appropriateness of a balanced supply of ω-3 fatty acids to support brain growth and development, with the capacity for synthesis of longer chain metabolites should the exogenous supply falter.

The desaturation and elongation of ALA to EPA and DHA in humans in vivo must be considered in context from the amounts and balance of ω-3 and ω-6 fatty acids supplied in the diet, the known effects of dietary ω-3 and ω-6 fatty acids on plasma and tissue glycerolipid fatty acids and ultimately, the pathways that govern glycerophospholipid assembly and remodeling. The ω-6 fatty acids are included because the ω-6 and ω-3 fatty acids are inseparably linked, from their supply in foods, to

their metabolism and acylation into membrane glycerophospholipids and ultimately their roles in modulating development, mental and physical performance, and health. Conversion of ALA to EPA and LA via 20:3ω-6 to ARA requires sequential addition of carbon atoms (elongation) and insertion of double bonds (desaturation) by Δ-6 and Δ-5 desaturases (Fig. 133.2); these enzymes occur in animal cells, phytoplankton, and zooplankton. The most widely described pathway for synthesis of DHA from EPA in animal cells, in which a Δ-4 desaturase has not been identified, involves sequential elongation of EPA to 24:5ω-3, Δ-6 desaturation to 24:6ω-3, then a single cycle of β-oxidation in peroxisomes to yield DHA (22:6ω-3) (Innis and Davidson 2008). Synthesis of 22:5ω-6 has been proposed to follow a similar pathway although other pathways for DHA synthesis in humans as well as separate pathways for metabolism of ω-3 and ω-6 fatty acids have been proposed (Innis and Davidson 2008).

The initial Δ-6 and Δ-5 desaturation of ALA and LA is accomplished by the same enzymes, allowing competition between LA and ALA, with saturation of enzyme activity at relatively low substrate concentrations, equivalent to less than 1% dietary energy from LA or ALA (Innis 2008, 2009). Except in a few highly specialized lipids, the ω-3 and ω-6 fatty acids are esterified at the *sn*-2 position of glycerophospholipids, for which the acylation sites within the cell are finite. The ω-3 and ω-6 fatty acid supply and desaturase enzyme activities must be integrated to the needs for fatty acids for glycerophospholipid synthesis and remodeling. Co-ordinate regulation of Δ-6 and Δ-5 desaturase expression and activity is achieved through several mechanisms, including several transcription factors for which the 18-, 20-, and 22-carbon chain ω-3 and ω-6 fatty acids are promiscuous ligands and ultimately suppress expression (Jump 2008). Although most information has been gathered in the liver, inhibition of hepatic desaturases activities is relevant since secretion of lipids low in EPA and DHA or enriched in ω-6/ω-3 fatty acid alters the plasma fatty acid pool and this is a major source of long chain ω-3 fatty acids for both the developing and mature brain (Innis 2008).

In healthy humans, except during high carbohydrate feeding, de novo lipogenesis is quantitatively low and the ω-3 and ω-6 fatty acids are distributed between oxidation depending on the needs for energy and acylation in structural and storage lipids. Dietary intakes of LA, including infants fed human milk or formula, are well in excess of 1% energy, thus desaturase substrate supply is unlikely to be limiting, and excess LA must be either acylated or oxidized. Comparative studies on fatty acid oxidation indicate that LA is preferentially retained when compared to 18:1ω-9 or ALA (Innis 1991); consistent with the well-known relationship between higher intakes of LA and higher LA in plasma and blood cell and tissue lipids of adults and infants (Putnam et al. 1982; Ponder et al. 1992; Sanders et al. 1994; Makrides et al. 2000; Skeaff et al. 2006). Studies using stable isotope labeled fatty acids have uniformly found that the proportion of a dose of labeled ALA appearing in plasma EPA and DHA is low, with 1% or less appearing in DHA, with slightly higher amounts in EPA (Hussein et al. 2005; Burdge 2006; Carnielli et al. 2007). Conversion of ALA to DHA tends to be higher in pregnant women, consistent with growth, decreases in infants with increasing postnatal age, and is lower when ARA and DHA are present in the infants' feeds (Burdge 2006; Carnielli et al. 2007). Consistent with the latter studies, increasing the dietary ALA does not increase DHA in the blood lipids of infants or pregnant women, and does not increase DHA in breast milk during lactation, although a small increase in EPA is usually found (Makrides et al. 2000; Innis 2004, 2005, 2009). EPA and DHA from foods or supplements on the other hand, are readily taken up, incorporated into plasma, blood cells, and tissue glycerophospholipids, but may also decrease ARA depending on the amounts of EPA and DHA consumed (Innis 2008, 2009). These findings indicate that Δ-6 and Δ-5 desaturase activities are "low" or repressed in humans, and not limited by substrate, which is the sum of LA and ALA. Usual dietary supplies of LA are considerably in excess of needs and dietary sources of EPA and DHA are readily used to support new tissue growth and membrane lipid turnover.

Single nucleotide polymorphisms (SNP) in genes for rate-limiting enzymes are becoming increasingly recognized as important modifiers of the relationship between diet and disease risk. Common minor allele variants in fatty acid desaturase (FADS) 1 and FADS2, which encode Δ-5 and Δ-6 desaturase, respectively, are associated with increased LA and decreased ARA, as well as decreased ω-6 and ω-3 fatty acid desaturation products in plasma and blood cell lipids and human milk (Schaeffer et al. 2006; Xie and Innis 2008). New findings to show the importance of SNP in the FADS1-FADS2 gene cluster are consistent with the understanding that forward flux through the desaturase pathway is limited by desaturase activity, rather than the fatty acid substrate supply. Whether SNP in the FADS2-FADS1 gene cluster interact with the fatty acid supply to modify brain development or neurological disease is uncertain, although epidemiological data to suggest an association between SNP in FADS2 and cognitive test scores in children who had been breast-fed as infants has been reported (Caspi et al. 2007).

The highly specific ω-3 or ω-6 fatty acid distributions among different glycerophospholipids and within the same glycerophospholipid in different membranes, including those of the brain, are not readily explained by the pathways of de novo glycerophospholipid synthesis or ω-3 and ω-6 fatty acid desaturation. The major pathways for diacyl PC and EPG synthesis are considered to be the cytidine diphosphate (CDP)-choline and CDP-ethanolamine pathways using diacylglycerol as a common precursor; methylation of EPG is important in PC synthesis; base-exchange of serine for choline or ethanalomine in existing glycerophospholipids generates PS; and decarboxylation of serine in PS generates diacyl EPG (Siegel et al. 2006), all pathways involving modification of only the polar head group. Rapid turnover of *sn*-2 position fatty acids in remodeling was first proposed in 1958 to explain the difference in fatty acid patterns of PC compared to TG (Lands 1958). Since that time, several lysophospholipid acyltransferases have been identified that recognize polar head groups and fatty acyl CoAs and these enzymes function to maintain membrane asymmetry and fatty acid diversity (Hishikawa et al. 2008). Although plasmalogens arise from synthesis in peroxisomes by sequential acylaton of dihydroxyacetone phosphate remodeling of their *sn*-2 position acyl chains is similarly important to the high levels of long chain ω-3 and ω-6 fatty acids in the brain (Cook et al. 1991; Siegel et al. 2006). However, acyl transferase specificity appears to be more dependent on carbon chain length than ω-3 or ω-6 fatty acid series, and this leads to competition among ω-3 or ω-6 fatty acids for acylation (Lands 1958; Cook et al. 1991; Hishikawa et al. 2008). In vivo and in vitro, neural cells readily acylate 22:5ω-6, including 22:5ω-6 derived from the diet, and thus taken up from plasma (Innis 1991; Stark et al. 2007; Novak et al. 2008). Together, this indicates that the balance of carbon chain 22 ω-6 and DHA available to brain, but not necessary their amounts, is important to achieving neural membranes high in DHA.

133.4 Essential Fatty Acids and Their Dietary Sources

The types, amounts, and balance of ω-3 and ω-6 fatty acids in different plant and animal foods are exceedingly diverse, and this links the importance of diet to brain development and function. The 18-carbon ω-3 ALA and ω-6 LA are synthesized in plants; although most plant parts are low in fat with a LA:ALA ratio close to 1. An exception are seed oils many of which such as corn, soybean, safflower, sunflower, and some nuts (hard-shelled seeds) such as almond and peanuts are abundant in LA. Use of these oils brings of necessity an increase in LA intake and in the dietary LA/ALA balance. ALA and LA are consumed in plant foods by terrestrial animals, modified by desaturation and elongation depending on the ALA and LA quantity and balance in the diet, and passed on to animals higher in the food chain. As in the laboratory, livestock, and poultry fed grains high in LA have tissue lipids high in ω-6 fatty acids and depleted of ω-3 fatty acids, particularly when compared to their

wild counterparts (Cordain et al. 2005; Eaton 2006). EPA and DHA, on the other hand, are synthesized in abundance in aquatic phytoplankton, and these fatty acids are consumed by molluscs, crustaceans, and fish with the result that wild fish, shellfish, and molluscs are rich sources of EPA and DHA that are also low in ω-6 fatty acids. To summarize, humans consume ALA and LA in both plant and animal foods, but the amounts and proportions of ALA and LA and their metabolites EPA and DHA, and ARA, respectively, vary widely depending on the choices of vegetable fats and fats from terrestrial and aquatic food sources.

Dramatic quantitative and qualitative changes to human ω-3 and ω-6 fatty acid nutrition that began slowly with the industrial revolution, escalated in the twentieth century with the widespread introduction of LA-rich vegetable oils into the food supply (Simpolous 1999; Cordain et al. 2005; Eaton 2006). Prior to the development of technologies to extract and refine oils from seeds that are safe for human and animal consumption, and processes to convert liquid oils into solid and semisolid margarines and shortenings, the amount of LA that could be consumed by humans and animals was necessarily low (Simpolous 1999; Cordain et al. 2005; Eaton 2006). Available data show an increase in LA from about 3% dietary energy, and a dietary ω-6:ω-3 fatty acid ratio of 2:1 or lower in the early 1900s. In the modern food supply, ω-6 LA represents over 90% of all polyunsaturated fatty acids, with an average of 6.7% dietary energy from LA in the U.S. (Simpolous 1999; Innis and Jacobson 2007; Friesen and Innis 2009; Harris et al. 2009). This shift to enrich the diet with LA and decrease ω-3 fatty acids with ω-6:ω-3 fatty acid ratio of 10:1 or higher, extends to the fatty acid nutrition of the unborn child through changes in placental fatty acid transfer, to the breast-fed infant through changes in human milk fatty acids, and to the diet of young children (Innis 2004, 2005, 2009).

Numerous studies focusing on dietary fatty acids and cardiovascular disease have provided ample evidence that the amount and types of ω-3 and ω-6 fatty acids in the diet impacts plasma lipid ω-3 and ω-6 fatty acids, and this in turn influences the ω-3 and ω-6 fatty acids in blood cells, and tissue lipids. The biology relating dietary ω-6 and ω-3 fatty acids to circulating and tissue glycerophospholipid ω-3 and ω-6 fatty acids in infants and children is not different from adulthood. Particular attention has focused on DHA because DHA is high in the brain and differences in dietary intake of DHA are the most important variable explaining differences in plasma, blood cell and human milk levels of DHA in healthy humans, with DHA necessarily lower in vegans and vegetarians than in individuals consuming mixed diets that include fish or other sources of DHA (Innis 2004, 2008, 2009). However, differences in dietary intake or blood levels of DHA is only of physiological consequence if the composition of the circulating fatty acid pool interferes with the ability of the brain to take up and accumulate DHA as needed in specific membranes.

133.5 Omega-3 Fatty Acid Supply and Uptake in the Developing Brain

Important questions relating to ω-3 fatty acids to brain development and function are the amounts and balance of fatty acid substrates required to meet the needs for DHA for turnover and synthesis of new membranes, either by uptake from plasma or elaboration within the brain from ω-3 fatty acid precursors. Although the activity of Δ-6 and Δ-5 desaturase is often considered highest in the liver, Δ-6 and Δ-5 desaturase are expressed at high levels in brain (Cho et al. 1999; Leonard et al. 2000). As described, LA and ALA are present in low amounts in the brain, <2% brain fatty acids, regardless of high LA in plasma TG, glycerophospholipids and unesterified fatty acids. Highly selective uptake, or preferential disposal via selective oxidation of the 18-carbon chain ω-6 and ω-3 fatty acids and EPA must, therefore, account for the high ARA, 22:4ω-6 and DHA in the brain. Early studies using radioactive isotopes reported that brain is able to take up ALA and form DHA, although more recent studies indicate that neurons and astrocytes in vitro are unable to complete the final steps in DHA

Table 133.4 Key features of omega-3 fatty acids

1. The omega-3 docosahexaenoic acid is a major polyunsaturated fatty acid in brain grey matter.
2. The amount of docosahexaeonic acid increases in brain grey matter with brain development and maturation.
3. When omega-3 fatty acids are lacking, the brain accumulates more of the omega-6 fatty acids.
4. Docosahexaenoic acid is needed for proper development and function of brain neurons and their neurochemical functions.
5. Inadequate docosahexaeonic acid is associated with poor learning and behavior development.
6. In usual diets, docosahexaeonic acid is found only in animal lipids. The richest dietary source is fish.

This table lists the key facts of omega-3 fatty acids in brain development and function

synthesis from 22:5ω-3, or 22:5ω-6 from 22:4ω-6, although EPA and ARA are formed from their respective ALA or LA precursors (Innis 1991, 2008). Several in vivo studies have shown that brain takes up DHA from plasma, particularly albumin-bound or lysophospholipid fatty acid pools at rates which in the rat are sufficient to meet the needs for brain DHA turnover, although albumin binding and previous DHA feeding both decrease uptake (Innis 1991; Chen et al. 2008; Ouellet et al. 2009). Convincing evidence is also available to show that DHA is taken up and incorporated into brain and retina glycerphospholipids, and this occurs whether the supply of DHA is via placental transfer, in breast milk, or as DHA in diet of the young or adult animal (Innis 2008). As discussed, dietary deficiency of ω-3 fatty acids results in high levels of 22:5ω-6 in the brain. However, 22:5ω-6 is usually <1% plasma glycerolipid and red blood cell fatty acids, even in infants fed formula with no DHA, and including those with high LA (Putnam et al. 1982; Ponder et al. 1992; Makrides et al. 2000). In summary, whether the brain can synthesize DHA and the origin of the high 22:5ω-6 that accumulates in the brain in ω-3 fatty acid deficiency remains enigmatic, although it is clear that the brain can take up ALA, EPA, DHA, and 22:5ω-6 from plasma, oxidation with recycling of carbons from ALA and EPA occurs, and Δ-6 and Δ-5 desaturase are present. Dietary DHA on the other hand, is readily and effectively taken up, and prevents excess accumulation of long chain ω-6 fatty acids (Table 133.4).

133.6 Omega-3 Fatty Acid Supply in Prenatal and Postnatal Development

Before birth, the infant obtains ω-3 fatty acids necessary for brain development by placental transfer, and after birth ω-3 fatty acids are supplied in breast milk or breast milk substitutes, and later on from foods. In the human placenta, the polarized syncytiotrophoblast consisting of a microvillous membrane facing the maternal blood and basal membrane facing the fetal blood separate the maternal and fetal circulations while at the same time allowing nutrient exchange (Cunningham and Mcdermott 2009). Several membrane and intracellular binding proteins that function in the uptake and transport of ω-3 fatty acids across the placenta have been identified (Innis 2005). Both Δ-6 and Δ-5 desaturase are also present and highly expressed in the placenta, although their functional roles are unclear (Cho et al. 1999; Leonard et al. 2000). It is well-known that the proportions of DHA and ARA are higher, while LA is lower in fetal than maternal plasma glycerolipids, although on a quantitative basis the amount in mother is higher due to the higher plasma lipid concentration in the mother (Innis 2005). The relative exclusion of LA from the fetal circulating lipids is intriguing and, similar to the exclusion of LA from the brain it is of probable, although unclear biological importance. Regardless, abundant experimental evidence has shown that placental mechanisms for ω-3 fatty acid transfer do not protect the fetus during maternal dietary ω-3 fatty acid deficiency through mobilization of ω-3 fatty acids from maternal tissues (Innis 2005). In animals, a diet limiting in ω-3 fatty acids, particularly when combined with high LA in pregnancy leads decreased maternal-to-infant DHA transfer and increased 22:4ω-6 and 22:5ω-6 in the fetal brain, including neuronal growth cones (Innis 2007).

In humans, differences in maternal DHA intake explain differences in DHA in infant-cord blood at birth and increasing maternal DHA intake through diet or supplements increases placental transfer of DHA (Innis 2005, 2008).

There is also no doubt that the quality of unsaturated fatty acids in human milk is a dynamic reflection of fatty acids in the food supply, as amply illustrated by *trans* fatty acids as high as 13–18% total milk fat among breast-feeding women in the U.S. and Canada (Innis and King 1999; Mosely et al. 2005). In the mid-1900s, LA represented a mean of about 7% of milk fat and this increased to mean levels of 12–16% energy by the 1980s (Innis 2004). Human milk DHA, on the other hand, has decreased perhaps as much as 50% in some western nations to median levels below 0.35% milk fat (Innis 2004), which with the increase in LA gives a milk diet with a ω-6/ω-3 fatty acid balance of about 10:1 similar to the adult diet (Simpolous 1999; Friesen and Innis 2009). In East African coastal regions where modern vegetable oils are not consumed, LA provides 4.2% milk fat with levels of DHA of 0.73% (Kuipers et al. 2007). However, human milk levels of 22:4ω-6 and 22: 5ω-6 are exceedingly low at <0.1% milk fat and are not increased in women with diets very low in fish or DHA, or with high LA (Innis and King 1999). In contrast, rats fed a ω-3 fatty acid deficient diet have increased milk 22:4ω-6 and 22:5ω-6, with levels of 22:5ω-6 over 0.35% and exceeding DHA (Jacobson et al. 2005). This interesting species difference may serve to protect the developing breast-fed human infant from excess long chain ω-6 fatty acids that could interfere with DHA uptake into the brain. Extending to the infant, differences in dietary intake of DHA from mother's milk or formulas explain the differences in circulating lipid DHA among infants, including the low DHA in infants fed by mothers following vegan or vegetarian diets or in infants fed formula without DHA.

The period from 12 months to about 6 years-of-age is a time of remarkable transition in diet and of rapid neural development. With weaning, the infants' milk or formula intake is gradually replaced with foods that with modern weaning practices generally focus on cereals, then vegetables and fruits, all of which are low in fat and contain no EPA or DHA (Innis 2009). Weaning thus leads to a decrease in fat and ω-3 fatty acid intake. Blood levels of DHA in children 18–60 months-of-age are low, similar to those in infants fed formulas lacking DHA, and an inverse relationship has been shown between red blood cell DHA and LA over the range of 2.7–3.8% energy from LA, consistent with reduced Δ-6 and Δ-5 desaturase activity with increasing LA, or perhaps competition for acylation (Innis et al. 2004). The lower LA intake among young children than in adults is explained by lower intakes of salad oils and higher intakes of dairy products. Several recent studies have shown that in children, as in other age groups, DHA intake from foods or supplements is the most important variable influencing the circulating lipid levels of DHA (Osendarp et al. 2007; Dalton et al. 2009; Innis 2009). In summary, the ω-3 fatty acid supply during pre-natal and early postnatal development is dictated by maternal diet and in early childhood by the ω-3 fatty acid composition of the child's diet. Differences in the intake of preformed DHA translate to differences in DHA in plasma and blood cell lipid DHA across all stages of the lifespan; these will translate to have physiologically meaningful implications for brain development and function if the circulating lipid ω-3 fatty acids are too low, or if fatty acids that compete for uptake or acylation are sufficiently high as to alter the balance of DHA/22-carbon ω-6 fatty acids incorparated into important membrane lipid pools.

133.7 Functions of Omega-3 Fatty Acids in the Developing Brain

While the popular lore of fish as brain-food is well-known, its origin can be traced not to ω-3 fatty acids but to the early eighteenth century discovery of high amounts of phosphorous in brain, a notion that phosphorus is involved in thought and thus intelligence, and the discovery that fish like brain, is

high in phosphorus. It is self-evident that lack of ω-3 fatty acids for acylation into glycerophospholipids for growth of new brain membranes or to replace losses in turnover must result in either failure of membrane synthesis, or synthesis using alternate fatty acids. Human brain development begins early in gestation with neuron proliferation and continues in preset timelines into adulthood (Huttenlocher 1990; Levitt 2003; Georgieff and Innis 2005). The frontal lobes that are responsible for executive functioning develop more slowly than other structures, with spurts of development from birth to 2 years-of-age, and again at 7 and 9 years-of-age, and in adolesence. At 2 years-of-age, the frontal cortex has attained only about 55% neuronal density of the adult (Huttenlocher 1990; Thatcher 1991) which suggests that sensitivity to adverse effects of inadequate ω-3 fatty acids can extend into childhood. As for other nutrients and stressors, it is reasonable that the time in development when the brain is faced with inadequate ω-3 fatty acids will dictate the consequence of the insult, which molecular events, membrane structures and function are altered, and the potential for reversal if adequate ω-3 fatty acids are provided later on. Also reasonable, deficiencies that impact early stages of development, such as neurogenesis and neuron migration, are likely to have more long-lasting and more far reaching implications than deficiency imposed on the mature brain.

The protracted period of brain development in humans, however, adds complexity to clinical studies on ω-3 fatty acid nutrition since deficiency at any age can presumably impact function, although with different consequences. The essential roles of DHA in the brain are fulfilled both through roles in membrane glycerophospholipids, thus potentially impacting numerous and diverse cell functions in which membranes and their lipids contribute, and roles of unesterified DHA and its neuroprotective metabolites. Studies focusing on early brain development have described morphological changes in the embryonic brain with under-development of the hippocampus in a pattern suggesting impaired cell cycle exit and cell migration, with deficits also in secondary neurite outgrowth and cortical dendritic arborization (Coti-Bertrand et al. 2006; Innis 2008; Novak et al. 2008). More recent in vitro studies have confirmed that DHA is important in neural stem cell differentiation, perhaps via regulation of transcription factors and promotion of cell cycle exit, and in neurite outgrowth (Dagai et al. 2009; Katakura et al. 2009). Neural cell membrane growth requires addition of newly synthesized lipids to the growing membrane through fusion of lipid transport vesicles with the plasma membrane, involving soluble *N*-ethylmaleimide-sensitive fusion protein attachment receptor (SNARE) proteins, a process similar to the fusion preceding release of neurotransmitters from their storage vesicles (Innis 2007). Within membrane glycerophospholipids, the six double bonds of DHA gives a shortened fatty acid chain in which motion and, therefore, conformational change is severely restricted by the lack of rotation at the double bond; thus stabilizing and condensing the membrane (Martinez and Morros 1996). The small polar head group of the EPG, on the hand, gives a comparatively large hydrophobic fatty acid region which tends to bend the membrane bilayer and facilitate formation of the non-bilayer phases that are important in membrane fusion, such as occurs during fusion of transport vesicles providing lipids to growing membrane surfaces, or neurotransmitters for secretion. Hippocampal membranes from animals fed a ω-3 fatty acid deficient diet had decreased membrane DHA and increased membrane-bound SNARE protein complexes, suggesting impaired fusion, or dissociation and recycling (Innis 2007). Altered serotinergic and dopaminergic neurotransmission has also been demonstrated in ω-3 fatty acid deficiency, with complex changes at multiple levels that include the vesicular pools (Chalon 2006; Innis 2007).

Signal-induced turnover of membrane glycerophospholipids leads to generation of second messengers, such as platelet activating factor, diacylglycerol, and 2-arachidonyl glycerol, and release of unesterified ω-6 and ω-3 fatty acids which can be further metabolized to neuroprotective or neuro-inflammatory molecules, or bind to transcription factors that influence gene expression (Bazan 2006; Innis 2007). In addition to determining the DHA available for release from the membrane, DHA also appears to regulate ARA release, potentially influencing synthesis of ARA-derived eicosanoids as

well as providing DHA for synthesis of neuroprotective molecules (Bazan 2006; Niemoller and Bazan 2009). Diets rich in EPA plus DHA when compared to ALA also differ in their effects on brain gene expression, with specific effects of dietary EPA and DHA on genes controlling synaptic plasticity, cytoskeleton, and membrane association, signal transduction, ion channel formation, and energy metabolism (Innis 2007). Some recent studies also suggest that EPA may influence synaptic plasticity and the PI3-kinase/Akt pathway and, like DHA, EPA also stimulates neurite extension (Liu et al. 2008; Kawashima et al. 2009), although the physiological significance of this in the developing brain in vivo is unclear.

133.8 Dietary Omega-3 Fatty Acids and Brain Development in Infants and Children

Studies relating to ω-3 fatty acids and brain development in infants and children fall into 3 general categories, observational studies that relate outcome to maternal or child ω-3 fatty acid intake or blood levels, dietary interventions in healthy pregnant and breast-feeding women or infants, and studies with clinical populations such as prematurely born infants who may have altered needs when compared to the infant born after full-term gestation. Studies on the potential benefits of breast-feeding on neurodevelopment favor a view that the complex mix of nutrients and growth factors in human milk contribute to better development of the breast-fed infant. Among these factors, the small amounts of DHA in human milk together with the abundance of DHA in the brain has generated a large number of studies on the potential benefits of adding DHA, or DHA plus ARA to formula on infant visual, mental, and motor skill development, and reviews have been published (Heird and Lapillone 2005; Simmer et al. 2008a, 2008b; Beyerlein et al. 2009). In general, these studies show that a dietary source of DHA with ARA is important for preterm infants, with inconsistent findings of benefit for infants born after term gestation.

Preterm infants born early in the third trimester of gestation (<33 weeks-gestation) are known to be at risk of nutrient deficiencies, with low body stores and nutrient needs that exceed those that can be met by human milk, unless fortified (Georgieff and Innis 2005). Studies with preterm infants fed formulas with DHA in amounts similar to human milk (0.2–0.38% fat), with ARA included have found some benefits to growth, early measures of visual acuity, and scores on neurodevelopmental tests, particularly in smaller infants (O'Connor et al. 2001; Simmer et al. 2008a). However, estimation of the amount of DHA needed to support accretion of DHA at the same rate as that in utero indicates a need for about 60 mg/day DHA, whereas milk with 0.35% fat as DHA fed at 120 ml/day to 1 kg infant can provide only 15 mg (Georgieff and Innis 2005). This suggests most human milk, which typically contains 0.2–0.3% fat as DHA is inadequate to support the needs of small preterm infants. Preterm infants (< 33 weeks gestation) at birth fed human milk with 1% DHA and about 0.5% ARA until their estimated full-term delivery date had higher erythrocyte glycerophospholipid DHA and higher sweep visual evoked potential acuity at 4 months-of-age than infants fed milk with 0.2–0.3% fat as DHA (Smithers et al. 2008). Bayley Mental Development scores at 18 months corrected age showed girls, but not boys, and all infants of birthweight < 1,250g had better test scores when fed milk with 1% rather than 0.2–0.3% fat as DHA milk (Makrides et al. 2009). These studies show DHA needs of preterm infants are not likely to be met by milk from mothers following usual western diets low in fish or preterm formulas with 0.35% fat or less as DHA.

Studies on ω-3 fatty acid nutrition and brain development in infants born after full-term gestation are more complex. Important variables include the ω-3 fatty acid supply in gestation, the variable ω-3 fatty acids in human milk, then weaning foods, and numerous dietary, family, environmental, and genetic

factors that impact child development. While randomization distributes variables among intervention groups, it does not lessen variability and thus the need for large samples sizes. Smaller cohorts with similar socio-demographic and dietary practices, however, may limit some of these problems. Interventions to increase ω-3 fatty acid intakes in pregnant and breast-feeding women or in infants and children can only benefit individuals in the group consuming an inadequate diet, assuming no other dietary deficiency limits the ability to respond (Innis 2009). The relationship between the intake of an essential nutrient and biochemical, molecular, and physiological endpoints in which the nutrient functions is nonlinear, since no additional physiological benefit occur when nutrient intake exceed needs. Rather, a parabolic response to increasing intake of essential nutrients are more usual, with adverse or pharmalogical effects at high intakes. Finally, infants and children are not in steady-state, and this poses the need for care to avoid ceiling effects when selecting tests and the ages at which tests are given.

Visual acuity has been widely used as an endpoint in studies on the need for dietary DHA in young infants. Studies in the U.S. involving infants fed formula with about 0.35% DHA and 0.72% ARA in the fat have reported improvement in visual acuity, whether the formula with DHA was fed from birth or after initial breast-feeding, as well as benefits to visual acuity when DHA was included in weaning foods (Birch et al. 2002; Hoffman et al. 2004; Birch et al. 2005). Other studies, however, have not detected differences in visual acuity between breast-fed infants and infants fed formula with no DHA, or between infants fed formula with and without DHA (Heird and Lapillone 2005; Simmer et al. 2008b). Similarly, while some evidence of improved performance in tests of early neural development have been reported for healthy term infants provided with DHA in formula, as a supplement or in infant foods, most studies have involved small numbers of infants and studies indicating no benefit have also been published (Heird and Lapillone 2005; Simmer et al. 2008b; Beyerlein et al. 2009; Innis 2009). Variability in DHA status at birth, among groups of breast-fed infants when included for comparison, and deficiencies introduced during weaning that impact performance on developmental tests given after 6 months-of-age are all factors that may contribute to inconsistent information.

Several prospective, observational studies have linked low intakes of fish (the major diet source of EPA and DHA) in pregnant women, low blood levels of DHA in pregnancy or in infants at birth, and low breast milk DHA to lower scores on tests of mental, motor, and visual system development in infants, with the effects extending into later childhood (Hibbeln et al. 2007; Innis 2008, 2009). More direct evidence of the importance of DHA is provided by interventions to show that fish oil or other sources of DHA during gestation and lactation can, in some settings improve early infant development including early problem-solving, hand–eye coordination, visual acuity scores, and psychomotor development. Some evidence of a relationships between maternal DHA status in gestation and performance on later standardized test of development have been found in later childhood, although evidence of benefits of maternal fish oil supplementation were absent (Helland et al. 2008), and confounding by nutrients such as vitamin D are possible.

More recently, attention has turned to the low ω-3 fatty acid intakes of young children, including children in developing countries. A recent study with 7–9 year-old children in South Africa given fish flour to provide 0.335 g 18:3ω-3, 82 mg EPA and 192 mg DHA for 104 days found evidence of improved verbal learning and memory, together with an increase in the red blood cell DHA and EPA, and a decrease in ARA (Dalton et al. 2009). On the other hand, studies in India involving over 500 children 6–10 years-of-age that included supplementation with 900 mg/day ALA plus 100 mg/day DHA found no benefits on growth or cognitive test scores although a wide range of domains were tested (Muthayya et al. 2009). Similarly, 110 mg/day EPA plus DHA had no effect on cognitive performance among children 7–10 years-of-age in Australia and Indonesia (Osendarp et al. 2007). While initial findings appear discouraging, correction of long-standing ω-3 fatty acid deficiency may not be simple, particularly if combined with multiple other nutrient deficits. Optimal intakes of DHA for healthy children are also unknown, as are the dosages needed to restore depleted tissue pools.

133.9 Summary

There is no doubt that DHA is critical for the brain at all stages of the life span. Strong biological evidence is available to show DHA plays key roles in the brain that span from neurogenesis and neurite outgrowth, to dopaminergic and serotinergic neurotransmission, to generation of potent anti-inflammatory and neuroprotective metabolites; all functions for which ω-6 fatty acids cannot substitute or interfere. Consuming a diet that provides DHA unequivocally provides DHA that in gestation can be transported across the placenta, in lactation is secreted in human milk, and in the child is readily absorbed and acylated into membrane glycerophospholipids. However, there is also no doubt that dietary intakes of ω-6 and ω-3 fatty acids have become severely distorted over the last one to two centuries, with a prolific increase in LA and loss of long chain ω-3 fatty acids from the food supply, and this extends to the fatty acids transported across the placenta, secreted in human milk, and to the foods available for feeding young children. This ω-6 and ω-3 fatty acid imbalance is becoming increasingly implicated in several major chronic diseases and this chapter raises the question of whether inadequate intakes of ω-3 fatty acids coupled with excessive LA contributes to poor DHA accretion in the developing human brain.

133.10 Application to Other Areas of Health and Disease

The roles of ω-3 fatty acids in neurogenesis, serotinergic, and dopaminergic transmission, and as a precursor to neuroprotective metabolites have broad relevance to diverse areas. Altered metabolism of the long chain ω-3 fatty acids, EPA and DHA, as well as inadequate ω-3 fatty acid intakes have been implicated in several neurological disorders, including depressive and aggressive disorders, as well as behavioral problems in children (Hibbeln 2009). Several studies have reported benefit of supplementation with EPA plus DHA, or DHA alone in these problems in children (Richardson and Montgomery 2005; Vaisman et al. 2008). Docoanoids, the oxygenated metabolites of 22-carbon chain fatty acids, such as neuroprotection 1, and docosatrienes, a conjugated triene metabolite of DHA have potent anti-inflammatory effects, and these appear to be important in the response to injury, such as oxidative stress or reperfusion damage following stroke; new studies in this field may offer therapeutic tools to protect the brain and enhance recovery following inflammatory or oxidative insults (Niemoller and Bazan 2009).

Summary Points

- ω-3 fatty acids are essential dietary nutrients, the amounts, and types of ω-3 fatty acids in the diet are important to the accretion and maintenance of brain DHA.
- Loss of DHA from the brain can have an adverse effect on neurogenesis and neurite outgrowth, serotinergic, and dopaminergic neurotransmission, and protection from neuroinflammation.
- DHA provided in the diet, transferred across the placenta, or provided in breast milk or milk substitutes, or in the weaning diet is taken up and incorporated into the brain.
- Diets low in DHA and EPA and high plant-derived ω-6 fatty acids are associated with increased ω-6:ω-3 fatty acids; these dietary patterns are linked to poorer infant and child neuro-cognitive development and several psychiatric problems in adults.

- Modern food production has introduced large amounts of plant-derived ω-6 fatty acids into the diet; this has led to enrichment of ω-6 fatty acids and loss of long chain ω-3 fatty acids, and an imbalance in ω-6 and ω-3 fatty acids in the food supply.
- Differences in dietary intake of DHA explain differences in blood lipid DHA and breast milk DHA.
- The role of EPA in brain function is unclear, but EPA may be important in modulating neuro-inflammatory processes and it may have a role in some attentional and depressive disorders.
- Infants born prior to 33 weeks gestation require more DHA than is supplied by milk from mothers following typical western diets, their milk, or formula needs at least 1% fat as DHA.

Key Terms

Fatty acid: A carboxylic acid with an unbranched chain of carbon atoms. The most usual fatty acids have an even number of carbon atoms and contain no double bonds, one double bond or more than one double bond, termed saturated, monounsaturated, or polyunsaturated, respectively.

Essential fatty acid: A polyunsaturated fatty acid with two or more double bonds of either the ω-6 series or ω-3 series.

Omega-3 fatty acids: A series of polyunsaturated fatty acids in which the first double bond from the methyl end of the fatty acid is at carbon number 3. Omega-3 fatty acids are essential nutrients.

Omega-6 fatty acids: A series of polyunsaturated fatty acids in which the first double bond from the methyl end of the fatty acid is at carbon number 6. Omega-6 fatty acids are essential nutrients.

Chapter 134
Dietary Choline for Brain Development

Amy R. Johnson and Steven H. Zeisel

Abbreviations

ACho	Acetylcholine
PtdCho	Phosphatidylcholine
SM	Sphingomyelin
VLDL	Very-Low-Density Lipoprotein
AI	Adequate Intake
UL	Upper Tolerable Limit
SAM	S-Adenosylmethionine
PEMT	Phosphatidylethanolamine *N*-methyltransferase
CHDH	Choline Dehydrogenase
BADH	Betaine Aldehyde Dehydrogenase
PCho	Phosphocholine
BHMT	Betaine:Homocysteine Methyltransferase
MS	Methionine Synthase
CDP-Choline	Cytidine Diphosphocholine
LTP	Long-Term Potential
ED	Embryonic Day
PD	Postnatal Day
SNP	Single-Nucleotide Polymorphism
AChE	Acetylcholineesterase
ChAT	Choline Acetyltransferase
TGF-β	Transforming Growth Factor-β
DCC	Deleted in Colorectal Cancer
MAPK	Mitogen-Activated Protein Kinase
CREB	cAMP-Response Element-Binding Protein
NGF	Nerve Growth Factor
H3	Histone 3
MeCP1, 2	Methyl-CpG-Binding Protein 1, 2
MBD 1–4	Methyl-CpG-Binding Domain 1–4

134.1 Introduction

In the last 20 years, a substantial body of literature has accumulated documenting the involvement of dietary choline in brain development and function. Epidemiological studies in humans (Shaw et al. 2004, 2006), as well as *in vivo* studies with rodents, indicate that the amount of choline made available to the developing fetus can have significant effects on brain formation (Fisher et al. 2001) and function, particularly in the hippocampus (Meck and Williams 1997c). In this chapter, we will discuss the effect of gestational dietary choline availability on hippocampal function, focusing primarily on memory and learning. We will also describe changes in cellular characteristics and explain how choline may be conferring these effects.

The availability to the developing fetus of extra choline enhances, while choline deficiency retards, an animal's ability to perform maze tasks designed to test memory and learning (Meck and Williams 1997a,c, 1988, 1999). Changes in the number, structure, and some functional aspects of hippocampal neurons occur as a result of both maternal dietary choline deficiency and supplementation during late pregnancy (Craciunescu et al. 2003; Li et al. 2004; Jones et al. 1999). Gestational choline availability is correlated with differences in expression and activation of proteins known to be involved in synaptic plasticity, neuronal proliferation, neuronal migration, and neuronal death (Mellott et al. 2004; Niculescu et al. 2005, 2006; Albright et al. 2005, 1999; Craciunescu et al. 2003). Although the underlying mechanisms by which choline elicits these memory phenotypes are not yet fully understood, experimental evidence suggests that choline's influence on gene expression at the level of DNA and histone methylation likely plays an important role (Davison et al. 2009; Niculescu et al. 2005, 2004) (Fig. 134.1).

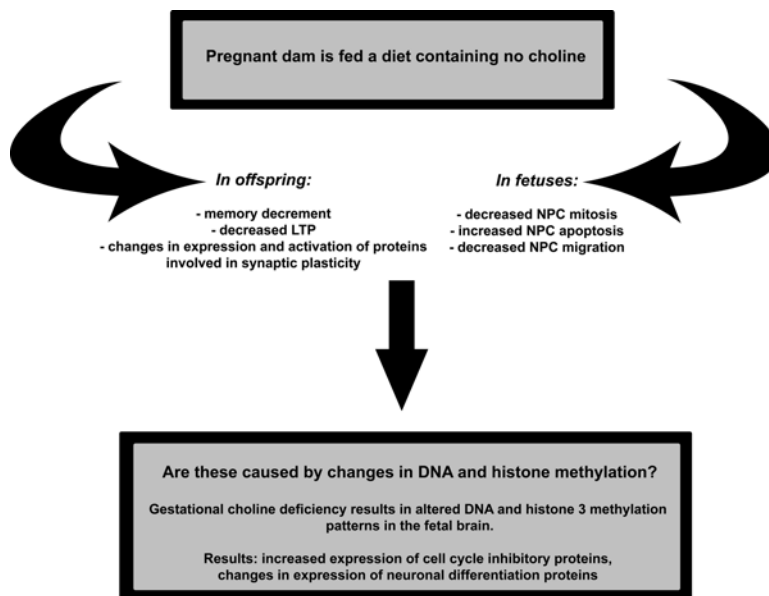
Many foods normally consumed by humans contain choline (http://www.ars.usda.gov/Services/docs.htm?docid=6232), but some populations, especially those that do not regularly consume meat and eggs, are at an increased risk of developing clinical choline deficiency. Pregnant or lactating


Fig. 134.1 Maternal choline deficiency during pregnancy changes brain development of both the offspring and fetus. In rodents, maternal dietary choline deficiency during pregnancy results in detrimental changes in the brain function of her offspring and development of her fetuses. Although the exact mechanism by which the changes occur is not fully understood, epigenetic gene control likely plays an important role. *LTP* long-term potential, *NPC* neural progenitor cell

women, men, postmenopausal women, and individuals harboring certain polymorphisms in genes involved in choline metabolism may have an increased requirement for dietary choline (Fischer et al. 2007). Gender and genetic profile are factors to be taken into account when determining adequate intake levels of choline, especially for women of reproductive age, as their diet directly influences the brain development of their baby.

134.2 Choline Is an Essential Nutrient

Choline is an essential nutrient for humans, and all cells require choline, or its metabolites, for maintenance of plasma membrane integrity and cellular signaling, as in the case of phopsphatidylcholine (PtdCho) and sphingomyelin (SM). Betaine, which is oxidized choline, is a major source of methyl groups in tissues and contributes to the pool of S-adenosylmethionine (SAM) available for the methylation of biological molecules including nucleic acids, proteins, and phospholipids. Also, choline may be acetylated to form acetylcholine (ACho), an important neurotransmitter and neurotrophic signaling molecule. The availability of choline can directly regulate the function of cholinergic neurons by influencing ACho concentrations within these cells (Zeisel 2006). Additionally, choline is required for the export of lipids from the liver because PtdCho is a necessary component of very-low-density lipoprotein (VLDL), hepatosteatosis, or fat accumulation in the liver, is a hallmark of dietary choline deficiency and can lead to liver damage and perhaps to carcinogenesis. Other characteristics of prolonged ingestion of a choline-deficient diet in humans include muscle cell damage, lymphocyte apoptosis, and a rise in plasma homocysteine concentrations (Zeisel 2006).

134.3 Dietary and Endogenous Sources of Choline

In 1998, the Institute of Medicine of the National Academy of Sciences (USA) set Adequate Intake (AI) levels for daily choline consumption (Institute of Medicine and National Academy of Sciences USA 1998). 550 mg/day is currently recommended for men and 425 mg/day for women (Table 134.1); it is estimated that typical daily choline intake by individuals eating normal diets is very close to, or less than, this recommendation (Shaw et al. 2004; Xu et al. 2008). Choline and choline metabolites

Table 134.1 Dietary reference intake values for choline (Information from Institute of Medicine, National Academy of Sciences USA, 1998)

Population	Age	Adequate intake (AI)	Tolerable upper limit (UL)
AI for infants	0–6 months	125 mg/day, 18 mg/kg	Not possible to establish[a]
	6–12 months	150 mg/day	
AI for children	1–3 years	200 mg/day	1,000 mg/day
	4–8 years	250 mg/day	1,000 mg/day
	9–13 years	375 mg/day	2,000 mg/day
AI for males	14–18 years	550 mg/day	3,000 mg/day
	19 years and older	550 mg/day	3,500 mg/day
AI for females	14–18 years	400 mg/day	3,000 mg/day
	19 years and older	425 mg/day	3,500 mg/day
AI for pregnancy	All ages	450 mg/day	Age-appropriate UL
AI for lactation	All ages	550 mg/day	Age-appropriate UL

AI adequate intake, *UL* upper tolerable limit

[a]Source of intake should be food and formula only

Table 134.2 Choline content in foods (Information from USDA, Nutrient Data Laboratory and Agricultural Research Service, 2008)

Food	Total choline[a] mg choline moiety/100 g food	Betaine mg/100 g food
Eggs: whole, raw	250	0.6
Chicken liver: raw	190	17
Cereal: wheat germ, toasted	180	410
Pork: cured, pan fried bacon	130	4.2
Beets: raw	6	130
Spinach: frozen, microwaved	28	130
Beef: liver, pan fried	420	6.3
Bread: whole wheat	27	38
Crackers: wheat	27	58
Bulgur wheat: cooked	6.9	83

[a]"Total choline" refers to free choline, phosphocholine, phosphatidylcholine, glycerophosphocholine and sphingomyelin content in food. Betaine is reported separately and therefore not included in this sum

can be found in significant amounts in many foods regularly consumed by humans. Additionally, some foods, such as infant formula, are fortified with choline. The United States Department of Agriculture has recently constructed a database reporting the choline content of a wide variety of foods (http://www.ars.usda.gov/Services/docs.htm?docid=6232). Foods highest in choline content per 100 g include beef and chicken liver, eggs, and wheat germ. Foods with high betaine content per 100 g include wheat bran, bulgur wheat, and spinach (Table 134.2). It is important to take betaine content into consideration since the presence of betaine will spare choline from use as a methyl-group donor, leaving more choline available for ACho or PtdCho biosynthesis.

In addition to dietary sources, choline can be synthesized de novo by the enzyme phosphatidylethanolamine *N*-methyltransferase (PEMT); this occurs primarily in the liver (Zeisel 2006). Using phosphatidylethanolamine and SAM as substrates, PEMT catalyzes the formation of PtdCho, which can be incorporated into cell membranes or hydrolyzed, generating a choline moiety. When fed a choline-deficient diet, mice with two mutated alleles of *Pemt* (*Pemt*[-/-]) developed hepatosteatosis and severe liver damage, both of which may contribute to their premature death. Feeding these mice with excess choline prevented these outcomes and reversed the liver damage if supplementation was initiated early enough (Walkey et al. 1998). The PEMT pathway is more than a means of augmenting PtdCho formation by the cytidine diphosphocholine (CDP-choline) pathway; the PEMT pathway is a major user of methyl-groups derived from methionine (generating homocysteine). Plasma homocysteine concentrations in *Pemt*[-/-] mice are half of those measured in wild-type mice and overexpression of *Pemt* increases homocysteine concentrations by 40% (Jacobs et al. 2005; Shields et al. 2005). The human *PEMT* gene is induced by estrogen and thus, young women have a lower dietary requirement for choline (premenopausal women are less likely to develop hepatosteatosis, liver, and muscle cell damage on a choline-deficient diet than are postmenopausal women and men (Fischer et al. 2007; Resseguie et al. 2007). However, pregnancy and lactation increases dietary choline requirements, and it is likely that most women need to eat choline during these periods (Zeisel 2006).

134.4 Genetic Polymorphisms Affect Dietary Choline Requirements

It is important to recognize that there is significant variation in dietary requirements for choline. Some individuals rapidly deplete when deprived of choline (days) while others take weeks to become depleted (Fischer et al. 2007). Some people require as much as 850 mg/day to prevent

organ dysfunction while others need less than 550 mg/day (Fischer et al. 2007). These differences are likely attributable to genetic variation among individuals. Although they would be expected to be resistant to choline deficiency, 44% of premenopausal women must eat choline, or they develop organ dysfunction in the same way that men do (Fischer et al. 2007). These differences are due, in part, to common single-nucleotide polymorphisms (SNPs) in the genes associated with choline and folate metabolism (da Costa et al. 2006; Kohlmeier et al. 2005). Eighteen percent of the Raleigh-Durham-Chapel Hill, North Carolina, USA population is homozygous (70% have 1 allele) for an SNP in the promoter region of *PEMT* (rs12325817) that makes them much more susceptible to dietary choline deficiency (odds ratio 25: risk of becoming choline deficient is increased 25x, $p = 0.002$) than are those without the SNP because endogenous production of choline molecules via PEMT is impaired (da Costa et al. 2006; Resseguie et al. 2007). 17-beta-estradiol, an estrogen analog, increases *PEMT* transcription and activity in human hepatocytes via an estrogen response element near the transcription start sites in both human and murine *PEMT* genes (Resseguie et al. 2007) and women with the common *PEMT* SNP are unresponsive to estrogen induction of the gene (manuscript in preparation). Humans with this SNP need more dietary choline as adults (da Costa et al. 2006), and we suggest that they are likely to need more choline during pregnancy to sustain normal fetal development.

134.5 Choline Metabolism

Figure 134.2 illustrates the pathways of choline metabolism. Choline can be utilized to synthesize PtdCho and SM for use in cell membranes, it can be oxidized to betaine for use as a methyl-donor and an organic osmolyte, and it can also be acetylated to form the neurotransmitter ACho.

A small portion of dietary choline is converted to ACho by the enzyme choline acetyltransferase (ChAT). This enzyme is found in high concentrations in cholinergic neurons ensuring that ACho is available for release by these cells. Since it is unlikely that choline and/or acetyl-CoA are present at levels that would saturate the ChAT enzyme, choline availability determines the rate of ACho synthesis (Blusztajn et al. 1987) and modulates the amount of this neurotransmitter released into the synapse (Cohen and Wurtman 1975; Ulus et al. 1989; Wecker 1991). Choline-containing phospholipids including PtdCho and SM, incorporated into cholinergic cell membranes, serve as a reserve of choline available for ACho synthesis in cells with a high demand for ACho (Blusztajn et al. 1986, 1987).
Fig. 134.2 The choline metabolic pathway. Metabolism of choline includes the interaction point between choline and folate metabolism. *ChAT* choline acetyltransferase, *CHDH* choline dehydrogenase, *BADH* betaine aldehyde dehydrogenase, *BHMT* betaine:homocysteine methyltransferase, MS methionine synthase, *MTHFR* methylene-tetrahydrofolate reductase, *MTHFD* methylene-tetrahydrofolate dehydrogenase, *PEMT* phosphatidylethanolamine N-methyltransferase
Fig. 134.3 Structures of selected choline metabolites. Choline, betaine, acetylcholine, and phosphatidylcholine play important roles in brain development and function

Two successive oxidation reactions convert choline to betaine via the formation of an aldehyde intermediate (Chern et al. 2000; Chi-Shui and Ru-Dan 1986; Haubrich and Gerber 1981). In mammals, this process involves two enzymes: choline dehydrogenase (CHDH) and betaine aldehyde dehydrogenase (BADH). This irreversible conversion takes place in the mitochondrial matrix following choline transport into these organelles. Once formed, betaine diffuses from the mitochondria into the cytosol where it can donate labile methyl-groups for SAM generation through the one-carbon metabolism pathway – the point of interaction between choline and folate metabolism. Choline oxidation occurs primarily in liver, kidney, and testis; CHDH enzyme has relatively low activity in whole mouse brain (Johnson et al. 2010).

An important role for choline is for biosynthesis of cellular membrane phospholipids, such as PtdCho (also known as lecithin) and SM. PtdCho represents more than 50% of the total phospholipid content in cell membranes. PtdCho synthesis is highly regulated and can occur through two pathways (Zeisel 2006). In the CDP-choline pathway, choline is phosphorylated, generating phosphocholine (PCho). PCho is converted to CDP-choline that is then combined with diacylglycerol, ultimately resulting in the formation of PtdCho. As discussed above, an alternative pathway synthesizes PtdCho from SAM and phosphatidylethanolamine through the enzymatic activity of PEMT. SM, another important component of membranes, is formed from PtdCho (Fig. 134.3).

134.6 Choline, Methionine, and Folate Metabolism Are Interrelated

The metabolic pathways of choline, methionine, and folate all interact at the point in which homocysteine is converted to methionine. A deficiency or excess of any one of these three nutrients will have an impact on the usage of the other two; therefore, dietary choline requirements must be considered with methionine and folate intake in mind (Zeisel 2006). Homocysteine is converted to methionine using methyl-groups from either betaine or methyl-folate. Choline is oxidized to betaine in two successive reactions as discussed above. Betaine:homocysteine methyltransferase (BHMT) methylates homocysteine using a methyl group from betaine resulting in the formation of methionine. Alternatively, methionine synthase (MS) uses folic acid and vitamin B_{12} to methylate homocysteine.

Alterations in these metabolic pathways, either by changes in dietary intake or the presence of SNPs in genes involved in these pathways, leads to compensatory changes in the usage of other methyl-group

donors (Jacobs et al. 2005; Jacques et al. 2001; Shelnutt et al. 2003; Watkins et al. 2002; Weisberg et al. 2001). Rodents treated with methotrexate, an antifolate drug, had decreased hepatic choline metabolite concentrations (Pomfret et al. 1990). On the other hand, feeding rats a choline-deficient diet resulted in significantly decreased SAM and methionine concentrations as well as increased plasma homocysteine levels (Varela-Moreiras et al. 1995). We have reported that dietary choline supplementation can revorse some of the effects of flate deficiency on fetal mouse brain development (Craciunescu et al. 2010). Humans developed elevated plasma homocysteine concentrations in response to a methionine load (da Costa et al. 2005).

134.7 Choline and Fetal Development

Pregnancy and lactation are times during which demand for choline by the fetus or neonate is very high and pregnant or lactating women could become choline depleted while meeting these needs. Pregnant rats have significantly reduced choline concentrations in their liver compared to nonmated controls and these females are also more sensitive to the effects of choline-deficient diets (Zeisel et al. 1995). Dietary choline intake is especially important for pregnant and lactating women since, as will be discussed later, choline availability influences brain development. As noted earlier, choline is also necessary for modulating maternal plasma homocysteine concentrations; high maternal plasma homocysteine during pregnancy is associated with an increased incidence of birth defects (Hobbs et al. 2005). Shaw and colleagues found that dietary choline intake among women in the United States varies enough (from less than 300 mg/day to more than 500 mg/day) to influence the risk of having a baby with a neural tube defect, with women in the lowest quartile for dietary choline intake having four times the risk of having a baby with a neural tube defect (Shaw et al. 2004). Birth defects occur in rodents when choline availability is restricted early in fetal development (Fisher et al. 2001, 2002).

Large amounts of choline are transported to the fetus across the placenta during gestation (Sweiry et al. 1986; Sweiry and Yudilevich 1985). Choline concentration in amniotic fluid is 10-fold higher than the concentration in maternal blood (S.H.Z, unpublished observation). Plasma or serum choline concentrations are 6- to 7-fold higher in the fetus than in the adult, but these levels diminish to levels measured in adult circulation within weeks following birth (Ozarda et al. 2002; Zeisel and Wurtman 1981). High circulating concentrations of choline in the fetus ensure adequate availability of choline for cell membrane biosynthesis and methylation mark maintenance in rapidly forming tissues. The choline content of human milk is also directly influenced by dietary choline intake, with lactating women eating low-choline diets producing milk with lower choline content compared to women eating a more choline-adequate diet (Zeisel et al. 1982). The choline content of human milk is very high at the beginning of lactation, but diminishes to concentrations typical of commercial bovine-derived infant formulas by 30 days postpartum (Holmes-McNary et al. 1996).

134.8 Perinatal Choline Supplementation Enhances Cognitive Function in Mice

The effect of perinatal choline supplementation (approximately three times normal choline intake) on attention, learning, and memory was first observed by testing Sprague–Dawley rats on radial arms mazes (Meck et al. 1988). In the initial experiments, rat fetuses received choline supplementation via maternal diet from embryonic day (ED) 9 through birth. At birth, pups were randomly cross-fostered to dams who had not received dietary choline supplementation. Supplementation of the pups continued

through postnatal day (PD) 30 by administration of choline by subcutaneous injection. Beginning on PD 30, and continuing throughout the remainder of their lives, all animals were fed a diet with adequate, but not excessive, amounts of choline.

Animals were tested with radial-arm maze tasks beginning between 2 and 6 months of age. By using mazes with increasing numbers of arms and subjecting the animals through several trials in rapid succession on the same day (massed trials) – thus increasing the difficulty of the task – researchers observed that the choline-supplemented pups outperformed those who were not supplemented at all degrees of testing difficulty except with the initial, easiest tests where no difference among treatments was observed (Meck et al. 1988). Perinatal choline supplementation resulted in improved performance in the working, reference and temporal memory aspects of this task, while choline deficiency impaired memory (Meck and Williams 1997a, 2003). Gestational choline availability alters memory formation strategies in rodents. Pups born to choline-supplemented dams used "chunking" strategies in memory performance testing (Meck and Williams 1997b). Chunking facilitates recall of more information because items to be remembered are grouped, or chunked, together in larger units, allowing for more efficient memory processing and retrieval. Proactive interference refers to the interference of memories from previous experiences with current memory performance. Perinatal choline supplementation significantly decreased, while choline deficiency increased, proactive interference in rats compared to normal choline controls (Meck and Williams 1999).

Adult rodents develop "senility" as they age; however, animals that received choline supplementation during the perinatal period do not show this decline in cognitive function (Meck and Williams 1997c, 2003). Conversely, accelerated age-related decline in simultaneous temporal processing was observed in animals born to choline-deficient dams. These tests were also replicated using other rat strains, as well as mice, and other tests of spatial memory, including the Morris water maze test with similar results (Brandner 2002; Schenk and Brandner 1995).

134.9 Choline Availability Alters Many Characteristics of Hippocampal Function

The hippocampus, located in the medial temporal lobe of the brain, is associated with declarative memory, new memory formation, spatial navigation, and other cognitive functions (Eichenbaum 2004). Because the radial-arm and Morris water maze studies described above indicated perinatal choline availability influences these cognitive functions, alterations in the hippocampus have been the focus of investigation. In humans, hippocampal development begins on ED 56 and continues through 4 years of age. In rodents, hippocampal development begins during late gestation, ED 11, and continues through PD 30. ED 11–17 and PD 16–30 are the two time periods in which the hippocampus is most sensitive to changes in choline availability (Meck et al, 1988).

Perinatal choline availability confers changes in morphological, electrophysical, and biochemical characteristics of the hippocampus in both fetal and adult rodent brain.

134.9.1 Gestational Choline Availability Effects in Fetal Hippocampus

Neural precursor cells are partially committed stem cells from which mature neurons are derived. These cells originate in the ventricular zone of the hippocampus and migrate to other areas of this region as they differentiate into neurons. The balance between neural precursor cell proliferation
Fig. 134.4 Choline availability affects numbers of mitotic cells in fetal hippocampus. Maternal dietary choline deficiency in timed-pregnant mice fed choline-supplemented (CS), control (CT) or choline-deficient (CD) AIN-76 diet from embryonic day 12 to 17 decreases mitosis in embryonic mice on ED 17 at the ventricular surface of the ventricular zone of the hippocampus. All mice were killed on ED17 and coronal sections were prepared from the brains from the fetuses from each group for the analysis of mitosis using the mitosis-specific marker anti-phospho-histone 3. *Panel A*, In CD fetal hippocampus compared with CT, there were fewer phospho-histone three positive cells at the ventricular surface of the ventricular zone adjacent to the fimbria (Fi), dentate gyrus (DG) and Ammon's Horn (AH), and this was reflected in the calculated values for the whole hippocampal section length of the ventricular zone (Hi). Compared with the CT group, the CS group had a higher incidence of phospho-histone three labeled cells at the ventricular surface of the ventricular zone only in the fimbria. The graph insert shows the equivalence of the sections in terms of total hippocampal ventricular zone length. Values are means ± SEM of at least six pups per group from six dams. Means without a common letter, $P < 0.05$ (for each pair using Student's *t* test, for all pairs using Tukey–Kramer HSD test, and comparison with control using Dunnett's method). *Panel B* shows a representative fetal hippocampus at a magnification of 50X with the regions of interest marked. *Panels C* and *D* are 400X magnifications of the boxed regions in panel *B*, and arrows designate representative labeled cells in the hippocampal regions. *ED*, embryonic day (Reprinted from Craciunescu et al. 2003. With permission)

(mitosis) and death (apoptosis) is altered by the amount of choline a dam consumes during late pregnancy. Fetuses of dams fed a choline-deficient diet from ED 11–17 had decreased numbers of mitotic cells in their hippocampus compared to control animals (Fig. 134.4). These animals also had increased numbers of apoptotic cells in this same region (Fig. 134.5). Choline supplementation had the opposite effect, with increased cell mitosis and decreased apoptosis in this region of the brain (Craciunescu et al. 2003). Changes in rates of neural precursor cell apoptosis are a means to regulate the number of cells in neuronal subpopulations in the hippocampus, which will alter the functional characteristics of this structure.

The expression patterns of many proteins are affected by the amount of choline supplied to the fetal brain. For example, calretinin, a calcium-binding protein and a marker of GABAergic neuron differentiation, is decreased in fetuses of choline-supplemented dams (Albright et al. 2003). Choline availability alters the expression of netrin-1 and its receptor deleted in colorectal cancer
Fig. 134.5 Gestational choline availability affects rates of apoptosis in fetal hippocampus. Maternal choline deficiency in timed-pregnant mice fed choline-supplemented (CS), control (CT), or choline-deficient (CD) AIN-76A diet from ED 11 through ED 17 increases apoptosis in ED 17 hippocampus. Coronal section were prepared from the brains of ED 17 fetuses from each diet group and were analyzed for apoptosis using a combination of classical apoptotic morphology, active caspase-3 immunoreactivity and TUNEL (terminal deoxynucleotidyl transferase (TdT-mediated dUTP-digoxigenin anti-digoxigenin fluoroscein conjugate antibody nick end-labeling). Consecutive serial sections were used for TUNEL/ active caspase-3 staining. *Panel A*: The graph shows apoptotic cell counts using morphological criteria (means ± SEM, $n = 10$–12 pups/ group from at least five dams), and TUNEL-cleaved caspase-3 immunostaining (means ± SEM, $n = 6$ pups/ group from three dams). Means without common letters differ, $P < 0.05$ (for each pair using Student's t test, for all pairs using Tukey–Kramer HSD test, and comparison with control using Dunnett's method). *Panel B*: A 50X magnification image of the right hippocampal hemisphere showing TUNEL-positive cells distributed in the cortical plate (CA1, CA2, CA3), dentate gyrus (DG) and fimbria (Fi). *Panel C*, A representative image at 400X magnification is shown; the arrows point to cells showing apoptotic morphology. *Panel D*, Higher power view of the boxed area in panel B, spherical TUNEL and activated caspase-3 positive nuclei indicated by arrows. *ED* embryonic day (Reprinted from Craciunescu et al. 2003. With permission)

protein (DCC), proteins involved in migration of neuronal precursor cells from the ventricular zone to the Ammon's horn, dentate gyrus, and fimbria (Albright et al. 2005). Alterations in the expression of netrin-1 and DCC resulting from gestational choline deficiency perturbed migration of neuronal precursor cells from the neuroepithelial layer to the dentate gyrus in fetuses (Albright et al. 1999). Expression of vimentin, transforming growth factor-β (TGF-β), and cell cycle regulatory proteins p15Ink4B and p27Kip1 in the brain also were changed by choline availability during gestation (Albright et al. 1998, 2001, 2003,). These changes in brain proteins suggest increased neural and glial cell differentiation in brains of fetuses from choline-deficient mothers. As will be discussed later, epigenetic control of gene expression is one likely mechanism through which choline can elicit these protein changes by controlling transcription of the gene that encode these proteins. The relative abundance of these proteins can result in enhancement or repression of mitosis and apoptosis.

134.9.2 Gestational Choline Availability Is Associated with Hippocampal Changes in Offspring

In morphological studies, hippocampal neurons with larger soma and increased numbers of primary and secondary dendritic branches were observed in animals perinatally supplemented with choline (Li et al. 2004). Hippocampal slices from animals whose mothers were perinatally supplemented with choline were electrophysiologically more responsive, that is, were more likely to exhibit long-term potential (LTP) at a lower electrical stimulus, than were hippocampal slices from control animals. Conversely, hippocampal slices from animals whose mothers were perinatally deficient in choline were less likely to exhibit LTP at a given electrical stimulus, than were hippocampal slices from control animals (Jones et al. 1999). Because increased LTP is regarded as a biomarker for the mechanisms underlying learning, these data support the observations using radial maze testing.

Alterations in expression and activation of specific proteins in response to prenatal choline supplementation have been measured in the hippocampus, which may influence the function of neurons in this brain region. Mellot and colleagues reported increased phosphorylation of mitogen-activated protein kinase (MAPK) and cAMP-response element-binding protein (CREB) in response to stimulation of the hippocampus of rodents born to dams that were supplemented with choline during pregnancy. These animals also were able to use spatial cues effectively to complete a water maze task 3 days before unsupplemented animals (Mellott et al. 2004). Both MAPK and CREB are proteins believed to be involved in synaptic plasticity. Activity of an enzyme that hydrolyzes PtdCho, phospholipase D, as well as nerve growth factor (NGF) expression is increased in offspring of choline-supplemented animals (Holler et al. 1996; Sandstrom et al. 2002). Taken together, these studies offer compelling evidence that dietary choline intake during pregnancy can have significant and lasting effects on the development and function of the brain (Tables 134.3).

Table 134.3 Effects of perinatal choline supplementation and deficiency on brain function and biochemistry

Hippocampal characteristic	Choline supplementation[a]	Choline deficiency[a]
Memory and learning	Improved working, reference, and temporal memory	Impaired memory, especially in difficult tasks
	Enhanced simultaneous temporal processing	Decreased attention to lesser preferred signal
	Increased used of chunking memory strategy	Increased proactive interference
	Decreased age-related memory decline	Accelerated age-related decline
	Increased neuron soma size	n.s.
Morphology	Increased number of dendritic branches	n.s.
Electrophysical properties	Increased LTP	Decreased LTP
Biochemistry	Increased expression/activation of: MAPK,[b] CREB,[b] Phospholipase D, NGF, ChAT	Decreased expression/activation of: MAPK,[b] CREB[b]
	Decreased expression/activation of: Calretinin	Increased expression/activation of: Calretinin
Cellular processes	Increased neural precursor cell mitosis	Decreased neural precursor cell mitosis
	Decreased neural precursor cell apoptosis	Increased neural precursor cell apoptosis

[a]Significant changes compared to animals fed a diet containing normal amounts of choline

134.10 Choline May Change Hippocampal Function by Altering Epigenetic Control of Gene Transcription

The exact mechanisms through which choline influences hippocampal development, and consequent changes in learning and memory are not completely elucidated. However, changes in gene expression observed in *in vitro* and *in vivo* choline deficiency studies suggest that changes in hippocampal development and function in the developing brain may be due to alterations in epigenetic transcriptional control of these genes.

134.10.1 Gene Transcription Can Be Enhanced or Repressed by DNA and Histone Methylation

"Epigenetics" literally means "above the genes" and refers to genetic transcription control related to a "code" that does not involve altering the DNA sequence of the gene. This code is constructed of patters of methylation on both DNA and histones, the proteins around which DNA is wound. In mammals, DNA methylation occurs on cytosine resides that are directly followed by guanosine bases (CpG sites) and approximately 60–90% of these sites are methylated at any time (Holliday and Grigg 1993). Areas characterized by a higher than expected number of CpG repeats are termed CpG islands and tend to be targets for methylation (Robertson and Wolffe 2000). CpG island methylation changes can result in changes in gene expression and, ultimately, phenotype of an organism (Cooney et al. 2002; Waterland and Jirtle 2003). Although there are exceptions, hypermethylation is generally associated with gene silencing while hypomethylation tends to result in increased gene expression, perhaps because methylated cytosines bind to a family of proteins (methyl-CpG binding protein (MeCP)1 and 2 and methyl-CpG binding domain (MBD) 1–4) that block binding of transcription enhancing factors to promoter regions of these genes (Hendrich and Bird 1998; Jones and Takai 2001). Additionally, specific lysine and arginine residues on histones can be methylated resulting in alterations in heterochromatin structure which may either permit or repress transcription of genes depending on the exact methylation site (Jenuwein and Allis 2001).

134.10.2 The Role of Choline in Epigenetic Gene Control

SAM is required for methylating DNA and histones and dietary choline can directly influence the amount of SAM available for these reactions. Consumption of diets enriched with methyl-group donors (choline, betaine, methionine, folic acid) and other cofactors required by enzymes for the metabolism of these nutrients (vitamin B_{12}) can result in hypermethylation of gene-specific DNA sequences in mice correlated to phenotypic changes observed (Waterland and Jirtle 2003; Wolff et al. 1998). As discussed above, the choline metabolite betaine is an important source of methyl-groups. Choline availability during fetal development in the rodent modulates CpG island methylation, resulting in altered gene expression in the hippocampus (Niculescu et al. 2006). Choline deficiency in the pregnant mouse dam is associated with hypomethylation of genes that inhibit cell cycling in fetal neural precursor cells, resulting in increased expression of these genes and decreased cell mitosis observed in these animals (Niculescu et al. 2004, 2005). Choline deficiency in the pregnant mouse dam also alters methylation patterns on lysine residues of histone 3 (H3) in brain and these changes

Table 134.4 Key facts about choline

– Choline is an essential nutrient.

– Choline is present in many foods commonly eaten by humans and it can also be synthesized within the body.

– Mutations in choline metabolism genes commonly occur in humans and can influence the amount of dietary choline required by an individual.

– Because the metabolic pathways of choline, folate, and methionine interact with one another, increases or decreases in choline availability will alter requirements for folate and methionine.

– Pregnant and lactating women may have higher requirements for dietary choline. Adequate dietary choline intake during pregnancy is required to support normal fetal development.

– Perinatal choline supplementation enhances the function of the rodent hippocampus, while choline deficiency results in memory decrement. Gestational choline availability can influence the structure and biochemistry of the fetal hippocampus.

Described are key concepts about choline and its effect on brain development, specifically hippocampal development and function. These points will be discussed in detail through the course of this chapter

result in differences in specific gene expression, namely, genes that regulate methylation (Davison et al. 2009) and neuronal cell differentiation (Mehedint et al. 2010). The collective body of literature accumulated to date on maternal dietary choline and fetal brain development strongly suggests that the manipulation of dietary choline during pregnancy can have profound and lasting effects on function of this organ throughout life (Table 134.4).

134.11 Applications to Other Areas of Health and Disease

Using rodent models, perinatal choline supplementation has been explored as a therapeutic treatment for the amelioration of several conditions associated with altered cholinergic neuron function. Neonatal choline supplementation significantly improved the performance of rats prenatally exposed to alcohol on a T-maze, a visuaspatial discrimination task (Thomas et al. 2000). Additionally, neonatal choline supplementation of these animals resulted in attenuation of behavioral defects associated with prenatal alcohol exposure, including overactivity and other spatial learning deficits (Thomas et al. 2007). Rett syndrome is a neurodevelopmental disorder characterized by abnormalities in the brain cholinergic system caused by mutation of the *MeCP2* gene. Neonatal supplementation of mice harboring the mutated *MeCP2* gene resulted in improved motor coordination, locomotor activity and grip strength in these animals in a gender-specific pattern (Nag and Berger-Sweeney 2007). These changes may be attributable to an increase in nerve growth factor expression in the striatum in the choline – supplemented animals (Nag et al. 2008). Perinatal and postnatal dietary choline supplementation improved spatial memory and reduced brain inflammation following traumatic brain injury in rats (Guseva et al. 2008). Prenatal choline supplementation also had neuroprotective effects in a rat model of status epilepticus (Wong-Goodrich et al. 2008; Yang et al. 2000). Together, these studies offer evidence that perinatal, and even postnatal, choline supplementation can influence brain function not only in the normally developing brain, but also in the abnormally developing brain.

Summary

• Choline is an essential nutrient for humans and there is sufficient variation in dietary intake as to have an effect on fetal development.

• Choline is required by all cells for maintaining cell membrane integrity, providing a source of methyl groups for methylation reactions, and for the formation of the neurotransmitter ACho.

- The developing fetus and neonate has a high demand for choline; therefore, pregnant and lactating women have an increased need for dietary choline.
- Perinatal choline supplementation of the fetus, during the time in which the fetal hippocampus is developing, improved cognitive function in these animals; this enhancement persisted throughout life.
- Gestational choline availability changes the expression of many proteins in hippocampal cells, which affect rates of division, apoptosis, and other functions of these cells. These changes may result from alterations in DNA and histone methylation patterns.
- Choline supplementation increases, and choline deficiency decreases, neural precursor cell proliferation in fetal brain; choline supplementation decreases, and choline deficiency increases, apoptosis of these cells. Choline deficiency retards neuronal migration and increases neuronal precursor cell differentiation into neurons and glia.

Definitions

Choline: A small lipotrophic molecule generally categorized as a B vitamin; essential for the normal function of all cells; present in many foods, particularly eggs and meats.

Mitosis: In eukaryotic cells, the process whereby the nucleus is divided to produce two genetically equivalent daughter nuclei with the diploid number of chromosomes (Lodish et al. 2004).

Apoptosis: Regulated process leading to cell death mediated by a caspase cascade and marked by a series of well-defined morphological changes; also called *programmed cell death* (Lodish et al. 2004).

Epigenetics: The study of heritable modifications in DNA methylation and chromatin structure that affect gene transcription.

Neuronal precursor cell: Pluripotent stem cells from which mature neurons are derived.

Chapter 135
Iodine and Brain Development

Pere Berbel and Gabriella Morreale de Escobar

Abbreviations

T2	3,5-Diiodo-L-thyronine or diiodothyronine
T3	3′,3,5-Triiodo-L-thyronine or triiodothyronine
T4	3′,5′,3,5-Tetraiodo-L-thyronine or thyroxine
rT3	3′,5′,3-Triiodo-L-thyronine or reverse-T3
BrdU	5-Bromo-2′-deoxyuridine
5-HTT	5-HT transporter
DAG	Diacyl glycerol
DiI	1,1′-Dioctadecyl-3,3,3′,3′-tetramethylindocarbocyanine perchlorate
DIT	Diiodotyrosine
E	Embryonic day
GABA	Gamma-aminobutyric acid
HAS	Human serum albumin
IP3	Inositol triphosphate
ICCIDD	International Council for the Control of Iodine Deficiency Disorders
D	Iodothyronine deiodinase
LID	Low-iodine diet
MMI	Methimazole
MAP	Mitogen-associated protein
MCT	Monocarboxylate transporter
MIT	Monoiodotyrosine
NHANES	National Health and Nutrition Examination Surveys
OATP	Organic anion transporting polypeptide
PLC	Phospholipase C
P	Postnatal day
PTU	Propylthiouracil
PKC	Protein kinase C
5-HT	Serotonin
TR	T3 receptor
TBG	Thyroid-binding globulin

TSH	Thyrotropin
TTR	Transthyretin
UI	Urinary iodine
WHO	World Health Organization

135.1 Thyroid Gland Function

135.1.1 Biosynthesis of Thyroid Hormones

The thyroid hormones thyroxine (3′,5′,3,5-tetraiodo-L-thyronine; T4) and triiodothyronine (3′,3,5-triiodo-L-thyronine; T3) are iodinated thyronines produced and released in the thyroid gland. Thus, reduced iodine in the form of iodide is required by the thyroid gland for thyroid hormone synthesis. Both, the iodide oxidation and binding to tyrosine residues of the thyroglobulin resulting in residues of monoiodotyrosine (MIT) and diiodotyrosine (DIT) (iodination reaction), and the subsequent MIT and DIT coupling in T3 and T4 residues bound to the thyroglobulin (coupling reaction) are catalyzed by thyroperoxidase, which is a transmembrane enzyme located in the apical membrane of thyrocytes. A typical distribution for a thyroglobulin containing 0.5% iodine (a normal amount for iodine-sufficient individuals) is five residues of MIT, five of DIT, 2.5 of T4, and 0.7 of T3 (Dunn and Dunn 2000). The substrates of the thyroperoxidase are follicular iodide and H_2O_2; the latter is synthesized and released to the follicular lumen by a dual-oxidase calcium-binding transmembrane enzyme coupled to the thyroperoxidase (Song et al. 2007). Iodide is transported to the follicular lumen by an ion channel also coupled to the dual-oxidase and thyroperoxidase complex (Fig. 135.1). Finally, synthesized thyroid hormones are released by thyrocytes due to thyrotropin (TSH)-induced pinocytosis and subsequent proteolysis of the iodinated thyroglobulin (Table 135.1).

The thyroglobulin iodination is a highly regulated process and is primarily controlled by H_2O_2 generation and iodide supply. Both, iodide release to the follicular lumen and H_2O_2 synthesis are acutely and synchronously regulated by the same intracellular signal cascades (Raspe and Dumont 1994). Thus, in thyroid hormone synthesis, the extrathyroidal pool of inorganic iodide available plays a crucial role, which is constituted by the iodide from the diet and the circulating iodide derived from the metabolism of the iodothyronines.

TSH positively regulates this process due to the presence of a TSH receptor in the basal membrane of thyrocytes. TSH receptors are coupled to Gs and Gq proteins, which respectively results in increased calcium and cAMP intracellular concentrations, activating a series of signaling cascades. These metabolic pathways trigger secretion, gene expression, H_2O_2 synthesis, and iodide transport to the follicular lumen (Song et al. 2007).

More iodine increases the ratios of DIT/MIT and T4/T3, while iodine deficiency decreases them (Dunn and Dunn 2000). In the case of mild iodine deficiency (i.e., urinary iodine in school children between 50 and 100 μg/l) to moderate iodine deficiency (i.e., urinary iodine in school children between 20 and 49 μg/l), the thyroid gland responds rapidly through autoregulatory mechanisms (independent from changes in circulating TSH) by decreasing the synthesis and secretion of T4 in favor of T3 (which is the active hormone that binds to specific nuclear receptors, see below). As a consequence, the circulating levels of T3 remain normal, or even increase slightly, and circulating TSH does not increase, as occurs in hypothyroidism (Morreale de Escobar et al. 2000, 2004).

Thyroid hormones in serum may circulate free or bound to a series of hormone-binding proteins. In normal man, approximately 0.03% of the total serum T4, and 0.3% of the total serum T3 are present
Fig. 135.1 Major metabolic pathways in thyrocytes involved in iodination and coupling reactions. Cartoon showing the major metabolic pathways in thyrocytes involved in the iodination of tyrosine (Tyr) and in the coupling of monoiodotyrosine (MIT) and diiodotyrosine (DIT) to form thyroid hormones. A sodium/iodide symporter (NIS) transports iodide into thyrocytes, transported into the colloidal lumen through an anion channel (pendrin; PE). Thyroperoxidase (TPO) oxidizes iodide in the presence of H_2O_2 and is then transferred to Tyr residues of thyroglobulin (Tg) to form MIT and DIT (iodination reaction). Again, TPO in the presence of H_2O_2 catalyzes the coupling of DIT and MIT, and of DIT and DIT to form residues of T3 and T4 coupled to Tg (coupling reaction). Thyrotropin (TSH) stimulates pinocytosis of Tg, which is subsequently hydrolyzed in the lysosomes of thyrocytes. Released T3 and T4 are then delivered to blood. H_2O_2 is produced at the apical plasma membrane by a NADPH dual-oxidase enzyme (Duox) coupled to TPO, in the presence of calcium. A high intracellular concentration of calcium favors both the iodination and coupling reactions. A high intracellular concentration of iodide favors iodination but inhibits coupling

in free or unbound form, immediately available to tissues (Refetoff et al. 1970). Under normal conditions, free hormone levels are maintained constant by appropriate stimulation or suppression of hormone secretion and disposal. The major serum thyroid hormone-binding proteins responsible for the maintenance of a large extrathyroidal pool of thyroid hormone are thyroid-binding globulin (TBG), transthyretin (TTR), and human serum albumin (HAS; Oppenheimer 1968). TBG binds 75% of serum T4, while TTR and HSA bind only 20% and 5%, respectively. One of the principal functions of T4-binding proteins in serum is to safeguard the body from the effects of abrupt fluctuations in hormonal secretion (Refetoff et al. 1970).

Thyroid hormones are transported to target tissues and in the central nervous system, the access of free thyroid hormones from the blood to neurons and glial cells is restricted by the endothelial cells of brain capillaries (the blood–brain barrier) and the epithelial cells lining the ventricular side of the choroid plexus (the blood–cerebrospinal fluid barrier). The mechanism of thyroid hormone transport through the plasma membrane of target cells is under study. Up to date, several transporters have been identified; they include amino acid transporters, organic anion transporting polypeptide (OATP), and monocarboxylate transporters (MCT; Abe et al. 2002; Friesema et al. 2005; Bernal 2005). Recent data show that brain-specific transporters of the OATP family, such as OATP1, 2, 3,

Table 135.1 Key features of iodine deficiency in thyroid function

1. The primary function of the thyroid gland is to produce adequate amounts of thyroid hormones (T3 and T4), which have genomic and nongenomic functions, regulating nuclear and mitochondrial gene expression, and intracellular metabolic pathways.
2. Thyroid hormones T3 and T4 are iodinated thyronines; therefore, an adequate iodine intake is fundamental for thyroid hormones synthesis.
3. During gestation, the maternal thyroid has to increase the synthesis of thyroid hormones since the mother is the principal source of T4 for the fetus. She is also the only source of iodine for the fetus during gestation and for the neonate during lactation (provided the infant is solely breast fed). This doubles the needs of maternal iodine intake to 250–300 μg per day.
4. Iodine deficiency is one of the most frequent causes worldwide of preventable mental retardation in children. A wide spectrum of iodine deficiency disorders has been described during gestation and the early postnatal period, including cretinism, neurocognitive delay, mental retardation, and attention-deficit hyperactivity disorders, among others.
5. Mild iodine deficiency may cause mild maternal hypothyroxinemia (i.e., circulating free T4 within the 0–10th percentile of the normal range, and normal T3 and TSH levels) that, from the beginning of gestation, causes a significant delay in the neurobehavioral development of children.
6. A daily fortification of iodine since the beginning of gestation is recommended by the WHO, so that the total iodine intake is 250 μg/day, to ensure a normal thyroid function for the mothers and their children during gestation and lactation.
7. Neurobehavioral problems of the children born to mildly hypothyroxinemic mothers are not ameliorated if the daily iodine fortification is delayed for 10–12 weeks from the beginning of gestation.

This table lists the key facts of iodine deficiency during gestation including the function of the thyroid gland, the adverse effects on the child (before and after birth) and the needs of iodine fortification during gestation, including the iodine intake recommended by the World Health Organization (WHO) and the International Council for the Control of Iodine Deficiency Disorders (ICCIDD)

and 14, the last with high affinity for T4, are mostly expressed in the endothelial cells of brain capillaries and in the choroid plexus (Gao and Meier 2001; Sugiyama et al. 2003; Ohtsuki et al. 2004; Roberts et al. 2008). MCT8 transporters are also expressed in the endothelial cells of brain capillaries and in the epithelial cells of the choroid plexus (Roberts et al. 2008; Ceballos et al. 2009), but they are more conspicuous in neuronal plasma membrane (Friesema et al. 2005) (Fig. 135.2).

135.1.2 Iodothyronine Deiodinases and Metabolism of Thyroid Hormones

Three selenoproteins catalyzing the deiodination of T4 and T3 have been identified, called type 1 (D1), type 2 (D2), and type 3 (D3) iodothyronine deiodinases. D1 is expressed mainly in the liver, the kidneys and the thyroid. D1 has high affinity for reverse-T3 (rT3; 3′,5′,3-triiodo-L-thyronine) and T4 and principally contributes to increase circulating T3 (Bianco et al. 2002; Bianco and Larsen 2005; Bianco and Kim 2006). D2 has been found in many peripheral tissues, especially in the astrocytes and tanycytes of the central nervous system (Guadaño-Ferraz et al. 1997). It is important for the local generation of T3 but does not contribute significantly to increase circulating T3. D3 is expressed in the central nervous system and mediates the degradation of T3 to diiodothyronine (3,5,diiodo-L-thyronine; T2) and T4 to rT3 (Bianco et al. 2002; Bianco and Kim 2006) (Fig. 135.3). In summary, the major role of deiodinases is to maintain adequate levels of T3 in target tissues in case of iodine sufficiency, while in iodine deficiency deiodinases maintain high levels in tissues and plasma. However, recent studies have found that the activating D2 and the inactivating D3 can locally increase or decrease thyroid hormone signaling in a tissue, independent of changes in circulating thyroid hormone concentrations in a temporal-specific fashion (Bianco and Kim 2006). These findings show that deiodinases play a much broader role than once thought, with great ramifications for the control of thyroid hormone signaling during vertebrate development and metamorphosis, as well
Fig. 135.2 Pathways of thyroid hormone transfer through nervous system membranes. Scheme showing major pathways of thyroid hormone transfer through nervous system membranes, some of the transporters and of the deiodination reactions involved. Organic anion transporting polypeptide (OATP; *black grey* or *blue ellipsoids*) and monocarboxylate transporter (MCT; *grey* or *red ellipsoids*) are indicated. Both, OATP14, with high-affinity for T4, and MCT8, with high affinity for T3, are expressed in the endothelial cells of brain capillaries. MCT8 is also found in neurons and mediates the transport of T3. Other not well-known transporters (?) in neurons, also involved in T3 transport, are shown (light grey or yellow ellipsoid). OATP transporters, other than OATP14, are noted. Deiodination of T3 and T4 pathways by D2 and D3 are shown. Activating D2 is mostly located in the endoplasmic reticulum (ER) of astrocytes, while inactivating D3 is located in the neuronal plasmatic membrane. *Nuc* cell nucleus, *CSF* cerebrospinal fluid
Fig. 135.3 Principal actions of the deiodinases in the central nervous system. The activating type II deiodinase (D2) catalyzes the conversion of T4 into T3. D2 also transforms rT3 into T2. Inactivating D3 transforms T4 into rT3, and T3 into T2. D3 is found in the plasmatic membrane (pm) of neurons while D2 is found in the endoplasmic reticulum (er) of astrocytes and tanycytes

as injury response, tissue repair, hypothalamic function, and energy homeostasis in adults (Gereben et al. 2008). In addition to deiodination, iodothyronines are also metabolized by conjugation of the phenolic hydroxyl group with sulfate or glucuronic acid (Visser 1996).

135.1.3 Function of Thyroid Hormones

Thyroid hormones act on mammalian development by regulating growth, maturation, and function in many organs and systems, such as brain, liver, heart, kidney, lung, skeleton, and skin. In addition, in lower vertebrates, thyroid hormones are the primary factors regulating the larvae-to-juvenile transition during metamorphosis (Power et al. 2001). In particular, the mammalian central nervous system is an important target of the thyroid hormone during all phases of the vital cycle, from fetus to adult. However, it is during the earlier stages of development that the central nervous system is more vulnerable to thyroid hormones imbalances (Berbel et al. 2007).

As already mentioned, the main active compound secreted by the thyroid gland is T3, which is also synthesized in target tissues by the deiodination of T4. T3 acts in the target cells by binding to nuclear and mitochondrial receptors and controlling of gene expression (Forrest and Vennström 2000). The T3 receptors (TR) are members of a large family of transcription factors with a ligand-binding domain that includes the receptors for endocrine or paracrine compounds such as steroids, retinoids, and vitamin D3 among others (Benoit et al. 2004). There are two TR genes, designated TRα and TRβ, located in different chromosomes, which encode a series of proteins, four of these are different T3 receptor isoforms (TRα1, TRβ1, TRβ2, and TRβ3) (Bernal 2005).

The action of thyroid hormones during the development of the central nervous system, including the generation of the active hormone, the ontogeny and distribution of receptors, and the molecular basis of thyroid hormone action in the brain has been recently reviewed (Bernal and Guadaño-Ferraz 1998; Forrest et al. 2002; Anderson et al. 2003; Bernal 2005; Santisteban and Bernal 2005; Flamant et al. 2007). T3 receptor TRα1 can be detected in the rat brain by embryonic day 12 (E12), and in the human brain by the 10th week of gestation (Bernal and Pekonen 1984; Pérez-Castillo et al. 1985; Bradley et al. 1992). In the adult rat brain, TRα1 still accounts for 70–80% of total T3 binding capacity (Ercan-Fang et al. 1996). T3 receptors are predominantly expressed in neurons but have been detected also in cultured oligodendrocytes, astrocytes, and microglia (Lima et al. 2001) and regulate the expression of many genes involved in the development and maturation of the brain (Bernal 2005; see below).

The thyroid hormone signaling, however, is more diverse and complex. Recent studies have shown broader context of extra- and intracellular regulation by thyroid hormones: control of ligand availability, changes in cell sensitivity to T3, nongenomic effects, and cross-talks with other signaling pathways (Flamant et al. 2007). An important nongenomic action of thyroid hormones in heart function and systemic vascular resistance (Davis and Davis 2002) has been observed, suggesting that thyroid hormones could promote the phosphorylation of nuclear thyroid hormone-receptors by the mitogen-associated protein (MAP) kinase, which would change their transcriptional activity (Davis et al. 2002). Thyroid hormone acting on cytoplasmic thyroid hormone-receptors could activate the phospholipase C (PLC)-inositol triphosphate (IP3) pathway to increase the intracellular concentration of calcium, released by the sarco/endoplasmic reticulum. In parallel, PLC could activate the diacyl glycerol (DAG)-protein kinase C (PKC) pathway; both PLC and PKC modulate the Na+/H+ exchanger in myoblasts L-6, modifying the intracellular pH. It is unknown whether, or not, thyroid hormones can also activate these pathways in neurons by a nongenomic pathway (D'Arezzo et al. 2004; Zinman et al. 2006a,b). Moreover, it has been observed that the activation of PKC and protein kinase A by thyroid hormones would inhibit the Na+/K+-ATPase, thus inhibiting the action of the

Na+/K+ and Na+/H+ exchangers in chicken liver cells (Incerpi et al. 2005). Recently, it has been observed in synaptosomes from the cerebral cortex of adult rats, that thyroid hormones have a rapid action (extranuclear) in different pathways involved in the regulation of the phosphorylation of proteins that influence the ATP synaptosomal uptake (Sarkar et al. 2006). All these data strongly suggest that thyroid hormones could have important nongenomic actions on nervous tissue, activating and/or influencing different metabolic pathways. Especially, an increase of the intracellular concentration of calcium and ATP might have important functional consequences in neurons, affecting many neuronal functions including neuronal migration and intraaxonal transport.

135.2   Iodine As a Crucial Micronutrient

135.2.1   Needs for Iodine At Different Ages and Physiological State of Individuals

The amount of daily iodine intake varies according to the age and physiological state of individuals (Table 135.2). Iodine intake is the principal source of circulating inorganic iodide and is therefore critical for the thyroid gland to produce adequate amounts of thyroid hormones. The concentration of inorganic iodide in the mother is particularly crucial during gestation and lactation, since during these developmental periods the mother is the only source of T4 and iodine for the fetus and of iodine for the neonate (Morreale de Escobar et al. 2004; Zoeller and Rovet 2004; Glinoer 2004, 2007).

135.2.2   Maternal and Fetal Thyroid Function During Pregnancy

The fetus depends on maternal T4 for normal development, since only very low amounts of maternal T3 reach fetal tissues. Almost all T3 found in the developing cerebral cortex is generated through local deiodination of T4, ultimately derived from the maternal circulating T4 (Calvo et al. 1990; Kester et al. 2004; Morreale de Escobar et al. 2008). To achieve this commitment, there are important changes in thyroid function of the mother during pregnancy, resulting in changes of iodine requirements. As a result of the increase of estrogens there is an increase of circulating thyroxine-binding globulin and

Table 135.2   Recommended minimum daily iodine intake

Group	Iodine requirements
Premature children	>30 μg/kg/day
Children 0–6 years[a]	90 μg/day
Children 6–10 years[a]	120 μg/day
Adults[a]	150 μg/day
Pregnant women	250–300 μg/day
Women during lactation	250–300 μg/day

This table lists the minimum daily iodine intake recommended by the World Health Organization (WHO, Andersson et al. 2007) and the International Council for the Control of Iodine Deficiency Disorders (ICCIDD; Zimmermann and Delange 2004) to different groups of population, according to the age and physiological state of individuals

human chorionic gonadotrophin. Human chorionic gonadotrophin transiently stimulates thyrocytes increasing thyroid hormone production while increased thyroxine-binding globulin contributes to an increase of the extrathyroidal pool of T4 (Glinoer 2007). Furthermore, the pool of circulating inorganic iodide is also compromised as a result of a significant increase in renal iodide clearance by 30–50%. In addition, D2 and D3 placental activity increases the peripheral metabolism of thyroid hormones, as does D3 in fetal epithelia (Bianco et al. 2002; Huang et al. 2003; Morreale de Escobar et al. 2008).

Thus, during gestation, it is essential for the mother to produce sufficient amounts of thyroid hormones for herself and her fetus. In addition to maternal thyroid hormones (fundamentally T4), the fetus also depends on the mother for its iodine supply, as does the neonatal thyroid during lactation. To achieve this, expectant mothers need to double the recommended normal daily intake of iodine for nonpregnant women by 250–300 μg/day. Furthermore, to meet neonatal requirements, iodine intake should remain increased during lactation provided the infant is solely breast fed (Kester et al. 2004; Andersson et al. 2007; Zimmermann and Delange 2004; Morreale de Escobar et al. 2008).

135.2.3 Iodine in Food

The iodine content of most foods depends on the iodine content of the soil. In general, iodine-deficient soils are in inland regions, mountainous areas, and places with frequent flooding, but they can be also found in coastal regions. Iodine concentration might be about 10 μg/kg of dry weight in plants grown in iodine-deficient soils, compared with about 1 mg/kg in plants from iodine-sufficient soils (Zimmermann et al. 2008).

Several food strategies have been proved to be efficient to increase iodine intake in iodine-deficient areas: (i) the use of iodinated salt in household, (ii) the incorporation of iodine to industrially elaborated foods (i.e., bread, milk, cheese), and (iii) to introduce dietary diversification (i.e., consuming food from iodine-sufficient areas and seafood). The use of iodinated salt in households has increased worldwide in the last ten years from less than 20–70%. Nevertheless, the highest prevalence of iodine deficiency is in Europe (52%), where the household coverage with iodized salt is the lowest (25%) (Zimmermann et al. 2008). Iodine incorporated to industrially elaborated foods, such as bread, milk, and milk derivates might also be a source of dietary iodine. However, the iodine content in food is usually unknown and in most cases not rightly indicated in the label. To avoid this, the Administration should regulate the iodine content of foods, controlling that the iodine labeled corresponds to the actual content. A recent study performed in Boston (USA) showed that the actual iodine content in seven out of eight infant formula analyzed was higher (on average 224%) than the labeled content (Pearce et al. 2004). Finally, dietary diversification incorporating foods from iodine-sufficient areas is a complementary way to prevent iodine deficiency. Eating seafood is an additional source of iodine because marine animals can concentrate the iodine from seawater; certain types of seaweed (e.g., wakame) are very rich in iodine. Dairy products might be relatively good sources of iodine provided iodine is commonly added to animal feed (Haldimann et al. 2005) (Table 135.3).

135.2.4 Iodine Fortification

With a normal diet consisting of the use of iodinated salt and eating food of marine origin 2–3 days per week, a daily iodine intake would be in the order of 250 μg per day, approximately the amount of iodine recommended during pregnancy and lactation by the World Health Organization (WHO) and

Table 135.3 Iodine content of some common foods

Food	Iodine (μg/100 g)[a]
Salt (iodized)[b]	6,000
Seaweed (dried)	70,000
Cod	115
Shrimp	40
Tuna, canned in oil	20
Milk (cow's)	69
Yogurt, low-fat	67
Mozzarella cheese	42
Red meat	5.9
Poultry	6.6
Vegetarian protein alternatives	10.9
Egg	162
Bread, baked	39
Potatoes	1.6
Pasta	7.9
Fresh fruit	1.8
Fresh vegetables	4.7

This table lists the iodine content of some common foods. The data have been extracted from Haldimann et al. (2005)

[a]The iodine content of foods can vary considerably; these values should be considered approximate (Pennington et al. 1995)

[b]The normal daily intake is about 1 g. [c] Provided iodine is commonly added to animal feed (Haldimann et al. 2005)

the International Council for the Control of Iodine Deficiency Disorders (ICCIDD) (Zimmermann and Delange 2004; Zimmermann 2007; Andersson et al. 2007) (Table 135.2). However, inadequate iodine intake actually affects a large number of pregnant women, and this situation persists even in areas where iodized salt consumption has been promoted for years and that have been classified as free of iodine deficiency (Azizi et al. 2003; Lazarus and Smyth 2008). Thus universal salt iodization, which proved to be sufficient for school children, may not be adequate for pregnant women (Andersson et al. 2007). Results published in the National Health and Nutrition Examination Surveys (NHANES) III (1988–1994) indicate that the median urinary iodine (UI) excretion for women of reproductive age is 128 μg iodine/l (6.9% of pregnant women with UI <50 μg/l). These values are well below than those found in a previous study NHANES I (1971–1974) (294 μg iodine/l), showing a decrease in iodine intake during pregnancy in USA (Hollowell and Haddow 2007).

In view of these findings, in 2007, WHO promoted iodine supplementation for pregnancy and lactation, so that the total iodine intake is 250–300 μg/day (Andersson et al. 2007). In Spain, the use of tablet containing 200 μg iodine is being promoted throughout the country and subsidized by the Spanish Public Health System.

Nevertheless, even if a pregnant woman is ingesting 250–300 μg of iodine daily (the recommended daily intake), a daily fortification with 100–200 μg iodine during a period of about 15 months (pregnancy plus lactation) does not represent danger for the fetus and neonate (Andersson et al. 2007; Zimmermann 2007; Velasco et al. 2009). The total amount of iodine intake does not block the developing thyroid gland of the fetus (see below). In contrast, the advantages of iodine supplementation are obvious: iodine supplementation from conception will ensure adequate maternal T4 during all of gestation and lactation; especially during the first half of gestation, in which the fetal brain is particularly vulnerable to iodine deficiency (Morreale de Escobar et al. 2004; Andersson et al. 2007).

135.2.5 Consequences of Iodine Excess Early in Life

Iodine supplementation, between the range recommended by WHO and ICCIDD (100–200 μg/day), given to pregnant women, even in iodine-sufficient areas, is safe for the fetus during gestation and for the neonate during lactation, because the adult maternal thyroid responds rapidly to an increase in circulating iodine by promptly activating autoregulatory mechanisms that are the opposite of those elicited by iodine deficiency. These mechanisms prevent thyroid function blockage due to an iodine excess.

These autoregulatory mechanisms do not mature until several weeks after term birth. Thus, late fetal and neonate's thyroid can be blocked for weeks if faced with an iodine overload, during a period when its brain requires T4 for its normal development. This might appear contradictory to the insistence of iodine supplementation during gestation and lactation. However, iodine supplementation during these periods is not dangerous because the amounts of iodine recommended are safe and of several orders of magnitude smaller than those that block thyroid functions in the mother, fetus, and neonate (Andersson et al. 2007; Zimmermann 2007). For example, such pathological abnormal amounts of iodine can be found in nonmedicinal compounds frequently used at home and clinically, such as iodine-containing disinfectants and contrast media (Table 135.4). In fact, the exposure of pregnant women and newborns, especially if born prematurely, to iodine-containing disinfectants and radiographic contrast media is contraindicated.

The possibly negative effects of an iodine excess during the neonatal period should not question the convenience of iodine supplementation during pregnancy, when using the amounts proposed by WHO and ICCIDD (Andersson et al. 2007; Zimmermann 2007; Glinoer 2007).

Table 135.4 Iodine concentrations in various compounds

Compound	Iodine content	Times the normal daily adult iodine intake
Iodinated salt	60 μg/g	0.25x
Amiodarone[a]	7,500 μg/tablet	50x
Disinfectants:		
Lugol's solution [b]	130,000 μg/ml	867x
Betadine (Povidone–iodine)	10,000 μg/ml	67x
10% Sodium iodide	85,000 μg/ml	567x
Radiological contrasts:		
Hexabrix (ioxaglate)	320,000 μg/ml	2,133x
Oragrafin (ipodate sodium)	308,000 μg/tablet	2,053x
Lipiodol (^{131}I-ethiodised oil)	380,000 μg/ml	2,533x
Renografin[c]	370,000 μg/ml	2,467x
Telepaque (iopanoic acid)	333,000 μg/ml	2,220x

This table lists the iodine content of various iodinated compounds of frequently used at home and clinically. The active principle is indicated within parentheses. The iodine content is expressed as times the normal daily adult iodine intake (150 μg iodine per day; see Table 135.2 for iodine requirements for other groups of the population)

[a]Amiodarone is an iodated antiarrhythmic agent that contains 37.3% iodine

[b]Standard Lugol's solution contains 5% iodine and 10% potassium iodide

[c]Renografin is a diatrizoate meglumine and diatrizoate sodium solution

135.3 Iodine Deficiency Disorders

135.3.1 Iodine Deficiency Disorders and Neurodevelopment

Iodine deficiency is one of the most frequent causes of preventable mental retardation in children worldwide. A wide spectrum of iodine deficiency disorders have been described during gestation and the early postnatal period (less than 3 years of age), ranging from abortion, stillbirths, congenital anomalies, deafness, cretinism, neurocognitive delay, and mental retardation, as well as attention-deficit hyperactivity disorders, among others (Hetzel 1994; Morreale de Escobar et al. 2007).

In children, the severity of the neurodevelopmental damage caused by iodine deficiency during gestation depends on the developmental period affected by this condition and on its severity. In 1990, it was estimated that 1,600 million people is exposed to iodine deficiency worldwide (28.9% of the world population). From these, 11 million suffered overt cretinism (the most extreme form of mental retardation due to iodine deficiency) and that 43 million people were affected by some degree of mental impairment (Glinoer and Delange 2000).

Epidemiological studies performed in The Netherlands (Pop et al. 2003; Kooistra et al. 2006), USA (Haddow et al. 1999), and Russia (Kasatkina et al. 2006) have shown neurological alterations in children from hypothyroxinemic mothers. Furthermore, a prospective study from Italy reported a positive correlation between iodine deficiency during the first half of gestation and the IQ score of their children (Vermiglio et al. 2004). In addition, 68.7% of them presented an attention-deficit hyper-activity disorder. In these studies, no signs of clinical or subclinical hypothyroidism were observed in the hypothyroxinemic mothers and their children were euthyroid at birth. In conceptual agreement with this, in a recent study performed in Spain (Berbel et al. 2009), it has been found that a mild hypo-thyroxinemia (i.e., circulating free T4 within the 0–10th percentile of the normal range) from the beginning of gestation causes a significant delay in the neurobehavioral development of children. Even more important is the finding that the deficient behavior of the children is not ameliorated if the 200 μg/day iodine supplementation is delayed for 10–12 weeks from the beginning of gestation.

135.3.2 Critical Periods in Brain Development

The central nervous system of vertebrates develops from the neural plate, which folds forming the neural tube to an extremely complex system of neurons and non-neuronal cells. During corticogenesis, different cohorts of proliferating neuroblasts located near the ventricular surface of the tel-encephalic vesicle of the neural tube successively stop dividing and become migrating neurons. During telencephalic corticogenesis in mammals, young cortical neurons migrate on radial glial processes from the ventricular zone into the cortical plate. The great majority (about 80%) of neurons migrate radially, while the rest do so tangentially (i.e., parallel to the pial surface) to their target area (O'Rourke et al. 1992). Radially migrating neurons follow an "inside-out" gradient in which the "early" cohort of cells reaching the cortical plate will be found in the adult layer VI, while the "late" neurons migrate to the superficial zone of the cortical plate and will be found in adult layers II and III. In rats, the bulk of radial migration starts by embryonic day 13 (E13), while the last cohort of cells leave the ventricular zone by E20 (Bayer and Altman 1991). Thus, in the rat, as in other mammals, including man (see below), most of neurogenesis and subsequent migration occurs when the

fetal thyroid hormones are not yet present (these begin to appear by E17.5–18). Therefore, maternal thyroid hormones are the only thyroid hormones present in the fetal cortex (Obregón et al. 1984). At the end of this process, neurons grow and differentiate to express their mature phenotype. The cortex becomes organized into functional areas and develops a mature pattern of connectivity according to the functional requirements of the system. Cortical neurons will receive and send connections from and to subcortical regions; they will establish ipsilateral intrinsic and associative connections and, contralateral homo- and heterotopic commissural connections. Most of these connections are exuberant and then specifically pruned and, eventually, connections with new targets will be alternatively established (Innocenti 1995).

During the development of the central nervous system, many genes are expressed in a spatiotemporal order (Bernal 2005). Changes in the expression of these genes may produce alterations in the organization and maturation of the central nervous system, thereby affecting its function. The expression of fundamental genes involved in this process has been shown to be regulated by thyroid hormones. The irreversibility and importance of damage will depend on when, where, and how alterations of gene expression occur (Bernal 2005). Thus, an analysis of structural and functional alterations caused by iodine deficiency during development may be of use in the search for new specific genes and add light to our understanding of neurological alterations related to iodine deficiency disorders (Berbel et al. 2007; Berbel and Bernal 2010).

In humans, neocortical development occurs between the 6th and 24th week of gestation, although the bulk of cortical cell migration occurs between the 8th and 24th week (Marín-Padilla 1978) and mostly before onset of fetal thyroid hormone secretion. The later occurs at midgestation (i.e., by the 18th week of gestation; Obregón et al. 1984). As previously indicated, neocorticogenesis begins comparatively later in the rat, at around E13, and is complete roughly at birth, with most of the process occurring between E14 and E19, again mainly before onset of fetal thyroid function (at E17.5-18). In addition, the postnatal development and maturation of the central nervous system is comparative longer in humans than in rats. However, despite these differences, similarities may be established when onset of fetal thyroid gland secretion is taken as the reference point (Fig. 135.4). For instance, the main waves of radial migration in the human neocortex occur during the first half of gestation, with peaks at 11 and 14 weeks of gestational age (Marín-Padilla 1978), roughly corresponding to waves of cell migration studied in rats which, as in humans, occurs before onset of fetal thyroid function (Fig. 135.4) (Berbel et al. 2001).

135.3.3 Experimental Models to Study Developmental Hypothyroidism and Hypothyroxinemia

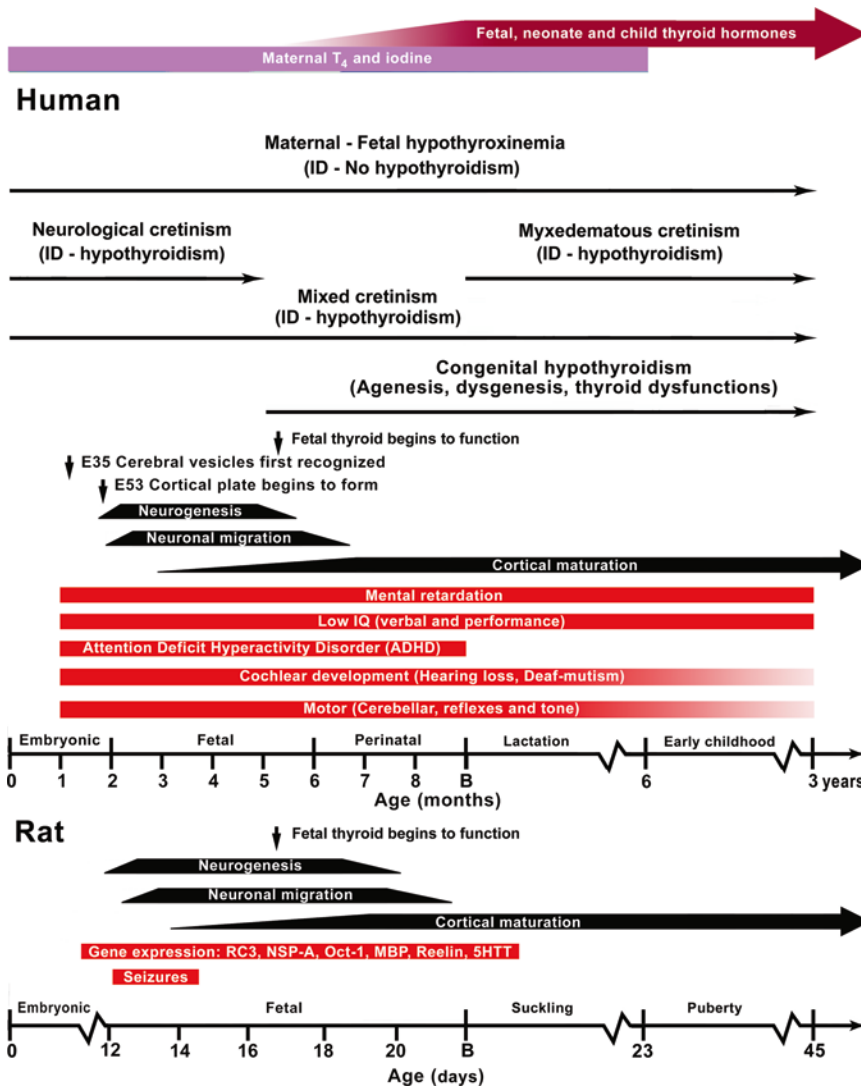
Several genetic models have developed during the last decades to study different forms of developmental and postnatal hypothyroidism, such as congenital hypothyroidism (Kratzsch and Pulzer 2008). These models include mutations of the TSH receptor ($hyt^{-/-}$ mice) (Biebermann et al. 1997), agenesis or functional impairment of thyrocytes ($TTF1^{-/-}$, $TTF2^{-/-}$, $Pax8^{-/-}$ mice) (Pasca di Magliano et al. 2000), and mutations of the TR ($TRa^{-/-}$, $TRb^{-/-}$, $TRa^{-/-}b^{-/-}$ mice as well as TRα or TRβ knock-in mutations) (Flamant and Samarut 2003). However, they present some limitations; for instance, some mutant pups does not survive more than 1 month after birth (e.g., Pax8$^{-/-}$ mice), some present other types of serious alterations that might interfere with hypothyroid symptoms (e.g., poor development of respiratory system in $TTF1^{-/-}$ mutants, renal dysfunction in Pax8$^{-/-}$ mutants, etc.; Park and Chatterjee 2005), and others do not present phenotypic alterations because of an absence of gene repression ($TRa^{-/-}$ mice) (Morte et al. 2002; Flamant et al. 2007).


Fig. 135.4 Main neurodevelopmental events and neurological alterations associated with iodine deficiency during fetal and neonatal life. Time scales and the respective developmental periods are indicated for humans and rats in the upper and lower panels, respectively. The period in which the child's thyroid hormone is secreted is indicated by the uppermost arrow. The gradation indicates the period in which the production of fetal thyroid hormones increases to reach neonate values. The period in which both T4 and iodine are transferred from the mother to the fetus is also indicated in an adjacent bar. Thyroid hormones deficiencies and their etiologies and clinical symptoms, which are indicated in parentheses, are shown in the upper part of the human panel. *Thin black horizontal arrows* represent the critical periods related to these disorders. Some major developmental events of the cerebral cortex are also indicated both for humans and rats (*black bars*). Major neurological alterations associated with maternal/fetal T4 and iodine deficiency and critical vulnerability periods are shown by *grey bars*. In the lower (rat) panel, *grey bars* indicate genes that are regulated by thyroid hormones and behavioral alterations associated with maternal and/or fetal T4 and iodine deficiency. For cochlear and motor disorders, heavy gradation indicates the period in which the brain is more sensitive to iodine deficiency (Modified from Berbel et al. (2007). With permission)

Other models are based on the administration of antithyroid drugs, which interfere with the uptake of iodine by the thyrocytes by inhibiting the sodium/iodine symporter (e.g., potassium perchlorate and thiocyanate) and the iodination of thyroglobulin by thionamide and thiourylene drugs such as propylthiouracil (PTU) and methimazole (MMI). They may be competitive substrates for thyroid iodide peroxidase, preventing the oxidation of iodide by this enzyme (Rosenberg 1952; DeGroot and Davis 1962). In addition to the effects on the thyroid gland, PTU (and, to a much lesser extent, MMI) partially inhibits the peripheral deiodination of T4. Thus, PTU acts also directly on body tissues to inhibit the normal formation of T3 from T4 (Escobar del Rey and Morreale de Escobar 1961; Oppenheimer et al. 1972). Surgical thyroidectomy is another procedure used to induce thyroid hormone deprivation (Morreale de Escobar et al. 1987; Berbel et al. 2010; Morte et al. 2010). Antithyroid treatments result in maternal, and to a greater and lesser extent, in fetal hypothyroidism. In contrast, surgical thyroidectomy performed to pregnant dams causes maternal but not fetal hypothyroidism. When performed postnatally it results in hypothyroidism of the pups.

Models for iodine deficiency during gestation on development of the central nervous system include monkeys (Mano et al. 1987), sheep (Potter et al. 1982), and rats (Li et al. 1986). These studies have shown changes in the cerebellum with reduction in weight and cell number, and delayed maturation. The influence of maternal hypothyroxinemia on cortical development has been recently studied in rats and mice (Berbel and Bernal, 2010). In experiments for chronic and severe maternal/fetal hypothyroxinemia, pregnant rats are either fed a low-iodine diet starting before and continuing during the entire pregnancy (LID pups) (Martínez-Galán et al. 1997; Lavado-Autric et al. 2003). In experiments for mild and transient maternal hypothyroxinemia, pregnant rats and mice are treated with MMI for 3 days beginning at E12 (i.e., the onset of fetal neocorticogenesis; $3MMI_{12}$ pups) (Ausó et al. 2004; Cuevas et al. 2005).

135.4 Alterations in Cortical Development

135.4.1 Altered Migration During Corticogenesis

The radial migration during corticogenesis has been studied in the cerebral cortex of hypothyroid rats (Berbel et al. 2007) as well as in other cortical regions of the brain such as the cerebellum (Bernal 2005). In the auditory and somatosensory cortical areas, there was a decrease in the proportion of 5-bromo-2′-deoxyuridine-positive (BrdU-positive) cells in the normally expected supragranular layers and an increase of BrdU-positive cells in the infragranular layers whichever the age of BrdU injection (Fig. 135.5a,b) (Lucio et al. 1997; Berbel et al. 2001). These studies also reported a high proportion of heterotopic neurons (i.e., cells found in abnormal locations) in the subcortical white matter (Lucio et al. 1997; Berbel et al. 2001) and corpus callosum (Goodman and Gilbert 2007) (Fig. 135.6).

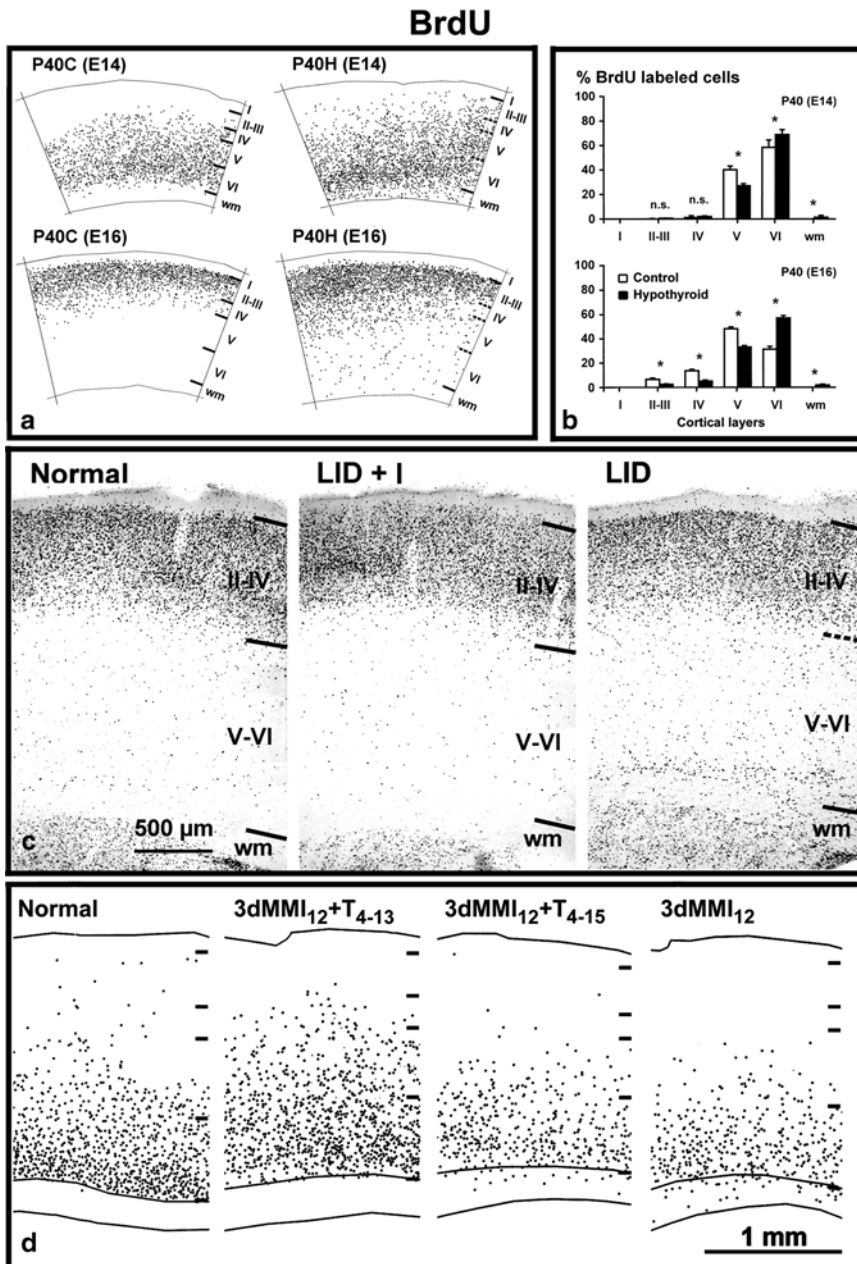
Fig. 135.5 (continued) since they are blurred in cresyl violet-stained adjacent sections. LID pups were born to rats that were fed a low-iodine diet during pregnancy and lactation. LID+I pups were born to dams that received LID containing KI (approximately 10 μg of iodine per day). Dams were injected intraperitoneally for 3 days with BrdU (20 mg/kg per day in physiological saline), starting at either at E14, E15, and E16 (Further details are given in Lavado-Autric et al. 2003). (**d**) Plots of BrdU-labeled cells from normal, $3dMMI_{12}+T4_{13}$, $3dMMI_{12}+T4_{15}$, and $3dMMI_{12}$ pups. The borders between layers are indicated by horizontal lines. Note the increased number of labeled cells, with respect to normal and $3dMMI_{12}+T4_{13}$, in the white matter (wm) of $3dMMI_{12}+T4_{15}$ and $3dMMI_{12}$ pups. $3dMMI_{12}$ pups were born to dams that received methimazole (MMI) from E12 to E15, $3dMMI_{12}+T4_{13}$ pups were born to $3dMMI_{12}$ dams infused daily with T4 from E14 to E16, and $3dMMI_{12}+T4_{15}$ pups were born to $3dMMI_{12}$ dams infused daily with T4 from E16 to E18 (Panels a and b – Modified from Berbel et al. (2001). With permission; Panel c – Reprinted from Lavado-Autric et al. (2003). With permission; Panel d – Reprinted from Ausó et al. (2004). With permission)


Fig. 135.5 Radial migration during corticogenesis in developmental hypothyroidism and maternal hypothyroxinemia. Developmental hypothyroidism and maternal hypothyroxinemia alter radial migration during corticogenesis. (**a**) Outlines of coronal sections of the primary somatosensory cortex from normal (P40C) and hypothyroid (P40H) pups, showing the distribution of BrdU-labeled cells at P40, following injections of BrdU at E14 and E16. Cells are more widely distributed in hypothyroid rats. Note the increased number of labeled cells, with respect to normal, in the white matter (wm) of hypothyroid rats at E14 and E16. Mediodorsal is to the right. (**b**) Histograms showing the mean percentage (±S.D.) of BrdU-labeled cells in normal pups (*white bars*) and hypothyroid pups (*black bars*), in different cortical layers. The number of labeled cells in the white matter (wm) is significantly higher in hypothyroid pups ($P < 0.05$; asterisks) (Further details are given in Berbel et al. 2001). (**c**) Photomicrographs of coronal sections of the primary somatosensory cortex showing BrdU-labeled cells in normal, LID+I and LID pups at P40. BrdU labeling after E17–19 injections shows that in the neocortex the radial distribution of BrdU-labeled cells is more widespread in LID than in normal and LID+I pups. The borders between layers are indicated by horizontal lines. Borders in the LID section are indicated by *dashed lines*
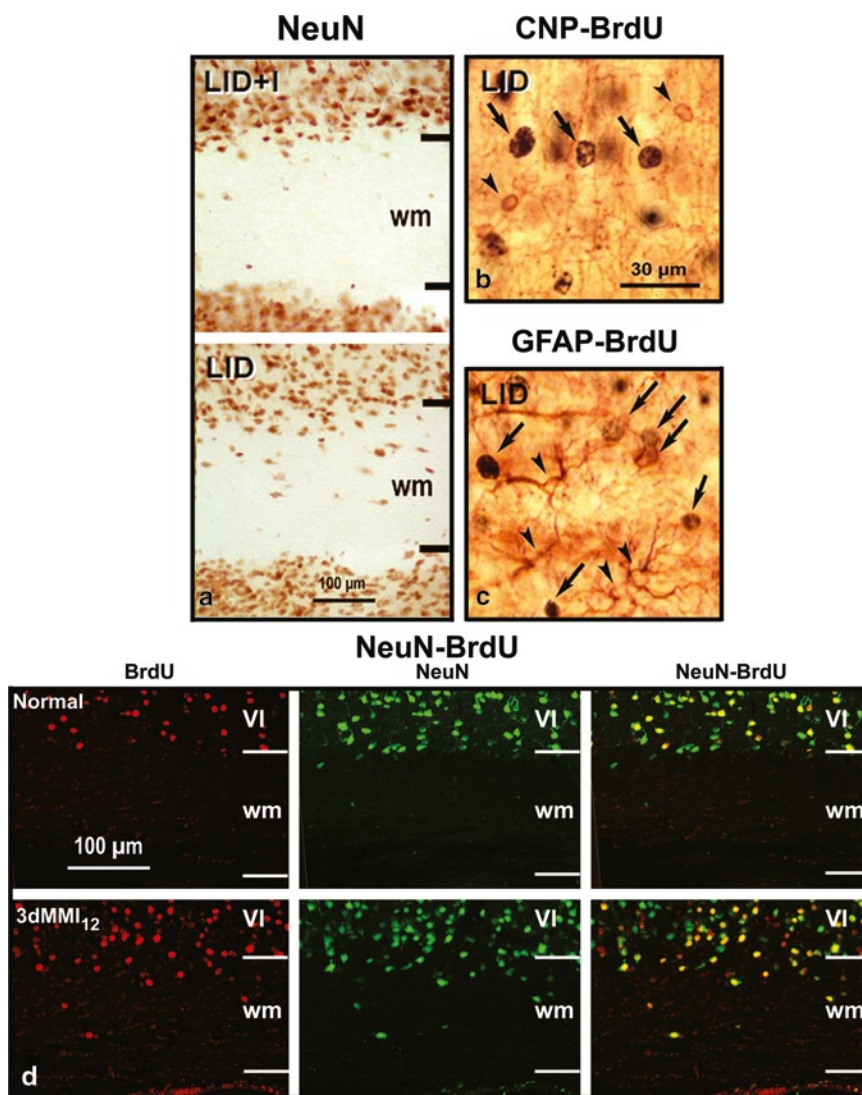

Fig. 135.6 Immunocytochemical characterization of heterotopic cells in maternal hypothyroxinemia. Immunocytochemical characterization of heterotopic cells. (**a**) Photomicrographs of NeuN-immunostained coronal sections of the primary somatosensory cortex in LID+I and LID pups at P40. The number of heterotopic NeuN-labeled neurons in subcortical white matter increases in LID as compared with LID+I pups. (**b**) and (**c**) CNP- and GFAP-positive oligodendrocytes and astrocytes, respectively, (*arrowheads*) and BrdU-labeled nuclei (*arrows*) are shown in layer V of LID pups. Note that CNP- and GFAP-positive cells are BrdU negative. The description of the experimental groups is given in Fig. 135.5. (**d**) Confocal photomicrographs showing BrdU and NeuN immunostaining in the primary somatosensory cortex of normal and 3dMMI$_{12}$ pups at P40. Single-labeling to BrdU (*left* and *red*) and to NeuN (*middle* and *green*), and double-labeling (*right* and *yellow*) are shown. Note the absence of immunoreactive cells in the subcortical white matter (wm) of the primary somatosensory cortex in normal pups. In the 3dMMI$_{12}$ pups, all cells in wm immunoreactive to BrdU (*left* and *red*) are neurons (*right* and *yellow*) (Panels a and b – Reprinted from Lavado-Autric et al. (2003). With permission; Panel d – Reprinted from Ausó et al. (2004). With permission)

These findings have also been confirmed in rat models for gestational hypothyroxinemia. In two recent studies, of chronic and transient maternal and fetal hypothyroxinemia, alterations in radial and tangential neuronal migration have been shown during neocorticogenesis, causing a blurred lamination in the neocortex and heterotopic neurons in the subcortical white matter (Lavado-Autric et al. 2003; Ausó et al. 2004; Cuevas et al. 2005) (Fig. 135.7). Similar results have been found in the cerebral
Fig. 135.7 Tangential migration during corticogenesis in maternal hypothyroxinemia. Maternal hypothyroxinemia affects tangential migration in the neocortex. (**a**) Low power fluorescent photomicrograph collage illustrating the tangential distribution of GFP-MGE control migrating neurons in wild control flat cortical mounts (*left*). The same for GFP-MGE hypothyroxinemic migrating neurons in hypothyroxinemic flat cortical mounts (*right*). Note the higher number of migrating neurons toward the medial (M) region in the control compared to the hypothyroxinemic cortical mount, where the distribution of the migrating neurons is more symmetrical. (**b**) On the *left* are histograms showing the mean (±SD) of the 90th percentile values of the distances from the outer limits of the GFP–MGE explants that are covered by migrating cells in the L, M, P, and A directions along the strips shown in the inset at the upper right corner of the graph. The distance covered by migrating cells in the M direction is higher when control and hypothyroxinemic GFP–MGE-derived cells migrate in control cortical mounts; these differences disappeared when they migrated in hypothyroxinemic ones. On the *right* are histograms showing the percentage of cells found in the L, M, P, and A sectors shown at the inset at the upper right corner of the graph. The percentages of cells are also greater in the M sector when control and hypothyroxinemic GFP–MGE-derived cells migrate in control cortical mounts than when they migrate in hypothyroxinemic ones. Statistically significant differences are indicated by asterisks; *n.s.* no statistically significant differences, *M* medial, *L* lateral, *P* posterior, *A* anterior (Reprinted from Cuevas et al. (2005). With permission)

cortex of pups born to late hypothyroidectomized rats (Berbel et al. 2010). These findings are in agreement with previous studies showing impaired maturation of radial glia in the hippocampus of pups born to chronic hypothyroxinemic rats (Martínez-Galán et al. 1997). Furthermore, these studies reported that substitution T4 treatment prevented the neurodevelopmental damage only when it was administered within one day after the induction of hypothyroxinemia. When T4 treatment began later, the alterations in neuronal migrations were not ameliorated (Ausó et al. 2004) (Fig. 135.5c,d). The presence of heterotopic neurons the subcortical white matter clearly shows an alteration of cell migration during corticogenesis, which may affect cortical function. In conclusion, these studies stress the importance of maintaining normal levels of maternal thyroid hormones during early pregnancy, especially that of circulating T4, to achieve normal neurodevelopment of the progeny.

135.4.2 Abnormal Cortical Cytoarchitecture

In adult hypothyroid rats, neocortical layering is blurred and only the lower border of layer I and the upper border of layer VI can be identified (Berbel et al. 1993). These changes are more pronounced in the somatosensory cortex where there is an absence of normal solid barrels. Instead, small dispersed patches of densely packed cells, located above the putative lower limit of layer IV can be observed (Fig. 135.8a; Berbel et al. 2001). In pups born to hypothyroxinemic pregnant rats, alterations in cortical cytoarchitecture were also found both in the neocortex and hippocampus. Cortical layering was also more blurred than in control rat (Lavado-Autric et al. 2003; Ausó et al. 2004) (Fig. 135.8b,c).

Although abnormal migration due to hypothyroidism is probably one of most important factors that can affect barrel cytoarchitecture, additional changes in the neocortical cytoarchitecture may be caused by other factors such as impaired neuronal maturation and connectivity (Ausó et al. 2001).

Developmental hypothyroidism also affected other aspects of cortical organization. By postnatal day 10 (P10), peanut agglutinin-negative areas were reduced by 11% in the hypothyroid as compared to the normal barrel cortex. In the adult, cytochrome oxidase labeling of barrels was reduced by 23% in the hypothyroid as compared to the normal barrel cortex (Berbel et al. 2001) (Fig. 135.9).

135.4.3 Abnormal Distribution and Maturation of Connections

Organization of intrinsic connections. In the auditory cortex, thyroid hormones have a selective effect on intrinsic connections as shown by immunohistochemistry for the calcium-binding proteins calretinin, calbindin, and parvalbumin, which stain different subpopulations of cortical gamma-aminobutyric acid (GABA)-ergic neurons forming inhibitory local circuits. The number, radial distribution, and morphology of immunopositive cells in hypothyroid and normal rats was similar, but the immunostaining pattern of *puncta* in hypothyroid rats is severely altered for calretinin and even more so for parvalbumin (Berbel et al. 1996). In hypothyroid rats, the number of parvalbumin positive terminals in layers II–VI is clearly less than in normal rats, with an especially pronounced reduction in *puncta* around unstained cell somata (Fig. 135.10a). Alterations in the tangential distribution of GABAergic cells might also occur, since the tangential migration of medial ganglionic eminence derived cells is altered in the hypothyroxinemic neocortex (Cuevas et al. 2005).

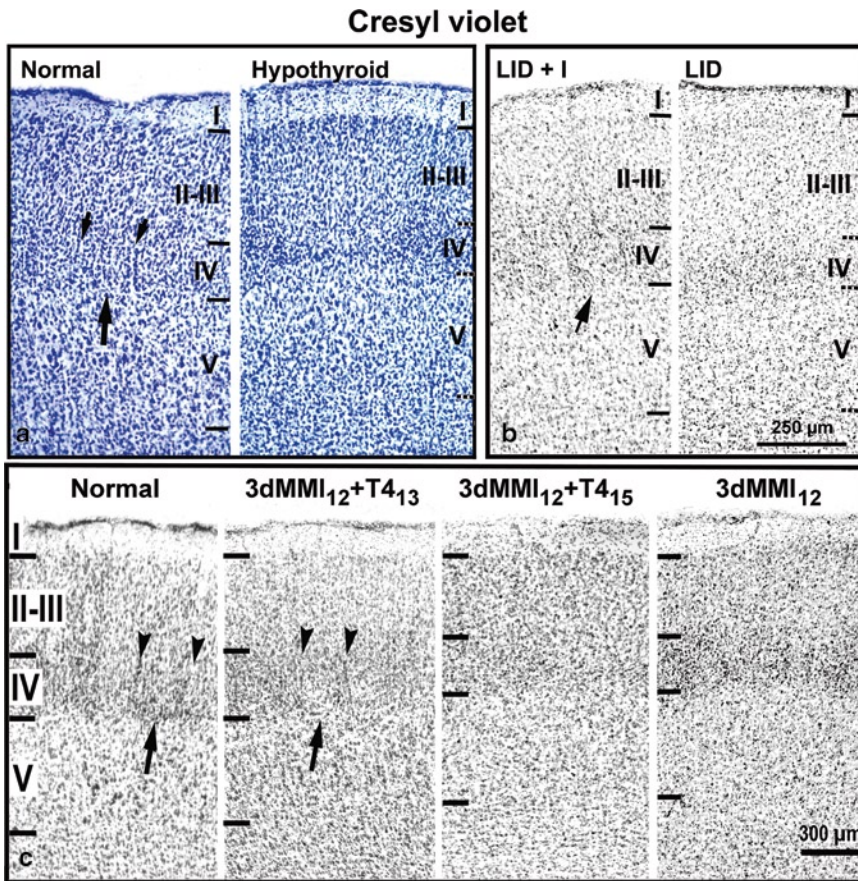
The decrease in immunostaining of parvalbumin terminals might result in a decreased inhibitory control of pyramids. This decreased inhibition might explain the high incidence of audiogenic seizures reported in hypothyroid rats (Van Middlesworth and Norris 1980) and in the pups of mild and transient hypothyroxinemic pregnant rats (Ausó et al. 2004) (Fig. 135.10b,c).


Fig. 135.8 (**a**) Cortical cytoarchitecture and laminar organization in developmental hypothyroidism and maternal hypothyroxinemia. (**a**) Cortical cytoarchitecture and laminar organization in developmental hypothyroidism and maternal hypothyroxinemia. Photomicrographs of cresyl violet-stained coronal sections showing the cytoarchitecture of the barrel cortex and layer borders in normal and hypothyroid rats. In normal rats, borders between layers are clear-cut, while in hypothyroid rats (*dashed lines*), they are blurred. Note that in layer IV of hypothyroid rats disperse patches of high cell density can be seen, instead of normal barrels (*arrow*). *Arrowheads* point the septae of a normal barrel. (**b**) Photomicrographs of cresyl violet-stained coronal sections showing the cytoarchitecture of the barrel cortex in LID+I and LID pups at P40. In the barrel cortex of LID+I pups, borders between layers are clear-cut, as expected in normal animals (*horizontal lines*), whereas in LID pups they are blurred (*horizontal dashed lines* in b and c). In layer IV of LID+I pups, barrels are normal and well defined, as indicated by an *arrow*. In contrast, barrels in layer IV of LID pups are not seen. The description of the experimental groups is given in the legend to Fig. 135.5. (**c**) Photomicrographs of cresyl violet-stained coronal sections showing the cytoarchitecture of the barrel cortex in normal, $3dMMI_{12}+T4_{13}$, $3dMMI_{12}+T4_{15}$ and $3dMMI_{12}$ pups at P40. Borders between layers (*horizontal lines*) are clear-cut in normal and $3dMMI_{12}+T4_{13}$ pups, whereas they are more blurred in $3dMMI_{12}+T4_{15}$ and $3dMMI_{12}$ animals. In layer IV of normal and $3dMMI_{12}+T4_{13}$ pups, barrels (*arrows*) are normal and well defined and demarcated by septae (*arrowheads*). In contrast, barrels in layer IV of $3dMMI_{12}+T4_{15}$ and $3dMMI_{12}$ pups are not seen (Panel b – Reprinted from Lavado-Autric et al. (2003). With permission; Panel c – reprinted from Ausó et al. (2004). With permission)

The immunocytochemical changes observed in hypothyroid rats may reflect alterations in the local circuitry, and thus, in normal cortical function.

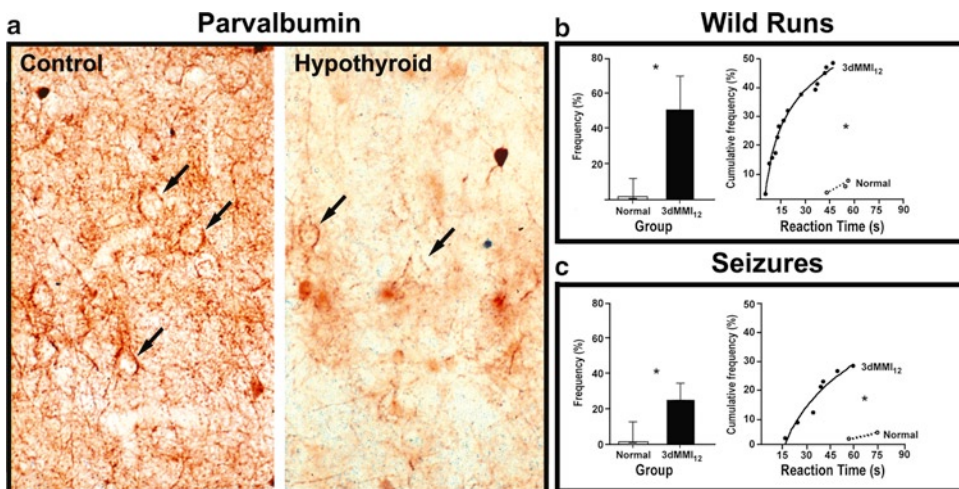
Number and maturation of callosal axons. Transfer of information between the cerebral hemispheres is critical for higher brain function. In mammals, cortical areas of the two hemispheres are reciprocally connected by the corpus callosum, as well as the hippocampal and anterior commissures. All these connections appear in the embryo and develop postnatally (Innocenti 1995). Developmental
Fig. 135.9 Organization of cortical maps in developmental hypothyroidism. Reduced development of cortical maps in developmental hypothyroidism. (**a**) Figurine showing the posteromedial barrel subfield (PMBSF) of the primary somatosensory cortex in the brain of a rat. (**b**) Computer reconstruction from photomicrographs of serial tangential sections through layer IV, showing cytochrome oxidase labeling in the barrel cortex of normal and hypothyroid rats. Note the reduced tangential extension of the cytochrome oxidase labeling in hypothyroid with respect to normal rats. (**c**) Area measurements in normal and hypothyroid rats. The dorsal view brain area was, on average, 24% smaller in hypothyroid rats (*upper left*). A similar reduction (on average, 27%) was observed in the PMBSF tangential area (*upper right*). In normal rats, the total peanut agglutinin-outlined barrel tangential area at P6-7 was on average 77% of the PMBSF area; in hypothyroid rats at P9-11, it occupied only, 66% of the PMBSF, representing an 11% reduction in hypothyroid rats (*lower left*). In adult normal rats, the cytochrome oxidase-labeled tangential area was, on average, 69% of the PMBSF area; in adult hypothyroid rats, it was only, on average, 46% of the corresponding PMBSF, representing a 23% reduction with respect to normal, (*lower right*). In all cases, differences were statistically significant ($P < 0.05$) (Panels a and b – Reprinted from Berbel (2003). With permission; Panel c – Reprinted from Berbel et al. (2001). With permission)


Fig. 135.10 Inhibitory local circuits and audiogenic seizures in developmental hypothyroidism. Altered inhibitory local circuits and increased audiogenic seizures in developmental hypothyroid pups. (**a**) Photomicrographs through layer V of the auditory cortex immunostained for parvalbumin in normal and hypothyroid rats. In normal rats, immunoreactive cells, processes, and perisomatic *puncta* can be seen. In hypothyroid rats, immunoreactive cells, processes, and perisomatic *puncta* can also be seen but they are less prominent than in normal rats. (**b**) and (**c**) Responses of normal and 3dMMI$_{12}$ pups to an acoustic stimulus. (**b**) Histograms on the *left* in (b) and (c) correspond to the proportion (median with 25th and 75th percentiles) of pups responding with wild runs and with wild runs followed by a seizure, respectively. Graphs on the *right* represent the cumulative frequency of pups from the same groups that respond with wild runs alone or followed by a seizure, respectively, at the intervals after onset of the stimulus that are shown in the abscissa. Asterisk indicates a statistically significant difference compared with normal (Panels b and c – Reprinted from Ausó et al. (2004). With permission)

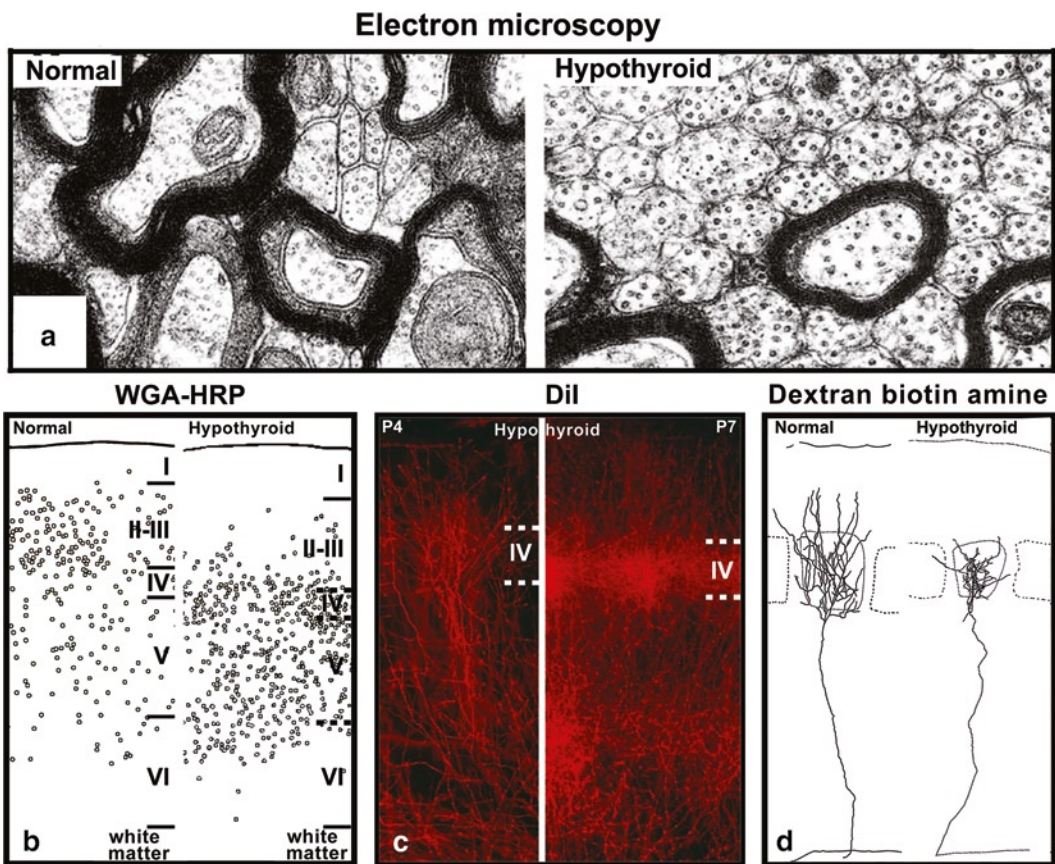
hypothyroidism does not affect the total number of axons in the anterior commissure (Guadaño-Ferraz, et al. 1994) and corpus callosum (Gravel et al. 1990) of the adult, although the maturation of commissural axons is dramatically impaired (Gravel and Hawkes 1990; Berbel et al. 1994) (Fig. 135.11a). The proportion of myelinated axons with respect to the total number of axons was greatly reduced both in the anterior commissure and corpus callosum of hypothyroid rats. In both commissures, myelinated axons were first observed at P12 in normal and at P14 in hypothyroid rats. In the anterior commissure at P180, the number of myelinated axons was significantly lower in hypothyroid (12.7% myelinated axons) compared to normal rats (32%), representing a 66% reduction in hypothyroidism. In the corpus callosum at P180, the reduction was similar (76%); there were 2.4% myelinated axons


Fig. 135.11 Cortical connections in developmental hypothyroidism. Developmental hypothyroidism alters cortical connections. (**a**) Electron photomicrographs of the postlimb of the anterior commissure at P180 in normal and hypothyroid rats. Note the increased number of myelinated axons in normal as compared to hypothyroid rats. (**b**) Plots of retrograde-labeled callosal neurons in the auditory cortex of normal and hypothyroid adult rats. In normal rats, an important proportion of labeled neurons are in supragranular layers II and III. On the contrary, in hypothyroid rats, almost all labeled neurons are found between layers IV and VI. (**c**) Thalamocortical tracing in hypothyroid rats during development. Photomicrographs of coronal sections from P4 and P7 hypothyroid rats which had the lipophilic carbocyanine DiI tracer (1,1′-dioctadecyl-3,3,3′,3′-tetramethylindocarbocyanine perchlorate) implanted in the ventrobasal thalamic nucleus. At P4, similar as in normal rats, DiI-labeled thalamic afferents enter the somatosensory cortex, and form clusters in layer IV. At P7, collaterals in layer IV form more dense clusters than at P4. (**d**) Coronal views of thalamocortical terminal arbors in layer IV in the posteromedial barrel subfield of normal and hypothyroid adult rats. The barrel limit is marked with dashed lines and delineates the cytochrome oxidase positive area. Note that in hypothyroid rats terminal arbors have shorter and tortuous branches (Panel a – Reprinted from Guadaño-Ferraz et al. (1994). With permission; Panel b – Reprinted from Berbel (2003). With permission; Panels c and d – Reprinted from Ausó et al. (2001). With permission)

in hypothyroid compared to 10% in normal rats (Berbel et al. 1994). The maturation of some cytoskeletal components is delayed or does not occur in hypothyroid rats (Gravel and Hawkes 1990; Nunez et al. 1991) as is also the case for axon caliber growth (Gravel et al. 1990; Berbel et al. 1994). Development and maturation of oligodendrocytes in the forebrain commissures of hypothyroid rats may also be affected. In fact, cortical expression of myelin-associated glycoprotein, proteolipid protein, and myelin basic protein in oligodendrocytes is strongly reduced (Muñoz et al. 1991).

Distribution of callosal neurons. In hypothyroid rats, the distribution of callosally projecting neurons has been studied in the visual and somatosensory (Gravel and Hawkes 1990), and auditory cortices (Berbel et al. 1993; Lucio et al. 1997). In the auditory cortex of developing (Lucio et al. 1997) and adult (Berbel et al. 1993) hypothyroid rats, the laminar distribution of labeled neurons was abnormal. In adult normal rats, 34% of callosal neurons were in the upper tier of the cortex (roughly corresponding to layers II–III and partially IV), while in hypothyroid rats, they were mostly located in infragranular layers (Berbel et al. 1993) (Fig. 135.11b).

The finding that callosal projections originate from deeper layers in hypothyroid rats (Berbel et al. 1993; Lucio et al. 1997) is interesting since the laminar origin of cortical projections is a particularly robust and reliable trait of cortical organization, related to the birth day of cortical neurons (McConnell and Kaznowski 1991; McConnell 1992). Studies in hypothyroid rats indicate that neurons destined to a given layer can migrate abnormally and be "trapped" in a different layer, but still form projections appropriate to their birth day.

In addition to altered radial distribution, the total number of callosal neurons increased auditory (Berbel et al. 1993), visual (Gravel and Hawkes 1990) cortices and in other cortical projecting neurons such as in the occipitospinal connections (Li et al. 1995), revealing maintenance of exuberant projections in hypothyroid rats.

Organization of thalamic afferents. In the barrelfield of adult hypothyroid rats, the radial distribution of thalamic afferents, anterogradely labeled with dextran-biotin amine and DiI, was similar to normal (Ausó et al. 2001). As in normal rats, hypothyroid thalamic afferents branched profusely in layer IV, reaching layers II–III and showing collaterals in layers Vb and VI (Fig. 135.11c). However, the spread of these collaterals was reduced in hypothyroid rats, resulting in more restricted projection areas (Ausó et al. 2001). Single reconstructions of terminal arbors confirmed the results. In hypothyroid rats, the collaterals in layer IV followed more complicated trajectories than in normal rats, and the number of axonal branches that reached layer II–III was reduced (Fig. 135.11d). The total length of terminal axon arbors was 49% smaller in hypothyroid rats. This arrested growth was also reflected in a reduced number of branches and by a 58% reduction in the number of buttons per terminal. In hypothyroid rats, ramification of the thalamocortical axons would appear to be stalled postnatally, resulting in a reduced synaptogenesis as suggested by the reduced number of buttons on the thalamocortical branches (Ausó et al. 2001).

Serotonin (5-HT) immunostaining is a good transient marker for thalamic afferents in the visual, auditory, and somatosensory areas of rats during the first postnatal days. In the barrel cortex of normal rats, labeling disappeared by P11–12, while in hypothyroid rat it disappeared by P16–17 (a 5 days delay; Fig. 135.12a) (Ausó et al. 2001). In both, normal and hypothyroid rats, the heavy 5-HT labeling in the barrel cortex is located in layer IV, although a light and diffuse immunoreactivity appeared in other cortical layers.

Hypothyroidism seems to dissociate stabilization of juvenile axons from maturation, growth in caliber, and myelination processes, which were previously thought to be necessarily linked (Innocenti 1991). Speculatively, the adult hypothyroid brain may retain aspects of developmental plasticity, as observed in hypothyroid vertebrates. In amphibians, the absence of thyroid hormones prevents the onset of metamorphosis, maintaining the tadpole in a juvenile state (Kollros 1981; Schönenberger and Escher 1988). In these tadpoles, as in hypothyroid rats, normal developmental changes, including regressive events, fail to occur.

135.4.4 Altered Gene Expression in the Somatosensory Thalamus and Cortex

Until P11, the expression of 5-HT transporter (5-HTT) in the ventrobasal thalamic nucleus and cerebral cortex of hypothyroid rats was similar to normal. By P15, gene expression disappeared in normal rats, whereas it persisted in the hypothyroid condition and paralleled the protracted 5-HT immuno-labeling in the barrel cortex (Fig. 135.12b; Ausó et al. 2001).

Other genes, such as the vesicular monoamine transporter (VMAT2) and 5-HT1B receptor, are normally expressed, indicating a selective effect of hypothyroidism on the 5-HTT expression and excluding the possibility of a generalized effect of thyroid hormones on the state of thalamic neuron maturation (Ausó et al. 2001). The 5-HTT gene downregulation is most probably indirect, given that no response element to thyroid hormones is present in the 5-HTT promoter (Heils et al. 1998). Interestingly, normal rat pups display a peak in brain tissue thyroid hormone levels by P10 (Guadaño-Ferraz et al. 1994) that could contribute to the regulation of 5-HTT and other genes whose transient expression is thyroid hormone dependent.
Fig. 135.12 Expression of serotonin and serotonin-transporter in developmental hypothyroidism. Altered expression of serotonin (5-HT) and serotonin-transporter (5-HTT) in developmental hypothyroidism. (**a**) Serotonin (5-HT) immunostaining in normal and hypothyroid rats during postnatal development. Photomicrographs of flattened neocortex tangential sections, containing parietal, temporal, and occipital cortices, showing 5-HT labeling in the somatosensory cortex of normal (*left*) and hypothyroid (*right*) rats at the indicated postnatal ages. At P4, heavily immunostained barrels can be seen. Decay of 5-HT labeling occurs by P11 in normal and by P16 in hypothyroid rats. Note that, in normal P12 rats, no barrels were immunostained, whereas in hypothyroid rats of the same age and at P15, they are still immunopositive. (**b**) Autoradiograms of in situ hybridization labeling using ^{35}S-labeled probes to serotonin-transporter (5-HTT). Coronal brain sections are shown at the level of the ventrobasal thalamic nucleus (VB). Both, in normal and hypothyroid rats at P8, strong 5-HTT expression is detected in the VB. At P15, a strong 5-HTT expression is still observed in the hypothyroid VB (Reprinted from Berbel (2003). With permission)

Reduced 5-HT levels in the brain during the critical period of barrel formation delay the formation and differentiation of layers II–III (Blue et al. 1991; Osterheld-Haas and Hornung 1996), and reduce the tangential extent of thalamocortical arbors within barrels (Bennett-Clarke et al. 1994). Thus, prolonged 5-HTT expression in the hypothyroid ventrobasal thalamic nucleus should decrease the concentrations of 5-HT in the extracellular space of sensory cortices, affecting their organization and differentiation.

In conclusion, we can see an asynchrony in the maturation of thalamocortical afferents and their cortical targets in hypothyroid rats. Cortical cells could be at a stage of maturation that does not allow them to respond to thalamocortical signals, resulting in an abnormal communication between thalamic axons and target cells (e.g., by a reduced synaptogenesis).

135.5 Correlates with Human Diseases

These experimental studies may help to better understand human epidemiological data, despite differences in the timing of neocorticogenesis between man and rats with respect to stages of pregnancy (Fig. 135.4). As already mentioned, the postnatal development and maturation of the central nervous system is comparatively longer in humans than in rats, but many similarities also exist (Berbel et al. 2007).

From experimental studies in rats, we can hypothesize that many events in human development might also be altered that affect cortical organization and function in the progeny of mothers who have suffered different degrees of hypothyroxinemia during gestation; a possibility that we cannot ethically confirm or disprove. These alterations may well be the underlying cause of the decreased mental development described in cretins born in areas of severe iodine deficiency. Also reported when the deficiency is mild and moderate (Vermiglio et al. 2004; Berbel et al. 2009) and the mothers are hypothyroxinemic without being clinically or subclinically hypothyroid. In fact, heterotopic cells have been described in the neocortex of therapeutically aborted human fetuses from an iodine-deficient area (Liu et al. 1984). These studies have reported heterotopic cells in the neocortex and abnormal cytoarchitecture similar to that found in rats. Although the mental impairment attributed to early maternal hypothyroxinemia is usually not as severe as that of congenitally hypothyroid children deprived of an early treatment with T4, the number of children at risk for neurodevelopmental deficits related to early maternal hypothyroxinemia is 150–200 times greater than that of newborns with congenital hypothyroidism (Morreale de Escobar et al. 2004).

135.6 Applications to Other Areas of Health and Disease

Every child has the right to receive an adequate supply of iodine to ensure his (or her) normal development and every mother has the right to receive adequate iodine nutrition during pregnancy and lactation to ensure that her unborn child experiences normal mental development. These rights were established in the resolutions of the Convention on the Rights of the Child (United Nations Assembly, New York 1989); The World Summit for Children (United Nations, New York 1990); The World Conference on Macronutrients: Elimination of "Hidden Hunger" (United Nations Children's Fund – UNICEF, WHO, Food and Agricultural Organization of the United Nations – FAO; Montreal 1991), and the World Conference on Nutrition (WHO, FAO; Rome 1992). Thus, to eradicate iodine deficiency and, consequently, to increase the quality of life of children must be one of the priority

goals of Public Health Institutions in developed countries and of the health areas concerning Primary Attention Care, Gynecology, Pediatrics, Endocrinology, Neurology, Nutrition, Psychology, and Preventive Medicine. Thyroid hormones exert both genomic and nongenomic actions during all the life cycle in many tissues, organs, and systems. In particular, they are crucial during early neurodevelopment, since key phases of the central nervous system development depend on the expression of genes that are regulated by thyroid hormones. These genes affect, among other things, proliferation, migration, and maturation of neurons and glial cells. To know how thyroid hormones regulate these phases of development may also help to understand altered regulatory mechanisms in other neurodevelopmental diseases such as schizophrenia and epilepsy with cytoarchitectonic alterations similar to those found in hypothyroidism and hypothyroxinemia. In fact, both hypothyroidism and hypothyroxinemia also increase the risk of suffering from these neurological diseases. Thyroid hormones exert a key role in the activation of peripheral glia (such a Schwann cells) playing a fundamental role in nerve regeneration and repair. The study of thyroid hormones on the regulation of the function of adipocytes is of basic importance for nutritionists and endocrinologists. In developed countries, the obesity in children is one of the principal factors affecting their quality of life and increasing the profile of cardiovascular risk factors. In addition, thyroid hormones may exert nongenomic actions in many cell types, regulating principal metabolic pathways. Thyroid hormone acting on cytoplasmic thyroid hormone-receptors could activate the PLC-IP3 and DAG-PKC pathways to increase the intracellular concentration of calcium and to modulate the Na+/H+ exchanger in myoblasts. These actions reveal a new role of thyroid hormones in cardiovascular functions. By combining basic and clinical investigation, new data will be obtained to better understand the basic phases of brain development and the genetic and physiological events underlying some of the human diseases mentioned above.

135.7 Concluding Remarks

In this chapter, we have insisted on the importance of the implementation of universal salt iodization and provision of iodine supplements during pregnancy and lactation, which can be easily implemented at a very low cost. Iodine supplementation does not exclude other ways to prevent iodine insufficiency such as the use of iodinated salt in households and in prepared foods, and the incorporation of foods from iodine-sufficient zones in the diet, such as seafood.

The present chapter does not address the controversy regarding implementation of maternal screening programs of thyroid function during the first trimester of gestation. Although Europeans from countries with National Health Systems favor such screening programs (Glinoer 1998; Morreale de Escobar et al. 2002), some North American learned Societies do not (Casey and Leveno 2006) on the questionable basis that there is not good evidence that identification and treatment improves maternal or infant outcomes.

In conclusion, we recommend the need of an iodine supplement, for all women considering conception and during pregnancy and lactation, at risk of suffering iodine deficiency, without waiting for confirmation that a pregnant woman's iodine intake is inadequate. We believe that iodine supplementation is independent from implementation of T4 screening of every pregnant woman and should be handled in the same way as folates, which are advised without prior evidence that the woman is folate deficient. We fully recommend iodine supplementation to assure that children reach the full potential of their mental capabilities according to their genetic endowment and epigenetic determinants, avoiding the tragedy of a reduced intelligence due to a preventable micronutrient deficiency such as an inadequate iodine intake.

Summary Points

- After starvation, iodine deficiency remains the most frequent cause worldwide of preventable mental retardation in children.
- Severe iodine deficiency results in a wide spectrum of disorders including cretinism.
- Mild iodine deficiency causes maternal hypothyroxinemia, which affects pregnant women even in apparently iodine-sufficient areas.
- Maternal hypothyroxinemia often goes unnoticed because T3 levels remain within the normal range, and thyrotropin is not increased.
- Recent epidemiological data have found that mild maternal hypothyroxinemia during the first month of pregnancy increases the risk of neurodevelopmental abnormalities in children.
- Experimental data in animal models have shown altered brain cortical cytoarchitecture in pups born to hypothyroxinemic dams. These alterations are prevented in hypothyroxinemic dams treated with potassium iodide.
- To prevent iodine deficiency during gestation and lactation, the WHO recommends a supplement of iodine for every expectant woman, in addition to the use of iodized salt in households and a diet comprising iodine rich foods, so that the total iodine intake is 250–300 µg iodine per day.

Definitions

Thyroid hormones: Thyroxine (T4) and triiodothyronine (T3) are endocrine hormones produced by the thyroid gland. The genomic action of thyroid hormone is mainly mediated by T3 (the active hormone). In nongenomic actions, T4 might have a prominent role activating metabolic pathways through link membrane receptors.

Iodothyronine deiodinases: Selenoproteins that catalyzes the deiodination of thyroid hormones in target cells.

Recommended iodine intake: Daily amounts of iodine intake, recommended by the World Health Organization, that are necessary to maintain an euthyroid status. The recommended iodine intake varies according to the age and physiological state of an individual. Expectant mothers need a daily intake of 250–300 µg iodine; double the recommended iodine intake for normal nonpregnant women.

Iodine deficiency: A condition in which the iodine secreted into the urine is below 100 µg per liter. Mild iodine sufficiency occurs when the urinary iodine is between 50 and 100 µg per liter, moderate if it is between 20 and 50 µg per liter, and severe iodine deficiency if is below 20 µg per liter.

Hypothyroxinemia: Low levels of circulating free T4. When T3 and TSH are within the normal range no subclinical or clinical hypothyroidism is diagnosed. Mild hypothyroxinemia during gestation may cause neurological damage to the fetus.

Hypothyroidism: Endocrine disease caused by insufficient production of thyroid hormone by the thyroid gland. Circulating T4 and T3 are below the normal range and TSH is above the normal range.

Subclinical hypothyroidism: It is caused by a deficient thyroid gland function. Circulating T4 and T3 are normal and TSH is above the normal range.

Cretinism: Brain damage caused by a severe iodine deficiency.

Telencephalic cerebral cortex: Also known as cerebral cortex, it is the outermost region of the cerebrum. It is divided into three major cortices: archicortex, paleocortex, and neocortex.

Radial migration: Migratory pathway from the germinal layers (subventricular layer) to the cortical plate that is followed by migrating neurons during the genesis of the neocortex. This is mostly followed by excitatory glutamatergic neurons.

Tangential migration: Migratory pathway from the medial ganglionic eminence to the cortex that is followed by migrating neurons during the genesis of the neocortex. This migratory pathway is mostly followed by inhibitory GABAergic neurons.

Key facts 1

- Iodine is an essential component of thyroid hormones: thyroxine (T4) and triiodothyronine (T3).
- Thyroid hormone synthesis results from the coupling of monoiodotyrosine (MIT) and diiodotyrosine (DIT) residues of colloidal thyroglobulin.
- Thyroid hormone release is due to thyrotropin (TSH)-induced thyroglobulin hydrolysis by lysosomal proteases of thyrocytes.
- Deiodination of T4 and T3 are catalyzed by type 1 (D1), type 2 (D2), and type 3 (D3) iodothyronine deiodinases.
- In the central nervous system, activating D2 catalyzes deiodination of T4 to T3. Inactivating D3 catalyzes deiodination of T4 to rT3 and that of T3 to T2.
- In the central nervous system, activating D2 is mainly found in astrocytes and tanycytes, while inactivating D3 is found in neurons.
- Thyroid hormones may exert both genomic and nongenomic actions on target cells, regulating gene expression in the nucleus and mitochondria, and metabolic signal cascades.
- Genomic action: T3 is the active hormone with high affinity for nuclear receptors.
- Nongenomic action: T4 might have a prominent role activating metabolic pathways through link membrane receptors such as integrins.

Key facts 2

- The amount of daily iodine intake varies according to the age and physiological state of an individual.
- The fetus depends on maternal T4 and iodine for normal development.
- Expectant mothers need a daily intake of 250–300 µg iodine; double the recommended iodine intake for normal nonpregnant women.
- The iodine content in foods depends on that of the soil. In general, iodine-deficient soils are in inland regions, mountainous areas, and places with frequent flooding, but they can be also found in coastal regions.
- The strategies to prevent iodine deficiency include (i) the use of iodinated salt in the household, (ii) the incorporation of iodine to industrially elaborated foods (i.e., bread, milk, cheese), and (iii) the introduction of dietary diversification (i.e, consuming food from iodine-sufficient areas and seafood).
- Mean intake of iodine does not ensure the amounts recommended by the World Health Organization (WHO) during pregnancy and lactation (250–300 µg iodine per day).
- WHO promotes daily iodine supplements during pregnancy and lactation, to reach the total daily iodine intake recommended by the WHO and ICCIDD.

Key facts 3

- The severity of the neurological damage depends both on the developmental period when the iodine deficiency is suffered and on the degree of the deficiency.
- Mild hypothyroxinemia (i.e., circulating free T4 within the 0–10th percentile of normal range and with normal T3 and TSH levels) from the beginning of gestation causes a significant delay in neurobehavioral development of children.
- Neurobehavioral outcome of children in a iodine deficient area is not ameliorated if iodine supplementation (200 μg iodine per day) is delayed 10–12 weeks from the beginning of pregnancy.
- Animal models have shown that chronic and transient maternal and fetal hypothyroxinemia causes, among others, alterations in radial and tangential neuronal migration during neocorticogenesis, resulting in a blurred lamination of the neocortex and heterotopic neurons in the subcortical white matter.
- Substitution T4 treatment prevented the neurodevelopmental damage only when it was administered one day after the induction of the hypothyroxinemia. When T4 treatment was begun later, the alterations were not ameliorated.

Chapter 136
Tryptophan Intake and the Influence of Serotonin on Development and Plasticity of Sensory Circuits

Claudio A. Serfaty

Abbreviations

5HT	Serotonin
5HT1B	Serotonin receptors of the 5HT1B subtype
AMPA	Glutamate receptors of the AMPA subtype
BDNF	Brain-derived neurotrophic factor
cAMP	Cyclic AMP
CREB	cAMP responsive-binding element
ECM	Extracellular matrix
GLUR1	Subunit of the AMPA receptor
GLUR2	Subunit of the AMPA receptor
IDO	Indoleamine 2,3-dioxygenase
IFN-γ	Interferon-gamma
LTD	Long-term depression of synaptic transmission
LTP	Long-term potentiation of synaptic transmission
MMP-9	Metalloproteinase 9
NMDAr	Glutamate receptors of the NMDA subtype
NR1	Subunit of the NMDA receptor
NR2A	Subunit of the NMDA receptor
NR2B	Subunit of the NMDA receptor
PKA	Protein kinase A
TNF-α	Tumor necrosis factor-alpha
tPA	Tissue plasminogen activator factor

136.1 Introduction

The intrinsic reorganization capacity of neuronal circuits, known as "neural plasticity" is one of most significant properties of brain self-organization that orchestrates brain development throughout early postnatal life. It underlies the acquisition of basic and higher brain functions, the construction of

C.A. Serfaty (✉)
Laboratory of Neural Plasticity, Fluminense Federal University, 100180, Niterói, RJ, 24001-970, Brazil
e-mail: claudio.serfaty@gmail.com; cserfaty@vm.uff.br

individuality and, ultimately, species adaptation and evolution. Neural plasticity occurs throughout life and is crucial during postnatal brain development when use-dependent synaptic modifications sculpt highly specific circuits for sensory, motor, and cognitive processing (Hensch 2005).

Serotonin (5HT) is an ancient molecule that appears during evolution in protozoans as an intracellular signaling molecule, hormone, and growth factor. Those functions precede its role as a classical neurotransmitter found in vertebrates (Turlejski 1996). Therefore, it is not surprising that in mammalian and nonmammalian species, 5HT exerts an enormous influence throughout the brain in almost every physiological process, from pain sensitivity, thermoregulation, circadian rhythm, appetite, aggression, sensorimotor activity, sexual behavior, mood, cognition, learning, and memory (Azmitia 2007).

Neuronal connections are capable of being constantly formed and eliminated in response to the physiological environment, stress, malnutrition, and all conditions that produce changes in brain structure. Accumulating research suggest that 5HT plays an important role in synaptic plasticity and brain maturation. Consequently, the disruption of serotonergic signaling may impair brain development leading to its associated disorders such as mental retardation (Serfaty et al. 2008).

Serotonin is metabolically derived from tryptophan, an essential amino acid that demands intake from its appropriate nutritional sources, mainly animal and to a lower extent, vegetable protein sources (Fernstrom 1977). Tryptophan is a limiting amino acid in corn, which is an easily accessible and inexpensive carbohydrate/energy source used by poor populations in developing countries. In fact, corn is a major carbohydrate that is broadly used by different cultures in South and Central America.

As malnutrition is one of the most important environmental factors that directly affect brain development, low tryptophan dietary content and a subsequent serotonergic dysfunction should be considered as a potential hazard for appropriate brain development.

136.2 The Development of Specific CNS Connections and the Retinotectal System as a Model for Topographically Organized Connections

During brain development, massive amounts of neurons and glial cells are generated. After migration to appropriate positions and differentiation into specific cell types, neurons start the process of dendritic and axonal outgrowth, target selection and synaptogenesis (Fig. 136.1). During this process, axons and their growth cones navigate through selective pathways guided by repulsive and attractive molecular gradients (Charron and Tessier-Lavigne 2005). On reaching the appropriate neuronal targets, the development of synapses takes place, mostly during postnatal life.

Since the pioneer studies of Roger Sperry, synaptic specification has been recognized as a major feature of brain processing, as it became clear that the sensory, motor, and cognitive abilities depend in a fundamental way, on the correct patterning of connections (Meyer 1998).

Two general strategies concur for the development of organized and specific connections found among mammalian species: an initial overproduction of neurons and synaptic contacts followed by the death of excess neurons and elimination of misplaced ineffective axons/synapses. About the time that neuronal contacts begin to emerge (starting during the last trimester in human gestation), about 50% of the immature neuronal population undergoes a process of natural neuronal death. This process is regulated by the availability of trophic factors: the so-called neurotrophins, like brain-derived neurotrophic factor (BDNF), can only be acquired by the most functional neurons/synapses. Also, during early postnatal development each axonal arbor is more expanded over the target territory than in latter stages of development and, as a result, immature neurons try to establish synaptic contacts in a more unspecific manner than mature neurons. Hence, during postnatal development neuronal

Human Brain Development
Fig. 136.1 Neurogenesis and development of the human brain. Diagram displaying the major steps of human brain development and its relation to the development of sensory, motor, and cognitive abilities (Reprinted from Grantham-McGregor et al. (2007, p. 61), with permission from Elsevier. Adapted from Thompson and Nelson (2001) and reproduced with permission of authors and American Psychological Association)

numbers decrease, transitory axons are selectively eliminated, and synapses from adjacent neurons converge at their targets into postsynaptic neighboring sites, giving rise to highly organized circuits. Those regressive events of neurogenesis are among the most important mechanisms that govern the selection of interconnecting neuronal populations in the brain.

As a model system for the study of organized brain circuits, the connections between the retina (retinal ganglion cells) and its target cells (superior colliculus or optic tectum) – the so-called retinotectal connections – have been extensively studied. It has been shown that the rodent uncrossed retinotectal pathway develops within the first three postnatal weeks, producing highly specific patterns of axonal connections at the target (Fig. 136.2). This form of developmental plasticity occurs mainly at the expense of axonal elimination and synaptic growth at appropriate territories.

The initial development of retinotectal topography is strongly influenced by repulsive/attractive molecules between retinal axons and target neurons. Retinal ganglion cells and their axons express a class of receptors to Ephrins-Eph recptors in gradients that change along the main retinal axis (dorsal to ventral/temporal to nasal). Those axons interact at the visual target with matching gradients of the corresponding Ephrin molecules located at post-synaptic membranes. The interaction of Eph receptors and Ephrins can either induce repulsion or attraction, thus providing positional molecular markers for the initial interconnection of neuronal populations, as proposed by Roger Sperry 4 decades ago. Indeed, ephrin knockout models have shown errors in connectivity of retinal axons along the target (Feldheim et al. 2000).

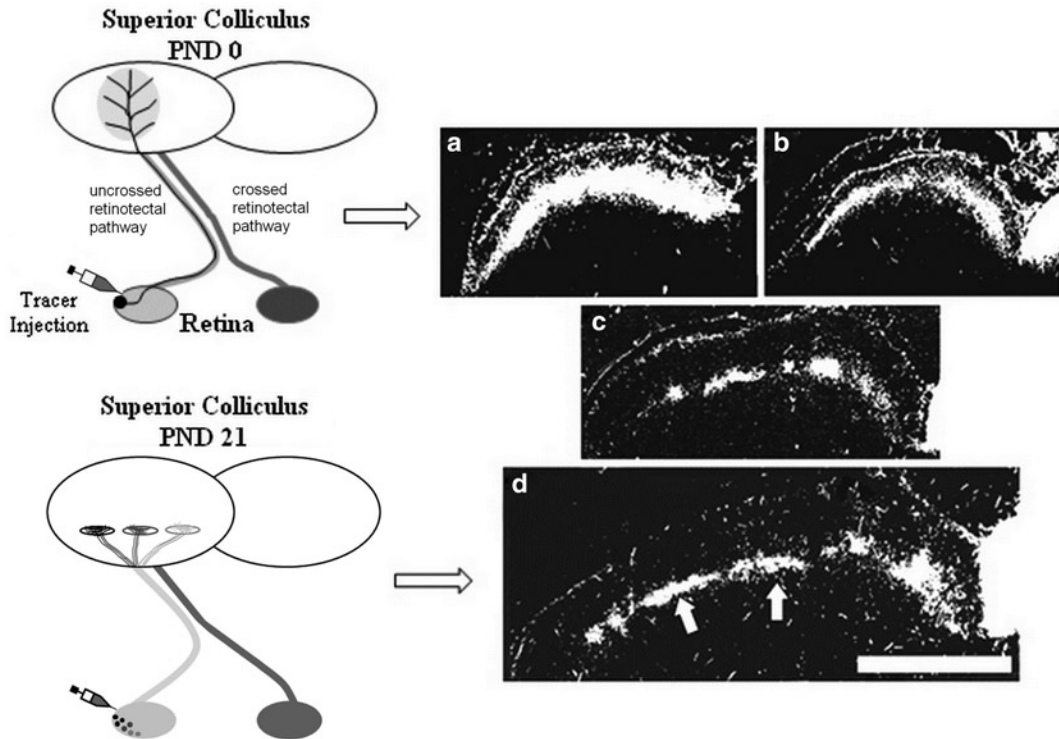
A later step of topographical refinement is achieved by activity-dependent mechanisms that are required to ensure the fine tuning of the correct representation of retinal axons over the superior colliculus, and thus circuitry maturation (O'Leary and McLaughlin 2005). This includes both spontaneous and evoked activity of retinal ganglion cells: even before the full differentiation of photoreceptors and eye opening, waves of correlated spontaneous activity between neighboring retinal ganglion cells seem to provide precise positional cues, thus simulating the normal activation bias and visual experience in retinal neurons (Wong et al. 1993). The resulting correlated presynaptic activity of neighbor axons induces an effective activation of postsynaptic neurons. The electrical coactivation of pre- and postsynaptic membranes triggers a process of selective synaptic stabilization while a failure of an axon to activate a postsynaptic neuron induces its selective elimination, a mechanism originally proposed by Donald Hebb in 1949. Therefore, Hebbian synapses (Butts et al. 2007) have been recognized to


Fig. 136.2 Development of retinotectal connections. Intraocular injection of a neuroanatomical tracer reveals the pattern of axonal labeling (white labeling in dark-field photomicrographs) of retinal axons in the superior colliculus. Retinotectal axons develop from a initially widespread pattern of connections found soon after birth (diagram in *upper left*; photomicrographs **a**, **b**). By the second and third postnatal week, misplaced retinal axons have been selectively eliminated and the remaining axons concentrate at specific termination zones (diagram *lower left*; photomicrographs **c**, **d**, *arrows*). All dark-field photomicrographs represent coronal sections through the visual layers of the rat superior colliculus ipsilateral to the injected eye. Scale bar = 500 μm (Photomicrographs reprinted from Serfaty et al. (2005, p. 130), with permission from Elsevier)

activate glutamate NMDA receptors (NMDAr) that function as correlation sensors, driving downstream intracellular molecular cascades for use-dependent synaptic stabilization.

136.3 Critical Periods for Brain Development

The use-dependent development of functional, organized central connections in the mammalian brain occurs during a time window known as the critical period. A modern conception describes the critical period as the developmental stage in which environmental cues provide rapid plasticity of neuronal circuits, necessary to the acquisition of appropriate sensory, motor, and cognitive skills. The end of the critical period considerably slows plasticity in the corresponding primary sensory brain areas although does not limit plasticity in associative areas of neocortex including the hippocampus. The duration of the critical period is highly variable between mammalian species and is inversely related to the species longevity: rodents display a 3-week critical period, while humans develop protracted critical periods that extend up to 5–12 years and possibly beyond

(Berardi et al. 2000). The critical period duration may be, therefore, related to the complexity of sensory–motor–cognitive learning and thus affects directly the species' ability to adapt to their environment.

The influence of the critical period on the development of sensory brain connections was demonstrated by partial (monocular) visual deprivation studies. Experimental eyelid suture resulted in shrinkage of the respective innervation domains in the primary visual cortex – the ocular dominance columns – resulting in a severe loss of visual acuity from the deprived eye (Mower et al. 1985). In humans, neonatal strabismus can also result in similar loss of visual acuity. Eye misalignment, if not appropriately treated until the age of 5, produce a permanent loss of visual acuity also known as amblyopia. This acuity loss is produced by the loss of synapses originating from the nonaligned eye. Furthermore, cats raised under visually biased environments (e.g. exposed to visually stereotyped patterns of horizontal or vertical lines) do not develop accurate discrimination of visual stimuli (except for those horizontal or vertical stimuli), as well as the proper binocular representation of the visual field (Crair et al. 1998).

The critical period has also been demonstrated by lesion studies. In the rodent visual system, monocular enucleation or restricted retinal lesions (Serfaty et al. 2005) have been used to induce reorganization of axons originating from the intact eye. Lesion experiments revealed the whole extension of the plastic capacity during the critical period, inducing a rapid reactive growth of axons from the nonlesioned eye within the first three postnatal weeks. Surprisingly, retinal lesions after this period also have been shown to elicit a considerable amount of reorganization that takes, however, several weeks to occur, revealing a slow stage of plasticity in the mature brain (Serfaty et al. 2005). Accordingly, lesion studies have been used to reveal the plastic potential of the brain and are powerful tools for studying the forces and mechanisms that guide use-dependent modifications of neural circuits.

136.4 The Molecular Basis of Plasticity: Dendritic Spines as a Source for Synaptic Integration

Use-dependent modifications that occur at a rapid rate during the critical period occur at specific loci called dendritic spines (Fig. 136.3). Those specialized dendritic structures concentrate the biochemical machinery for use-dependent modifications in synaptic function, thus influencing the outcome of full brain development. In fact, disorders related to mental retardation are often correlated to structural and functional modifications in those structures with enormous impact on sensorimotor development as well as cognition deficits (Grossman et al. 2006).

As mentioned above, the plasticity of the developing synapses relates to the expression of glutamate NMDA receptors (NMDAr) that play a critical role as a sensor for correlated activity. During early postnatal development of the visual system, NMDAr display a composition with NR1/NR2B subunits, a configuration that allows an increased capacity for processing simultaneous inputs (extended synaptic integration), as would be expected for immature synapses. By the time of eye opening, however, NMDAr switch their subunit composition to NR1/NR2A, a configuration that requires strict temporal coactivation times, necessary for the development of highly specific connections (Lu and Constantine-Paton 2004). In accordance with a role for NMDA receptors in synaptic development and stabilization, it has been shown that the pharmacological blockade of NMDA receptors disrupts the normal connectivity pattern and, as a result, increase the sprouting of the uncrossed pathway following the partial deafferentation of the contralateral converging retinotectal projection (Colonnese and Constantine-Paton 2001).

Recent evidence also shows that the expression of glutamate AMPA receptors, and its GLUR1 and GLUR2 subunits regulate the size and shape of neuronal dendritic spines affecting the number and type of synaptic inputs, as well as the complexity retinotectal circuits (Haas et al. 2006). Activity
Fig. 136.3 Dendritic spines and glutamate receptors turnover. Most glutamatergic excitatory synapses occur at specialized loci along dendrites called dendritic spines. Those protruding structures are highly dynamic and change their size/shape in response to afferent stimulation. Dendritic spines concentrate glutamate receptors such as NMDA and AMPA receptors, linked to complex intracellular machinery that allows either the insertion or removal of AMPA receptors from the plasma membrane. The dynamics in AMPA receptors distribution underlies use-dependent modifications of synaptic strength

and NMDA-induced calcium influx can trigger either the membrane insertion or the internalization of AMPA receptors at synaptic membranes, resulting in long-term potentiation (LTP) or long-term depression (LTD) of synaptic activity, the physiological basis of learning and memory (Terashima et al. 2008).

In accordance with the role for NMDA receptors in synaptic plasticity, it has been shown that the development and plasticity of retinotectal projections is also influenced by other signals downstream the NMDA receptor activation. This includes local messengers such as nitric oxide and arachidonic acid, both synthesized by their calcium-dependent enzymes: nitric oxide synthase and phospholipase A2, respectively. The pharmacological blockade of those enzymes in neonatal and adult rats, respectively, disrupted the normal topographical patterning of retinal axons, suggesting their roles in the stabilization of developing and mature connections in the superior colliculus (Campello-Costa et al. 2000, 2006). Interestingly, nitric oxide and 5HT appear to have several common actions since it has been shown that 5HT depletion increases NOS activity (Tagliaferro et al. 2001).

136.5 Serotonin and Brain Plasticity

A large amount of evidence from pharmacological, biochemical, and clinical studies revealed a massive influence of 5HT for the normal CNS function and development. Serotonin acts as a growth factor during embryogenesis, since the appearance of 5HT axons throughout the brain and spinal cord occurs prior to the differentiation of most neurons. Through its receptor activity, 5HT orchestrates complex cascades of events, leading to changes in brain structure. Serotonin is involved with dendritic remodeling, dendritic spine formation, and synaptic plasticity (Sodhi and Sanders-Bush 2004). It has also been shown to affect the development and plasticity of many sensory systems including the visual (Gu and Singer 1995) and the somatosensory cortex (Lane et al. 2002).

The glutamatergic input from retinal ganglion cells to subcortical targets is greatly influenced by 5HT. Several studies described an inhibitory functional role for 5HT in the mammalian retinotectal

(Mooney et al. 1994) and retinogeniculate (Chen and Regehr 2003) synaptic transmission during development. The inhibitory action of 5HT involves presynaptic 5HT1B receptors (Mooney et al. 1994). The same modulatory role of 5HT was shown in the somatosensory cortex, where it inhibits excitatory thalamocortical transmission (Laurent et al. 2002). In the *Xenopus* retinotectal system, 5HT also inhibits retinal input to tectal neurons by means of 5HT1A and 5HT1B receptors. The activation of those receptors decreases intracellular levels of cyclic AMP (cAMP), a second messenger that influences cellular metabolism (Debski and Cline 2002). Therefore, in the sensory systems, 5HT appears to exert a modulatory function, possibly as a noise filter, which may be important for the process of axonal elimination of misplaced and to the stabilization of correctly placed synapses.

Serotonin interacts with BDNF, the astroglial growth factor S100β, and other chemical messengers (Azmitia 2007). The serotonergic system regulates its own differentiation by sequential activation of 5HT1A receptors, BDNF, and its receptor trkB, and activation of cAMP responsive-binding element (CREB) and ATF-1 transcription factors (Herdegen and Leah 1998). S100β stabilizes microtubules, the main framework of the cytoskeleton of neurons and astrocytes, and produces neurite extension (Ostendorp et al. 2007). In addition 5HT influences GABAergic, glutamatergic, and dopaminergic neurotransmitter systems (Sodhi and Sanders-Bush 2004). Furthermore, the activity of brainstem serotonergic neurons in rodents and cats has a slow and rhythmic pattern of firing, producing a constant release of 5HT that allows its action as a trophic molecule and a coordinator of brain development and plasticity rather than a neurotransmitter system involved in point-to-point rapid activity (Jacobs and Azmitia 1992).

Chronic administration of fluoxetine, a 5HT reuptake inhibitor, increases BDNF levels and thus the trophic influences on developing axons (Sodhi and Sanders-Bush 2004). On the other hand, a low-tryptophan diet has been associated with decreased 5HT and BDNF content in the mouse cortex (Lee et al. 1999).

Serotonin deprivation through the use of selective neurotoxins has been shown to impair brain plasticity (Gu and Singer 1995). On the other hand, 5HT overstimulation achieved by monoamine oxidase (MAO) knockout as well as by the use of a 5HT reuptake inhibitor has been shown to induce increased axonal outgrowth and sprouting in retinofugal (Bastos et al. 1999; Upton et al. 1999) and thalamocortical axons (Salichon et al. 2001).

136.6 Nutritional Tryptophan Restriction: Impact on Brain Development and Plasticity

Tryptophan is an essential amino acid that crosses the blood–brain barrier to enter in the CNS and the only source for 5HT synthesis (Sodhi and Sanders-Bush 2004). As a result, tryptophan restriction diets have been proposed as an efficient way to induce nonpharmacological 5HT deprivation (Fadda et al. 2000). Recent evidence from a nutritional tryptophan restriction model (Table 136.1) showed a reduction in 5HT immunoreactivity in neurons of the raphe nuclei in young rats fed through their mothers with a corn/gelatin-based diet (Fig. 136.4a–e) (González et al. 2008). Neuronal tracing studies revealed in those animals a developmental delay in the time course of axonal elimination in retinotectal connections. In the low-tryptophan diet group, axons originating from the temporal retina were still apparent at the posterior aspect of the superior colliculus by postnatal day 10. At the same developmental stage, animals fed with control diets, containing normal levels of tryptophan, presented nearly no ectopic axons at the caudal colliculus (Fig. 136.5a–f). These data suggest that a reduced serotonergic signaling would delay the time course of this major regressive event. However, this effect could not be attributed to a reduction in protein synthesis since no differences could be

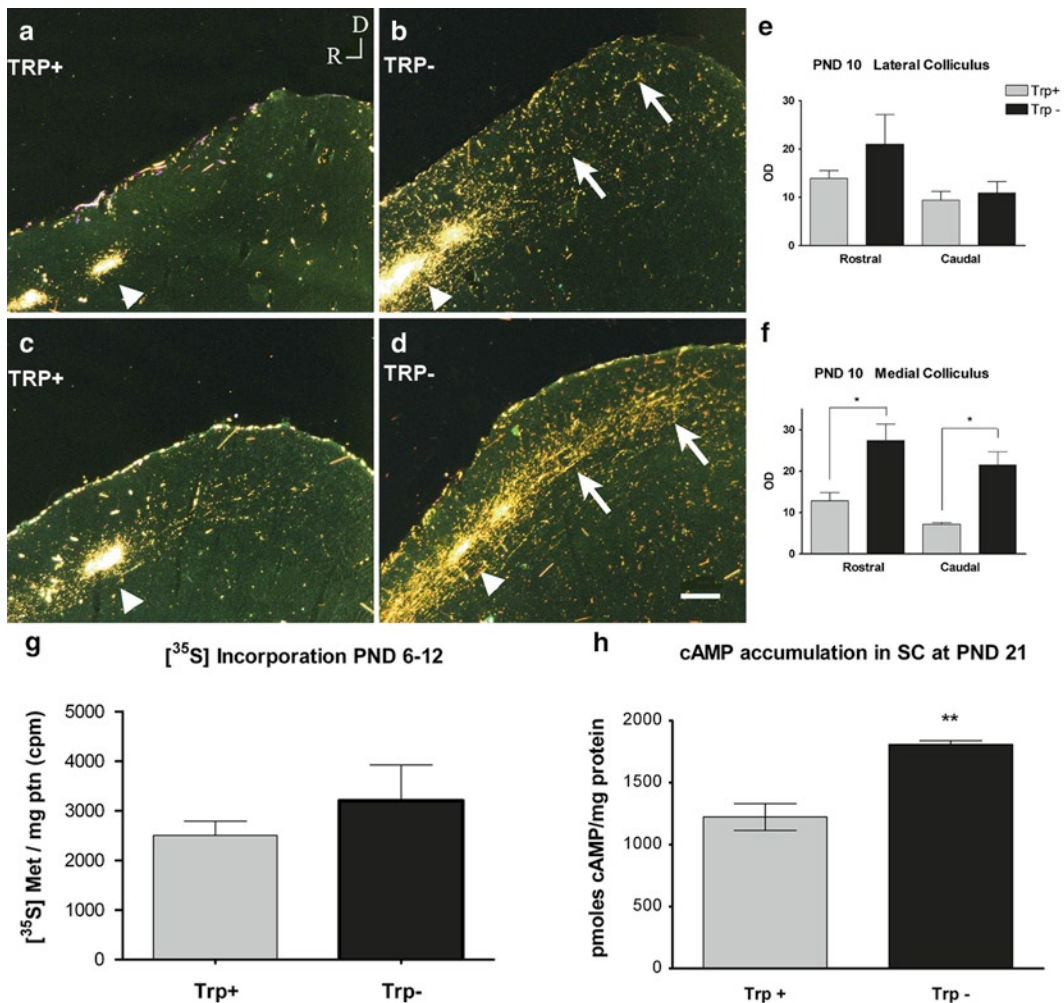

Fig. 136.5 Tryptophan restriction delays development of sensory visual connections. At postnatal day 10, rats fed with diets containing normal levels of tryptophan show axons from the temporal retina converging into clusters of terminals in the anterior aspect of the superior colliculus (**a**, **c**, *arrowheads*). Tryptophan restriction (Trp⁻) results in increased density of axons in inappropriate posterior portions of the superior (PND 10) (**b**, **d**, *arrows*). This effect was significant in the medial half of the colliculus where development lags behind the lateral half. The delay in axonal elimination and sensory development is not related to changes in protein synthesis (G). Tryptophan restriction results in increased levels in cAMP (H). *Trp⁺* tryptophan-complemented diet, *Trp⁻* Tryptophan-restricted diet. Error bars represent SEM. observed in experiments of [³⁵S] methionine incorporation between control and tryptophan-restricted groups. Those observations were, therefore, consistent with a general decrease in developmental plasticity in the sensory systems leading to delayed patterns of axonal elimination and circuit formation (González et al. 2008).

In conformity with those observations, direct evidence of limited plasticity induced by tryptophan malnutrition was obtained after lesion experiments (Penedo et al. 2009). Under normal conditions, a unilateral retinal lesion enforces a sprouting reaction of intact axon's terminal arbors into denervated territories (Serfaty et al. 2005) (Fig. 136.6). However, animals fed with a low-tryptophan diet showed

much less sprouting than obtained from control animals with similar lesions (Fig. 136.7a–c). The restoration of normal nutritional tryptophan levels during the critical period completely restored this form of plasticity (Fig. 136.8a–c). Nevertheless, the observed plasticity deficits could not be reverted by a normalization of tryptophan levels initiated after the closure of the critical period (Fig. 136.8d–f) (Penedo et al. 2009).

A corn-based, hypoproteic diet also resulted in dramatic alterations in the cerebellum development. A retardation of Bergmann glial cell maturation and a concomitant delay in granule cell migration has been reported. An increase in dendritic arbors among granule and Purkinje cells indicating a perturbation of cerebellar neuronal circuitry has also been reported (Del Angel-Meza et al. 2001). Tryptophan restriction has also been shown to reduce dendritic spines and arborizations in hippocampal and prefrontal cortical neurons (Feria-Velasco et al. 2002). Importantly, reduced 5HT immunoreactivity has also been shown to occur with a low-protein diet (Orozco-Suarez et al. 2003) suggesting that both global protein malnutrition and tryptophan restriction may have similar consequences on serotonergic hypofunction.

Nutritional tryptophan restriction has been associated with high basal levels of cAMP (González et al. 2008), which could be acting as a stabilization signal for developing synapses. An abnormally increased cAMP signaling could activate protein kinase A (PKA)-dependent CREB phosphorylation and thus, induce an overstabilization of immature synapses, thus delaying the process of natural axonal elimination. Overstabilized synapses would also decrease their ability to undergo use-dependent modifications as shown by the reduced axonal plasticity found in lesion studies (González et al. 2008; Penedo et al. 2009). Since 5HT signaling pathways involve, in sensory subcortical nuclei, 5HT1A and 5HT1B receptors, both of which reduce cAMP synthesis, high levels of cAMP found after the administration of low-tryptophan diets suggest a direct pathway between tryptophan restriction and 5HT receptors (Fig. 136.5g and h). The reduced serotonergic signaling after the administration of low-tryptophan diets could also be related to decreased AMPA receptors activation, since it has been shown that the long-term depletion of 5HT resulted in decreased expression of GLUR1 AMPA receptor subunits in cortical neurons (Shutoh et al. 2000).
Fig. 136.7 Nutritional restriction of tryptophan reduces brain plasticity. Dark-field photomicrographs of sections through the lateral aspect of the visual layers of the superior colliculus of rats fed with Standard, Trp⁺, or Trp⁻ diets. Temporal retinal lesion was performed at postnatal day 10 (PND 10) and labeling of intact retinal axons at PND 14 (**a–d**) or PND 32 (**e**). Control groups displayed a normal sprouting of uncrossed axons to the subpial aspect of the superior colliculus (**a**, **b** *arrows*). Trp⁻ rats showed reduced axonal growth to the collicular surface (**c**, *arrowhead*). Rats that received the Trp⁻ diet until PND 10, and were subsequently given a Trp⁺ diet from PND 10 to PND 14 also failed to display normal plasticity (**d**, *arrowheads*). Animals that received a Trp⁻ diet from the day of birth until PND 32 also presented a reduced axonal growth to the collicular surface compared to the standard or Trp⁺ groups (**e**, *arrowhead*). Optical density analysis (**f**) confirmed the plasticity deficits observed in Trp⁻ fed groups ($p < 0.001^{***}$, 0.01^{**} and 0.05^{*}; $n = 4$). Error bars represent SEM. Scale bar = 100 μm. *Trp⁺* tryptophan-complemented diets, *Trp⁻* tryptophan-restricted diets. Medial, right; Lateral, left (Reprinted from Penedo et al. (2009, p. 111), with permission from Elsevier)

Therefore, the data suggest that 5HT may act in a bidirectional way: decreased 5HT signaling (as a result of tryptophan depletion) restrains whereas 5HT accumulation (as a result of antidepressant treatment) increases axonal remodeling in the sensory systems.

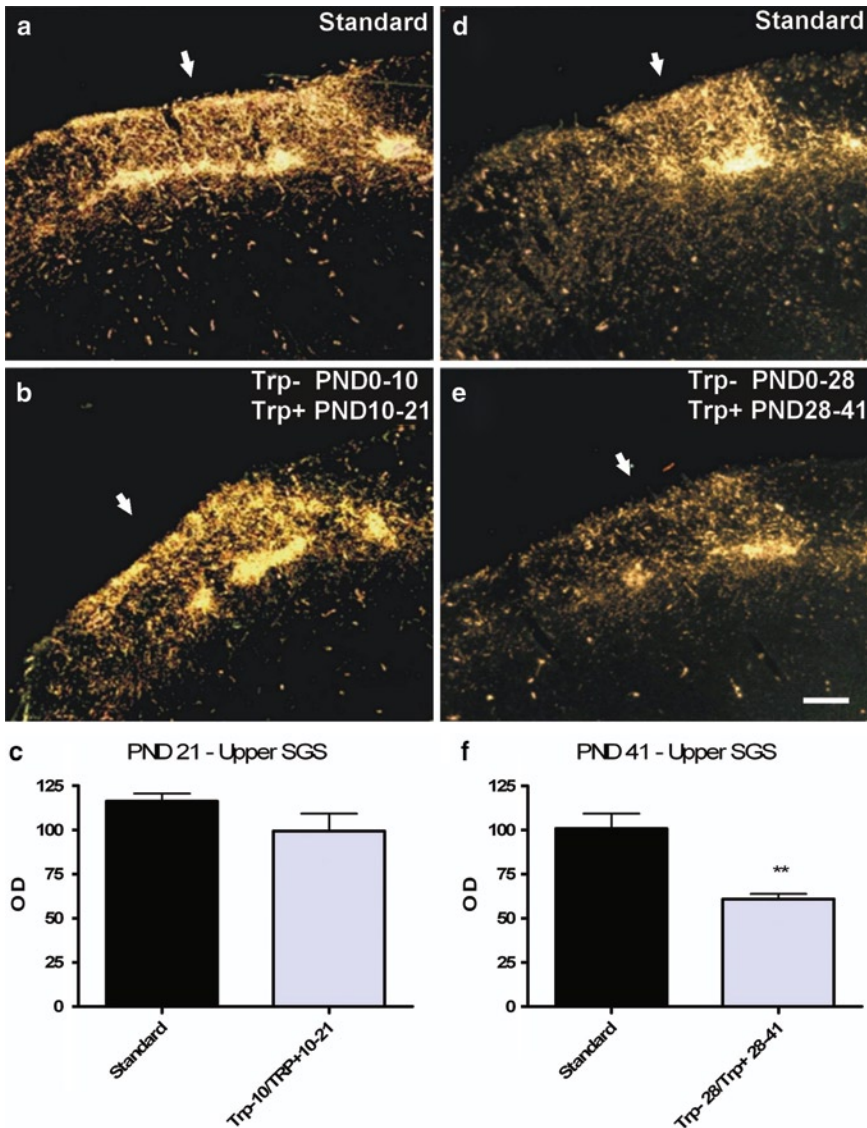
Taken together, experimental data on tryptophan nutritional restriction suggest that the resulting 5HT depletion profoundly influences brain development, especially the fine tuning of axonal


Fig. 136.8 A critical period for nutritional tryptophan complementation upon brain plasticity. Dark-field photomicrographs of coronal sections through the superior colliculus at PND 21 (**a**, **b**) or PND 41 (**d**, **e**) of standard and Trp⁻/Trp⁺ diets following a temporal lesion to the contralateral retina at PND 10. The reintroduction of tryptophan in the diet during the critical period (between PND 10–21) restored plasticity deficits (**b**) as compared to the standard rodent laboratory diet (**a**). Notice similar sprouting of retinal axons to the collicular surface (*arrows*). However, the reintroduction of normal amounts of dietary tryptophan after PND 28 (1 week after the closure of the critical period in rats) resulted in a marked reduction of lesion-induced axonal sprouting (**e**, *arrow*) as compared to control normally fed rats (**d**, *arrow*). Optical densities revealed no differences between control and early refeeding groups (**c**). Late refeeding resulted in decreased plasticity (**f**) ($p < 0.01$, $n = 4$). Error bars represent SEM. Scale bar = 100 μm. *PND* postnatal day, Trp⁺ tryptophan-complemented diets, Trp⁻ tryptophan-restricted diets. Medial, right; Lateral, left (Reprinted from Penedo et al. (2009, p. 112), with permission from Elsevier)

connections and circuitry formation. The consequences of tryptophan deprivation on plasticity may be completely reversed by appropriate complementation during the critical period. However, an extended nutritional deprivation throughout this decisive time window may result in severe loss of use-dependent plasticity with enduring consequences for the developing brain.

136.7 Tryptophan Malnutrition Alters Extracellular Matrix Proteases

A recent study brought new evidence for the involvement of extracellular matrix (ECM) proteases in cell migration and plasticity. Metalloproteinase 9 (MMP-9), a zinc-dependent matrix protease, appears to be critical on developmental and lesion-induced plasticity in the visual system. It has been shown that the expression and biological activity of MMP-9 was higher in the rodent superior colliculus during initial stages of development. Both expression and activity of MMP-9 decreased as this brain structure matures and plasticity progressively declines (Oliveira-Silva et al. 2007). The time course of MMP-9 modulation fits the critical period of visual system development within the first three postnatal weeks. Moreover the blockade of MMP-9 activity produced a distortion in retinotectal mapping, suggesting a functional role for this matrix metalloproteinase in brain development. Interestingly, recent data indicate that the nutritional tryptophan restriction reduces the activity of MMP-9 (Penedo et al. 2009).

Thus, proteolysis of ECM by MMP-9 may perform a permissive or inductive role upon axonal remodeling and synaptogenesis during development in a tryptophan dependent way. This is in keeping with previous data showing that the inhibition of MMP activity by a specific antagonist was able to modify the ability of *Xenopus* retinal ganglion cells to make connections into the optic tectum (Hehr et al. 2005). Recent reports have also shown that MMPs are related to synapse formation, remodeling, and plasticity (Nagy et al. 2006). Vaillant et al. (1999) showed that the peak of MMP 3, 9 expression and activity occurs in the rat cerebellum between PND 3 and PND 10, a period of intense synaptogenesis, where these molecules participate on the laminar organization of this structure (Vaillant et al. 1999).

During development of the visual cortex, the use-dependent modifications of dendritic spines that occur during the critical period is related to the ECM proteolytic activity by tissue plasminogen activator factor (tPA), which has been related to BDNF expression and GABAergic differentiation (Oray et al. 2004).

Therefore, the role as a presynaptic inhibitory neurotransmitter and axon growth enhancer makes tryptophan and its main metabolite, 5HT, interesting modulators of brain development. Serotonin allows the initial growth of widespread target-directed connections that is observed in early development, acts as a noise filter of excess, noncorrelated activity, that occurs when patterns of electrical activity induce use-dependent modifications of neural circuits, and has a possible link with matrix metalloproteinase activity, probably through BDNF expression, thus providing a common modulatory pathway for axonal and dendritic remodeling during developmental and lesion-induced plasticity.

136.8 Tryptophan Malnutrition and the Delay in Brain Development

Brain development consists of a series of succeeding, overlapping, and interdependent steps, which results in the buildup of sensory, motor, and cognitive skills (Fig. 136.1). It is worth noting that even small delays in developmental differentiation could be potentially harmful to this complex series of events leading to long-lasting changes in brain performance. Delaying a biological process could alter complex cascades of events such as synaptic use-dependent adjustments. This point of view is in contrast with previous ideas that considered developmental delay as a nonharmful, self-limiting event. In view of recent results, this matter should be object of further studies in order to carefully evaluate the impact of developmental delays on cognition and learning deficits.

Especially in developing countries more than 200 million children exposed to enduring malnutrition, poverty, and poor health will experience poor levels of cognition and education failing to reach their full potential (Grantham-McGregor et al. 2007). As brain development depends on the gradual

acquisition of processing abilities, a slow-down in sensory maturation would have a direct impact on motor and cognitive development. It is important to mention, however, regarding policies for nutritional care, that despite the general brain vulnerability to nutritional and other insults, recovery is always possible and should be implemented especially with an early intervention.

This would be particularly important for the prevention of neuronal deficits among poor populations, which frequently and repeatedly undergo low-protein malnutrition. More importantly, due to cultural habits, corn is often used as an alternative, low-cost carbohydrate source. As a result, tryptophan malnutrition should be seriously considered as a potential hazard for brain use-dependent development and tryptophan complementation implemented in malnourished children as a public health strategy.

136.9 Applications to Other Areas of Health and Disease: Tryptophan and the Neuroimmunomodulation of Chronic Disease

Low serum/plasma tryptophan concentration has been reported as a direct consequence of protein malnutrition. However, low levels in tryptophan concentration, particularly in the brain, have also been observed under infectious, autoimmune, and malignant disorders that involve cellular immune activation (Th1-type). Those chronic inflammatory conditions have been reported to increase the levels of cytokines such as interferon-gamma (IFN-γ) and tumor necrosis factor-alpha (TNF-α). Those cytokines, known to mediate cellular immune responses under normal acute conditions may, under chronic conditions, increase within the brain, the activity of indoleamine 2,3-dioxygenase (IDO) an enzyme that is responsible for the catabolism of tryptophan to kynurenine and as a result decrease brain 5HT levels. In fact, IFN-γ immunotherapy has been shown to elicit depressive symptoms that were alleviated by conventional antidepressant treatment. Therefore, it appears that low systemic tryptophan concentrations might be a consequence of either nutritional or chronic inflammatory conditions, leading to decreased neural plasticity and depression.

136.10 Key Features of Tryptophan, Serotonin Brain Development

The brain circuits dealing with sensory, motor, and cognitive areas are point-to-point connected in a use-dependent way during postnatal development. This is particularly true for the main sensory, motor, and cognitive circuits and also for the circuits involved in learning and memory. Tryptophan is an essential amino acid and a key nutritional factor for 5HT synthesis. As a neuromodulatory system, 5HT influences synaptic transmission throughout the brain and, thus, synapse formation during postnatal life. It is, therefore, not surprising that serotonergic disruption is closely related to psychiatric disorders such as depression, schizophrenia, and dementia as well as with mental retardation. In Down's syndrome, serotonergic neurons fail to differentiate as a result of reduced expression of 5HT receptors (mainly 5HT1A subtype) and a subsequent downregulation in S100β protein, a trophic factor for serotonergic differentiation. As a result, it has been observed that Down's syndrome patients appear to express reduced densities of dendritic spines suggesting an overall reduction in synaptic use-dependent plasticity throughout the brain. The prenatal exposure to alcohol has also been associated with decreased levels of 5HT in the brain leading to variable deficits associated with altered synapse formation.

Summary Points

- The intrinsic reorganization capacity of neuronal circuits, known as neural plasticity, is one of the most significant properties of brain self-organization that underlies the acquisition of basic and higher brain functions.
- The use-dependent development of neuronal circuits occurs during a postnatal critical period. During this time window, sensory stimulation sculpts neuronal circuits with appropriate sets of connections. The successful development of sensory connections drives most of motor and cognitive development thereafter.
- During brain development 5HT plays an important role in neuronal differentiation, axonal outgrowth, synapse formation, and brain plasticity.
- Tryptophan is an essential amino acid and the only source for 5HT synthesis. As a result, a low-tryptophan diet results in 5HT deprivation.
- Tryptophan dietary restriction during the critical period alters sensory development. It has been associated with a delay in the normal elimination of incorrect axonal connections and with a reduction in neural plasticity.
- Tryptophan malnutrition can result either form a tryptophan-restricted diet or from global protein malnutrition. As tryptophan complementation during the critical period is able to repair plasticity deficits, it should be considered as mandatory in nutritional complementation strategies.

Definitions

Critical period: A postnatal period of brain development when synapses and neuronal circuits develop in a use-dependent way. The critical period is therefore essential to acquisition of major circuits for sensory, motor, and cognitive processing

Glutamate AMPA receptors: Glutamate is the major excitatory neurotransmitter in the brain. AMPA receptors are membrane proteins, which form channels permeable to sodium ions. The activation of AMPA receptors generates ionic currents and electrical activation of postsynaptic neurons.

Glutamate NMDA receptors: A class of glutamate receptors that form ion channels permeable to calcium. The activation of NMDA receptors requires the simultaneous electrical activation of the postsynaptic membrane by other converging inputs. This feature makes NMDA receptors unique since they can signal for converging activity into neural networks.

Growth cones: The tips of growing axons and dendrites are formed by specialized structures called growth cones. Growth cones navigate through developing pathways and interact with the extracellular milieu directing axons to specific areas of the brain.

Long-term potentiation (LTP)/Long-term depression (LTD): Long-term use-dependent modifications in synaptic strength induced by periods of intense afferent stimulation or reduced afferent activity, respectively. Synaptic plasticity mediated by LTP and LTD is the basis of learning and memory as well as in synaptic development.

Monocular enucleation: Experimental manipulation in which the removal of one eye produce denervation and reactive sprouting of nonlesioned axons from the intact eye into central visual nuclei of the brain.

Natural neuronal death: Also know as naturally occurring neural death. During the late stage of neuronal development approximately 50% of neurons generated fail to establish connections with target neurons and die due to the lack of neurotrophic factors released by target cells. Natural neuronal death is believed to ensure an appropriate balance between interconnecting neuronal populations.

Neuronal tracing studies: Most of neuroanatomical data have been generated through the use of neuronal tracers, molecules that are incorporated into neuronal membranes and transported either from the cell body to the axonal tips or backward from axonal tips to cell bodies. Neuronal tracers can therefore reveal the morphology of neuronal structures and connections.

Ocular dominance columns: The visual cortex accommodates afferents that convey information from both eyes. Those thalamocortical afferents are segregated into spatially discrete alternating loci known as ocular dominance columns. The columnar organization is necessary for binocular processing of vision and is affected by the imbalance of visual stimulation that occurs in strabismus.

Optic tectum: Main target of retinal axons found in nonmammalian species. A homologue of the **superior colliculus** found in mammals.

Regressive events: During brain development some events leading to natural neuronal death and elimination of transitory axons and synapses are known as *regressive events of neurogenesis*.

Retinal ganglion cells: Main output retinal neurons that convey information from the retina to the central visual nuclei in the brain through the optic nerve.

Retinofugal projections: Axonal connections from retinal ganglion cells through the optic nerve toward subcortical visual nuclei.

Retinogeniculate: Neuronal pathway between the retina and the lateral geniculate nucleus of the thalamus.

Retinotectal: Neuronal pathway between the retina and the superior colliculus/optic tectum.

Retinotectal topography/Topographically organized connections: Neighboring neurons in the retina project their axons to matching postsynaptic neurons in the superior colliculus. A topographical matching between the retina and target nuclei ensures the correct representation of the visual field into the brain. Topographical representations are a common feature of sensory and motor systems and reflect the specificity of neuronal circuits.

Spontaneous and evoked activity: Neurons are very specialized cells that are able to generate electrical activity. This activity can be either spontaneous or evoked by afferent stimulation. Sensory neurons display spontaneous activity during early stages of development (e.g. last trimester of human gestation or early post natal life in nonprimate species) when sensory systems are not fully developed.

Thalamocortical: Neuronal pathway between the thalamus and the sensorial areas of the cortex.

Use-dependent plasticity/Use-dependent synaptic modifications: Ability of changing neuronal circuits in response to environmental changes or injury. Use-dependent plasticity modifies synaptic strength between interconnected neurons in neuronal networks.

Uncrossed retinotectal pathway: Retinal ganglion cells located at the temporal retina connect to the same side of the brain forming an uncrossed (or ipsilateral) pathway. Retinal ganglion cells located at the nasal retina connect to the opposite side of the brain forming a crossed pathway.

WISC	Wechsler Intelligence Scale for Children
Z	Z score

137.1 Introduction

Slow growth in infancy and early childhood is the key clinical sign of the condition traditionally called *failure to thrive* (FTT) in pediatrics. It is most widely identified by slow weight gain, though other anthropometric measures are sometimes also used, generally height or weight for height. FTT, does not, however, refer to the key clinical sign, so *weight faltering* is coming to replace it in many contexts, and this term also makes it clear that we are dealing with a sign, not a diagnosis. Whatever terminology is used, two kinds of research problem arise, concerning the causes and the consequences of the slow weight gain, and both have important behavioral aspects.

Traditional terminology also distinguishes between FTT that is attributable to an underlying medical condition and FTT that is not. The term "organic" has been used of the first, and is contrasted with "nonorganic", used of the second. There are two problems with this traditional terminology. First, there are clearly organic sources of variability in weight gain other than those attributable to underlying medical conditions, as the genetics of adiposity shows. Second, the distinction can be taken to imply an oversimple relationship between the medical condition and the child's poor weight gain, when the relationship can be quite complex. Cerebral palsy, for example, can lead to serious malnutrition by damaging a child's oral-motor skills, leading to lower food intake and poorer weight

gain, but it is also associated with depression in the children's mothers, which may also affect their feeding of the child (Reilly and Skuse 1992). In children with gastro-intestinal reflux, a quite common condition in the first 2 years, inflammation of the esophagus is associated with significantly lower energy intake (Mathisen et al. 1999), and esophagitis might operate by making food intake aversive. The distinction made in the traditional terminology can still be important, but needs to be made with care, recognizing that there are many possible routes from a medical condition to poor weight gain.

The weight gain of infants identified as failing to thrive is improved by nutritional interventions (Whitten et al. 1969; Wright et al. 1998a) and it is reasonable to assume that its immediate cause is undernutrition. There are many possible explanations for undernutrition, but assuming that it is post-natal, they fall into four main classes:

1. Characteristics of the wider or more local family economic environment that affect the availability of food.
2. Patterns of care provided to infants and young children that affect their food intake.
3. Individual characteristics of infants that affect their food intake.
4. Individual characteristics of infants that affect their absorption of nutrients.

The first of these classes of explanations (1) is one that has been widely invoked (Spencer 2007). But clear evidence that FTT in infancy in industrialized countries is in fact related to the economic circumstances of the infant's family has never been available, and recent epidemiological work in the UK suggests that there is no clear relationship between the two (Spencer 2007). The first epidemiological study of this (Wright et al. 1994) examined weight gain over the first year in affluent, intermediate, and deprived areas of Newcastle-upon-Tyne, as identified from census data. The highest rates were found in the deprived and the affluent areas, with lower rates in the intermediate areas. A larger study (Blair et al. 2004) in which the family was classified by social and economic indicators within the family, rather than indicators based on area of residence, found that rates of FTT were not related to the social class of the family (Fig. 137.1) or to the educational attainment of the child's parents. Case-control studies also show no relationship (Drewett et al. 1999; McDougall et al. 2009). In the absence of solid evidence on its relevance, this class of explanation is not discussed further here.

Possible explanations related to patterns of care (class 2) might involve differences in mother–child interaction, and there is a substantial body of work concerning both mother–infant interaction
Fig. 137.1 Failure to thrive (FTT) in infants with mothers in different social classes. The bars show the proportion of infants (with 95% confidence intervals) in a UK population cohort study whose weight gain was in the lowest 5% in different social classes (UK Registrar General's occupational classification). Sample size: 11,718 (Reprinted from Blair et al. (2004). By permission of the Oxford University Press)

and attachment patterns in FTT. Possible explanations in class 3, concerning individual food intake patterns, include differences in infant appetite or feeding behavior. These topics are dealt with in some detail next.

The last of these classes of explanation (class 4), related to the absorption of nutrients by individual children, is of importance in infants whose slow weight gain is caused by an underlying medical condition. An example is cystic fibrosis, in which there is malabsorption of proteins and fats from the gut. This leads to poor weight gain, so FTT is often one of the earliest signs of the disorder (Giglio et al. 1997). There are many other examples, but in general these are best dealt with in reviews concentrating on the individual disorders concerned, so this class of explanation will not be discussed further here.

As regards the consequences of FTT, there is now a substantial body of research on early behavioral and on later intellectual development in FTT. This is also dealt with next.

137.2 Identifying Children Who Fail to Thrive

FTT in infancy has traditionally been identified using an attained weight criterion: a low weight for age relative to the distribution of the weights of children of the same age and sex in a reference population. The criterion can be expressed in centiles (for example, a weight below the third centile) or in standard deviation units or z scores (for example, a weight more than 2 SD below the average). The exact cut-off is arbitrary. Weight is used rather than length because its measurement is more precise and because weight is more sensitive to short-term changes. Weighing is also the procedure traditionally used to monitor growth in infancy in the UK.

Although FTT is intended to refer to slow weight gain after birth, a low weight for age can result from a slow weight gain either before or after birth, or from a combination of the two, so the use of an attained weight criterion preferentially selects infants with a low birthweight (Olsen et al. 2006). This means that problems associated with a slow weight gain after birth are confused with problems associated with a low birth weight (and so also, if the infants are not specifically excluded, with problems of a preterm birth). This confusion is undesirable. It is obvious that the determinants of undernutrition before and after birth are quite different and different explanations must be sought for them. Similarly, the cognitive effects associated with a low birthweight need to be distinguished from the cognitive effects associated with slow weight gain after birth, since the prevention of the first would need quite different strategies from the prevention of the second.

The confusion can be avoided by using an attained weight criterion that is conditional on birthweight (Cole 1995, 1996; Wright et al. 1994). In principle the procedure used is to compare an infant's weight at a particular age with that of other infants of the same age, sex, and birthweight. The difference between the infant's weight and the average weights of infants of the same age, sex, and birthweight then provides a measure of relative weight gain from birth: it is zero if the infant's weight gain is average, negative if it is below average, and positive if it is above average. In practice the difference is calculated as the residual from the linear regression of the later weights on birthweights (see Key Points and Fig. 137.2). If z scores are used for the weights this gives a z score that reflects weight gain from birth, but which is independent of birthweight (and uncorrelated with it). Again the exact cut-off used has been arbitrary, usually corresponding to a weight gain from birth below the fifth centile. An important research question is whether this criterion does in fact distinguish between groups with clearly different outcomes, an issue dealt with next.

Although weight gain criteria conditional on birthweight have come into use in recent research, especially in the UK, many earlier studies have identified FTT using attained weight criteria, and so
Fig. 137.2 An illustration of the use of a weight gain criterion that is conditional on birthweight. The scatterplot shows the weight of male infants in a birth cohort at the 6–8-week check plotted against their weight at birth, each in SD (*z*) scores. Reading up on a vertical line from a particular SDS at birth there is a range of 6–8-week weights. The regression line shows the average weight at 6–8 weeks. Full circles indicate those with weight gain in the lowest 5% (Details of the cohort from which the data were taken can be found in McDougall et al. 2009)

consider groups of infants who fail to thrive but whose average birthweight is also relatively low (Sherry 1999). In some studies, these have included infants born preterm. It is important then to consider whether comparisons between these infants with low attained weight and other infants have properly controlled for birthweight, for example by using controls matched on birthweight or by regression methods, if inference concerning the importance of slow weight gain after birth are to be made; and many have not.

It is also important to consider how the children concerned were identified. The most valuable studies have screened whole populations (Blair et al. 2004; Skuse et al. 1992; Wright et al. 1994), allowing inferences that are not biased by the referral process. Many studies, however, have used groups of children identified through pediatric clinics, child psychiatrists, or child protection services. There is an obvious selection bias here, since children may be referred to such clinics not simply because their weight gain is poor but also because developmental problems or more general concerns about the family have been identified (Batchelor and Kerslake 1990).

137.3 Mother–Child Interaction

Mothers provide most of the care of young infants, and a long tradition of research in this area has examined differences in mother–child interaction between the mothers of children who fail to thrive and those of control children. Studies of this kind are time-consuming. FTT is found in only a small proportion of infants and there are no useful predictors of the families in which it will occur, so most studies of mother–child interaction in FTT have been case-control studies, in which interaction was studied after the condition has been identified. While this is understandable, it does limit the

inferences that can be made from positive findings, since it cannot in general distinguish between differences that precede the weight faltering and differences that follow it, a distinction which is of obvious importance in considering causal order.

The first controlled study of mother–child interaction was carried out by Pollitt and colleagues (Pollitt et al. 1975). Cases and controls, 16 of each, averaged 3 years old at the time of the study and the weights and heights of cases were below the third centile. When compared with the mothers of the control group the mothers of the cases showed significantly less physical and verbal interaction with their children, and they were less likely to praise them and more likely to scold, slap, or show annoyance with them.

Berkowitz and Senter (1987) selected cases with height or weight below the fifth centile or dropping over two centile lines, with controls matched on age, ethnic group, birth order, and mother's age. There were no differences between the two groups in 9 of 12 maternal behaviors. The mothers of the case children made fewer positive vocalizations and fewer responses to their infant's vocalizations. However, the infants themselves produced fewer vocalizations and it is not clear whether the smaller number of responses from the mothers resulted simply from their having fewer infant vocalizations to respond to. No differences were found in mutual interactions or mutual gazing.

Hutcheson et al. (1993) compared cases and matched controls, with raters blind both to the group membership of the children and to the research hypotheses. They found no main effect group differences on any maternal infant or dyadic interactional characteristics. There was a significant group by age interaction in maternal affective tone, which was less positive with older cases, but more positive with younger cases. This might suggest that this maternal characteristic developed as a result of the infant's FTT, rather than being a cause of it.

Another study (Drotar et al. 1990) investigated interactional behavior using the scales originally developed by Ainsworth (Ainsworth et al. 1972). Observations took place in the home when infants were around 7 months of age, and involved feeding, play, and social interaction. The case infants were clinically referred, and control infants were obtained from pediatric clinics and hospitals. The case and control groups were matched for the child's age at hospitalization, for sex, race, and birth order, for maternal education and age, and for family size, income, and structure. Selection criteria for both groups included a birthweight above 1.5 kg. This is, however, sufficiently low to include infants who were born preterm or small for gestational age, and the groups were not matched on birthweight. In all the general interaction scales, and one of the three feeding scales (termination), significantly higher ratings were given to the control group mothers than to the mothers of the infants who failed to thrive, who were less sensitive, cooperative, accepting, and accessible, showed less positive affect and emotional expressiveness during interactions, and terminated feeding episodes in a more arbitrary fashion. However, as the authors noted, differences between the groups appeared to arise because of especially high scores in the control group mothers, rather than especially low scores in the FTT group mothers. Another difficulty in interpreting this study is the lack of control for birthweight.

Puckering et al. (1995) examined mother–child interaction outside the feeding situation in a group of children with persistently poor growth from birth to 4 years. This study used a case group chosen by population screening and an equal number of controls carefully pair-matched to the cases (this included matching on birthweight). Extensive observations were made during two home visits. Mothers' behavior was rated on a positive dimension (e.g., socially interacts with child, responds positively to child, complies with child's request) and a negative dimension (e.g., conflict between mother and child, negative response to child's distress, ignores child's requests). Puckering et al. used the rating scales to obtain measures of "simple" maternal behaviors, which were simple frequency scores, and "conditional" measures, which were expressed as a proportion of the total number of child behaviors in a given category. They found significant differences between the case and control groups on three of the five simple measures for the positive dimension (total amount of social

interaction, positive responses to child, follows child's lead in interaction), but on none of the conditional measures. With respect to the negative dimension, significant differences were found on only one of the six simple measures (negative response to child's request), and on none of the conditional measures. The lack of effects on the conditional measures shows that there were no significant differences between case and control dyads once the contribution of the child to the interaction had been taken into account. The differences in mothers' simple measures of positive behaviors may have been a result of the case children's lower general cognitive ability, with these children making fewer requests and comments during interaction with their mothers.

In summary, a number of the studies comparing children who failed to thrive and controls have reported significant differences between the groups in mother–child interaction (Berkowitz and Senter 1987; Drotar et al. 1990; Hutcheson et al. 1993; Pollitt 1975). But since the quality of interaction was measured after the onset of FTT, differences between the groups in this could be either a cause or a consequence of FTT. The latter possibility is made more likely by the finding that the negative maternal affective tone seen in the mothers of older children who failed to thrive was not seen in the mothers of younger children with the condition (Hutcheson et al. 1993).

One study (Vietze et al. 1980) is therefore of special interest because it used a prospective longitudinal design (and did not rely on infants being referred). A cohort of 1,400 women was interviewed prenatally. From this cohort, 498 were selected for follow-up until the infants were 18 months of age. Infants and mothers were observed during a scheduled feeding period in the hospital soon after the birth. Infants who *subsequently* failed to thrive were identified, and the infant–mother interactions with these case infants were compared with those of control infants selected randomly from the larger sample. Four types of maternal behavior (vocalize to infant, visual attention to infant, smile at infant, touch play) and three types of infant behavior (vocalize, visual attention to mother, cry) were coded. Vietze et al. found no differences between case and control mothers in any of the prenatal assessments. After the birth, the mothers of infants who went on to fail to thrive spent significantly less time visually attending to their infants than the mothers of controls, but there were no differences between the groups in the three other indices of maternal behavior. Vietze et al. also investigated dyadic behavior, involving both mother and infant. Mother of male infants who went on to fail to thrive were more likely to terminate their responses when interacting with the infant, less likely to maintain responding in the face of lack of response from the infant, and more likely to "drop out" of the interaction. These findings seem to imply that certain types of very early dyadic behavior may relate to subsequent FTT, at least in boys. However, the case infants in this study also had significantly lower birthweights, and gestational ages at birth, than the controls. Pollitt et al. (1978) investigated relations between birthweight, infant–mother interaction, and weight gain during the first month of life. Forty categories of behavior (24 maternal and 16 infant) were analysed. While only three types of maternal behavior were associated with weight gain, ten were associated with birthweight. Maternal behavior involving social interaction, such as talking or vocalizing to the infant, was not associated with weight gain, but was associated with birthweight. These results illustrate the particular importance of proper control for birthweight in future studies in this area.

One other rather general problem with this research on mother–child interaction is the large number of measures used in each analysis, and the large number of different ways that have been used to analyze the interaction. This makes is difficult to exclude Type-1 errors (false positives), and to assess the replicability of results. These problems are not shared with research on attachment, in which a single procedure, the strange situation, with a single outcome variable, has been used in most of the published studies (Chatoor et al. 1998; Crittenden 1987; Gordon and Corcoran Jameson 1979; Ward et al. 1993, 2000). Each of these studies shows a higher rate of insecure attachment in the FTT group children than in a control group, though the differences were not all statistically significant within each study, some of which were rather small.
Fig. 137.3 Weight gain over the first year in a 1-year birth cohort of children identified as failing to thrive and a control group (mean *z* scores with 95% CIs). All cases whose weight gain was in the lowest 5% over the first 18 months are included and an equal number of controls (*N* = 270). Note that relative to controls the weight gain of the cases was very poor from birth (Reprinted from Drewett et al. (1999). By permission of Wiley-Blackwell)

These studies all used referred children with the associated problems of referral bias. In one case (Crittenden 1987) the children came from families receiving child protection services and they had a substantiated history of child abuse or neglect. Not surprisingly they also had very high rates of insecure attachment (94%), but this may be a consequence of the history of abuse and neglect rather than a consequence of FTT. There is, however, an interesting corroboration of this relationship between poor weight gain and insecure attachment in a study from a poor area of Chile, in which children were screened via routine data collected in well baby clinics, so that there was no obvious referral bias. Only 7% of 41 underweight children were securely attached, compared with 50% of 40 control children.

There probably is an association here, but we cannot assume from the association that insecure attachment leads to FTT. Attachment develops in the second half of the first year, while FTT, when its course has been examined (Drewett et al. 1999), often develops from birth (Fig. 137.3). It follows that insecure attachment is unlikely to be a cause of FTT. It could be a consequence of it.

137.4   Nutrition and Feeding Behavior

Except cases in which an underlying medical disorder is associated with reduced absorption of food components, any explanation of FTT has to explain why the food intake of the child is lower than is necessary to maintain a normal level of weight gain. Direct evidence for reduced food intake among children who fail to thrive is not easy to find, however, principally because of the usual difficulty of measuring nutritional intake in natural situations over extended periods. Over individual meals it can be measured accurately, and their energy intake is substantially lower than that of age-matched controls (Drewett et al. 2002; Parkinson et al. 2004). Explanation of this difference requires detailed observational studies of the child's feeding.

After the first few weeks of life, microanalysis of food intake in infants is not simple, because for most of the first year they are in the weaning period, in which infants are in a transition from feeding on milk to feeding on solid foods, and from being fed by a mother or other carer to feeding independently. The age of the infant is therefore a key variable, and any analysis must be able to deal with the various components of mealtime behavior over the weaning period. In dealing with solid food there are three possible components. First, the mother or other carer may feed the infant, for example, by putting a spoonful of food into a child's mouth. Second, the infant may feed independently, essentially in the same way as an adult does, for example by pushing a spoon into a bowl of food and then eating the food from the spoon. Third, the mother or other carer may facilitate food intake while not actually feeding the child, for example, by picking up a biscuit and handing it to the child for the child to eat. These components may vary over time, from meal to meal, and with different food types. It follows that a general coding scheme for the microanalysis of food intake over the weaning period must be able to handle all three. A coding scheme of this kind has been developed by Parkinson and Drewett (2001). Some of the coding elements are shown in Fig. 137.4; they correspond to the three possible components of weanlings' meals given earlier.

This coding method has been used to examine food intake in children who fail to thrive (Drewett et al. 2002; Parkinson et al. 2004). Energy intake was significantly lower in children who failed to thrive than in controls of the same age in both studies. In Drewett et al. (2002), there were also identifiable differences in the feeding components. The case (FTT) children fed themselves significantly less often, and although they were given or handed food equally often by their mothers, they refused it more often, suggesting that it is a lower appetite in the children that was responsible for their slower weight gain, as mothers' own reports often suggest (Wilensky et al. 1996). There were, however, no clear differences in the study of Parkinson et al. (2004). The difference may be because the cases in the earlier study were recruited via a specialist clinical service, while the cases in the later study were recruited by the screening of a whole birth cohort. Children with obvious feeding problems tend to be more readily identified as failing to thrive in clinical practice than children with the same poor weight gain who do not have obvious feeding problems (Batchelor and Kerslake 1990).

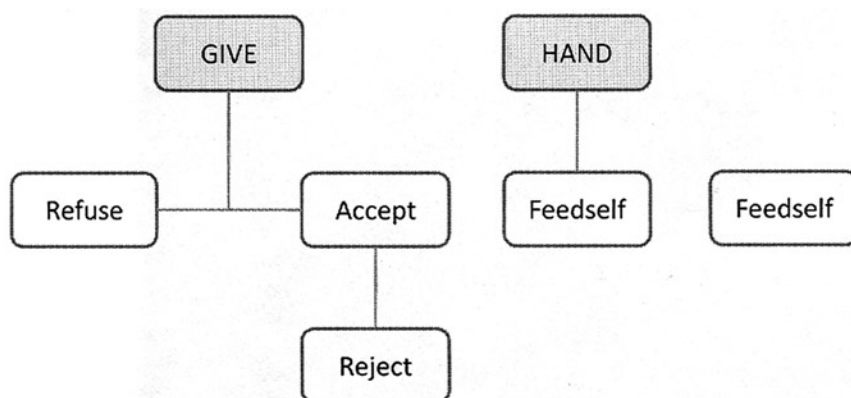
A follow-up of all infants who met the criterion for FTT in a 1-year birth cohort in a single large northern city in the UK (Newcastle-upon-Tyne) showed that these children were shorter than con-


Fig. 137.4 Simplified representation of a coding scheme for the microanalysis of feeding behavior in the weaning period, based on coding scheme in Parkinson and Drewett (2001). During the weaning period infants may be fed by the mother; or they may feed themselves with some assistance from the mother; or they may feed themselves without assistance. Code sequences for each are illustrated. The two capitalized elements (GIVE, HAND) code carer behavior; the other elements (Refuse, Accept, Reject, Feedself) code the child's behavior

trols at 12 years of age, and also had a lower average body mass index (BMI) (Drewett et al. 2006). This suggests that they would be less likely to become overweight or obese. Probably as a consequence, they also showed higher levels of body satisfaction. The same study examined anxiety, depression, and self-esteem using the children and both their teachers and parents as informants, but there was no evidence of any difference in any of these measures. The children did, however, themselves report that their appetites were low compared with that of their best friend.

137.5 Intellectual Development

The most clearly documented adverse effect associated with FTT is reduced intellectual ability. This is detectable as slightly delayed development in infancy and early childhood and as a slightly lower measured intelligence in later childhood. There are currently no studies examining intellectual sequelae in adults. Figure 137.5 shows a summary of controlled studies in children (Corbett and Drewett 2004). Three of these studies used cases referred to hospitals or specialist clinics, and the mean deficit in these was about 13 IQ points. Seven used cases identified by the screening of whole populations, and the mean deficit in these was 4 IQ points.

Although this is no longer considered appropriate (Spencer 2007) historically developmental delay has often been used in clinical practice as an identifying criterion for FTT, so it is not surprising that the deficit is greater in the studies in which clinically identified cases have been used. The studies
Fig. 137.5 Results of a meta-analysis of studies of intellectual sequelae of failure to thrive in infants and young children. All the studies compare an affected group and a control group, and used IQ tests, except for Wilensky et al. (1996) who used Bayley Scales. The standardized mean difference and its 95% CI are shown for each study. The top N three studies used cases identified through hospital or other specialist clinics. In the other studies recruitment was through primary care clinics by whole population screening (Reprinted from Corbett and Drewett (2004). By permission of Wiley-Blackwell)

using whole-population screening based solely on anthropometric criteria provide a more generalizable estimate of the average intellectual deficit associated with FTT, which is about 4 IQ points.

A subsequent and entirely independent estimate comes from data collected in the ALSPAC study (Emond et al. 2007). This is a large population-based birth cohort study located in Avon in southwest England. In this study the deficit (based on 258 cases and 5510 controls) was 3 IQ points, which is reasonably close to the previously published value based on the meta-analysis of earlier studies (4 IQ points). This study examined separately the relationship of IQ with slow growth over the first 6 weeks and over the remainder of the first year. Strikingly, there was a strong association with weight gain over the first 6 weeks, but no association at all with weight gain over the later part of the first year (Fig. 137.6). A similarly early sensitive period has been shown for the relationship between slow weight gain and developmental delay in infancy (Skuse et al. 1994). Equally strikingly, the relationship between weight gain in the early period and later IQ in the ALSPAC study is approximately linear over the whole range of weight gains (Fig. 137.6). At least in considering this relationship, therefore, there is in fact no threshold value which separates out a group of slowly growing children who are at risk of intellectual deficits from a larger group who are not. The traditional cut-point is entirely arbitrary.

Observational studies of this kind can never provide certainty concerning causal relationships. It is possible that some underlying medical condition leads both to lower measured intelligence and to a lower food intake, giving rise to the association between lower IQ and FTT, but to date no candidate condition has been put forward, and it is hard to think of a condition that would have this graded effect across the whole range of weight gains. It is probably more likely that we are dealing here with a graded nutritional effect restricted to a sensitive period just after birth, and that it is related to a similar graded nutritional effect just before birth. For many years it has been difficult to disentangle the intellectual sequelae of a preterm birth and those of being born small for gestational age (Drewett 2007). But there is now clearly replicated evidence that birthweight is related to later intellectual development even in infants born at term (Shenkin et al. 2004). This relationship also has no thresh-
Fig. 137.6 Relationship between measured intelligence in childhood and weight gain soon after birth and later in the first year. The graph shows (*diamonds*) measured intelligence at 8 years plotted against weight gain from birth to 8 weeks (*F* = 36.09, *p* < 0.0001) and (*squares*) measured intelligence at 8 years plotted against weight gain from 8 weeks to 9 months (not significant). *N* is >7000 (Data from Emond et al. (2007), where details of control variables can also be found)

old corresponding to the traditional criterion of a low birthweight infant (a birthweight below 2,500 g). Over the whole range of birthweights measured intelligence increases with increased birthweight. The overall raw difference is about 10 IQ points. It is a plausible hypothesis, then, that later IQ is particularly sensitive to nutritional substrates just before or just after birth, and that we are dealing here with a single graded effect of nutrition on intellectual development, though its determinants are of course quite different before and after birth.

Weight monitoring of infants in primary care may serve a variety of purposes. It may, for example, identify medical conditions that would not otherwise be identified, at any rate so early in life. Whether it is effective or cost-effective for this purpose has yet to be determined. If, as the evidence suggests, it is the early weeks after birth that are important in the relationship between weight gain and intellectual development, then as regards intellectual outcomes most weight monitoring in the UK is likely to identify the condition too late for intervention to be effective. Procedures for identifying slow weight gain that are conditional on birthweight can identify it at the earliest point at which the relevant weights are generally available, the 6–8-week medical check (McDougall et al. 2009). But even this would be too late for effective intervention. The implication is that for this purpose it is not screening and treating that will be the key to progress, but primary prevention.

137.6 Application to Other Areas of Health and Disease

Conditional weight gain measurements of the kind used in recent research on FTT are based on entirely general statistical procedures (Healy 1974). They are not restricted to identifying changes from birth. Weight faltering can be identified over any period, and the methods used can be used in any context in which a measure of weight gain is needed that is independent of a starting weight. One might expect them to be of value in research concerning the predictors in infancy of later obesity, for example. The difference would be that infants with the fastest weight gain would be of special interest, rather than the infants with the slowest weight gain. They may also be of value in research concerning nutritional aspects of some medical conditions. An example is sickle cell anemia. The average IQ in children with sickle cell anemia in the UK is about 5 points lower than that of their siblings (Knight et al. 1995). Although there is evidence of direct central nervous system damage in this disorder, growth retardation in children with sickle cell disease in significant over the first 2 years and it is related to the child's IQ (Knight et al. 1995). It would be of value to know whether the sensitive periods over which poor weight gain is associated with lower IQ in FTT are also important in this condition.

In light of the evidence given here of an early sensitive period for intellectual development, the importance of the common loss of weight in the first 10 days after birth (Wright and Parkinson 2004) might also need to be reconsidered. Weight loss in the days immediately following birth in otherwise healthy infants is not usually considered of any particular importance. A recent study, however (James et al. 2007), showed that the loss or gain of weight over this period is directly related to the infant's milk intake (Fig. 137.7). So weight gain over this period depends on nutritional intake just as it does at other times, and there is no reason to ignore the nutritional importance of this period in relation to later intellectual development. Improving support for the very early stages of breastfeeding may have benefits beyond those for physical health. It needs to be born in mind, however, that different weight gain trajectories in infancy do not necessarily have consequences that are all desirable or all undesirable. Just as FTT in infancy is associated with shorter stature but also with lower adiposity and better body image in the pubertal period (Drewett et al. 2006), so faster weight gain in infancy is associated with a slightly higher IQ, but also with a greater risk of obesity (Reilly et al. 2005).
Fig. 137.7 Relationship between milk intake and weight gain immediately after birth. Weight change over the first 7 days of life plotted against mean daily milk intake. The weight change measure is the residual in grams from the regression of weight on day 7 on weight at birth. *N* is 89. The line is a locally estimated (lowess) regression line (Reprinted from James et al. (2007). By permission of Wolters Kluwer Health)

Summary Points

- FTT is a term used for infants and young children whose weight gain is unusually slow.
- As the term is intended to refer to weight gain after birth, it needs to be identified using a measure of weight gain after birth. Most suitable is a conditional weight gain measure taking into account the infants' birthweight and their sex. This avoids the confounding of prenatal and postnatal weight gain.
- The use of children clinically identified as failing to thrive in subsequent research generally overestimates the adverse sequelae of slow weight gain owing to biases in the identification and referral process. Identification by whole population screening provides more representative results.
- There is some evidence that slow weight gain in infancy is associated with different patterns of mother–child interaction, and reasonably good evidence that it is associated with insecure attachment. There is some evidence that it is associated with lower food intake, perhaps resulting from a lower appetite.
- There is good evidence that it is associated with developmental delay in infancy and a slightly reduced IQ at school age. This is, however, a graded effect. Higher IQ is associated with faster weight gain across the whole of its range.
- The effect is specific to weight gain in the first 6–8 weeks of life. Current weight monitoring practice in the UK is unlikely to detect weight faltering in time for preventative interventions to be effective as regards intellectual development.

Key Points: Weight and Weight Gain in Infancy

To understand the significance of an infant's weight it needs to be related to that of other infants of the same age and sex (the reference population). This can be achieved by expressing the infant's weight as a centile, which is typically done in clinical practice by plotting it on a growth chart. Alternatively, it can be expressed as a standard deviation (SD) or z score, which is more common in scientific work.

The reference population can be the one from which the infant is drawn, or an external reference population, such as the infants whose weights are summarized in the UK 1990 reference curves (Freeman et al. 1995).

An infant with a low weight for age relative to the reference population (e.g., with an z score below – 1.645, corresponding to the fifth centile) has gained weight more slowly since conception than most of the population, but not necessarily gained weight more slowly since birth.

The difference between an infant's z score for weight and their z score at birth is a measure of weight gain from birth, but is not easily interpreted as infants with different birthweights gain weight at different rates. The average weight at a given later age of infants of different birthweights can be established using the linear regression of later weights on birthweights:

$$Z_2 = \beta_0 + \beta_1 (Z_1) + e,$$

$$e \sim N(0, s).$$

Here Z_2 is the average weight at the later age of infants whose weight at birth is Z_1. Infants vary around the average, a variation summarized in the error term or residual (e), which has a normal distribution with a mean of zero and a standard deviation s. It is sometimes called a "thrive index" in this context (Wright et al. 1994). Because the weights are used in the form of standard scores (Z_1 and Z_2) the value b_0 will be close to 0 (so the term can generally be omitted) and b_1 will correspond to the correlation coefficient. A value of e below $-1.645s$ then indicates that the infant's weight gain was below the fifth centile.

Figure 137.2 shows the application of this procedure to male infants in an actual 1-year birth cohort to identify those whose weight gain was poor over the time from birth up to the 6–8 weeks medical check. It identified the infants with the slowest weight gain (the slowest 5%), as shown. Note that these infants were identified prospectively, using an external weight gain standard and regression line, not retrospectively, using data from the sample.

The method has been generalized so that any initial or final age can be used (Cole 1996), and a corresponding graphical method has also been developed for clinical use (Wright et al. 1998b).

Key Terms

Failure to thrive: Term used in pediatrics of infants whose growth is unusually slow. It is now generally identified using exclusively anthropometric criteria, though other criteria, especially developmental delay, have been used historically. Growth monitoring in infancy relies heavily on weighing, and slow weight gain or a low attained weight are the most generally used criteria for FTT.

Body mass index: An indirect measure of adiposity, calculated as weight (in kg) divided by height (in m) squared.

Intelligence quotient: A measure of intellectual ability from an intelligence test, such as the Wechsler Intelligence Test for Children (WISC). In populations similar to those on which the test has been standardized it has a mean of about 100 and a standard deviation of about 15.

Sensitive period: An age range over which a variable is particularly likely to affect development.

Weight faltering: A term used as an alternative to "FTT." It is essentially equivalent to "unusually slow weight gain." "Growth faltering" is a more general term and might also involve other anthropometric measurements.

138.1 Introduction

Video game play is a common leisure activity from childhood through mid-adulthood (Yee 2006; Nielson Company 2007). A majority of households (65%) in the U.S. currently have a video game console. It is expected that by 2012 nearly 200 million U.S. households will have one of the newest next generation game consoles and that 80% of these will be connected to the internet (GRABstats. com 2009).

Teenage males have the highest (88%) access to games in the home (Nielson Company 2007). However, although video games used to be mostly within the purview of adolescent males, their appeal has grown among women and the middle-aged (e.g., Yee 2006; Nielsen Company 2007; GRABstats.com 2009). In 2008, over a quarter (26%) of Americans over 50 years of age played video games regularly. And while males do spend significantly more time playing video games than females (e.g., Roberts and Foehr 2004), 40% of video game players are women (GRABstats.com 2009). Sports, role playing, and first person shooter games are the most popular (Ballard and Visser 2009). See Table 138.1 for *Rates of Video Game Play*, Table 138.2 for *Most Frequently Played Game Genres*, and Table 138.3 for *Key Facts about Video Game Play and MMORPG Play*.

Since video game use is becoming ubiquitous, it is important to examine the potential health effects of heavy video game play (Brown and Witherspoon 2002). Most of the research concerning

Table 138.1 Video game play usage by age and gender

Percentage of video game play by age and gender[a]	Males	Females	Total
Ages 17 and under	17%	8%	25%
Ages 18–49	NA	NA	49%
Ages 50 and up	NA	NA	26%
Ages 18 and up inclusive	42%	33%	75%

This table includes data on video game usage for males and females both overall and from four lifespan age groups

[a]Source for statisitics: GRABstats.com 2009

Table 138.2 Most frequently played video game genres among males by age group (Source for statistics: Ballard and Visser 2009)

Game genre	Adolescent males (14–17 years)	Young adult males (18–25 years)
Sports	21.4%	40.6%
First person shooter	22.9%	22.8%
Role playing	18.6%	7.9%
Fighting	15.7%	5.0%
Racing	4.3%	5.9%
MMORPG	5.0%	2.0%
Strategy	5.8%	5.0%
Music	1.4%	3.0%
Puzzle	0%	1%
Other	4.9%	6.8%

This table includes data regarding the most frequently played video game genres among adolescent (ages 14–17) and young adult (ages 18–22) males

Table 138.3 Key facts about video game play and MMORPG play

1. Most households in the U.S. have a video game console.
2. More males than females play video games, but an increasing number of women are regularly playing video games.
3. Adolescents and young adults play video games more often than those of other developmental statuses, but game play is increasing among children and those in middle age.
4. There is a wide variety of video game genres including sports, fighting, action/war, music, racing, strategy, puzzles, and role-playing games.
5. Historically most video games have been played in a sedentary fashion, but newer game consoles allow for physically active game play.
6. Massively multiplayer online role playing games (MMORPGs), which are played in a virtual world by a large number of players at once, have recently burgeoned in popularity.
7. MMORPG players create avatars and take on roles (e.g., shaman, soldier) in a virtual community; avatars progress through a variety of levels and accumulate goods and wealth.
8. MMORPG players report that they come to depend on one another and often feel responsible for being online for many hours per week in case the services of their avatar are needed by others. Some MMORPG players spend more time playing than working.
9. Researchers have found a number of both negative (hostility, aggression) and positive (cognitive gains, improved mood) affects of both console and online video game play.

This table provides key facts about video game play and MMORPG play

video games has focused on their potential impact on aggression and hostility. There is evidence that violent video game play can result in negative affect, including hostility, and increases in aggressive cognitions and behavior (see Ballard et al. 2006 for a review). However, when played in a social context, even violent video games can be tied to positive emotions and to positive responses

toward playing partners (Ballard and Visser 2009). While previous research examining hostility and aggression has been tangentially related to health issues, there is some recent research that examines the impact of video game play on health factors more directly. Historically, much of the research examining the link between media use and physical health correlates has focused on television (TV). This is likely due to the fact that, until recently, there have been much higher rates of household access for TV than for video games (Motl et al. 2006). However, over the past few years there has been increased interest in the impact of video game play on eating, body weight, and activity levels. This research has focused on two types of gaming: traditional sedentary video game play and physically active video game play. This review will address (a) rates of obesity, overweight and physical activity in the U.S.A, (b) correlations between sedentary media use and overweight and obesity, (c) hypotheses and evidence regarding sedentary media use, obesity, and activity levels, (d) evidence regarding physically active video game play, (e) applications for health, and (f) directions for research.

138.2 Rates of Overweight and Obesity and Physical Activity

Rates of obesity have risen steadily in developed countries over the past few decades (Center for Disease Control (CDC) 2006; Trust for America's Health (TAH) 2009). In the U.S., 15.5% of children, 15.3% of adolescents, and 30.5% of adults are classified as obese (American Obesity Association (AOA) 2005). When overweight children and adults are included, these statistics increase to 45.5% for children and adolescents and 67% for adults (TAH 2009). See Table 138.4, *Key Facts about Obesity*. Many variables, including biological factors and diet, play a role in an individual's weight retention. However, recent changes in lifestyle – many Americans have increased their caloric consumption, but decreased their energy expenditure – may account for much of the recent increase in obesity (e.g., Hill et al. 2005). Lower levels of physical activity are clearly related to higher levels of body fat and higher body mass index (BMI; Stallmann-Jorgensen et al. 2007; Ballard et al. 2009). Physical activity may be declining in part because people spend more time engaged in sedentary behaviors (Nelson et al. 2007). Most American adults (53%) do not participate in regular physical activity and many (25%) are not active at all (CDC 2006). Only 22% of adults engage in the recommended amount of physical activity. Similarly, less than one-third of children engage in regular, intense physical activity (TAH 2009). Since both physical inactivity and obesity increase the risk of a host of problems across domains of functioning (e.g., health, psychological, and social problems; AOA 2005; Hill et al. 2005), these trends are of grave concern. For example, recent increases in rates of diabetes – among both children and adults – and high blood pressure are thought to be related to increases in obesity (TAH 2009).

Table 138.4 Key facts about obesity by age group (Source for statistics: TAH 2008)

	Children and adolescents	Adults
Percentage overweight	30.1	36.5
Percentage obese	15.5	30.5
Total overweight + obese	45.5	67.5

This Table provides information about the percentage of children, adolescents, and adults who are overweight and/or obese

138.3 Correlations Between Sedentary Media Use and Overweight and Obesity

A number of studies suggest that sedentary media use is a risk factor for obesity across the lifespan and across cultures (Proctor et al. 2003; Jago et al. 2005; Parsons et al. 2005; Heelan and Eisenmann 2006; Nelson et al. 2007; Stallmann-Jorgensen et al. 2007; Thomson et al. 2008).

TV Screen Time and Overweight and Obesity. Most studies have examined TV screen time and have found that time spent watching TV was significantly, positively correlated with weight, BMI, and/or percent body fat among children, adolescents, and adults in the U.S.A, France, Canada, and Great Britain (Lowry et al. 2002; Jago et al. 2005; Parsons et al. 2005; Heelan and Eisenmann 2006; Stallmann-Jorgensen et al. 2007; Nelson et al. 2007; Thomson et al. 2008)). However, using a cross-sectional design, Vandewater et al. (2004) failed to find a relationship between TV screen time and BMI among the children in their sample. But longitudinal evidence suggests that the relationship between TV screen time and BMI increases over time. For example, in a longitudinal study in Great Britain, Parsons and colleagues (2005) found that the relationship between TV viewing and BMI increased across time; there was a stronger positive relationship between TV viewing and BMI among their participants in adulthood than there had been in childhood or adolescence. Similarly, in a longitudinal study among American children who were followed from the preschool years through adolescence, Proctor and colleagues (2003) found that heavy TV viewing was a good predictor of increased body fat across time; that is, children who watched the most TV had the greatest increases in body fat across the course of the study. Several studies reported stronger correlations between TV screen time and BMI among females than among their male counterparts (Lowry et al. 2002; Oppert et al. 2005; Parsons et al. 2005). Media use may be a better predictor of weight status in females because they spend more time inside engaging in sedentary activities than do males (e.g., Hager 2006) and because males have higher activity levels in general (e.g., Mhurchu et al. 2008).

Time Spent in Video Game Play and Overweight and Obesity. Thus far, only a few studies have examined links between video game play and BMI. Both Ballard and colleagues (2009) and Vandewater and colleagues (2004) found significant positive correlations between rates of video game play and weight status. Specifically, Ballard and colleagues (2009) found that length of video game play during one sitting was significantly, positively related to BMI (see Fig. 138.1). The frequency of massively multiplayer online role-playing game play (MMORPG play; e.g., World of Warcraft) was significantly, positively correlated with BMI (Ballard et al. 2009; see Fig. 138.2). There was a stronger relationship between MMORPG play and BMI than console play and BMI. Contextual factors related to these different types of gaming might be related. For example, time spent playing a lengthy session of online computer games, which often move slowly and are controlled with one hand, can be more conducive to snacking than playing console games, which require rapid manipulation of a controller using both hands. Increased snacking is one of the factors hypothesized to mediate the link between media use and increased risk of obesity. Refer to Table 138.5 for correlations between overall game play, MMORPG play, BMI, body fat %, and exercise.

138.4 Hypotheses Regarding Media Use, Obesity, and Activity Levels

Robinson (2001) and Vandewater and colleagues (2004) posit three mechanisms to explain why sedentary media use is likely to increase the risk of overweight and obesity. The first is the "couch potato" hypothesis, which suggests that time spent engaged in media use displaces the time available
Fig. 138.1 Body mass index as a function of the length of playing video games in one sitting. The longer participants spent playing videogames in an average session, the higher their average BMI. Results are expressed in terms of how BMI is related to how long on average, in min, participants reported playing MMORPGs (Drawn from Ballard et al. 2009)
Fig. 138.2 Body mass index as a function of the frequency of playing MMORPG games. While most participant did not play MMORPGs, among MMORPG players the frequency of playing online games was related to higher BMI. Results are expressed in terms of how BMI is related to how many times in 1 week participants reported playing MMORPGs

for physical activity. Vandewater and colleagues (2004) suggest that this hypothesis could explain the link between obesity and various types of electronic media, including TV, video games, and the internet. The second hypothesis proposes that people engage in increased consumption of high calorie foods while engaged in media use, particularly while watching television. While this hypothesis

Table 138.5 Correlations between all video game play, MMORPG play, BMI, body fat, and exercise (Source for statistics: Ballard et al. 2009)

	1	2	3	4	5	6
1. Frequency of video game play	–	0.28**	0.14	0.11	0.00	−0.21*
2. Length of average game session	0.29**	–	0.27**	0.15	−0.21*	−0.06
3. BMI	0.29**	0.35***	–	0.21*	−0.19*	−0.08
4. Body fat %	0.15	0.26*	0.21*	–	−0.11	−0.08
5. Frequency of exercise	−0.12	−0.47***	−0.19*	−0.10	–	0.35***
6. Length of average exercise session	−0.04	−0.05	−0.08	−0.08	0.36***	–

This table provides correlations between the frequency and length of video game play, BMI, body fat %, and frequency and length of exercise among adolescent and young adult males. Correlations above the diagonal represent all video game play. Correlations below the diagonal represent MMORPG play

$*p < 0.05, **p < 0.01, ***p < 0.001$

may not be as salient regarding those playing video games using a hand-held controller as it is to those watching TV, it might be relevant when considering games played on a computer or via the internet (Ballard et al. 2009). The third hypothesis suggests that decreases in metabolic rate may occur as a result of reduced activity levels during media use, leading to more rapid weight gain (Klesges et al. 1993; Robinson 2001; Vandewater et al. 2004). The research examining these hypotheses is summarized next.

138.5 Sedentary Media Use and the "Couch Potato" Hypothesis

The "couch potato" hypothesis claims that media use displaces time that might be spent in other, more physically active or constructive endeavors. Media activities can be intrinsically enjoyable and rewarding. Players report that they typically play for an hour or more in one sitting (Ballard et al. 2009). Some media, particularly video games, may result in a sense of flow (i.e., pleasurable immersion in everyday activities) causing players to lose track of time (e.g., Sherry 2004). If this occurs, players may spend more time engaging in the media activity than planned and fail to complete other tasks. There is also evidence that media is used to procrastinate or avoid other responsibilities (Klassen and Kuzucu 2009). However, there is mixed evidence as to whether media use actually displaces time that might otherwise be spent in physical activity.

Ballard and colleagues (2009) examined the hypothesis that media use displaces time for physical activity among 116 male undergraduates. Of these, 26 reported frequent MMORPG play. Overall, frequency of video game play was significantly, negatively correlated with length of exercising. Length of typical video game play during one sitting was significantly negatively correlated with both frequency of exercise and days of walking. However, exploratory analyses indicated that game type seems to mediate the association between game play and exercise. The frequency of playing sports video games was significantly, positively related to the frequency of exercise and days of vigorous physical activity. Conversely, length of playing MMORPG games during one sitting was significantly, negatively related with frequency of exercise (Ballard et al. 2009). This is particularly interesting since MMORPG play was more strongly linked to high BMI than video game play in general. Sessions of online play tend to be longer than sessions of console play and may be more likely to interfere with other activities (e.g., Yee 2006). Vandewater and colleagues (2004) found that both the most active and the least active adolescents in their study played higher rates of video games than did moderately active children. Likewise, the adolescents in the lowest and the highest weight statuses played more video games than did adolescents in the mid-weight range.

In terms of other media, several studies (Lowry et al. 2002; Vandewater et al. 2004; Jago et al. 2005; Motl et al. 2006) found significant negative correlations between TV screen time and activity among adolescents. However, Ballard and colleagues (2009) found that among undergraduates an increased frequency of watching visual media (TV, DVDs, films, etc.) predicted an increased frequency of exercise, accounting for 5.6% of the variance. Other studies also failed to find a negative relationship between media use and physical activity (e.g., Van de Bulck 2000; Parsons et al. 2005; Heelan and Eisenmann 2006; Laurson et al. 2008). Similar to Ballard and colleagues (2009), Snoek and collegues (2006) found a significant positive correlation between TV screen time and physical activity for undergraduates. Finally, Van de Bulck (2000) reports that Flemish youth were just as likely to be involved in sports regardless of levels of media use.

Thus, the literature is unclear as to the impact of media use on physical activity; there may be several personality or other individual difference variables that mediate the relationship between media use and activity levels. There is evidence that heavy users of one media type also tend to use other types of media heavily (Roberts and Foehr 2004; Ballard et al. 2009). Lanningham-Foster and colleagues (2006) argue that most individuals who engage in heavy media use are likely to replace media use with other sedentary behaviors rather than with more physically demanding activities. Ballard and colleagues (2009) examined whether video game play was correlated with other media use to help test the displacement hypothesis. The frequency of video game play was not related to the use of other media (i.e., reading for enjoyment or watching TV, DVDs, etc.). However, length of video game play during one sitting was significantly, positively related to time spent reading for enjoyment and significantly, but negatively related to watching TV, DVDs, or films. Ballard and colleagues (2009) suggest that people may displace one type of media use with another and that different game genres (e.g., sports games versus MMORPGs) may displace activities differentially.

138.6 Sedentary Media Use and Increased Caloric Intake

The second hypothesis posited to explain the relationship between media use and obesity suggests that caloric intake increases during media screen time (Van den Bulck 2000; Brown and Witherspoon 2002; Snoek et al. 2006; Thomson et al. 2008). This hypothesis has been primarily examined with regard to television, but there is evidence that children eat more snacks while watching TV than when playing video games, playing on the computer, reading, or doing homework (Gorley et al. 2004; Matheson et al. 2004). A number of studies indicate that TV screen time is positively related to increased snacking, particularly in regard to energy dense snack foods (high in fat and/or sugar) and high calorie drinks (Van den Bulck 2000; Gore et al. 2003; Snoek et al. 2006; Thomson et al. 2008). Further, about one third of children's meals were eaten while watching TV (Matheson et al. 2004). Snacking while watching TV was associated with higher caloric intake and more calories from fat than snacking at other times, but there was no difference in caloric intake or calories from fat while eating meals, regardless of where meals were eaten (Gore et al. 2003). However, children were less likely to eat healthy foods, such as vegetables, while watching TV than at other times (Matheson et al. 2004). TV advertisements tend to promote high fat foods that are low in nutritional value and could contribute to this trend (Vandewater et al. 2004; Powell et al. 2007; Thomson et al. 2008). Thomson and colleagues report that snack food slogan recognition accounted for a significant amount of the variance in the relationship between TV viewing and unhealthy snacking. Children who do consume more calories from fat while watching TV have a significantly higher BMI (Matheson et al. 2004) and engage in significantly less physical activity (Snoek et al. 2006), which would moderate the relationship between snacking and BMI. In sum, while a significant portion of

children's daily caloric intake takes place in front of the TV screen, studies indicate that very little (<1%) of their caloric intake takes place while playing video games (Matheson et al. 2004; Roberts and Foehr 2004). However, the few studies that have examined video games and snacking have focused on console games, which are played using a controller in both hands, and have not examined snacking during the play of online games.

138.7 Sedentary Media Use and Decreased Metabolic Rate

The third hypothesis regarding the association between media use and obesity posits that increased screen time results in decreases in metabolic rate (e.g., Klesges et al. 1993). Only a few studies have examined this hypothesis. In one study Klesges and colleagues (1993) found that regardless of normal versus overweight weight status, girls' metabolic rate decreased significantly during TV viewing as opposed to when they were at rest. However, a second study comparing rest, reading, and TV viewing did not replicate these findings (Cooper et al. 2006).

Research on video games suggests that even sedentary game play increases physiological arousal and metabolic function (e.g., Ballard et al. 2006; Lanningham-Foster et al. 2006; Wang and Perry 2006; Mark and Janssen 2008). Lanningham-Foster and colleagues (2006) report that playing console video games while seated significantly increased energy expenditure over baseline levels. Similarly, Wang and Perry (2006) found that heart rate, systolic and diastolic blood pressure, oxygen consumption, respiratory rate, and energy expenditure all increased from baseline during seated console video game play. In a brief longitudinal study, Ballard and colleagues (2006) found similar results with regard to cardiovascular reactivity, but also found that desensitization occurred and arousal diminished with repeated instances of game play. Physically active video game play has stronger effects on arousal and metabolism (e.g., Lanningham-Foster et al. 2006).

138.8 Correlates of Physically Active Video Game Play

Physically Active Video Game Systems. The first physically active video game to attain popularity was Dance Dance Revolution (DDR). DDR, which began as an arcade game, requires players to use whole body movement to follow increasingly complex dance patterns on a weight-sensitive mat. The game can be played individually or competitively. More recently DDR has been adapted for home gaming systems. Another active gaming system that has attained some popularity is Sony's EyeToy. The EyeToy uses a USB camera mounted on the TV to integrate the player's image into the game. The player's movements control the flow of games including boxing, dancing, and biking.

The newest and most popular physically active gaming system is the Nintendo Wii. The Wii offers a variety of games (e.g., golf, tennis, and boxing) that require the participant to mimic the motions of each activity with a hand-held wireless remote and/or using a weight and balance sensitive pad (e.g., yoga; Nintendo Wii 2007). Typically the primary controller is held in the dominant hand and a secondary controller, the nunchuk, is held in the nondominant hand. Some games only require use of the primary controller and other games require both controllers. Typically the dominant hand is used more in controlling game play (e.g., baseball, tennis, bowling), but some games (e.g., boxing) require equal use of both hands.

Research on Physically Active Games. A number of recent studies have found significantly higher energy expenditure and/or physiological reactivity during the play of video games that promote

physical activity than during sedentary game play (Lanningham-Foster et al. 2006; Unnithan et al. 2006; Exner et al. 2009). Several of these studies will be described in detail.

Using a cross-sectional design, Maddison and colleagues (2007) examined energy expenditure while playing physically active video games, such as DDR and EyeToy Knockout, as compared with nonactive console games. Energy expenditure was measured via oxygen consumption (VO_2). Heart rate and activity counts were also gathered. Not only did playing the physically active games result in significantly more energy expenditure than the console games, the physically active games required as much energy expenditure as are typically reported during moderately intense physical activities such as brisk walking and jogging. A second longitudinal study found similar results (Mhurchu et al. 2008). In addition, the children who were randomly assigned to the active video game group showed decreases in overall video game play, increases in physical activity, and decreases in levels of body fat, suggesting that active game play facilitated interest in other activities.

In a similar study, Lanningham-Foster and colleagues (2006) had 8–12-year-old children play either a traditional console video game while seated or one of two physically active video games (EyeToy Nicktoons Movin' or DDR). Children's energy expenditure increased significantly above baseline levels even when they played the seated console game. However, when they played the active games energy expenditure was significantly higher than when they played the seated game. In fact, energy expenditure more than doubled when children played the active game and was equivalent to what the energy expenditure children typically demonstrate when playing actively outside. Children who were obese had, in absolute terms, significantly higher energy expenditure when playing activity-promoting games than did lean children. Lanningham-Foster and colleagues (2006) found similar results in a study with adult participants.

Graves et al. (2008) examined the relationship between energy expenditure and upper limb/total body movement during active video game play. Adolescents, aged 11–17 years, played a seated racing game on the XBOX 360 and three Wii Sports games (tennis, bowling, and boxing). Upper limb and body movement were significantly greater when the adolescents played the Wii games than when they played the sedentary racing game. As a result, adolescents' heart rate and energy expenditure were significantly higher when they played the Wii Sports games than when they played the sedentary racing game. The use of the nondominant arm was greater when playing the boxing game. Subsequently, heart rate and energy expenditure were significantly higher during the Wii boxing game than the Wii bowling or tennis games.

Using a complex design, Epstein and colleagues (2007) completed a study where children played a bicycling or dancing game. Both games could be played either actively (i.e., dancing on a pad or without the pad while watching an instructional video or pedaling and steering a stationary bicycle) or played using a controller. Conditions also varied in terms of how interactive game play could be. Children were given a choice as to how they played the games. Children preferred the interactive dance game to sedentary option. However, no difference was determined in preference for the bicycling game. Children who were not overweight were more active in playing the interactive dance game than were overweight children.

Like most video games, Wii games become more challenging as you continue to play them. Sell et al. (2008) examined the impact of gamer experience on energy expenditure. Participants in the study were 19 undergraduate males with varying levels of video game experience. The result indicated that the gamers with more experience played with a greater level of intensity and subsequently had higher levels of heart rate, oxygen consumption, respiration, and energy expenditure than the inexperienced participants.

In the only study directly comparing active video game play with other types of physical activity, Graf and colleagues (2009) compared DDR and Wii Boxing play to watching TV and walking on a treadmill among adolescents, aged 10–13. They found that physically active game play was related

to significantly higher energy expenditure than watching TV. Energy expenditure during the play of DDR and Wii Boxing was comparable to that when walking on the treadmill. They conclude that physically active video game play is a good way to promote exercise among children who play a lot of video games. Overall, the results of these studies indicate that while real exercise is preferable, virtual activities are better than sedentary activities and might create increased interest in other physical activities (Mhurchu et al. 2008; Graf et al. 2009).

138.9 Summary

In general, sedentary media use is related to lower activity levels, more snacking, and higher BMI. However, it is not clear whether sedentary media is supplanting more physically active endeavors, as Robinson (2001) and Vandewater and colleagues (2004) suggest. Rather, evidence exists (Ballard et al. 2009) that people may have a set pool of time for media use and that increases in the use of one type of media might result in decreases in the use of other forms of media. With regard to video games, different game genres might be differentially related to time use and activity levels. In the study by Ballard and colleagues (2009), the negative correlation between MMORPG play and exercise was stronger than that between game play in general and exercise. In addition, those who played more sports games also exercised more. Thus, choice of game genre may reflect individual differences in general interests, such as the player's motivation for playing video games, personality, sociability, or activity preferences that mediate the relation between game play and other activities. For example, those who enjoy physical activities, such as playing basketball, snowboarding, etc., may prefer games with similar active themes. On the other hand, individuals who play MMORPGs have been found to be less open to new experiences and more introverted (Ballard et al. 2008). Further, they often make sacrifices in other areas of their lives (e.g., social interaction, work) to devote time and energy to game play (Yee 2006). Thus, they may either be more willing to sacrifice physical activity to have more time to play games or be less inclined to be physically active in the first place. At the other end of the spectrum, physically active video games are related to high levels of energy expenditure and have promise for increasing activity levels and aiding in weight reduction. Summary points are included in Appendix A.

138.10 Applications for Health

The research reviewed suggests that there are clear implications for how video game play and other media use might affect health. Overall, the research suggests that the heavy use of sedentary media has clear negative implications for health. Increased TV screen time and sedentary video game play, particularly of MMORPGs, increases the risk of overweight and obesity. This, in turn, increases the risk of related health problems, such as diabetes, high blood pressure, heart disease, and cancer (AOA 2005; Hill et al. 2005; TAH 2009). Given this, it seems to be important to accomplish three goals. Efforts should be aimed at (1) reducing levels of sedentary media use, (2) reducing caloric intake during sedentary media use, and (3) increasing levels of physical activity. One way to accomplish these goals may be to increase levels of physically active video game play. Physically active games are engaging and serve as an alternative form of exercise. They could be used directly to increase levels of physical activity, would not be as conducive to snacking as sedentary media use, and might lead to increased physical fitness and to weight reduction. Further, since there is evidence

Table 138.6 HHS (2008) guidelines for physical activity for children and adults

	Children	Adults
Moderate physical activity	1 h seven times per week	2½ h per week minimum 5 h recommended
Vigorous physical activity	Three times per week	1¼ h per week minimum 2½ h recommended

This table lists the times per week that children should engage in moderate and vigorous physical activity. The table also lists the hours per week that adults should engage in moderate and vigorous physical activity; both minimum and recommended number of hours of activity are provided

that physically active games foster interest in other activities, their use might increase the likelihood of players engaging in more exercise and outdoor activities.

Recommendations for Physical Activity. The U.S. Department of Health and Human Services (HHS 2008) has specific recommendations for activity levels for children and adults. See Table 138.6 for these recommendations. Given that most gamers play video games several times a week, with the average session lasting over an hour (Ballard et al. 2009), physically active video game play could easily help gamers meet the requirements for moderate activity. Further, active video game play could help develop regular exercise habits among adolescents and young adults. This is important, as the health and exercise habits developed in emerging adulthood are tied to exercise habits and health status as adulthood progresses (e.g., Seidell et al. 2005).

While exercising outside or in the gym is preferable to using video games for exercise, physically active games seem to be a reasonable alternative. Furthermore, they may be more practical for those with limited time, unconventional work schedules, or during inclement weather. However, socioeconomic disparities may decrease access to new generation consoles for those in the working class. This is unfortunate, as those individuals are at higher risk for overweight, obesity, and health problems (TAH 2009).

138.11 Directions for Research

There are several fruitful avenues for future research in this area. Brief longitudinal studies could have participants maintain a log of traditional physical activity, sedentary media use, active video game play, and eating (including snacking) to examine how these factors develop and interact over time. Weight status and other health factors (e.g., blood pressure) could be monitored intermittently to study their relationship to media use, diet, and physical activity. Experimental studies could be used to examine how those assigned to an active game play regime compare with those assigned to using only sedentary media compared with regard to factors such as weight loss, controlling for other physical activity. Researchers could also examine how adding active game play might be used in conjunction with other weight loss programs.

There need to be more direct comparisons of the energy expenditure of physically active game play and the parallel traditional physical activity. Games such as tennis or dancing would be ideal to examine. Studies should also investigate how using whole body movement versus using simply wrist and controller movement for games such as Wii boxing or tennis impact cardiovascular activity and calories burned. While whole body movement is considered normative for playing those games, players can be successful playing while seated using rapid wrist motions instead of arm and body movement.

Finally, researchers should develop interventions aimed at encouraging healthier approaches to media use. Lanningham-Foster and colleagues (2006) suggest that most people will not replace media with more physically demanding activities. Therefore, it is important for health care professionals and game designers to link media and physical activity together through mediums such as interactive gaming and to educate both children and adults about healthy snacking.

Summary Points

- Rates of obesity have risen steadily in developed countries over the past few decades.
- Sedentary media use is a risk factor for obesity across the lifespan and across cultures.
- A significant portion of children's daily caloric intake takes place in front of the TV screen, but little of their caloric intake takes place while playing video games.
- Sedentary media use is related to lower activity levels, more snacking, and higher BMI.
- MORPG play is more strongly linked to high BMI than video game play in general.
- Sedentary console video game play increases physiological arousal.
- There is significantly higher energy expenditure and physiological reactivity during physically active video game play than during sedentary console game play.
- People may have a set pool of time for media use; increases in the use of one type of media might result in decreases in the use of other forms of media.
- Different video game genres might be differentially related to time use and activity levels.
- There are clear implications for how video game play and other media use might affect health.
- Interventions should be aimed at reducing levels of sedentary media use, reducing caloric intake during sedentary media use, and increasing levels of physical activity, perhaps including physically active video game play.

Key Terms

Energy expenditure: Calories burned (can be measured in multiple ways).

Energy-dense food snacks: Snacks with high fat, sugar, and/or calories.

Flow: Pleasurable immersion in everyday activities that often causes the individual to lose track of time (e.g., Sherry 2004).

Massively multiplayer online role-playing games (MMORPGs): Games played in an online virtual world by a large number of players at once. Players create avatars and take on roles (e.g., shaman, soldier). Avatars can move up through a variety of levels.

Next generation game consoles: Gaming systems now in development, such as the potential PlayStation 4 and Wii 2.

Obesity: For adults obesity is defined as a BMI > 30 and for children obesity is defined as a BMI > the 95th percentile (CDC 2006).

Overweight: For adults overweight is defined as a BMI of 25–29.9 and for children overweight is defined as a BMI of 85th–95th percentile (CDC 2006).

Physically active game play: Game play that requires gross motor movement (e.g., boxing, dancing) and/or balancing (e.g., yoga).

Sedentary media use/game play: Media use (TV, reading, traditional seated console video game play) that does not require gross motor movement.

Chapter 139
Disinhibited Eating and Body Weight in Youth

Lauren B. Shomaker, Marian Tanofsky-Kraff, and Jack A. Yanovski

Abbreviations

BED	Binge eating disorder
BMI	Body mass index (kg/m^2)
BN	Bulimia nervosa
EAH	Eating in the absence of hunger
LOC Eating	Loss of control over eating

139.1 Disinhibited Eating and Body Weight in Youth

The prevalence of overweight has tripled for children (ages 6–11 years) and has more than doubled for adolescents (ages 12–19 years) over the past 3 decades (Odgen et al. 2008). Approximately 9 million youth in the United States currently meet criteria for overweight, defined as a body mass index (BMI; kg/m2) equal to or exceeding the 95th percentile for age and sex (Institutes of Medicine 2005). Such statistics are alarming because overweight youth are at heightened risk for a host of serious medical problems (Yanovski 2001), as well as psychosocial and behavioral problems (Crow et al. 2006; Csabi et al. 2000; Israel & Ivanova 2002). Given the epidemic problem of pediatric obesity, there is a critical need to illuminate the behaviors that promote overweight in children so that successful prevention and intervention strategies may be designed and implemented.

Overweight results from an energy imbalance in which energy intake exceeds energy expenditure. Frequent exposure to large portions of palatable, inexpensive, readily available, and energy-dense foods has become increasingly common over the last 30 years, and such exposure has been suggested to increase the likelihood of excess intake and, hence, excess weight gain in youth (Hill & Peters 1998). The current chapter focuses upon a number of aberrant eating patterns that may play a role in promoting a positive energy imbalance and in turn, overweight. We use the term disinhibited eating to refer to a range of eating behaviors that involve a lack of restraint over food intake,

including binge eating and loss of control (LOC) eating, emotional eating, and eating in the absence of hunger (EAH; Table 139.1). For each disinhibited eating behavior, we provide a definition, review the available evidence for its role in overweight, and discuss the correlates of or risk factors for the behavior. Subsequently, we consider the overlap and differentiation among the various disinhibited eating behaviors in youth. The next section of the chapter focuses upon the importance of careful assessment and treatment of disinhibited eating behaviors in the context of pediatric obesity intervention and prevention efforts. We also discuss potential treatment options for disinhibited eating itself. The chapter concludes with a consideration of applications for other areas of health and disease and a discussion of future research directions.

139.2 Disinhibited Eating Behaviors and Body Weight

An individual's intake at any given time is typically initiated by physiological cues for hunger and terminated by physiological cues for satiation. A number of appetitive hormones play a role in governing food intake behavior (Table 139.2). Furthermore, this process is complicated by the influence of auxiliary factors including subjective experiences such as feeling LOC over what or how much is eaten, affective states such as transient or enduring negative affect, and the availability and

Table 139.1 Key facts about disinhibited eating

1. Disinhibited eating includes a range of eating behaviors that all involve a lack of restraint over food intake
2. Examples of disinhibited eating behaviors include binge eating, loss of control (LOC) eating, emotional eating, and eating in the absence of hunger (EAH)
3. Disinhibited eating behaviors occur with considerable prevalence among youth
4. Disinhibited eating behaviors are more common among overweight (than non-overweight) children and adolescents and are associated with a heightened risk for excessive weight gain over time in children and adolescents
5. Some evidence suggests that disinhibited eating behaviors may interfere with standard-of-care weight loss treatment

Table 139.2 Appetitive hormones that play a role in governing food intake behavior

Hormone	Brief description
Ghrelin	Hormone produced in antrum of stomach that rises in response to fasting and stimulates hunger and food intake
Leptin	Fat-cell-derived hormone that signals the central nervous system when there has been change in energy stores
Cholecystokinin (CCK)	Hormone rapidly released in response to the entry of fat in the duodenum and triggers satiety, leading to meal termination
Peptide YY_{3-36} (PYY_{3-36})	Hormone secreted from the gastrointestinal tract in response to food intake and thought to exert an impact on satiety and meal termination
Insulin	Pancreatic hormone that promotes the rapid uptake and use of glucose by almost all body tissues; in the hypothalamus, increased insulin causes satiety and a reduction in food intake
Glucagon-like peptide 1 (GLP-1)	Hormone released in response to food intake from the distal intestine and induces satiety and short-acting meal termination
Amylin	Pancreatic hormone that rises rapidly with food intake and triggers satiety and short-acting meal termination
Gastric inhibitory peptide (GIP)	Gastric hormone that induces insulin secretion in response to ingestion of fat and glucose

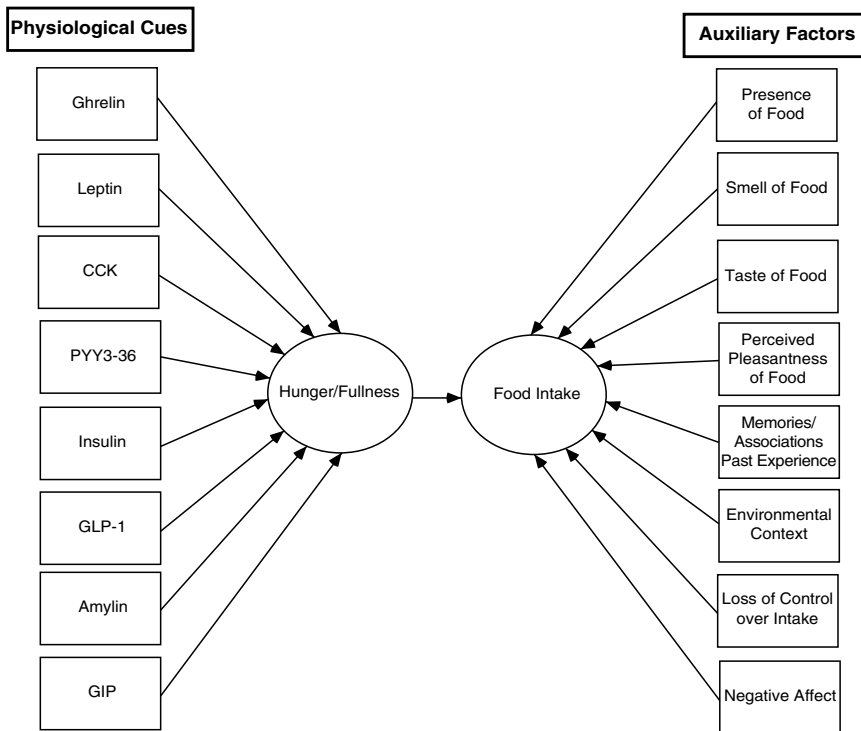
This table provides a nonexhaustive list of hormones known to play a role in governing food intake behavior


Fig. 139.1 Theoretical influences of physiological cues and auxiliary factors on food intake behavior. Physiological cues include the interplay of appetitive hormones regulating hunger and fullness, including ghrelin, leptin, cholesystokinin (CCK), peptide YY_{3-36} (PYY_{3-36}), insulin, glucagon-like peptide 1 (GLP-1), amylin, and gastric inhibitory peptide (GIP). Auxiliary factors include the presence of food, the olfactory and gustatory properties it elicits, its perceived pleasantness, past memories or associations that the food experience triggers, environment or context, subjective experiences of loss of control over eating, and transient or chronic negative affect

desirability of palatable food (Fig. 139.1). Recent evidence suggests that a propensity for food intake in response to triggers other than those physiological cues which reflect hunger and satiety may play a significant role in promoting a positive energy balance and the development of overweight in youth. To date, a relatively small literature exists on disinhibited eating and body weight in youth.

139.3   Binge Eating and LOC Eating

139.3.1   Binge Eating and Body Weight

Binge eating is defined as overeating an objectively large amount of food while experiencing a lack of control over what or how much is being eaten (American Psychiatric Association 2000). Binge eating is a core symptom of bulimia nervosa (BN) and binge eating disorder (BED) as outlined in the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) (American Psychiatric Association 2000). The criteria for BN and BED are displayed in Table 139.3. Although few children and adolescents meet frequency and all symptom criteria for BN or BED, prevalence rates for binge eating in the absence of a full-syndrome eating disorder range from

Table 139.3 Diagnostic criteria for bulimia nervosa (BN) and research criteria binge eating disorder (BED)

Bulimia nervosa (BN)	Binge eating disorder (BED)
(A) Recurrent episodes of binge eating; an episode of binge eating is characterized by both of the following:	(A) Recurrent episodes of binge eating; an episode of binge eating is characterized by both of the following:
1. Eating, in a discrete period of time (e.g., ≤2-h period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances	1. Eating, in a discrete period of time (e.g., ≤2-h period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances
2. A sense of lack of control over eating during the episode	2. A sense of lack of control over eating during the episode
(B) Recurrent inappropriate compensatory behavior in order to prevent weight gain, such as self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; fasting; or excessive exercise	(B) The binge eating episodes are associated with three or more of the following:
	1. Eating much more rapidly than normal
	2. Eating until feeling uncomfortably full
	3. Eating large amounts of food when not feeling physically hungry
	4. Eating alone because of being embarrassed by how much one is eating
	5. Feeling disgusted with oneself, depressed, or very guilty after overeating
(C) The binge eating and inappropriate compensatory behaviors both occur, on average, at least twice a week for 3 months	(C) The binge eating occurs, on average, at least 2 days a week for 6 months
(D) Self-evaluation is unduly influenced by body shape and weight	(D) Marked distress regarding binge eating is present
(E) The disturbance does not occur exclusively during episodes of anorexia nervosa	(E) The binge eating is not associated with the regular use of inappropriate compensatory behaviors (e.g., purging, fasting, excessive exercise) and does not occur exclusively during the course of anorexia nervosa or BN

The Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR) (American Psychiatric Association 2000) provides criteria for a diagnosis of bulimia nervosa (BN) and recommended research criteria for a diagnosis of binge eating disorder (BED). Few children and adolescents meet full criteria for these disorders

approximately 6% to 57%, with the highest estimates among weight loss treatment-seeking (versus community) samples and higher prevalence among adolescents (versus children) (Britz et al. 2000; Tanofsky-Kraff 2008).

Binge eating typically emerges in childhood or adolescence. It has been found to occur with greater frequency (e.g., 2:1) among girls compared with boys in some samples (Ackard et al. 2003). Cross-sectional data point to a relationship between the presence of binge eating episodes and children and adolescents' body weight. For instance, among young children (6 years of age), parental reports of children's binge eating were correlated with children's overweight status (Lamerz et al. 2005). In a large survey-based study of boys and girls (9–14 years), children's self-reports of binge eating in the past month were associated with body weight (Field et al. 1999). A consistent relationship between binge eating and body weight also has been found among adolescents. In a school-based study of 7th–12th graders, overweight adolescents self-reported binge eating more frequently than their normal weight peers (Neumark-Sztainer et al. 1997). Similar findings have been reported in other adolescent community samples (Ackard et al. 2003; Field et al. 1997).

In studies of weight loss treatment-seeking overweight children and adolescents, those reporting binge eating typically have a similar BMI to those who do not endorse binge eating (Glasofer et al. 2007;

Mirch et al. 2006). However, overweight children (6–12 years) seeking weight loss treatment who self-reported at least one episode of binge eating in the 6 months prior to pretreatment assessment were found to become hungrier sooner following a preload, reported a greater subjective desire to eat, and ingested more energy during laboratory test meals (Mirch et al. 2006). Furthermore, children and adolescents with binge eating can be distinguished by greater psychological symptoms (e.g., depression and disordered eating attitudes) compared with their counterparts without binge eating (Glasofer et al. 2007; Goossens et al. 2007; Isnard et al. 2003).

Binge eating behaviors have also been shown to predict weight gain in a number of longitudinal, pediatric studies. Among adolescent girls from a community sample, binge eating as assessed by interview predicted elevated growth in weight gain (Stice et al. 1999) and obesity onset (Stice et al. 2002) over a 4-year period. In a large community cohort of youth 9–14 years of age, boys, but not girls, who reported binge eating gained significantly more weight compared with those who reported neither binge eating nor dieting (Field et al. 2003). Further, among 6–12-year-old children at heightened risk for adult obesity by virtue of their own overweight status or parental overweight, self-reported binge eating episodes predicted greater gains in body fat mass approximately 4 years later (Tanofsky-Kraff et al. 2006).

139.3.2 LOC Eating and Body Weight

Binge eating in youth, particularly pre-pubertal children, can be difficult to assess because children may be manifesting only early signs of the behavior or may have difficulty reporting their eating behaviors and accompanying emotional experiences. Similarly, what constitutes an unambiguously large amount of food in developing boys and girls of different ages and pubertal stages can be challenging to determine. For example, reported consumption of two large hamburgers, a large French fries, and a large soft drink might be considered unambiguously large for a pre-pubertal 8-year-old girl; however, the size of the same reported amount of food consumed would be much more ambiguous in a 15-year-old boy in the midst of a growth spurt.

An emerging body of data illustrate that the experience of LOC over eating, regardless of the reported amount of food consumed, may be the most salient marker of risk for overweight in youth. Loss of control over (LOC) eating is defined as a subjective experience of being unable to control or stop what or how much one is eating. The prevalence of LOC ranges from 4% to 45%, with higher estimates among overweight youth (versus nonoverweight), adolescents (versus preadolescents), and when assessed via questionnaire (versus semi-structured interview) (Tanofsky-Kraff 2008).

In a large, multisite study of binge eating behaviors in children and adolescents, youth were categorized as those who either reported at least one episode in the prior month of LOC in concert with consumption of an unambiguously large amount of food (i.e., an objective binge eating episode) or LOC when the amount was not objectively large (i.e., a subjective binge eating episode) (Tanofsky-Kraff et al. 2007a). Both groups were more likely to be heavier than youth with no episodes. In a study of children 6–13 years of age, those who reported any type of LOC eating by interview were more likely to be overweight and have greater body fat mass than children who reported overeating without LOC or no episodes of overeating (Tanofsky-Kraff et al. 2004). Youth with LOC eating also exhibit greater psychological symptoms and disordered eating cognitions and behaviors than their counterparts without LOC (Tanofsky-Kraff et al. 2004; Morgan et al. 2002).

A recent observational study of children's and adolescents' eating in the laboratory supports the possibility that LOC eating is related to behavioral patterns that might promote excessive weight gain. Among nontreatment seeking overweight and normal weight 8–17-year-olds, youth reporting

at least one episode of LOC in the past month by interview consumed a greater percentage of calories from carbohydrates, consumed a smaller percentage from protein, ate more snack and dessert-type foods, and ate less meats and dairy at laboratory test meals, compared with those without LOC (Tanofsky-Kraff et al. 2009a).

In a recent prospective investigation of 6–13-year-old children over the course of 4–5 years, those with LOC gained a significant 2.4 kg of additional weight per year than those children without LOC (Tanofsky-Kraff et al. 2009b). Further longitudinal studies of LOC eating and body weight are warranted.

139.3.3 Etiology of Binge and LOC Eating

It is well accepted that no single factor causes binge or LOC eating. Rather, these behaviors likely develop from the complex interaction of multiple biopsychosocial factors.

Socio-cultural perspectives on binge eating posit that ubiquitous cultural messages promoting the "ultra-thin" ideal of feminine beauty play a role in binge eating onset. Youth are inundated with such unrealistic ideals of beauty and a myriad of often unhealthy strategies for becoming thinner or leaner. Perceived socio-cultural pressure to be thinner or to lose weight from media and interpersonal sources such as parents and peers has been shown to predict the onset of binge eating in adolescent girls (Stice 2002). Similarly, parents' or peers' modeling of body image dissatisfaction or disordered eating behavior also predicts the onset of binge eating in adolescent girls (Stice 2002). Interpersonal theories of binge eating emphasize the role of difficulties in close, interpersonal relationships with parents, friends, and/or romantic partners in triggering and/or maintaining binge eating patterns.

In addition to these more direct effects on binge eating, perceived pressure to be thin from relationships or the media may indirectly impact binge eating in a number of ways. Affective theories posit that perceived pressure to be thin may lead to negative affect, which in turn triggers binge eating as an attempt to alleviate emotional distress. Consistent with this theoretical perspective, youth (ages 8–13 years) with LOC eating have been shown to report more maladaptive emotion regulation strategies than youth without LOC (Czaja et al. 2009). Although binge or LOC eating may temporarily alleviate negative affect, such eating patterns ultimately are not effective in coping with distress, and binge or LOC eating behaviors may be perpetuated. As another indirect effect, perceived pressure to be thin has been posited to lead to idealization of the ultra-thin ideal and body image dissatisfaction, which in turn promote dieting. Dietary restraint theory proposes that dieting, defined as a conscious attempt to restrict caloric intake in order to change body weight or shape, is a trigger for binge eating (Polivy & Herman 1985). From a cognitive-behavioral psychology perspective, dieting would likely trigger a disinhibited response over eating when dieting rules are at all violated, especially when one holds rigid rules about intake. Among children and adolescents, self-reported dieting has also been shown to be associated with both symptoms of eating disorders and weight gain (Stice et al. 1999; Field et al. 2003; Tanofsky-Kraff et al. 2006). Yet, limited work has examined the direct effects of dieting on binge or LOC eating specifically in youth.

It is possible that dietary restraint and cognitive-behavioral models might be more relevant for those susceptible to BN as compared with BED. Indeed, there is a significant percentage of overweight children who binge eat and who have never dieted (Claus et al. 2006). Interestingly, in a sample of overweight children 6–13 years of age, 25.7% reported a history of both LOC eating and dieting, among whom two-thirds reported that LOC preceded dieting (Tanofsky-Kraff et al. 2005a). These data suggest the presence of additional factors that might predispose youth to LOC or binge eating. Bolstering this possibility, family and twin studies suggest that binge eating is moderately heritable (Javaras et al. 2008; Klump et al. 2007). Recent genetic and neuroimaging investigations in

adults also provide very preliminary evidence that LOC or binge eating could be related to genetically influenced, systematic differences in neural networks relevant for processing food reward and regulation of appetite, satiety, and mood (Davis et al. 2009). Available evidence does not at present suggest that abnormalities in the peripheral humoral signals for hunger or satiety are involved in the pathogenesis of binge eating behaviors (Geliebter et al. 2004).

139.3.4 Binge Eating and LOC Eating Summary

- Binge and LOC eating are disinhibited eating behaviors reported by a substantial percentage of overweight youth.
- Binge and LOC eating are risk factors for obesity; both have been shown to predict excess weight and adiposity in youth.
- The onset and maintenance of binge and LOC eating are likely influenced by a variety of genetic, social, and psychological factors.

139.4 Emotional Eating

139.4.1 Emotional Eating and Body Weight

Emotional eating refers to consuming food in an attempt to cope with transient or enduring negative emotions. Among adults, negative affect is the most commonly cited trigger for binge eating; in children and adolescents, emotional eating is also associated with LOC or binge eating (Goossens et al. 2007; Tanofsky-Kraff et al. 2007b). However, emotional eating can occur in the absence of experiencing LOC over eating. Among nontreatment-seeking children and adolescents aged 8–18 years, over 50% reported eating in response to emotions (Tanofsky-Kraff et al. 2007b). Very limited pediatric research has examined the link between emotional eating and body weight, and the available evidence for its association with risk for obesity is mixed. One cross-sectional study found that self-reported emotional eating was associated with overweight status in 9–12-year-old children (Braet & van Strein 1997). However, other cross-sectional studies have not found a relationship between children's or adolescents' emotional eating and body weight (Tanofsky-Kraff et al. 2007b). Although a few laboratory studies have reported a main effect of negative (versus neutral) mood induction on greater observed food intake in adults, the majority of such studies report no significant main effects (Stice 2002). Adults who report excessive restraint over eating have been shown to be vulnerable to greater intake when stressed (Heatherton et al. 1991; Tanofsky-Kraff et al. 2000). However, what moderating factors may serve to make certain youth vulnerable to overeating in response to negative affect requires further investigation. To our knowledge, no studies to date have prospectively examined the impact of emotional eating on changes in body weight in youth.

139.4.2 Etiology of Emotional Eating

By definition, emotional eating is precipitated by transitory or chronic experiences of negative affect. However, there is a wide variety of possible ways to cope with negative affect, suggesting that genetic and/or psychosocial factors may predispose particular individuals to respond to negative affect by eating.

Affective theories of disinhibited eating posit that food is often sought to alleviate or provide comfort from negative affective states. Temporary alleviation of negative affect while eating may serve to negatively reinforce emotional eating episodes. Psychologically, binge eating has been suggested to temporarily reduce negative affect by serving as an "escape" from self-awareness (Heatherton & Baumeister 1991); but also, physiologically, food consumption influences the 5-HT (serotonin) system, implicated in mood (Steiger et al. 2005), such that emotional eating may temporarily enhance mood via a physiological pathway.

139.4.3 Emotional Eating Summary

- Emotional eating is a frequent component of binge or LOC eating episodes but also may occur in the absence of experiences of LOC.
- It is undetermined whether emotional eating in and of itself confers risk for excess weight gain.
- In theory, a propensity for emotional eating may promote excess intake and a positive energy balance, but much further research is needed to test this hypothesis.

139.4.4 Eating in the Absence of Hunger (EAH)

139.4.5 EAH and Body Weight

Eating in the absence of hunger refers to eating in response to the presence of palatable foods in the absence of hunger. It has been proposed that EAH is best measured by directly observing children's actual ad libitum energy intake following the consumption of a meal that induces fullness. Observations of EAH in carefully controlled laboratory settings reveal that girls 5 and 7 years of age who consumed large amounts of snack foods in the absence of hunger were 4.6 times more likely to be overweight (Fisher & Birch 2002). Similarly, in a large sample of Hispanic girls and boys 4–19 years of age, youth who displayed high levels of EAH (above the sample median) had a 50% greater likelihood of being overweight, after adjustment for age and sex (Fisher et al. 2007). Investigations of EAH in settings outside the laboratory yield similar results. After a normal classroom lunch, preschoolers' consumption of snacks was positively associated with their weight to height ratio (Cutting et al. 1999). This relationship was only observed among girls in the study (Cutting et al. 1999), whereas other studies of EAH outside the laboratory have found the relationship for boys. For example, in several studies of children between 7 and 13 years of age, snack intake as measured after a school meal or at home was positively associated with boys' BMI standard scores or overweight status, whereas the relationship did not reach significance for girls (Hill et al. 2008; Moens & Braet 2006).

Although there are limited data on the prevalence of EAH in youth, most studies find that more than two-thirds of a given sample of children or adolescents display this behavior to at least some degree (Moens & Braet 2006). Few longitudinal studies of EAH have been undertaken. In an early childhood cohort of Caucasian girls studied at ages 5, 7, and 9 years, EAH was observed to increase with age (Birch et al. 2003). At age 5, girls consumed on average 125 ± 8 kcal ($M \pm SD$) in the absence of hunger, 174 ± 9 kcal at age 7, and 225 ± 11 kcal by age 9, which constituted approximately 7%, 9%, and 11% of age- and sex-specific daily energy needs, respectively (Birch et al. 2003). In a sample of Hispanic children and adolescents 4–19 years of age (11.75 ± 0.2), each 1-year increase in age was

associated with eating an additional, approximate 40 kcal more in the absence of hunger, after accounting for sex, total energy expenditure, and overweight status (Fisher et al. 2007). Further, EAH predicted weight gain a year later after adjusting for age, sex, and puberty, but the effect was attenuated (p = 0.17) after accounting for initial BMI status (Butte et al. 2007). Additional study of the role that EAH may play in promoting excess weight gain in youth is warranted. In particular, very little work has examined EAH in adolescents. It is possible that EAH may be most likely to exert an effect on weight gain at specific developmental periods (e.g., puberty) during which youth experience rapid and substantial physical growth, and significant interindividual variations in weight gain are expected.

139.4.6 Etiology of EAH

An initial family study of EAH as assessed in the laboratory suggests that EAH is a moderately heritable, observable behavior (heritability of 0.44–0.50). This estimate is similar to that of other eating behaviors and attitudes such as self-reported dietary restraint and perceived disinhibition over eating (de Castro & Lilenfeld 2005; Provencher et al. 2005; Wade et al. 1999) and illustrates that there are both genetic and environmental factors influencing phenotypic variation in EAH.

Five-year-old boys at high risk for obesity, based on maternal prepregnancy weight and child's weight status, were found to be over twice as likely to eat large amounts in the absence of hunger than low risk boys (Faith et al. 2006). In a prospective study tracking girls from age 5 to 13 years, girls who had two overweight parents displayed higher levels of EAH at every age and showed the largest increases in EAH over time compared with girls with only one overweight parent or no overweight parent (Francis et al. 2007). Such data suggest familial influences on EAH via a combination of polygenetic risk factors and environmental factors such as social modeling of disinhibited eating behavior. Although much remains to be determined about genetic influences on EAH, a recent study found that children 4–5 years of age who had risk polymorphisms in the rs9939609 SNP of the *FTO* gene (known to be associated with obesity) ate more snack foods after a school meal (Wardle et al. 2009). These data are intriguing but require replication with larger samples and more controlled eating circumstances (e.g., serving children a standardized meal prior to the EAH paradigm).

Available data also support a role for parental feeding practices in relation to children's EAH. Among young girls (age 5), maternal restriction of daughters' intake has been shown to predict increases in EAH over 2–4 years (Fisher & Birch 2002; Birch et al. 2003). The relationship between maternal restriction and increases in EAH was strongest when either daughter or mother was overweight (Birch et al. 2003; Francis & Birch 2005). Therefore, parental feeding practices very likely interact with real concerns about a child's weight status. However, overly restrictive efforts to control children's food intake may potentially produce iatrogenic effects that lead children to eat even more in the absence of hunger.

139.4.7 EAH Summary

- EAH may represent a behavioral phenotype associated with children's risk for overweight.
- Further prospective investigations are required to determine the impact of EAH on excess weight gain.
- Preliminary data support a role for familial influences on EAH, via both genetic (e.g., *FTO*) and environmental (e.g., social modeling or feeding practices) factors.

139.5 Similarities and Differences Among Disinhibited Eating Behaviors

All forms of disinhibited eating behaviors in youth share in common a lack of reliance on physiological cues for hunger and fullness to determine initiation and/or termination of food intake. Therefore, in theory, disinhibited eating behaviors may share a common pathophysiology of impaired awareness, recognition, and/or registration of appetitive cues; alternatively (but not mutually exclusive), such behaviors might reflect a common susceptibility to reliance on external or emotional cues to determine intake.

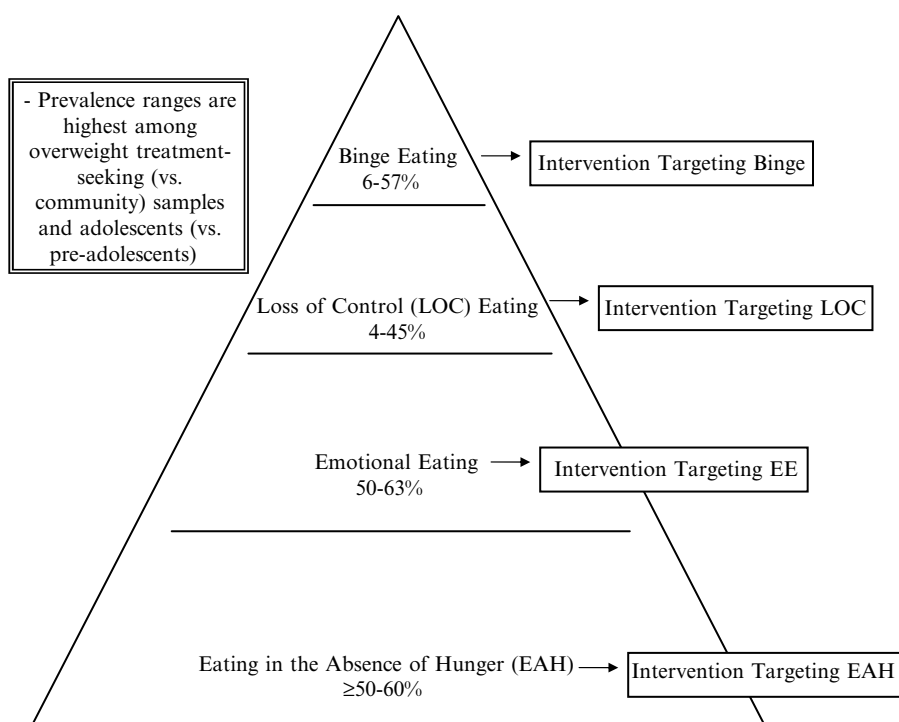
Congruent with this perspective, the existing data point to overlaps among binge or LOC eating, emotional eating, and EAH in youth (Tanofsky-Kraff et al. 2007b; Tanofsky-Kraff et al. 2008). We propose that disinhibited eating behaviors are likely to be organized in a pyramidal fashion (Fig. 139.2), such that binge eating occurs in the smallest subset of youth, LOC eating is slightly more common, emotional eating occurs with the next greatest frequency, and EAH is the most common disinhibited eating behavior in youth. Also important to this conceptualization is that behaviors at the top of the pyramid (i.e., binge or LOC eating) commonly involve behaviors in the bottom half of the pyramid (i.e., emotional eating or EAH); however, emotional eating and EAH do not necessarily involve feelings of LOC over eating or unambiguous overconsumption. Behaviors are ordered from bottom to top in increasing likelihood of having accompanying psychological distress, such that binge eating is perceived as the most pathological. Similarly, based upon our existing knowledge, we tentatively posit that the combination of having more than one type of disinhibited eating is likely to be related to greater risk for psychological problems, and potentially excessive weight gain. For example, the combination of both experiences of LOC or binge eating and high levels of negative affect appears to be related to worse psychological correlates for youth (Goldschmidt et al. 2008).


Fig. 139.2 Pyramid conceptualization of disinhibited eating behavior and targets for intervention

Yet, whether such co-morbidity is also tied to risk for excess weight gain in youth and subsequent obesity is unclear.

We do not yet have a full understanding of the age-span and time course for the onset and development of disinhibited eating behaviors. EAH has been observed in children as young as preschool, yet it has also been shown to increase with age. Binge eating primarily emerges in adolescence. However, we believe that preadolescent youth may manifest symptoms of binge eating such as LOC eating, perhaps prior to developing into full binge episodes. Both preadolescent and adolescent youth report emotional eating; however, its developmental course and implications are not well understood. Disinhibited eating behaviors also may be more common among girls versus boys (Ackard et al. 2003), although sex differences may not emerge until adolescence.

139.5.1 Similarities and Differences Summary

- Disinhibited eating behaviors share a reliance on external or emotional cues to regulate food intake rather than utilizing physiological signals of hunger and fullness to govern eating behavior.
- Binge eating may be the most pathological type of disinhibited eating behavior, especially as it relates to risk for psychological problems and excess body weight gain; the combination of experiencing multiple types of disinhibited eating behaviors may also be of significance for health outcomes.
- Disinhibited eating behaviors occur in preadolescent and adolescent youth, with the frequency and severity increasing during adolescence. We still have much to learn about the onset and developmental time course of different types of disinhibited eating behaviors.

139.6 Assessment of Disinhibited Eating

A range of assessment techniques are available for measuring disinhibited eating behaviors in youth (Tables 139.4 and 139.5). As displayed in Table 139.4, a number of self-report and parent-report questionnaires exist for measuring binge eating, LOC eating, emotional eating, and EAH. The principal

Table 139.4   Questionnaire assessment of disinhibited eating

Abbreviation	Questionnaire
BES	Binge Eating Scale (Gormally et al. 1982)
CEBQ	Children's Eating Behavior Questionnaire (Wardle et al. 2001)
DEBQ	Dutch Eating Behavior Questionnaire (van Strein et al. 1986)
DEBQ-C	Dutch Eating Behavior Questionnaire for Children (van Strein and Oosterveld 2008)
DEBQ-P	Dutch Eating Behavior Questionnaire – Parent Version (Braet and van Strein 1997)
EAH-C	Eating in the Absence of Hunger Questionnaire – Child Version (Tanofsky-Kraff et al. 2008)
EAH-P	Eating in the Absence of Hunger Questionnaire – Parent Version
EDE-Q	Eating Disorder Examination – Questionnaire (Fairburn and Beglin 1994)
EES-C	Emotional Eating Scale, Adapted for Children (Tanofsky-Kraff et al. 2007b)
QEWP-A	Questionnaire on Eating and Weight Patterns – Adolescent Version (Johnson et al. 1999)
QEWP-P	Questionnaire on Eating and Weight Patterns – Parent Version (Johnson et al. 1999)
YEDE-Q	Youth Eating Disorder Examination – Questionnaire (Goldschmidt et al. 2007)

Reliable and well-validated questionnaires exist for assessing aspects of disinhibited eating behavior in children and adolescents

Table 139.5 Overview of tools for assessment of disinhibited eating in children and adolescents

Assessment	Binge or LOC eating	Emotional eating	EAH
Questionnaire youth self-report	QEWP-A EDE-Q, YEDE-Q BES	EES-C DEBQ, DEBQ-C	EAH-C
Questionnaire parent-report	QEWP-P	DEBQ-P CEBQ	EAH-P
Semi-structured interview	EDE, ChEDE C-BEDS SCID-BN, BED modules	SPEEI	SPEEI
Observation	Let yourself go and eat as much as you want	Mood induction prior to measured food intake	Measured snack intake after serving a meal

Methods for assessing disinhibited eating in children and adolescents include youth self-report on questionnaires, parent report on questionnaires, semi-structured interviews, and observations of children's eating

EDE Eating Disorder Examination (Fairburn & Cooper), *ChEDE* Eating Disorder Examination Adapted for Children (Bryant et al. 1996), *C-BEDS* Children's Binge Eating Disorder Scale (Shapiro et al. 2007), *SCID* Structured Clinical Interview for the Diagnosis of DSM-IV Disorders, Bulimia Nervosa, and Binge Eating Disorder Modules (First et al. 1997; Spitzer et al. 1995), *SPEEI* Standard Pediatric Eating Episode Interview (Tanofsky-Kraff et al. 2007a), Questionnaire abbreviations are described in Table 139.4

advantages of questionnaire instruments are that they are low in cost and easy to administer, score, and interpret. Conversely, drawbacks of self-report measures of eating behavior include evidence that youth, especially those who are overweight, frequently underestimate food intake (Fisher et al. 2000). Parents also tend to underreport their children's intake (Baranowski et al. 1991). Further, youth and parents tend to show little agreement on disinhibited eating behaviors such as binge eating (Steinberg et al. 2004). Given these limitations, observational assessments of actual energy intake are often desirable.

Semi-structured interview methods comprise another means of assessing disinhibited eating in youth (Table 139.5). Interviews include the widely used and well-validated Eating Disorder Examination (EDE; ≥ 14 years of age) (Fairbun & Cooper 1993) and the Eating Disorder Examination Adapted for Children (ChEDE; <14 years of age) (Bryant et al. 1996). The Children's Binge Eating Disorder Scale (C-BEDS) is a brief, structured, interviewer-administered scale developed to screen for symptoms of BED in children (aged 5–13 years) (Shapiro et al. 2007). Also, the semi-structured Standard Pediatric Eating Episode Interview (SPEEI) was recently developed to assess detailed information about eating episodes among children of all ages (Tanofsky-Kraff et al. 2007a). Interview methods have the advantage of being able to probe or query youth's specific behaviors and thoughts and feelings surrounding eating episodes. Potential limitations include time constraints, interviewer training, lack of anonymity, and social desirability.

Finally, observations of disinhibited eating behavior can be conducted in a controlled setting such as the laboratory or a clinic or in children's natural environment such as at school or at home. Although observational measures are often neither feasible nor readily transferable to clinicians working with youth and families in the community, such measurements have been shown to be valid indicators of children's eating (Tanofsky-Kraff et al. 2007c). In our own lab, for example, we have assessed binge and LOC eating by asking youth to "let yourself go and eat as much as you want" from a multi-item food array (>9,000 kcal) (Mirch et al. 2006; Tanofsky-Kraff et al. 2009a) (Fig. 139.3). Emotional eating in the laboratory can be assessed by inducing a temporary mood state and subsequently observing intake (Goldschmidt et al. 2009). Finally, EAH is frequently observed by serving children a meal and asking them to eat until they are no longer hungry, and

Fig. 139.3 Multi-item food array for use in laboratory studies of disinhibited eating (>9,000 kcal). Foods include white bread, wheat bread, Kaiser rolls, ham, turkey, American cheese, chicken nuggets, peanut butter, grape jelly, tomatoes, lettuce, carrots, tortilla chips, jelly beans, M&M's, bananas, grapes, oranges, oreos, vanilla wafers, pretzels, mayonnaise, mustard, BBQ sauce, mild salsa, ranch dressing, 2% milk, lemonade, water, and apple juice

then subsequently measuring intake of highly palatable snack foods (Fisher & Birch 2002). The benefits of laboratory studies include the ability to control the exact conditions, directly observe eating behaviors, and precisely measure energy intake. There is some concern that laboratory studies may not elicit eating behaviors typical of natural environments; however, most participants in prior studies describe their behavior in the lab as typical of their ordinary eating behavior (Tanofsky-Kraff et al. 2007c).

An important consideration for assessment of disinhibited eating behavior in youth is that an ideal and thorough assessment may require measures from multiples sources (e.g., children and parents), who frequently have different, unique perspectives of a target child's eating behavior. Additionally, typically low correspondence has been found among observational assessments, youth report on questionnaire, parent report on questionnaire, and interviews assessing disinhibited eating behavior (Tanofsky-Kraff et al. 2005b). We do not yet have enough evidence to suggest that one method is superior to another, simply that the minimal shared variance highlights the importance of gathering assessment of disinhibited eating behavior via multiple methods.

139.6.1 Assessment of Disinhibited Eating Summary

- Approaches for the assessment of disinhibited eating in youth include children's and parents' reports on questionnaires, semi-structured interviews, and observations of children's eating behavior.
- There are advantages and disadvantages to each assessment technique and the methods for assessing disinhibited eating in youth tend to show limited agreement.

- Structured interviews are currently considered the "gold standard" for assessing disinhibited eating, but further empirical data are needed to validate the criteria employed.
- The most thorough assessment of disinhibited eating in youth would include reliance on as many sources (i.e., children and parents) and methods (i.e., questionnaires, interviews, observations) as possible.

139.7 Prevention and Treatment of Disinhibited Eating

Given that current treatments for obesity have met with limited long-term success, there has been an increased recognition that "one size may not fit all." In particular, interventions may need to be tailored to address subsets of overweight or at-risk for overweight individuals whose disinhibited eating problems serve to maintain or enhance their weight problems. Data from adult studies of overweight individuals with and without binge eating problems suggest that disinhibited eating may interfere with the efficacy of standard-of-care obesity treatment. In a meta-analysis of studies examining the impact of binge eating or BED on weight loss treatment outcome (Blaine & Rodman 2007), individuals with BED fared worse during treatment, with individuals having BED losing significantly less weight than non-binge eaters. In a recent study of over 5,000 adults with type II diabetes mellitus, the influence of binge eating at both baseline and post-treatment on weight loss treatment outcome was examined (Gorin et al. 2008). Participants who either never reported binge eating or reported ceasing to binge eat lost significantly more weight compared with those who persisted or commenced binge eating over the course of treatment. Studies investigating the impact of disinhibited eating behavior on weight loss treatment outcomes in youth are greatly needed.

One of the most exciting current avenues of research involves targeting disinhibited eating behavior for the treatment of obesity. The majority of available data come from randomized controlled trials of adults with BED. Cognitive-behavioral treatment (CBT) approaches, which combine cognitive therapy and behavioral strategies for modifying binge eating, diet, and exercise, have shown efficacy for reducing binge eating and weight among adults with BED (National Institute for Clinical Excellence 2004). Interpersonal psychotherapy (IPT) for adults with BED has also shown promising results (Wilfley et al. 2002). IPT targets reductions in binge eating and weight by addressing the interpersonal problems that maintain binge eating behaviors. Among adults, some pharmacological treatments also have been shown to be more efficacious than placebo in producing short-term reductions in binge eating and inducing small weight loss (Reas & Grilo 2008).

Because available treatments primarily have been shown to induce weight stabilization or modest weight loss rather than significant, sustained weight loss over time in adults with BED, very recent, novel research has turned to the targeting of disinhibited eating behaviors in youth for the prevention of adult obesity. Although designed as an intervention for binge eating, an internet-facilitated CBT program was reported to produce greater reductions in BMI and binge eating compared with a wait-list control (Jones et al. 2008). Another program that holds promise involves administering group IPT to girls at risk for adult obesity by virtue of having LOC eating and being above-average weight (Tanofsky-Kraff et al. 2007d).

Although most interventions have focused on binge or LOC eating, a small body of literature suggests that interventions targeting emotional eating or EAH might also hold promise for obesity treatment or prevention. Appetite Awareness Training (Craighead & Allen 1995) involves training individuals to regulate intake by paying attention to internal sensations for hunger and fullness rather than other eating triggers or cues (e.g., emotional). An age-appropriate adaptation piloted for youth in middle childhood showed that the intervention group had greater short-term weight and BMI reductions compared with a wait-list control (Bloom et al. 2005). It has also been shown that EAH

is modifiable with very young children. A 6-week intervention delivered in preschools produced improvements in children's observed self-regulation of intake (Johnson 2000).

139.7.1 Prevention and Treatment of Disinhibited Eating Summary

- Disinhibited eating behaviors, particularly binge eating, have been shown to interfere with standard-of-care behavioral weight loss programs among adults.
- Interventions targeting reductions in disinhibited eating behavior among overweight adults with BED have been shown to be somewhat helpful in reducing binge eating and inducing short-term weight loss or weight maintenance.
- More research is needed to investigate whether targeting the emergence of disinhibited eating behaviors in children or adolescents could serve to prevent youth from gaining too much weight as they grow.

139.8 Overall Summary and Future Research Directions

Disinhibited eating behaviors – referring to binge or LOC eating, emotional eating, and EAH – are prevalent among youth. Emerging evidence, particularly for binge and LOC eating, points to a role for their impact on excessive weight gain. There is a strong need for more longitudinal research, especially on emotional eating and EAH, to examine whether these disinhibited eating behaviors are prospective risk factors for obesity. Also important is to understand the etiology of disinhibited eating in youth. Available data suggest a role for both biological or genetic factors, as well as an impact of environmental influences. How these various factors interact to produce disinhibited eating behavioral phenotypes is a key avenue for future study.

139.9 Applications to Other Areas of Health and Disease

Knowledge of disinhibited eating behaviors' role in the etiology or maintenance of obesity has important implications for a wide range of health professionals who act to prevent and treat obesity. It will be particularly important to disentangle the impact of disinhibited eating behavior on standard-of-care weight loss interventions such that treatments can be tailored according to individual needs and what is most likely to be successful for a given youth.

Summary Points

- Disinhibited eating behaviors, referring to a range of eating behaviors that involve a lack of restraint over food intake, include binge or loss of control (LOC) eating, emotional eating, and eating in the absence of hunger (EAH).
- Disinhibited eating behaviors are prevalent among youth.
- Disinhibited eating, especially binge or LOC eating, may play a role in promoting excessive weight gain in children and adolescents.
- In theory, biological or genetic and environmental factors influence the emergence and course of disinhibited eating behaviors in youth.
- A promising new avenue of investigation focuses upon interventions targeting pediatric disinhibited eating behaviors in an effort to prevent or treat obesity.

Key Terms

Binge eating: Overeating while experiencing a lack of control over what or how much is being eaten.

Dieting: Conscious attempts to restrict caloric intake in order to change body weight or shape.

Disinhibited eating: Range of eating behaviors involving a lack of restraint over food intake.

Eating in the absence of hunger (EAH): Eating in response to the presence of palatable foods in the absence of physical hunger.

Emotional eating: Consuming food in an attempt to cope with transient or enduring negative emotions.

Loss of control (LOC) eating: Experiencing a lack of control over eating regardless of the amount of food ingested.

Overweight: BMI (kg/m^2) equal to or exceeding the Center for Disease Control's 95th percentile standard for age and sex.

140.1 Introduction

In the modern era, the consumption of food is not merely a means for intake of nutrients and energy for sustaining life. Beyond the sustenance role, food selection and eating behavior play important roles in our social lives and provide tools for communication, social interaction, and identity expression (Murcott 1983). People use a variety of criteria to conceptualize their everyday food choices and eating behaviors. As a social event, food consumption is influenced by various social and cultural values, and at an individual level, one may often possess stereotypes about food and eating behavior.

The purpose of this chapter is to provide a brief overview of gender-based food stereotypes, which constitute an intriguing aspect of eating stereotypes from the cultural perspective, and to explore the feasibility of introducing indirect measures for gender stereotypes toward food. Our focus on this topic is not intended to discount the critical role played by other major stereotypes, but rather we aim to introduce a novel approach in assessing a specific aspect of food stereotypes, which could be applicable to analyzing other facets as well. To acquire a comprehensive picture of eating stereotypes, we recommend the excellent review by Vartanian et al. (2007).

140.2 Stereotype As a Mediator of Eating Behavior

In the last few decades, several studies, mostly performed in Western countries, have started to reveal the existence of various food and eating stereotypes. A stereotype is defined as a commonly held belief about the characteristics of individuals, members of social groups, or objects (Table 140.1).

e-mail: yujiwd@affrc.go.jp; yuji_wada@nifty.com

Table 140.1 Key facts of stereotypes

- A stereotype is a commonly held belief about the characteristics of all members of several groups or categories (e.g., race, ethnicity, age, or gender). This concept was introduced into social psychology in the early 1920s.
- It is generalizations about individuals, objects, or events based on limited, sometimes inaccurate, but often easily available information. Stereotypical attitudes are often formed with no or limited contact with members of the stereotyped category and by second-hand information rather than first-hand experience.
- Some cognitive factors could play important roles in both formation and use of stereotypes (Hamilton 2005). For instance, stereotype can reduce the demand of information processing. By categorizing people or objects, we bypass the need to attend to each individual that we encounter. Categorization as a foundation of stereotype also distinguishes "us" from "them." This provides individuals some psychological benefits. In comparing our own group with some other "inferior" group, we can feel pride in belonging to our group.
- Stereotypes have positive and negative impacts on the stereotyped group (Macrae et al. 1996). An especially worrying aspect of stereotypes is that they tend to dehumanize people, placing all members of a group into a homogeneous category (e.g., "Catholics," "Asian," and "scientists").
- People have stereotypical attitudes toward particular foods (e.g., high-/low-fat foods, ethnic foods, genetically modified foods). Such food-related stereotypes further influence consumers' food selections and food product evaluations. People also have stereotypical attitudes toward others based on their food intake. Such food consumption stereotypes are usually judged based on what and how much a person eats (Vartanian et al. 2007).

This table summarizes key facts of the stereotype

People have stereotypical attitudes toward particular foods and eating behaviors. For example, people tend to categorize foods as good or bad. This was first described in people with eating disorders (Garner et al. 1982): anorexia nervosa patients classify carbohydrates, sugar, and meat as "bad" foods based on mythical beliefs. Such tendencies were later generalized to include people in the general population (Rozin 1986). The bad/good food stereotypes further affect people's judgment: eaters of the "good" or "bad" foods are viewed by others in association with good or bad moral values based on what they eat (Stein and Nemeroff 1995).

Stereotypes can also be associated with foods and eating habits in specific countries or regions. For example, children who live in the U.K. exhibit rejective responses to unfamiliar French meat dishes due to stereotypes such as, "the French eat frogs" (De Moura 2007). Moreover, recent studies have begun to reveal further impacts of food stereotypes on consumers' interpretations and behaviors. Oakes (2004) demonstrated that foods containing fat, sugar, and salt lead consumers to think that the foods are deficient in vitamins and minerals. Niva (2007) reported that consumers tend to think that functional foods are healthy but unsavory. Chambers et al. (2007) found that a stereotype among U.K. consumers that local food products are more expensive than imports may prevent them from buying local products. Hoogland et al. (2007) demonstrated that an organic logo on food packages provides consumers with a positive but expensive impression, producing only small net impacts on consumers' purchase intentions. Wansink et al. (2007) revealed that a wine with a favorable (new from California) label, served complementarily with a fixed-price meal to adult diners caused a significant increase in meal intake than the same wine with an unfavorable (new from North Dakota) label. These studies have clearly demonstrated that people form stereotypical attitudes toward some food categories and the stereotypes further influence consumers' food selections and food product evaluations.

140.3 Gender-Based Food Stereotypes in Western Countries

Among the stereotypes associated with food and eating, one of the most consistently observed is a gender stereotype, in which femininity and masculinity are primarily associated with specific foods. For example, U.S. college students categorized "toasted bagel with cream cheese" and "spaghetti

with tomato sauce" as feminine foods, while "flapjacks with syrup" and "broiled sirloin" were classified as masculine foods (Mooney and Lorenz 1997). In addition, certain foods enhance or diminish the feminine or masculine impression projected by the individuals who eat them: those individuals who are described as consuming feminine foods are evaluated as more feminine and less masculine than those described as consuming masculine foods, regardless of the gender of the evaluators (Mooney and Lorenz 1997).

In Western countries, association of femininity and masculinity with specific foods is often correlated with their profiles such as health value, caloric content and fat content, and further with good/bad classifications that arise from these profiles (e.g., Barker et al. 1999; Oakes 2004, 2005a,b; Stein and Nameroff 1995). In addition to types of food, there are also gender stereotypes toward the total amount of food ingested (see Vartanian et al. 2007 for review). Specifically, ingestion volume association with female targets is well studied, and many studies have reported that the ingestion of a small amount of food is significantly bound to femininity (Basow and Kobrynowicz 1993; Chaiken and Pliner 1987). Beyond a scientific interest, investigations of gender stereotypes are of great social importance because gender stereotypes not only influence impressions of femininity or masculinity for target individuals, but also produce further impressions, including personal qualities and likeability (Mooney et al. 1994; Mooney and Lorenz 1997).

140.4 Measuring Gender-Based Food Stereotypes Among Young Japanese

As described before, most studies on gender-based food stereotypes have been conducted in Western countries. On the other hand, there have been relatively few reports on gender-based food stereotypes in Asian countries. Cross-cultural perspective is important in the area of gender stereotype because socio-cultural factors are closely associated with gender-role pressure on food selection and eating behaviors (e.g., Hsu 1989). Thus, we explored gender-based food stereotypes among young Japanese (Kimura et al. 2009). In this section, we introduce the research outline for Kimura et al. (2009).

140.4.1 Measuring Femininity and Masculinity of Foods

Two separate experiments based on Mooney & Lorenz (1997) were conducted to identify foods for the feminine and masculine food categories among young Japanese (Table 140.2). To express food at a conceptual level, the names of dishes (e.g., prepared foods) were used throughout the studies.

In study 1, fourteen Japanese undergraduate and graduate students (eight females and six males; average age = 26.5 years; SD = 5.1) were asked to name at least five foods (dishes) that they perceived as very feminine or very masculine, respectively. As a result, 48 dishes were listed as feminine foods and 41 as masculine foods (average 6.21 responses (SD = 2.41) for feminine food and average 6.64 responses (SD = 2.01) for masculine food). Then, the 28 dishes that were named by more than two participants were advanced to the second study. The dishes that were named by the largest number of respondents were *cake* (named by 10 students) among feminine dishes, and *ramen* (Chinese noodle soup; named by 10 students) among masculine dishes.

In study 2, 22 Japanese undergraduate and graduate students (10 females and 12 males; average age = 22.4 years; SD = 1.5) were asked to categorize each of 28 dishes as feminine, masculine, or neutral (neither feminine nor masculine).

Table 140.2 Key features of Japanese food culture

- The term "traditional Japanese foods" basically means traditional Japanese-style meals which were developed around the seventeenth and eighteenth centuries.
- The masculine-evaluated foods listed in Table 140. 3 were incorporated into the Japanese diet around the late nineteenth to early twentieth centuries, and thus are categorized as early-modern traditional Japanese foods.
- A typical Japanese-style meal consists of rice, soup, vegetables, and fish or meat. Kamei et al. (2002) evaluated nutritional contents of take-out lunches supplied in Japan, and revealed that traditional Japanese-style meals were relatively good regarding total energy, fat–energy ratio, and lipid-related proportions than Western-style fast foods.
- While rice is the primary staple, several kinds of noodles (including *soba*, *udon*, and *ramen* (Chinese-noodle soup) and bread are also popular for light meals in contemporary Japan.
- Recently, the diet of Japanese has been rapidly changing to a Western style. In fact, the annual per capita consumption of rice dropped by nearly 30% from 88.0 kg in 1975 to 61.0 kg in 2006.

This table summarizes key features of the contemporary Japanese food culture

Table 140.3 Feminine/masculine foods among young Japanese

	Feminine foods		Masculine foods	
	Food name	Agreement rate	Food name	Agreement rate
1	Cake	1.00	*Gyu-don* (beef rice-bowl)	1.00
2	Fruit	0.95	*Ramen* (Chinese noodle soup)	0.95
3	Pudding	0.95	*Yakiniku* (grilled/barbecued meat)	0.95
4	Ice cream parfait	0.95	*Katsu-don* (breaded pork cutlet rice-bowl)	0.95
5	Pasta	0.86	*Tonkatsu* (deep-fried, breaded pork cutlet)	0.95
6	Salad	0.86	*Sutēki* (beef steak)	0.91
7	Ice cream	0.86	*Yakisoba* (pan-fried noodles)	0.86
8	*Ichigo* (strawberry)	0.86	*Yakitori* (grilled chicken)	0.82
9	Chocolate	0.86		
10	Cookie	0.77		

This table lists the most feminine-/masculine-evaluated foods among young Japanese. All the feminine and masculine dishes listed in this table were evaluated as feminine and masculine, respectively, by more than 75% of the raters, and none of them were evaluated as the opposite classification

140.4.2 Feminine-/Masculine-Evaluated Foods Among Young Japanese

Table 140.3 shows the dishes evaluated as the most feminine/masculine among young Japanese. All the feminine and masculine dishes listed in Table 140.3 were evaluated as feminine and masculine, respectively, by more than 75% of the raters, and none of them were evaluated as the opposite classification (e.g., none of the feminine foods were evaluated as masculine, and vice versa). The dishes which were most frequently evaluated as feminine/masculine foods in study 1 (*cake* for feminine, *ramen* for masculine) were also selected in the list of the most feminine and masculine dishes, respectively, in study 2.

Feminine foods among young Japanese could be categorized into low-fat foods, sweets, and fruits (Fig. 140.1). They are also categorized as Western foods (with the exception of strawberries). Such foods are usually expressed in *katakana* (the phonetic characters used to spell loan words brought into Japanese from other (typically Western) languages). Fruits can be expressed either in their native Japanese forms or as loan words (in *katakana*) in everyday Japanese. In the present study, they were presented as loan words.

The masculine foods, with the exception of beef steak, were incorporated into the Japanese diet around the late nineteenth to early twentieth centuries, and thus are categorized as early-modern traditional Japanese dishes (Fig. 140.2). However, beef steak is considered a Western food. These

Fig. 140.1 Samples of feminine foods. Examples of feminine foods selected in study 2 (pasta and salad)

Fig. 140.2 Samples of masculine foods. Examples of masculine foods selected in study 2**:** *katsu-don* (breaded pork cutlet rice-bowl) and *gyu-don* (beef rice-bowl)

foods are commonly expressed in *kanji* characters (Chinese characters; ideograms), *hiragana* (basic syllabary characters for expressing Japanese words; phonograms), *katakana*, or a mixture of all three. Most of the masculine foods could also be categorized as high fat.

140.4.3 Measuring Stereotypes Toward Food with the Indirect Attitude Measure

Traditionally, the measurement of stereotypical attitudes, including gender-related stereotypes, has been dependent on participants' responses of explicit attitudes (Mooney et al. 1994). However, explicit attitude measured in this way is subject to the risk of reflecting a skewed attitude flawed by self-presentation or social desirability biases (Greenwald et al. 2002).

To circumvent such plausible risks, indirect attitude measures such as the affective priming paradigm (e.g., Fazio et al. 1986) and the implicit association test (IAT; Greenwald et al. 1998) have gradually come into use as alternatives to direct measures. The former is sometimes called a semantic priming paradigm when semantic primes, rather than affective primes, are used (e.g., Macrae et al. 2002). The virtue of these techniques is that they are independent of a direct verbal report of the relevant topics being studied. Rather than asking participants directly about their attitudes on a certain topic, these techniques indirectly infer their attitudes by examining their response patterns (e.g., changes in response time) toward stimuli related to the topic.

Recently, affective/semantic priming paradigms have gradually come into use in studies on attitudes and preferences toward food and eating disorders (Czyzewska and Graham 2008; Lamote et al. 2004;

Roef et al. 2005), but their application to food and eating stereotypes has yet to be explored. Indirect measurements would be of great potential use in these research domains because attitude assessments in such a socially sensitive area may be substantially influenced by factors like social appeal and social desirability (Kimura et al. 2009).

Therefore, we also explored the feasibility of introducing indirect measures for the study of gender stereotypes toward food using a semantic priming paradigm: participants were primed with a food name and immediately after the priming, they were presented with a forename, as the target stimulus, and asked to decide whether the forename given was masculine or feminine. By doing so, the semantic association between foods and genders was estimated (Kimura et al. 2009), and the conformity between indirect and self-report attitudes was also considered.

140.4.4 Applying the Semantic Priming Task to Measure Gender-Based Food Stereotypes

In study 3, 37 Japanese undergraduate and graduate students (19 females; 18 males; average age = 24.5 years; SD = 2.1) were recruited to take part in a word discrimination task experiment. The experiment involved two subsequent sessions: the semantic priming task session and the self-report session for gender-based stereotypical attitudes toward food. The semantic priming task session was conducted to measure implicit gender-based stereotypes toward food names. No explicit association between primes and targets was provided for participants, so that target response was not predictable from the primed food names. At the beginning of each trial, a fixation marker was presented for 500 ms. It was then replaced by the prime stimulus (a feminine or masculine food name), which was presented for 200 ms. After a 50 ms interstimulus interval with a blank screen, the target stimulus (a female or male Japanese forename) was presented. Participants were instructed to press the corresponding button upon judging the gender of the target forename as quickly and accurately as possible. The target stimulus remained on the monitor until a response was given or for 2,500 ms if no response was given. After an intertrial interval of 3000 ms, the next trial started (Fig. 140.3).

Fig. 140.3 The time course of stimulus presentation in the semantic priming task. In this task, participants were primed with a food name (e.g., steak) and immediately after the priming, they were presented with a forename (e.g., Ichiro), as the target stimulus, and asked to decide whether the forename given was feminine or masculine

Blank screem (3000ms)

Target: forename (until response or 2500ms)

Blank screen (50ms)

Prime: food name (200ms)

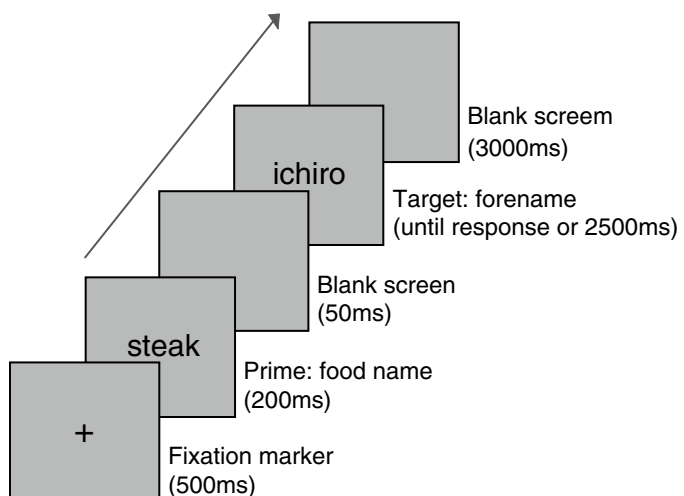
Fixation marker (500ms)


Table 140.4   Female/male Japanese forenames used in the priming task

	Female forenames		Male forenames	
	Forename	Mean femininity/ masculinity	Forename	Mean femininity/ masculinity
1	*Megumi*	1.07	*Takeshi*	6.87
2	*Reiko*	1.07	*Goro*	6.87
3	*Maiko*	1.13	*Ichiro*	6.87
4	*Michiko*	1.13	*Taro*	6.80
5	*Yoko*	1.13	*Daisuke*	6.80
6	*Yukiko*	1.13	*Ken-ichi*	6.80

This table lists the most feminine- and masculine-rated Japanese forenames and their mean femininity/masculinity scores (7-point scale: 1 = *very feminine* to 7 = *very masculine*)

The gender choice and reaction time (RT) were recorded. Participants were informed that pairs of words would be sequentially presented at the center of the PC monitor, and were instructed to concentrate only on the second word (forename).

The six foods evaluated as the most feminine and the six evaluated as the most masculine in study 2 were selected as the prime stimuli (see Table 140.3). A pilot survey was conducted to select the target stimuli. Fifteen participants (nine females and six males; average age = 24.3 years; *SD* = 2.2; range: 22–29 years) were asked to rate a list of 100 Japanese forenames (50 each of female and male) for their femininity/masculinity (7-point scale: 1 = *very feminine* to 7 = *very masculine*) and for their commonness (7-point scale: 1 = *very uncommon* to 7 = *very common*). We equalized the number of characters and the lengths of syllables of all the forenames so that they all had three or four characters and/or syllables. The six most feminine- and masculine-rated Japanese forenames, respectively, were selected as the target stimuli (see Table 140.4 for a full list of the targets). The femininity/masculinity scores of the selected female target stimuli (mean=1.11) differed significantly from those of the selected male target stimuli (mean=6.84), $t(14) = 42.15$, $p < 0.01$, but the typicality scores did not differ significantly, $t(14) = 1.01$, *n.s.* (mean for female target stimuli = 6.54; mean for male target stimuli = 6.39).

Prime and target stimuli were presented in white letters on a black background. After the semantic priming task, the self-report questionnaire for gender stereotypes was conducted to measure explicit gender-based stereotypical attitudes toward foods. Participants were asked to estimate the gender of the typical eater of each of the 12 dishes used as priming stimuli. A 5-point bipolar scale from feminine (1) to masculine (5) was used.

140.4.5 Reaction Time Analysis

The mean scores and standard error for RT in the semantic priming task are presented in Fig. 140.4 (Kimura et al. 2009). A 2 (target's gender: feminine forename vs. masculine forename) × 2 (semantic congruence: congruent vs. incongruent) × 2 (participant's gender: female vs. male) analysis of variance (ANOVA) was performed on RT. A significant main effect of semantic congruence, $F(1, 34) = 25.96$, $p < .01$, with a shorter RT for the congruent ($M = 450$ ms, $SD = 47.58$) than for the incongruent ($M = 491$ ms, $SD = 65.27$) conditions was found. There were neither significant differences in the RTs among the participant or target genders nor any interaction among factors.

Fig. 140.4 The mean RT of the semantic priming task (in ms). The RT for the semantically congruent condition (i.e., a female forename presented after a feminine food prime) was significantly shorter than that for the incongruent condition (i.e., a female forename presented after a masculine food prime). Error bars indicate standard error (male participants: $n = 17$, female participants: $n = 19$). *RT* reaction time, *MT* male target, *FT* female target
140.4.6 Error Rate Analysis

It has been demonstrated that participant response is not only faster, but also more accurate under the congruent condition than under the incongruent condition of the semantic priming test (Lamote et al. 2004). We calculated the error rate as a measure of response accuracy using the following equation: error rate = number of wrong responses/number of all responses. The mean scores and standard error for error rate in the semantic priming task are presented in Fig. 140.5. A $2 \times 2 \times 2$ (target's gender $\times$ participant's gender $\times$ semantic congruence) ANOVA was performed on the error rate of responses. The analysis of the error data exhibited a similar but more complex pattern compared with those of RT. As in the RT results, we found a significant main effect of semantic congruence, $F(1, 34) = 21.85$, $p < 0.0001$, with a higher error rate for incongruent ($M = 0.028$, $SD = 0.01$) than for congruent ($M = 0.005$, $SD = 0.03$) conditions. On the other hand, we found a significant interaction between a target's gender and the participant's gender $F(1, 34) = 4.60$, $p < 0.05$) and among all three factors ($F(1, 34) = 7.41$, $p < 0.05$). To analyze the interaction among the three factors, *post-hoc* analyses (Tukey's honestly significance difference (HSD) test) were performed. Six significant simple–simple main effects were found. The tests of simple–simple main effect showed that error rates of the incongruent condition were higher than those of the congruent condition (A) for the male participant with male target condition, (B) the male participant with female target condition, and (C) for the female participant with female target condition ($p < 0.01$ for all). Regarding the difference in target genders, the tests of simple–simple main effects detected that (D) error rate for male targets was higher than that for female targets ($p < 0.05$) in the male participant with incongruent condition. In contrast, (E) error rates for female targets was higher than that for male targets in the female participant with incongruent condition ($p < 0.01$). Regarding the difference in participant gender, the tests of simple–simple main effects indicated that (F) error rates for male participants were higher than those for female participants ($p < 0.01$) in the male target with incongruent condition.

140.4.7 Self-Report Analysis

The explicit gender-based stereotypical attitude toward each food name measured by self-report questionnaire was also analyzed to confirm whether the 12 foods selected in studies 1 and 2 were actually perceived as feminine or masculine by the participants in the experimental sessions (Kimura

Fig. 140.5 The mean error rate of the semantic priming task (in percentages). The error rate for the semantically congruent condition was significantly lower than that for the incongruent condition. The results of error rate measurements also demonstrated an interaction among the factors. Error bars indicate standard error (male participants: $n = 17$, female participants: $n = 19$). *MT* male target, *FT* female target
et al. 2009). A 2 (participant gender: female vs. male) × 2 (food femininity/masculinity: feminine food vs. masculine food) ANOVA was performed on the ratings of femininity/masculinity. A significant main effect of food femininity/masculinity ($F(1, 34) = 279.56$, $p < 0.01$) was found. The masculine foods ($M = 4.31$, $SD = 0.46$) were rated as more masculine than the feminine foods ($M = 1.72$, $SD = 0.52$). There were no significant differences in the masculinity/femininity ratings between participant genders or in the interaction among factors.

140.4.8 Validity of the Semantic Priming Paradigm on Measuring Gender-Based Food Stereotypes

The results of study 3 demonstrate that RT for the semantic priming task provides a good reflection of the semantic association of masculinity or femininity with specific foods. RT of the semantic priming task robustly reflected the gender-related semantic congruency between the prime stimuli (food names) and the target stimuli (forenames). Specifically, RT for the semantically congruent condition (i.e., a female forename presented after a feminine food prime and a male forename presented after a masculine food prime) was significantly shorter than that for the incongruent condition (i.e., a female forename presented after a masculine food prime and a male forename presented after a feminine food prime). This result suggests that there are tight associations between specific food names and gender among young Japanese.

Analysis of the error rate also supported the existence of a similar food-gender association pattern. Moreover, the result of error rate measurement demonstrated an interaction among the factors: target gender, participant gender, and semantic congruence. However, it is still unclear whether it is most appropriate to adopt the error rate measurements or to treat them as subsidiary to RT measurements. If we adopt the error rate measurements, the interaction may suggest the existence of complex associations between the factors tested. The error rate was higher when a participant's gender and a target's gender were opposite (c.f., D and E in the "Results" section). This leads to the postulation that, in young Japanese, the association between food and gender is stronger when the associated gender is opposite to the participant's gender than when it is the same as the participant's gender. This tendency was more explicit in male participants than in

female participants (c.f. A, B, C, and F in the "Results" section). That is, young, male Japanese tend to feel that women are supposed to eat feminine foods, while young, female Japanese are less biased. Such asymmetry in young Japanese may raise further cultural interest because the studies with Western subjects using explicit measures revealed the opposite tendency: Females have stronger gender-stereotypical thinking toward foods and tend to avoid eating masculine foods (e.g., Basow and Kobrynowicz 1993; Chaiken and Pliner 1987; Mooney et al. 1994). Although the current experiment is not sufficient to conclude whether there is a cultural difference in the way women and men hold gender stereotypes toward what women or men should eat, this would be an interesting issue to explore in the future.

140.5 Comparison of Gender-Based Food Stereotypes Between Japanese and Western Consumers

To the best of our knowledge, we have provided the first report of a three-phase cross-validation study on gender-based stereotypes toward foods among young Japanese: the most masculine or feminine foods were screened in the first phase, the candidate foods were explicitly assessed for their femininity or masculinity in the second phase, and, finally, the gender associations for the 12 foods determined to be the most feminine or masculine were validated explicitly and implicitly in the third phase. Given this, it would be worth discussing the current results from a cultural perspective.

140.5.1 Masculine Foods

Consistent with the results of the wealth of studies using Western subjects, there are gender-based stereotypes toward specific foods among young Japanese. Most of the masculine foods that were selected in study 2 include both traditional Japanese dishes and Western dishes commonly consumed in Japan (Table 140.3), including beef steak, which was also found to be masculine in a former study using Western subjects (Mooney and Lorenz 1997). These masculine foods are basically categorized as high-fat foods consisting mainly of meat or meat with rice. The association between masculinity and high-fat foods is consistent with results of a former study on dietary social stereotypes (Barker et al. 1999), and with the fact that, based on a large-scale survey of dietary records for US college students (Huang et al. 1994), young males consume more high-fat foods than do young females.

140.5.2 Feminine Foods

On the other hand, most of the feminine dishes that were selected in study 2 consisted exclusively of Western foods (Table 140.3). This was in marked contrast with the case of masculine dishes that consisted mainly of early-modern traditional Japanese foods. Since, to our knowledge, there is no study on the association between foreign/domestic foods and genders, we cannot provide any further comparative discussion on the current observation, but this would be an intriguing issue for future exploration.

    The feminine foods included low-fat foods (i.e., pasta, salad, and fruits) as in former studies on Western consumers (Barker et al. 1999; Mooney and Lorenz 1997). Although some high-fat foods

were chosen, they were all sweets, and no meat or rice dishes were selected. There is no direct study assessing the stereotypical association between femininity and sweets, but behavioral studies have consistently revealed a female craving for sweets in Western countries (Pelchat 1997; Rozin et al. 1991; Zellner et al. 1999). It seems reasonable to consider the stereotypical association between femininity and sweet foods a cross-cultural phenomenon. On the other hand, the dissociation of femininity from rice and meat seems to reflect a rather complex behavior in view of a recent food craving study on young, female Japanese: it was demonstrated that the young women had strong cravings for rice and meat, but that the cravings were not always related to their actual eating behaviors (Komatsu 2008). Komatsu postulated that the desire for thinness and the subsequent restraint in eating behavior may be the reason for such dissociation, but the current results suggest another possibility: the gender-based stereotypes that rice and meat are associated with masculinity may also induce the craving-behavior dissociation.

Kimura et al. (2009) revealed that, consistent with studies based on Western subjects, there are robust gender-based stereotypes toward foods among young Japanese that high- and low-fat foods are associated with masculinity and femininity, respectively. This study also suggests a specific tendency among young Japanese: there is a plausible complex association among masculinity, high-fat foods, and early-modern traditional Japanese foods; femininity is associated with sweets regardless of the fat content of foods, whereas there is a dissociation from rice and meat. Further research is necessary to clarify these culture-specific tendencies.

140.5.3   Application Toward Areas of Health

The recent tendency among young Japanese to avoid eating traditional Japanese foods, particularly rice, has raised growing social and political concern (Ministry of Health, Labour and Welfare Japan 2007; see also Table 140.2). It is plausible that the gender-based food stereotype among young Japanese females of associating rice with masculinity, together with forming a psychological barrier against eating masculine foods, may add to such tendencies.

These stereotype-based barriers among young Japanese females against Japanese foods might lead to loss not only for the Japanese food industry, but also for the health of individuals, given the health benefits of eating Japanese foods. For example, Kamei et al. (2002) evaluated the nutritional contents of take-out lunches supplied in Japan, and revealed that traditional Japanese-style diets were healthier in respect to total energy, fat–energy ratio, and lipid-related proportions relative to Western-style fast foods. They concluded that such Japanese-style dishes provide an advantage for preventing several kinds of lifestyle-related diseases. This further implies that an increase in the consumption of Japanese-style dishes may lead to a decreased risk of lifestyle-related diseases. Thus, the possibility of technical interventions for reducing such gender-specific biases toward Japanese foods and eating should be explored. Implicit measurements, as exemplified in the semantic priming tasks in the current study, provide effective tools in examining static and dynamic aspects of consumer stereotypes toward foods and eating.

140.6   Conclusion

There is a robust association between specific foods and masculinity or femininity among young Japanese, as has been revealed for Western subjects. As advocated by a classical study on the product personality by Wells et al. (1957), and the "you are what you eat" hypothesis of foods by Nemeroff

and Rozin (1989), stereotypes toward foods could further affect the personality of the eater, thus generating another facet of gender-based stereotype.

Research on stereotypes toward foods and eating has drawn growing interest, but is still in the development phase. To accelerate progress in this area, elaborated analysis of the social factors related to stereotypes toward foods and eating, such as culture, gender, and age is indispensable. In addition to such static analysis, dynamic intervention studies on how to reduce stereotypes are necessary.

Summary Points

- People have stereotypical attitudes toward particular foods and eating behaviors.
- Gender stereotypes occur when femininity and masculinity are consistently associated with the type of food that individuals eat. People sometimes judge the femininity and masculinity of others based on their food intake.
- There is a robust association between specific foods and masculinity or femininity among young Japanese, as has been revealed for Western subjects.
- The feminine-evaluated foods among young Japanese included low-fat foods (i.e., pasta, salad, and fruits) as with Western consumers. Although some high-fat foods were chosen, they were all sweets, and no meat or rice dishes were selected.
- The masculine-evaluated foods among young Japanese are basically categorized as high-fat foods as with Western consumers, consisting mainly of meat or meat with a carbohydrate (i.e., beef rice-bowl, Chinese noodle soup, and beef steak).
- The semantic priming task provides a good reflection of the semantic association of masculinity or femininity with specific foods. This technique provides effective tools for examining static and dynamic aspects of consumer stereotypes toward foods and eating.

Key Terms and Definitions

Consumption stereotype: Stereotypes related to food consumption and eating behavior (mostly what and how much individuals eat). In certain situations, people may exploit these stereotypes and eat in a particular way so as to project a desired impression to others (Vartanian et al. 2007).
Gender stereotype: These are culturally specific, publicly shared characteristics that are associated with one particular gender role (Holroyd et al. 2002). Several studies have shown that people use the gender stereotype as a basis for their food selection and eating behavior.
Implicit attitude: Attitudes measured by implicit attitude measures such as the affective/semantic priming test and the implicit association test (IAT). These techniques indirectly infer attitudes by examining response patterns (e.g., changes in response time) toward stimuli related to the topic.
Semantic priming task: A reaction time task that involves the successive presentation of a *prime* (usually words or pictures) and a *target* (words or pictures) that have polar balance (e.g., positive vs. negative). It is considered that the intensity of semantic association between prime and target may be reflected in response time and accuracy.
Explicit attitude: Attitudes measured by a self-report questionnaire. A self-report questionnaire has the advantage of being able to measure attitudes easily. On the other hand, these techniques may be diminished by the risk of reflecting skewed attitudes flawed by social desirability or self-presentation biases.

Starvation and Nutrient Deficiency

Chapter 141
Diet-Related Behavioral Mechanisms in Times of Economic Constraint

A.R. Kelles, M. Shroff, and A. Rinehart

Abbreviations

SES   Socioeconomic status
CVD   Cardiovascular disease
DM   Diabetes mellitus
CHD   Coronary heart disease
BMR   Basal metabolic rate
WHO   World Health Organization
DHHS   Department of Health and Human Services
USDA   Unites States Department of Agriculture
CDC   Centers for Disease Control
FSP   Food Stamp Program
WIC   Special Supplemental Nutrition Program for Women, Infants, and Children
SNAP   Supplemental Nutrition Assistance Program
FAO   Food and Agriculture Organization
HIV   Human immunodeficiency virus
AIDS   Acquired immunodeficiency syndrome
GHI   Global hunger index
IFPRI   International Food Policy Research Institute

141.1 Introduction

Obesity is a global epidemic with a rapidly increasing predominance among low-income populations. Unfortunately, low-income populations are also the least capable of dealing with the health and economic consequences directly associated with obesity and indirectly with obesity-related chronic diseases (Russell 2004; Leive and Xu 2008). Increases in chronic disease prevalence among low-income populations could ultimately lead to overall reduced quality of life as well as a substantial increase in days of work lost in the global work force (Goudge et al. 2009). Similar to the impact of obesity,

chronic undernutrition, still prevalent in many developing countries, leads to increased infectious disease risk and is associated with substantial days of work lost (McIntyre et al. 2006).

To curtail the global trend towards decreased health among low-income populations it is important to understand the mechanism by which economic constraint leads to adverse disease outcomes. Research has identified several possible pathways, such as the impact of economic constraint on accessibility/usage of healthcare services, physical activity, and dietary behaviors (Gordon-Larsen et al. 2006; Nelson et al. 2006; Goudge et al. 2009; Larson et al. 2009; Pollack and Armstrong 2009). A goal of this chapter is to explore specifically the mechanism by which economic constraint influences dietary behaviors among low-income populations. This information can be incorporated into the development of efficient and effective interventions and policies aimed at improving health status among the poor. Creating policy measures to support low-income populations, however, is complicated because dietary behavior responses to economic constraint differ substantially depending on the local, national, and international environmental contexts. For example, economic constraint in a developed country setting often leads to the consumption of high-energy but low-nutrient dense diets (Drewnowski and Darmon 2005). The impact of economic constraint in some developing country settings may resemble a developed country yet for others it may lead to an overall insufficient intake of both micronutrients and total calories (Hakeem 2001; Popkin 2001; Shafique et al. 2007; Vorster et al. 2007; Ntandou et al. 2009). Due to the diversity in dietary behavior response to economic constraint, we will explore this relationship in both a developed and developing country setting.

The accessibility of resources such as foodstuffs/food markets, transportation, safe environment, and healthcare is not solely influenced by the economic ability of an individual or family. In fact, the relationship between dietary choices and economic constraint differ substantially by the economic, social, and political state of an individual's or family's environment. More specifically the relationship differs for those in a developing versus a developed country setting and within countries by the level of urbanicity (Vorster 2002; Popkin 1998). There is a global nutrition phenomenon, referred to as the nutrition transition, documenting a shift from undernutrition to overnutrition as the economic wealth of a developing country increases (Popkin 1998). This transition is accompanied by an increase in food availability particularly in urban areas. The increase in food availability results in an increase in overconsumption, particularly of highly processed carbohydrates, animal fats, and a concurrent decrease in fresh fruits and vegetables (see Fig. 141.1). Compounding the emergence of this unhealthy lifestyle is a population shift from active to sedentary transportation as well as agriculture to service-oriented occupations leading to an overall sedentary population. These changes in both dietary and physical activity patterns lead to a shift in disease prevalence from infectious diseases to the emergence of obesity and related chronic diseases such as cardiovascular disease (CVD), hypertension, diabetes mellitus (DM Type 2), and many types of cancers (Ntandou et al. 2009; Misra and Khurana 2008). This phenomenon is often referred to as the epidemiologic transition (see Fig. 141.2) (Manton 1988; Mathers and Loncar 2006; Stuckler 2008). Occurring with the increased economic growth on a national level is the decrease in both fertility and mortality leading to a shift towards an aging population structure. This change is known as the demographic transition and is in part a result of increased active family planning, increased number of women in the work force, and overall improvements in sanitation and healthcare (Manton 1988; Mathers and Loncar 2006). An aging population, concurrent with the increase in obesogenic lifestyles, leads to the increase in obesity and chronic diseases versus infectious diseases found in middle- and high-income developed countries.

Within a country, both accessibility to and affordability of food resources affect the dietary behaviors of economically constrained populations. Food accessibility and affordability are in turn dependent on contextual wealth and development of a given geographic area. In a developed country, accessibility to resources, although an issue, may not be as much a limiting factor to healthy dietary

__The Nutrition Transition__

__Stage 1__	__Stage 2__	__Stage 3__	__Stage 4__	__Stage 5__
Society of hunter gatherer subsistence living	Agricultural society with high rates of undernutrition	Society experiencing industrialization with an increase availability of diverse 'rich' diets	Industrialized society with diets: high in saturated and trans fat, cholesterol, processed simple carbohydrates, and low in complex carbohydrates, and fiber	Society beginning to engage in lifestyle modifications to prevent or delay chronic disease onset

Low-income countries: developing → Increasing National GNP → **High-income countries: developed**

Fig. 141.1 Key features of the nutrition transition. This figure represents the general dietary trends observed depending on the wealth and development of a country. The trend can be used to compare the expected dietary patterns between countries but can also be used to represent the changes that occur as a country experiences increases in wealth and development and transitions from a preindustrial to a highly industrial economy

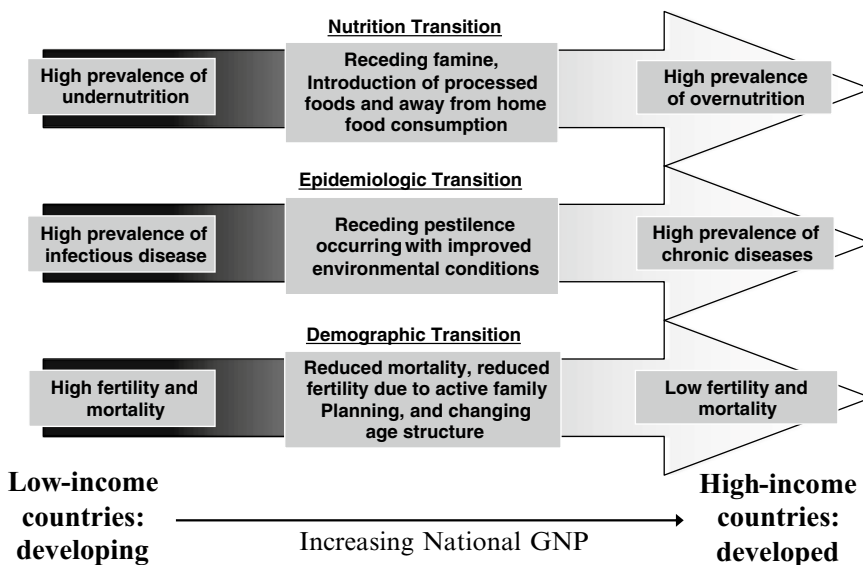
Stages of Demographic, Epidemiologic, and Nutrition Change


Fig. 141.2 The dietary and disease patterns as well as the population structure for countries at varying stages of wealth and development. These trends are inextricably intertwined and occur simultaneously as a country undergoes transition from a preindustrial to a highly industrialized country

behaviors as affordability among low-income groups (Darmon and Drewnowski 2008). Within a developing country context, however, there is substantial diversity in the availability of resources often, depending on the urbanicity of the environment (Dixon et al. 2007). In low- and middle-income developing countries, in a more urban environment, generally there is a greater access to resources. To create effective policies and interventions, it is therefore crucial to identify the local and national environmental context since this will determine to some extent how individuals and families will respond when faced with economic hardship. Policies and interventions in both developed and developing countries will be explored further in this chapter.

141.2 Developed Countries: Trends in Obesity and Related Diseases

In the past century, the prevalence of chronic disease has increased steadily in developed countries where people have ready access to energy-dense diets. In 1960, the estimated obesity prevalence in the US was 13.4%, but by 2000 this number had risen to 30.9% (Flegal et al. 2002). It is now estimated that roughly 2/3rds of Americans are overweight or obese (Ogden et al. 2006). As a result, researchers recently projected a decrease in the life expectancy for the twenty-first century (Olshansky et al. 2005). Similar trends exist throughout Britain and Europe (Seidell 2000). It is well documented that obesity is significantly correlated with an increased risk of many chronic diseases such as CVD, endocrine disorders, many forms of cancer, pulmonary disorders, musculoskeletal disorders, gastro-intestinal, hepatic and reproductive disorders (Brown et al. 2009). In the last decade new research has identified substantial metabolic activity in adipose tissue indicating a neuroendocrine link between obesity and chronic diseases such as CVD and diabetes (Ohman et al. 2009; Korner et al. 2009). We now know that adipose tissue releases chronic disease-related inflammatory mediators known as adipokines such as adiponectin and aromatase. For example, research indicates that Adiponectin may be the causal link between abdominal fat and atherosclerosis (Hansen et al. 2009). Aromatase, which promotes the conversion of estrogen to a carcinogenic metabolite, is now targeted using drug inhibitors as a post-menopausal breast cancer treatment (Maccio et al. 2009). Screening for overweight status can help identify high-risk individuals; however, the estimated accuracy of this tool is continually modified as our understanding of the neuroendocrine nature of adipose tissue expands. For example, a recent study in Japan found significant increases in visceral fat associated with a high risk of coronary heart disease (CHD) even among subjects with a low to normal estimated BMI (Popkin 1994). These findings have lead to a proposed lowering of the BMI cutoffs for overweight status in Asian populations (International Diabetes Institute 2000). New findings such as these also remind us that we are still in the early stages of uncovering the relationship between obesity and chronic disease.

141.2.1 Identifying Modifiable Obesogenic Behaviors

Given the strong correlation between obesity and chronic disease risk it is crucial that researchers identify modifiable behaviors leading to obesity that can be targeted by policies and interventions. Studies indicate that the rising rates of obesity are largely a result of the energy-dense diets associated with technological innovations, urbanization and improved socioeconomic status (SES) (Bleich et al. 2008). Specifically, technological advances in agriculture, food-preparation, cooking appliances, and food storage have led to significant decreases in the price of food. Greater reductions in

Table 141.1   Key features of diet quality (Kant 1996; Arvaniti and Panagiotakos 2008)

1. Diet quality, independent of diet quantity, is critical in the prevention of chronic diseases such as obesity. There are innumerable studies that have identified an association between chronic disease risk and specific dietary attributes such as the distribution of energy among the different macronutrients or the dietary adequacy of specific micronutrients

2. Diet quality is an overall balance of macronutrients with an intake of micronutrients to meet recommended levels relative to total energy intake

3. Several scoring systems exist to measure diet quality. Each system is aimed at measuring diet quality or the adherence to national dietary recommendations or guidelines constructed with the specific aim of chronic disease risk reduction (e.g. cardiovascular disease (CVD), hypertension, and cancer), including:

   (a) *Healthy Eating Index (HEI)* – was developed by the US Department of Agriculture and based on the Dietary Guidelines for America and the Food guide pyramid. The HEI has 10 component scores each with a maximum diet quality adherence score of 10, including:

    (i) Five components measure adherence to the recommended servings of each of the following major food groups: grains, vegetables, fruits, milk, and meat

    (ii) Dietary fat intake as a percent of total energy

    (iii) Saturated fat intake as a percent of total energy

    (iv) Cholesterol intake

    (v) Sodium intake

    (vi) Measure of dietary diversity

   Although the HEI provides a measure of overall dietary quality, several large scale studies found a lack of association with diet quality measured by the HEI and chronic disease risk. This lack of association may be due in part to the exclusion of food components that play a protective role such as fiber and essential fatty acids.

   (b) *Diet Quality Index (DQI)* – was specifically designed to measure diet quality as a reflection of chronic disease risk based on scientific guidelines provided by the scholars in the diet and health area. The components include:

    (i) Three components based on recommendations of dietary lipid intake (total fat, saturated fat, and cholesterol)

    (ii) Two components based on recommendations for simple and complex carbohydrate intake

    (iii) Although weighted less heavily in the total score, several components were included based on dietary protein, calcium, sodium, fluoride and supplement use

   This Index was revised (DQI-R) to include the most current US dietary guidelines and modified (DQI-I) to take into consideration diet characteristics such as: adequacy, variety, moderation, and overall balance

Several scoring systems have been created to quantify dietary quality for research and public policy purposes. This table outlines several of these indices

food prices have occurred for sweets, fats, and sugar-sweetened caloric beverages than for fresh fruits and vegetables (Drewnowski and Darmon 2005). This price disparity in turn has promoted the consumption of calorie-rich and nutrient-poor diets among low-income populations. To improve diet quality (see Table 141.1), researchers have estimated 35–40% additional food costs for low-income families (Jetter and Cassady 2005).

141.2.2 Defining the Environmental Context Associated with Obesogenic Behaviors

Various national policies and interventions exist to reduce the consumption of energy-dense foods, yet obesity continues to rise in developed countries like the United States, Canada, France, Germany, Great Britain, and several Scandinavian countries (Popkin 1994). Rising obesity trends may be due in part to a lack of consideration for the environmental context where obesity predominates.

Interventions directly targeting obesogenic behaviors often do not take into consideration underlying household factors such as SES that may influence an individual or family's ability for behavior change. In developed countries, higher rates of obesity are observed in low- versus high-income populations leading to an increased risk of many chronic diseases among the poor (Popkin 2004). This may be a direct result of the poor quality diets observed in many low-income populations. Compared to high-income families, economically constrained families are less likely to consume whole grains, lean meats, fish, low-fat dairy products, and fresh fruits and vegetables. Additionally, these low-income families tend to consume higher quantities of fatty meats, refined grains, and added fats (Darmon and Drewnowski 2008). Diets high in these energy-dense foods are associated with increased obesity risk as well as CVD and type II diabetes (Mendoza et al. 2007).

In general, as the economic status of an individual or family decreases there is an increased reliance on cheaper high-calorie diets rather than the more expensive nutrient-dense diets. Fruits and vegetables, which tend to be the most expensive foods per calorie, provide high quantities of micronutrients and fiber and thus improve the overall quality of a diet. However, fruits and vegetables are often prohibitively expensive for low income families, particularly given their relatively short shelf-life. Affordable high-calorie diets tend to consist of highly processed foods with longer shelf-lives that are high in simple sugars, saturated and trans- fats. Additionally, high-calorie foods are generally better tasting and convenient to prepare (Mendoza et al. 2007). Unfortunately, these highly processed foods are typically less satiating and therefore lead to overconsumption of total calories (Drewnowski and Darmon 2005). As a result, low-income families often meet or exceed calorie needs, but are deficient in micronutrients which come primarily from the more expensive fruits and vegetables (Andrieu et al. 2006).

141.3 Developed Countries: Why Low SES Leads to Poor Health Outcomes

There are multiple factors thought to link the effect of SES to health outcomes. Low SES groups receive less nutrition education and have poor access to healthcare services (Heck and Parker 2002; Devoe et al. 2007). Low-income families also commonly seek care for health problems later than middle or high-income families due to rapidly rising healthcare costs (Bodenheimer 2005). This leads to later diagnoses and ultimately more expensive healthcare interventions. Despite an increasing need of medical care for chronic diseases related to poor diet and sedentary lifestyles, there is a shortage of physicians interested in meeting this demand. Physicians report a lack of time, poor patient compliance, insufficient training, and lack of adequate insurance reimbursement as barriers to appropriately addressing care needs for the obese (Tsai et al. 2006). Additionally, technological innovation leading to the development of labor-saving household devices and passive forms of transportation has been estimated to contribute up to 40% of current weight gain in the United States (Lakdawalla and Philipson 2002).

141.3.1 Impact of SES on Dietary Behaviors

One of the most significant factors leading to poor health in developed countries is the impact of SES on diet behaviors. Individual and household SES is more dynamic than previously thought as families fall in and out of poverty due to unforeseen economic events and household expenses (Cornia 1994; Lokshin and Popkin 1999). Economic events can lead to periods of food insecurity characterized

by a general decrease in food availability and a concurrent reduction in diet quality due to decreased purchasing power. Generally, low-income families experience food insecurity at higher rates than middle and high-income families because they are more susceptible to falling either temporarily or permanently in to poverty during periods of economic crisis (Cornia 1994; Lokshin and Popkin 1999). Further, psychosocial problems associated with food insecurity can contribute to disease-promoting diet behavior. Specifically, individuals from poorer families experience higher levels of loneliness, boredom, and depression which can lead to behaviors such as excessive snacking, skipped meals, and sedentarianism (Darmon and Drewnowski 2008). Economic constraints can present a conflict between competing priorities such as food preferences and affordability of these foods (Dore et al. 2003) adding to the psychological stress. Wealth disparity, increased household size, unexpected family expenses, loss of food stamp benefits, and unemployment can also lead to food insecurity among families (Rose 1999). Additionally low-income families report a lack of cooking skills, lack of motivation (Dibsall et al. 2003; Henry et al. 2006) and disinterest in cooking (Henry et al. 2006) as barriers to healthy eating.

141.3.2 Who Is the Most Severely Impacted?

During periods of economic duress, the nutritional status of adults typically declines first as a result of prioritizing their children's nutritional needs over their own (Messer and Ross 2002). Despite efforts of parents to ensure adequate nutrition for their children, lower rates of breastfeeding among low-income families as compared to middle- and high-income families often results in poor childhood nutritional status. Given that dietary habits are established in childhood, children of low-income families are at particular risk of establishing lifelong poor quality dietary habits particularly during economic crises (Wang et al. 2002; Nicklas 1995). Poor dietary quality in childhood decreases overall immune function, increases the rate of dental caries, and can lead to cognitive deficiencies (Nelson 2000) and can permanently downregulate basal metabolic rate (BMR) increasing the risk of adult onset obesity.

141.4 Developed Countries: Pathways by Which Socioeconomic Status Affects Diet Quality

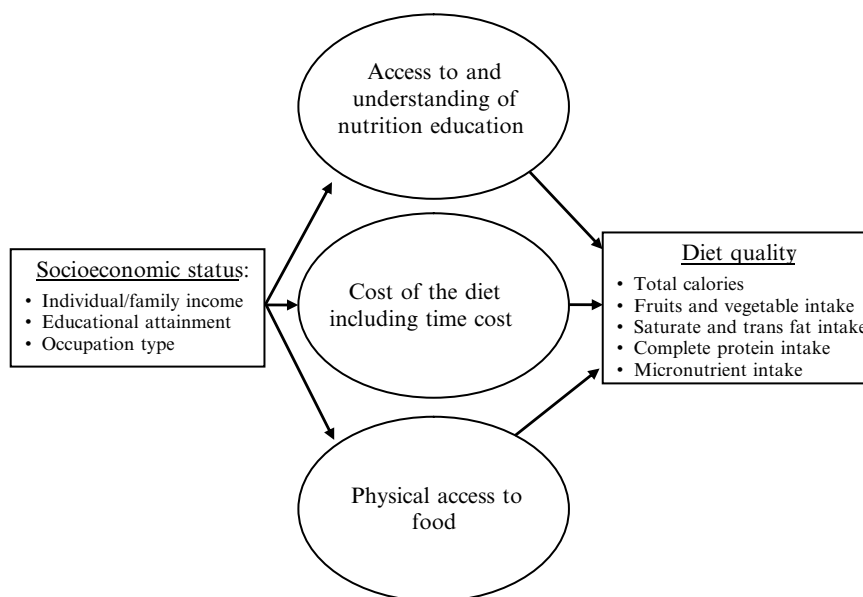
There are multiple proposed pathways linking the effect of SES to decreased diet quality and poor health outcomes (see Fig. 141.3). Low-income groups receive less nutrition education (Variyam et al. 1996) and have poor access to healthcare services (Devoe et al. 2007). Physical access to healthy foods is recognized as a significant factor in diet-related disease for low-income groups (Gittelsohn and Sharma 2009). Proximity to supermarkets that offer a variety of fruits, vegetables, and low-fat dairy products exist in lower concentrations in economically impoverished areas and can limit accessibility to healthy food choices for low-income families (Larson et al. 2009). Additionally, concentration of fast food restaurants is higher in low-income neighborhoods (Smoyer-Tomic et al. 2008). The low walkability and perceived safety of low-income neighborhoods limits access to facilities offering fresh produce, low-fat dairy products, and unprocessed lean meats and poultry (Maziak et al. 2008; Mujahid et al. 2008a, b). Low-income individuals from urban environments are subject to long commute times and have low vehicle ownership which dramatically decreases accessibility of large food markets (Larson et al. 2009). Further, reduced wages force many low-income individuals to work extended hours decreasing both the time available to travel to distant grocery stores and


Fig. 141.3 Etiologic mechanism by which socioeconomic status (SES) impacts dietary quality. This figure illustrates the impact of SES on diet quality in developed countries. Nutrition education as well as accessibility and affordability of food are all intermediary factors linking low SES to poor diet. These factors are therefore key potential areas for interventions designed to successfully promote dietary change

prepare fresh home-prepared meals (Jabs and Devine 2006). Physical access to food stores can be complicated in districts that span large rural areas (Sharkey 2009). Quality of roads, tight district budgets, and work and commuting schedules can also complicate access for low-income families. Overall limited physical access to healthy food choices promotes the consumption of unhealthy prepackaged shelf-stable processed foods exacerbating the excess intake of total calories and insufficient micronutrient observed in low-income populations. As with food insecurity, individuals in urban versus rural areas experience more stress, which feeds psychosocial elements of disease-promoting dietary behaviors (Quine et al. 2003).

Food choices are made primarily on the basis of cost, taste, and convenience, rather than health and variety (Glanz et al. 1998). The high cost of nutrient-dense foods is likely the most significant determinant of inadequate consumption of fruits and vegetables, high quality lean meats and dairy products (Drewnowski and Specter 2004). The percentage of total family income accounting for food purchases inside and outside of the home is lowest for US families. Despite food expenditures accounting for the lowest percentage of the family budget, US families consume one of the most energy-dense diets in the world (Meade and Rosen 1996). Food costs take up a greater percentage of low- versus high-income family budgets creating an incentive for low-income families to purchase prepackaged and prepared calorie-rich foods to satisfy dietary needs. In contrast, unless consumed relatively quickly, the more expensive fresh foods such as fruits and vegetables are more likely to spoil than processed foods posing a highly inefficient use of money for overworked low-income families (Dowler 1997). Furthermore, low-income families tend to purchase highly processed fatty meats (Guenther et al. 2005) and high-fat dairy products (Prattala et al. 2003) such as hot dogs, prepackaged hamburgers, and processed cheese products due to cost and time limitations. Compared to dietary guidelines from the US Department of Health and Human Services (DHHS) and Department of Agriculture (USDA), a significant proportion of low-income families consume an excess of unhealthy fats and added sugars (DHHS and USDA 2005; Darmon and Drewnowski 2008). Overall,

low-income families in developed countries often meet or exceed calorie needs, but fall far short of dietary guidelines of 400 g of fruits and vegetables set by the World Health Organization (WHO 2010). Consequently, this insufficient intake of fruits and vegetables leads to inadequate micronutrient intakes among many low-income individuals and families (Andrieu et al. 2006). The consumption of low quality diets in response to the high cost of nutrient-dense diets has been observed in other developed countries such as the UK, France, and Denmark (Darmon et al. 2004).

141.5 Developed Countries: Public Policies and Interventions to Promote Health

A combination of environment reconfiguration, public policy initiatives, and multilevel economic strategies may be required to reduce the prevalence of obesogenic dietary and physical activity behaviors (see Table 141.2) (Sallis and Glanz 2009). Historically, policy recommendations in developed countries have focused on reducing calorie consumption (Bleich et al. 2008), increasing fruit and vegetable consumption (WHO 2010), and increasing physical activity (CDC 2009). Decreasing total calories by limiting dietary fat has had limited success. Instead of decreasing total calories, individuals commonly substitute fatty foods with high-glycemic foods that make weight loss difficult and that contributes to diet-related disease (Pawlak et al. 2002). On the other hand, limiting carbohydrates in the diet is difficult to sustain and may be associated with high intake of saturated fats (Strychar 2006). Consumption of fruits and vegetables is a major determinant of dietary energy-density due to their high water and micronutrient content. Increasing intake of fruits and vegetables along with whole-grains and fish has been consistently associated with improved health outcomes (Kant 2004). Altering the food environment to improve accessibility to health food choices and subsidizing specific fruits and vegetables may help increase diet quality for low-income populations (Powell et al. 2009). Point-of-purchase techniques (e. g. health information and detailed menu labeling where purchasing decisions are made) in addition to subsidies for fresh produce may be important components to policies that support individual food preference yet promote healthy dietary habits. Such campaigns could be utilized in worksites, universities, grocery stores, and restaurants, but few adequate research trials have been conducted to evaluate the effectiveness of such efforts (Seymore et al. 2004). As a mechanism to prevent weight gain, stimulate weight loss and maintain weight loss, a recent Center for Disease Control (CDC) and Prevention task force proposed recommendations to improve physical activity in communities (CDC 2009). Such an evidence-based campaign would combine billboards, radio, television, newspapers, mailings, self-management education, worksite programs, tenant-based rental assistance programs, center-based programs for low-income children, enhanced school-based physical education, and behavioral and social support interventions. Many of these tools have been tested and have successfully increased physical activity levels individually but they have not been evaluated as a comprehensive intervention.

141.5.1 Public Policies and Interventions Aimed at Dietary Behavior Change

Awareness of health assistance programs and services in the digital age can be problematic for low-income individuals. In rural areas, low-income individuals are much less likely to use internet resources to acquire health information (Miller 2009). Low-income groups will benefit from government-sponsored programs that equalize access and provide incentives for purchasing healthy, nutrient-dense foods.

Table 141.2 Examples of developed country government-sponsored food interventions targeting low-income individuals and families

National program	Type of intervention	Governing body	Target audience	Program goal	Potential limitation
Expanded Food, Nutrition and Food Stamp Education Program	Nutrition-related education program only	USDA Cooperative State Research, Education, and Extension Service	Low-income families with a particular focus on youth	Educate families on healthy food choices	Can fail to take into account individual preferences, behavior patterns, and high cost/accessibility of healthy food
Food Stamp Program (FSP)/Supplemental Nutrition Assistance Program (SNAP)	Direct assistance to supplement food purchasing power only	USDA Food and Nutrition Service	Employed low-income individuals and families	Reduce food insecurity among low-income families	Subject to social restraints such as complex application forms, lengthy time required for participation, cultural and language barriers, as well as social stigma
Special Supplemental Nutrition Program for Women, Infants, and Children (WIC)	Nutrition-related education and direct assistance to supplement food purchasing power	USDA Food and Nutrition Service	Low-income pregnant, breastfeeding and nonbreastfeeding postpartum women, and their infants and children of ages up to 5 years old	Reduce incidence of low birth weight and iron deficiency anemia among infants	May not reach adequate number of at risk population due to age and gender restrictions. Limited sources of fruits and vegetables covered by subsidies
Housing Assistance Program	Indirect nonfood subsidy	Department of Housing and Urban Development	State housing credit agencies provide affordable housing to 35,000 low-income households	Increase food budgets and improve overall diet quality	Limited impact on food purchasing practices towards healthier food choices

This table summarizes the existing US government programs aimed at improving dietary quality of low-income individuals and families. There are a wide range of program methods used to address poor dietary practices in developed country settings. However programs that include subsidizing targeted healthy food choices as well as providing general nutrition education may result in the most successful sustainable improvements in dietary quality in low-income populations

Programs focusing on diet education alone have been largely ineffective with respect to improving diet quality. Often, dietary advice does not take into account individual preferences and long-standing behavior patterns or the prohibitive costs of healthy food choices. Governmental programs such as the Expanded Food and Nutrition Education Program, and the Food Stamp Education Program rely exclusively on educational tools to low-income families as a means of improving food choices. Their recommendations often focus on strategies and foods with low palatability and convenience for families (Lino 2001). In place of dietary advice, studies from the UK and US have shown that providing vouchers for purchasing fruit and vegetables was a simple and effective way of increasing fruit and vegetables intakes for groups of low-income women (Burr et al. 2007; Herman et al. 2006). Unfortunately, the effectiveness of assistance programs can be limited significantly by social restraints. For example, form requirements, time required for participation, cultural and language barriers, and social stigmas can deter qualifying individuals from taking part in food assistance programs. The magnitude of the perceived assistances from the program also plays a role in sign-on rates. These barriers to utilization are difficult to quantify and measure. However, experts suggest that linking related aid/benefits into the same program may increase utilization and ultimately improve overall effectiveness (Remler and Glied 2003).

The US Food Stamp Program (FSP), now known as the Supplemental Nutrition Assistance Program (SNAP), helps low-income individuals and families purchase healthy foods and provides education on healthy eating practices and methods to incorporate physical activities into daily routines (USDA 2009). Low-income households that are enrolled in an FSP have a significantly lower incidence of food insecurity (Rose 1999). However, high dietary energy-density has also been found in diets of FSP recipients (Mendoza et al. 2006). To satisfy family dietary needs, recipients often ensure calorie-sufficiency foremost (Wilde et al. 2000) and ultimately fail to shift purchase behavior toward healthier foods (Drewnowski 2003). Additionally, food stamp recipients tend to consume more added sugars, meats, and fats and failed to improve intake of fruits, vegetables, grains, and dairy products after receiving assistance (Wilde et al. 2000). Subsidizing lean deli meats as well as specific fruits and vegetables might also improve diet quality in these low-income populations (Dore et al. 2003).

The Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) program is another federally sponsored program managed at the state level that acts to provide nutritious foods, information on healthy eating, and appropriate health referrals for low-income women, infants, and children up to age 5 (FNS USDA 2009). WIC has lead to higher birth weight and lower incidence of iron deficiency anemia in infants born to participants of this program (Owen and Owen 1997). WIC provides assistance for the purchasing of milk, cheese, eggs, iron-fortified cereal, fruit juice, and adds canned tuna and fresh carrots for breastfeeding women. WIC does not provide subsidies for other fruit and vegetables. A pilot initiative which added an additional $10 weekly-voucher to the WIC program was highly utilized among program recipients and increased fruit and vegetable consumption by 0.8–1.4 servings per day depending on the purchasing environment (Herman et al. 2006) (see Table 149.1).

141.5.2 Public Policies and Interventions Created to Impact Purchasing Power

Indirect attempts, such as housing subsidies have been used to increase the percentage of family budgets available for the purchase of healthy food. However, despite improvements in housing subsidies, available income for food spending remained inadequate to promote the consumption of a nutritious diet (Kirkpatrick and Tarasuk 2007). In general, government-sponsored programs and subsidies aimed at increasing overall purchasing power have had limited impact on the improvement of diet quality

in low-income populations. An increase in economic resources tends to increase the quantity of less-expensive, energy-dense foods that are purchased rather than stimulating the purchase of healthy food choices. To be successful, future policy initiatives should be multilevel strategies to enhance accessibility to healthy food choices, provide subsidies for foods such as fresh fruits and vegetables, provide nutrition education, and promote the participation in existing government assistance program.

141.5.3 Individual/Family-Initiated Dietary Behavior Change

A recent study in Russia shows that there are some behavior modifications that are undertaken by individuals and families outside the context of government assistance to retain dietary habits during times of economic constraint. During a recent economic crisis, total energy intake of low income children remained robust, but diet composition shifted suggesting that low-income families purchased significantly less-expensive foods and prepared more meals at home. Both low and high-income families conserved diet structure by purchasing foods which provided more calories per unit cost (Dore et al. 2003). Specifically, low-income families demonstrated economic resilience by increasing consumption of less-expensive eggs and dairy products in order to provide stable sources of protein (Dore et al. 2003). This information can be used to subsidize targeted foods to ensure that families are able to purchase sufficient high quality calories.

141.6 Developing Countries: The Current Health Situation

Developing countries are characterized by low-scoring human indices such as life expectancy, per capita income, and level of literacy. Within a developing country context, the proportion of the population facing intermittent and/or chronic economic constraint far outnumbers the proportions observed in developed countries. A substantial percent of economically constrained individuals and families fall below the World Bank defined cut point for poverty, $2.00 per person per day and even the extreme poverty cut point of $1.25 in many low and middle-income countries (WB 2007). A disproportionate number of this impoverished population resides in rural areas. In contrast, many urban centers in developing countries are experiencing economic growth with a steadily growing middle-class superimposed over the urban poor. Typically, rural areas have poor transportation systems, health care infrastructure, sanitation conditions, and educational programs, which inhibit rural area growth and development. In contrast, urban centers are rapidly developing transportation infrastructure, organized healthcare systems, and educational programs including access to a diverse array of higher education institutions. Overall, economic opportunities for growth are limited in rural areas due to accessibility to resources. Similar to the dynamics observed in developed countries, populations in many developing country urban areas are limited primarily by the affordability of resources and existing services.

141.6.1 Environmental Context Underlying Obesity and Chronic Disease Trends

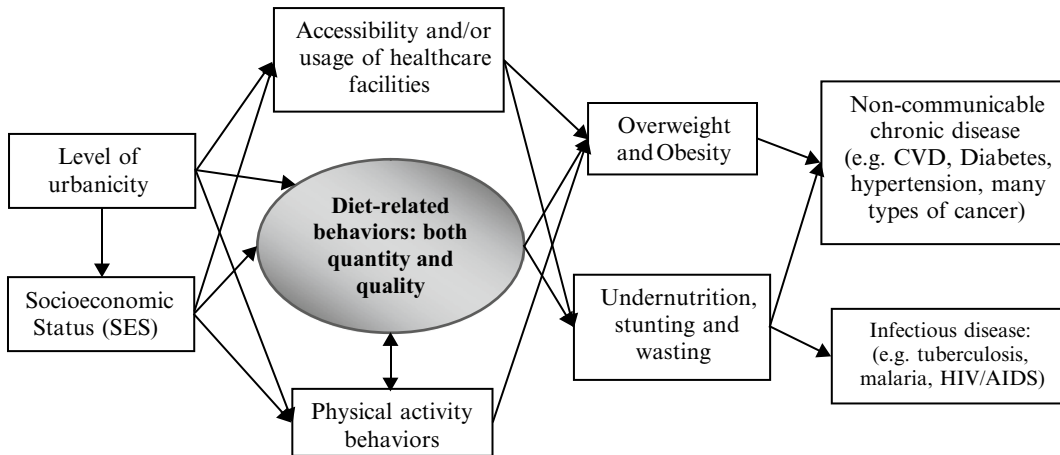
This widespread disparity in economic development, resource availability, and affordability of goods in developing countries also impacts dietary behaviors and ultimately health (see Fig. 141.4). Unlike developed nations, these countries are experiencing a rapid shift in health outcomes with increasing


Fig. 141.4 The etiologic pathway from the socio-economic status of low-income populations leading to health status in developing countries. This figure emphasizes that, given the tremendous range of accessibility and affordability of resources (which is highly dependent on regional urbanization), there are multiple disparate pathways leading to the contrasting health outcomes of either chronic or infectious disease in developing countries. As a result blanket national policies to address malnutrition have the potential of addressing one form of malnutrition and ignoring or even exacerbating the other. Therefore, it is recommended that policy makers identify the specific etiologic framework underlying the disease status of an area and customize interventions to specific target populations

rates of obesity and chronic diseases (Popkin 2007). In economically middle-income countries of Latin America and parts of Asia, more than one third of the population is overweight (Popkin 2007). Although low-income countries in sub-Saharan Africa and south Asia are still struggling with a high prevalence of undernourished people there is a rapid rise of obesity in the urban areas (Popkin 2007). The shift from undernutrition to overnutrition is commonly referred to as the nutrition transition and the trend from infectious to chronic disease is referred to as the epidemiologic transition (Popkin 2006a). These shifts, however, occur superimposed over persistent undernutrition and infectious disease among certain low-income subpopulations. Two major factors influencing this disparity is the level of national wealth (determined by per capita income) and regional urbanization within the country both of which affect food availability as well as income potential and purchasing power. Substantial growth and development has occurred in many middle-income countries, particularly in urban centers, which has accelerated the nutrition and epidemiologic transitions towards overconsumption and increasing chronic disease prevalence. Although not as progressed, even in low-income countries where severe undernutrition persists, increases in obesity and chronic disease are occurring in response to the globalization of market systems (Gillespie and Haddad 2003). One stark difference between the urban populations in developing versus developed nations is that many adults in low and middle-income countries were chronically undernourished during the crucial developmental stages from childhood to early adulthood. Severe undernutrition during physiologic development can cause a permanent lowering of an individual's BMR. Therefore with an increased accessibility to western highly processed diets accompanying national development, these adults are even more prone to obesity than their low-income developed country counterparts.

The food accessibility and affordability in low and middle-income countries differs substantially depending on the level of urbanization of a particular region. In urban areas of developing countries food accessibility is less of a challenged than affordability. Like the developed country poor, low-income urban populations are rapidly shifting towards consumption of highly processed foods that are cheap, convenient, energy-dense, and micronutrient-poor with the exception of sodium which typically exists in excesses of recommendations (Popkin 1998, 2001). Income limitations restrict

low-income individuals and families from purchasing expensive fruits, vegetables, and high quality lean animal products. In contrast, rural populations struggle with the accessibility as well as the affordability of nutrient-rich quality foods.

141.6.2 Rising Global Food Prices Cause a Further Decline in Diet Quality

The recent global trend of rising food prices is negatively impacting access to food in developing nations at an alarming rate. Specifically, rising food prices impact both dietary convergence and dietary adaptation – terms used by researchers to explain the change in dietary pattern among population in developing countries (FAO 2004; Hawkes 2006). Dietary convergence refers to a reduction in the diet diversity found in a majority of traditional diets to a narrow range of globally accessible staple grains, meats and poultry, edible oils, salt, and sugar (FAO 2004). For example, a dramatic increase in the consumption of meat and poultry products as well as edible oils and processed high-glycemic index foods has replaced the more traditional rice and vegetable-based diet in many Asian countries (Ding and Malik 2008). A similar shift has occurred in Colombia in the last decade due to the increased production of poultry in response to a national policy which increased the import of cheap animal feed. In India, dietary convergence is characterized by increases in the consumption of quality protein sources such as eggs and milk. However, significant increases in the consumption of salty snacks, edible oils, and processed sugary foods such as baked goods and candy has also occurred in India (FAO 2004).

Dietary convergence is a function of rising food prices coupled with changes in individual or family income. Essentially, the price of a commodity influences availability and in turn consumer demand, thus creating a cyclical pattern to the availability, affordability, and consumption of specific food products. This pattern is heavily influenced by the national political environment and the government strategies towards food trade. Ultimately, products which are produced in high quantity on a global scale such as edible oils and processed sugary foods are relatively cheaper than traditional foods that are produced in much smaller quantities, thus tipping the scales towards less healthy dietary choices.

Dietary adaptation occurs in the population due to the changes in lifestyle such as increase use of transportation, eating out for convenience, and relying on cheaper foods to achieve calorie needs (FAO 2004). Adaptation is an individualized lifestyle change in response to environment changes such as: increasing food marketing and advertisements, increasing accessibility to convenient street food or fast food outlets and an increasing prevalence of supermarkets. Although dietary adaptation is less common among the severely/chronically poor in developing countries it is becoming rapidly more prevalent in intermittently poor and middle income groups. For example, recent increases in advertisements of calorie-rich low-nutrient foods in Brazil have lead to significant increases in energy-dense diets in middle-class communities. In the Philippines and other Asian countries, the change from traditional meal patterns to habits based on convenience is leading to increased consumption of processed foods high in fat, sugar, and low in micronutrients (FAO 2004; Rayner et al. 2007).

141.7 Developing Countries: Implications for Policy Makers

Given the substantial income disparity within developing countries and the complex web of environmental factors influencing dietary behavior patterns, policy makers should consider a multi-pronged strategy to address malnutrition. Low-income populations are not equipped to handle the increased

chronic disease risk associated with the emerging obesity occurring as a result of increased food accessibility and affordability (Popkin 2009). As described previously, however, the level of food accessibility and affordability is highly influenced by the level of national wealth and regional urbanization. Therefore, each developing country should customize policies and programs for the disparate economic and geographic populations facing the nutrition and epidemiological transition.

National policies created to improve the health and dietary patterns of economically-constrained groups that target only a segment of the population can often create more problems than they address (Ng et al. 2008). In particular, this is true for middle-income countries where the dual-burden of undernutrition and overnutrition occur in the same communities and in many cases in the same households. For example, in Chile, a government program designed to reduce undernutrition, exacerbated the problem of obesity for specific subgroups in urban areas of the country. In contrast, a government program in Mauritius aimed at the prevention of CVD in areas of high-risk individuals, successfully decreased obesity rates in this population (FAO 2004). As the nutrition transition continues throughout the developing world, governments must design targeted programs to address persistent undernutrition while simultaneously developing programs to address the growing prevalence of obesity and chronic diseases (see Table 141.3).

Table 141.3 Examples of developing country government-sponsored food programs and policies targeting low-income populations

Country	Type of program/policy	Target audience	Program goal	Observed outcomes
Bangladesh	Challenging the Frontiers of Poverty Reduction	Ultra poor communities in rural Bangladesh	Reduction of poverty to create a foundation for sustainable economic developments to support long term diet and health improvements	Increase intake of grains and vegetables but no reduction in mortality
Mauritius	Health Promotion program through Ministry of Health supported by health policy change	National level program to improve health status in both urban and rural environments	Reduction of cardiovascular diseases (CVD)	Increase in obesity rates due to switching of oils but reduction in cholesterol levels
Republic of Korea	Mass media campaigns to promote traditional foods and diets	Rural communities	Retain traditional diets and increase intake of vegetables and grains	Increase fresh fruit and vegetable consumption and reduce fat intake particularly animal fats
Brazil	Trade liberalization	Agrarian regions	To allow foreign investment, reduce farm tax, and lower import taxes on fertilizers and pesticides	Increase production of soybean oil to become second largest soybean exports but contribute to high consumption of soybean oil around the world

This table summarizes existing policies and programs aimed at improving health and dietary quality of low-income individuals and families in developing countries. With the given diversity of health challenges faced by urban versus many rural populations, government and nongovernmental programs will need to customize policies and interventions, e.g. programs to increase accessibility of fruits and vegetable in rural areas and a distinct program to decrease consumption of edible oils in the urban settings

141.7.1 Public Policies and Interventions Aimed at Dietary Behavior Change

An integral component of a multifaceted developing-country intervention strategy should include nutrition education programs to elucidate the negative health consequences of diets excessive in processed fats, and sugar, and deficient in micronutrient-rich fruits and vegetables. Given that traditional diets in many developing countries were inherently high in unprocessed grains, vegetable oils and fruits and vegetables, a strategy could be to preserve and reinforce the consumption of these already culturally-accepted dietary practices. For example, the Republic of Korea's Ministry of Rural Development has successfully preserved traditional dietary practices in rural communities through nutrition education on the importance of fruits and vegetables reinforced by the use of traditional Korean food recipes (Popkin et al. 2001). This has lead to decreased rates of obesity in this country in spite of the improved economic condition in the country.

The impact of economic independence on food industry dynamics and its consequent effect on the health of a population must be considered in the process of creating developing country health policy. The food industry in a country not only depends on agricultural productivity but on national and international food trade policies as well. Before making drastic changes, policy makers must carefully examine the possible consequences of modifying trade restriction and regulations in the food industry. Often it is assumed that removal of trade restrictions will automatically benefit a low-income population. For example, in Brazil, the government recently altered policies around the production of soybean oil in the country. Multiple changes were made including: opening the market to foreign investors, removing the export tax on soybean oil, restructuring the taxation for soybean farmers, and levying taxes on the imports of fertilizers and pesticides. This resulted in the reduction of prices of the edible oil not only within Brazil but also globally. This price reduction lead to significant increases in oil consumption in Brazil and is now believed to be one of the causes of increased obesity within the country. This policy also increased soybean oil consumption globally and is believed to have caused the destruction of local oilseed production in India and China, thus negatively impacting the national economies of these countries (Popkin et al. 2001; Hawkes 2006; Rayner et al. 2007).

141.7.2 Public Policies and Interventions Aimed at Overall Poverty Reduction

Given that poverty is a primary cause of poor diet quality in developing countries, programs aimed at alleviating poverty may significantly reduce malnutrition. Specifically, policy makers should consider programs to improve population quality of life by encouraging local farming, increasing accessibility to micro-finance schemes, improving the health care infrastructure, and establishing sustained educational systems (Russell 2004; Popkin 2009). Policies geared towards local community culture and practices may have an advantage over national programs with respect to improving the quality of dietary behaviors and lifestyles. Currently, in many sub-Saharan African and Asian countries, local farmers who do not produce sufficient quantities to support their communities, are becoming more dependent on foods imported via global trade. This has lead to a significant increased consumption of processed foods high in fats and sugar. To prevent this trend, governments should invest in local farming by subsidizing specific crops for poor farmers in a manner that supports local habits as well as fertilizers that will allow them to grow these crops. Often, they may not be in line with the globalization of food trade markets but it will allow the local farmer to sustain their local diets and enable a

correspondingly healthy lifestyle (Rayner et al. 2007). Micro-finance schemes, such as the programs designed by Nobel Peace prize winner Mohammed Yunus, have dramatically improved the quality of life of the ultra-poor in rural Bangladesh (Haseen 2007). This financial support has allowed rural populations to become financially viable and revive local industry of agriculture and goods. To combat poverty and malnutrition in developing countries it is also to improve the health care infrastructure promoting a healthier population free from debilitating infectious conditions such as HIV/Acquired Immunodeficiency Syndrome (AIDS), tuberculosis, and malaria. The cost of these diseases can be substantial and government and nongovernmental organizations should consider expanding the preventive services to rural populations where low-income groups predominate (Russell 2004).

Possibly the most important public policy strategy is the need for education in developing country communities – both in terms of overall education and nutritional education. The basic primary and secondary programs serve a dual purpose of building an intellectually stronger future generation as well as increasing awareness of basic nutritional needs and the hazards of inappropriately consumed foods. Institutions should have both nutritional education and hands on food-related programs as part of both the primary and secondary curriculum.

141.8 Conclusion

In recent decades rapid increases in obesity and associated chronic diseases have occurred with a disproportionately high rate of increase among low-income populations. For developed countries where affordability is a significant barrier to good nutrition, nutrient dense foods such as fruits and vegetables are prohibitively expensive for economically-constrained population. As a result low-income individuals and families rely heavily on cheap highly processed energy-dense foods. Although policies and programs exist to help alleviate food insecurity, these policies and programs have had limited success in improving the nutrient density of diets among the poor. To curb overconsumption and improve diet quality, developed country policies and interventions must address the price barrier as well as provide nutrition-based education typical of traditional interventions. In developing countries, barriers to quality nutrition include both the affordability of as well as accessibility to nutrient-rich food commodities. In urban centers where economic growth has lead to food environments similar to those found in developed countries a majority of low-income families rely on highly processed convenience foods high in fats and sugars and low in nutrients to meet energy needs. This has lead to tremendous increases in obesity and chronic disease prevalence. Low-income populations in rural developing country settings face an added barrier of food accessibility. In times of economic crisis, low-income individuals and families are more likely to experience intermittent or chronic periods of food insecurity. As a result, infectious diseases associated with chronic undernutrition are still common in rural areas of developing countries. Given the dramatic variance in dietary behavior response to economic constraint in developing countries, policies and interventions must be customized by region and take into consideration the specific barrier to quality nutrition.

Summary Points

- Obesity is a global epidemic with a rapidly increasing predominance among low-income populations. Unfortunately, low-income populations are also the least capable to deal with the health and economic consequences directly associated with obesity and indirectly with obesity-related chronic diseases.

- One of the most recognized etiologic pathways influencing obesity risk is the impact of income status on dietary behaviors and subsequent nutritional status which in turn impacts obesity risk.
- An individual or family's dietary behavior response to economic constraint is dependent on the local, national, and international environmental context.
- In developed countries, economic constraint tends to result in selective purchasing of relatively cheap processed foods high in refined carbohydrates, saturated fats, and trans fats with a concurrent decrease in expensive fruits and vegetables, lean meats, and low-fat dairy products. Consequently many low-income individuals are malnourished consuming excess calories and insufficient micronutrients.
- In many urban settings of middle-income developing countries the relationship between economic constraint and dietary behavior modification closely resembles the pattern observed in developed countries. In rural settings dietary behavior change in response to economic constraints tends to resemble patterns observed more commonly in low-income developing countries.
- In low-income developing countries, researchers have observed substantial food insecurity resulting in diets insufficient in both total calories and micronutrients among poor populations facing periods of economic constraint. This is particularly evident in rural areas where a lack of purchasing power is compounded by a lack of food availability.
- The prohibitively high cost of fruit and vegetable as well as quality meat and dairy products is at the root of insufficient intake among economically constrained populations. For this reason policies and interventions aimed at providing nutrition education as a means of improving diet quality have had negligible success.
- To be effective, policies and interventions to improve nutritional status in economically constrained populations must take in to consideration the environmental context driving the dietary behavior changes.
- In a developed country context: policies and interventions that increase economic resources for food purchasing successfully reduce incidence of food insecurity, but fail to increase consumption of nutrient-dense foods such as lean meats and fish, whole grains, and fruits and vegetables.
- Given the availability of resources, incorporating subsidies for targeted foods such as fruits and vegetables into existing or new polices and interventions may substantially increase the potential for success in developed countries.
- In developing countries there is a wide range of accessibility to and affordability of healthy food choices and is highly dependent on the urbanization of a region
- In developing countries policy makers must identify whether the cause of malnutrition is an accessibility or affordability issue to create successful sustainable interventions, e.g. if the barrier to diet quality is affordability using a food-specific subsidy might be appropriate whereas an accessibility barrier might require agricultural-based support

---

Key Terms

Nutrition transition: A phenomenon in low and middle-income countries where decreases in undernutrion concurrent with emerging overnutrition occur with increases in national gross domestic product.

Epidemiologic transition: A phase of development in a country context where a recession in the prevalence of infectious disease occurs simultaneously with an increase in the incidence of chronic noncommunicable diseases. Typically this transition is accompanied by improved national healthcare, sanitation, family participation in active family planning, and an increase in women working outside the home.

> **Demographic transition:** The transformation in a country where steady decreases in initially high birth and death rates are observed resulting in a shift towards an older population structure. This shift occurs most commonly as a country transitions from a preindustrial agrarian-focused economy to one that is highly industrialized.
>
> **Food insecurity:** A state where an individual or family lives in with intermittent or chronic hunger due to sporadic access to food and is in fear of starvation.
>
> **Poverty:** Defined by the world bank as $2.00 per person per day and for extreme poverty $1.25 per person per day.

142.1 Introduction

The Russian physiologist Pavlov considered eating as the most powerful relationship an organism has to its surrounding world (Pavlov 1953). This "food connection" is heavily regulated by internal state variables such as hunger. Prolonged periods of starving are one of the most tragic experiences of humanity and even mild conditions of food deprivation clearly affect consummatory behavior as reflected in the saying "hunger is the best spice".

Everybody knows about the effects of deprivation. The effects appear intuitively so obvious that the phenomenon receives paradoxically rather too little than too much attention. Consider for instance the work of Pavlov and Skinner, in which food stimuli play a central role. The empirical finding that the contingent pairing of a tone and food establishes new behaviors is nowadays taught in high school. After training, the dog salivates to a previously neutral stimulus. Similarly, knowledge

about the Skinner box, in which rats may learn to vigorously press a button to obtain food, is well perceived in the public. Imagine what would happen, if the animals were tested while satiated? The simple answer is they would probably not learn to press the button or to salivate. The role of deprivation in these learning principles is easily overlooked. However, Pavlov was very clear in his writing by stating that even the most avaricious dog will not learn the salivary response when satiated (Pavlov 1953). Accordingly, internal state variables have profound effects on responding to and learning about food cues.

In humans, the effects of prolonged periods of reduced food consumption were investigated in the Minnesota semi-starvation experiment, which was conducted during Second World War by Keys and colleagues (Keys et al. 1950). Food intake was greatly limited for several months resulting in pronounced loss of body weight (~25 kg). The experiment revealed massive physiological and psychological effects of semi-starvation. One notable finding is that food became the most important thing in life (Keys et al. 1950). Preoccupation with food and episodes of binge eating may be also induced by voluntary restricting food intake as in dieting and restrained eating (Polivy 1996). However, deprivation need not be sustained over long periods to affect the human feeding system. Acute food deprivation is associated with increased food consumption compared to nondeprived control groups (Spiegel et al. 1989; Drobes et al. 2001; Mauler et al. 2006) and increases the reinforce value of food in behavioral choice paradigms (Raynor and Epstein 2003).

142.2 Deprivation and the Feeding System: Conceptual Considerations

Deprivation affects almost every aspect related to food intake. Animal research over the past decade allows sketching a basic scheme of the feeding system providing a conceptual framework for the understanding of the effects of food deprivation on ingestive behaviors. As illustrated in Fig. 142.1, the organization of goal-directed ingestive behaviors rests on the integration of information about internal state (e.g., food deprivation), cues from the environment (e.g., availability of palatable food), and behavioral state (e.g., circadian rhythm). Furthermore, ingestive behavior is temporally organized in distinct appetitive and consummatory phases (cf., Timberlake 2001). To obtain food, one has first to look for potential food sources. A general search mode occurs when the subject does not know where to look for food. Exploratory behaviors bring the organism close to food and a focal search mode is engaged readying the organism for consummatory behaviors of chewing and swallowing. Ethological observations reveal reflexive-stereotypic behaviors during food consumption, while appetitive behaviors are more variable and non-stereotypic. These motivational stages differ in many respects such as temporal and spatial proximity to food consumption, engagement of distinct perception-action units, and specific cues sensitizing the engagement of stages. Recent research also suggests that the weighting of external and internal information differs among motivational stages. When food was readily available, consumption was controlled by the palatability of the food independent whether the animal underwent food restriction (~85% of normal weight) or not. Conversely, measurement of anticipatory locomotor behaviors revealed significant deprivation effects, which were independent from food palatability (Barbano and Cador 2005).

Great progress has been made to delineate mechanisms how information about internal state is represented in the brain and controls ingestive behaviors. The brain perceives an array of interosensory signals conveying information about the availability of food and nutrients generated by the gastrointestinal tract, postabsorptive sites (pancreas, liver, muscle), and stored nutrients in adipose tissue (Woods et al. 2000; Berthoud and Morrison 2008). While it is recognized that multiple brain regions are important for perceiving internal state, specific nuclei in the hypothalamus are consid-

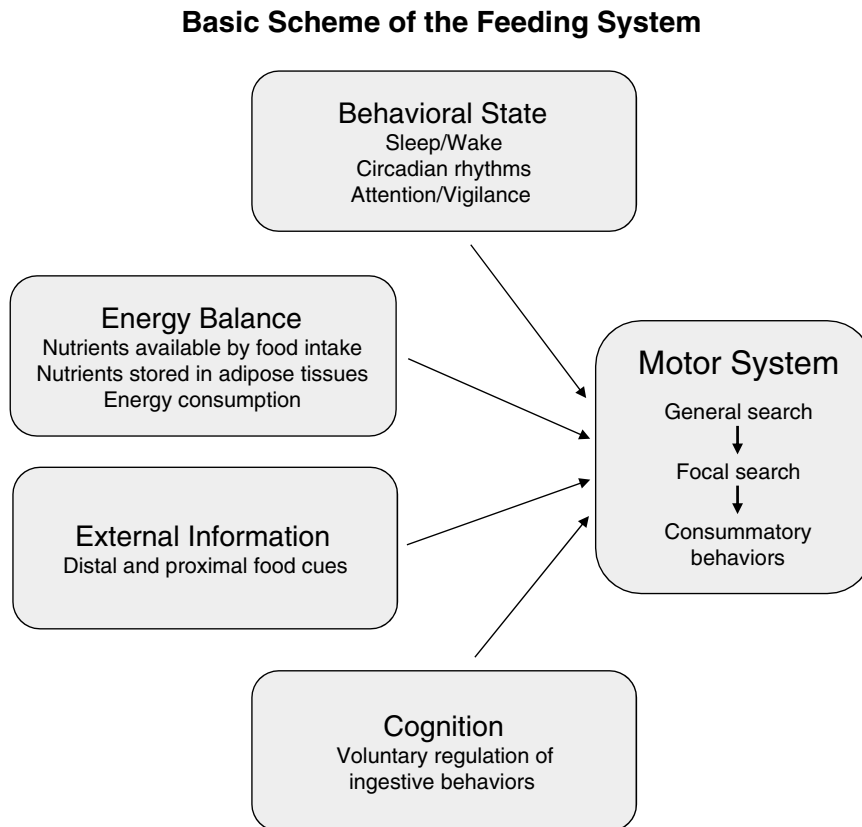
Basic Scheme of the Feeding System


Fig. 142.1 Conceptual framework of the organization of the feeding system (Based on Swanson 2000; Timberlake 2001)

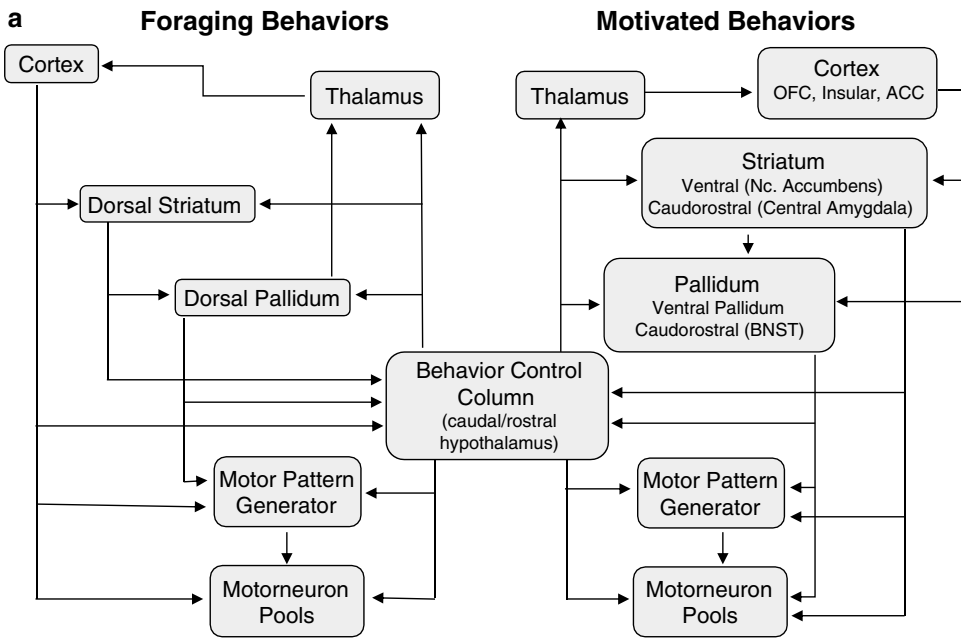
ered as key sites for the integration of metabolic-related information. The nucleus (Nc) arcuatus is assumed to integrate metabolic information via two populations of neurons (Neuropeptide Y (NPY)/ Agouti-related Protein (AgRP), Proopiomelanocortin (POMC)). These neurons are sensitive to a number of metabolic-related information (e.g., leptin, insulin, ghrelin) and exert opposite actions on feeding behavior. Efferents from these neurons to the paraventricular, lateral, and ventromedial hypothalamus provide a gateway for the translation of metabolic information to adaptive feeding responses as these neurons project widely through the entire brain (Swanson 2000; Watts and Swanson 2002; Berthoud and Morrison 2008). Based on anatomical, developmental, genetic, and functional data, Swanson introduced the concept of the behavioral control column in the rostral hypothalamus, which is considered as key motor control structure for motivated behaviors of feeding, reproduction, and defense (Swanson 2000). Consistent with its presumed role for ingestive behaviors, the paraventricular Nc affects many brain regions implicated in the selection, planning, and execution of specific somatic motor behaviors (cortical, striatal, and pallidal motor structures, brain stem motor nuclei), endocrine and autonomic responses and behavioral state regulation (see Fig. 142.2a). Overall, distinct nuclei in the rostral hypothalamus appear critical for the representation of internal state and provide mechanisms how food deprivation exerts motivational control on ingestive behaviors.

The incentive value of food is dynamically adjusted according to variations in internal state of energy balance. Even the tastiest food item is not consumed when satiated. This finding requires that

Neural Mechanisms of the Feeding System


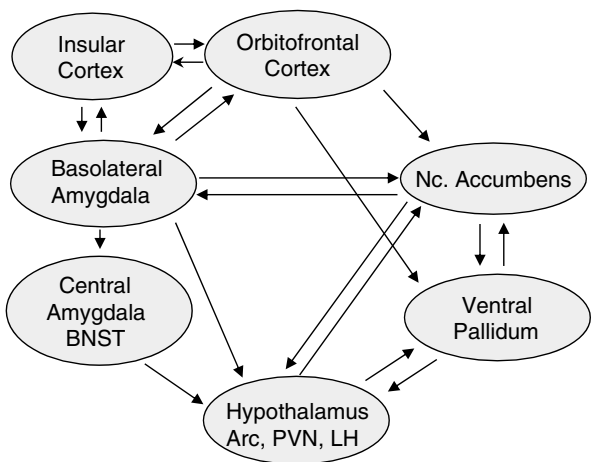


Fig. 142.2 (**a**) Illustration of the concept of the behavioral control column in the medial zone of the hypothalamus. The rostral segment is thought to regulate basic classes of motivated behaviors (ingestive, reproductive, defensive). Exploratory or foraging behaviors are assumed to involve the caudal segment (The graph is based on Swanson (2000) and Watts & Swanson (2002) and the reader is directed to these sources for details) (**b**) Schematic diagram of key structures of the motive circuitry implicated in the perception of reward and the activation of adaptive behavioral responses

reward perception is at least in some neural structures profoundly dependent on internal state of energy balance. Many neural structures sensitive to food reward have been revealed in the past decade. In the rat, a motive circuitry has been delineated responding to appetitive food stimuli including regions in the orbitofrontal cortex, insular cortex, amygdala, Nc. Accumbens, ventral pallidum,

ventral tegmental area, and dorsal thalamus (see Fig. 142.2b; Kalivas and Nakamura 1999; Holland and Gallagher 2004; Berridge and Kringelbach 2008; Smith et al. 2009). While the specific contributions of these structures to the organization of motivated behaviors remains to be determined, unique contributions among selected structures in controlling ingestive behaviors have been demonstrated. For instance, recent research has revealed "hedonic hot spots" in the Nc. accumbens and ventral pallidum of the rat brain with different functions in instrumental responding to and consumption of food and hedonic liking responses measured by facial expression (Smith et al. 2009). Furthermore, core structures of the motive circuitry are differentially implicated in the phenomenon of classically conditioned eating. In the learning phase, a cue is repeatedly presented when hungry rats are allowed to eat. During testing, presentation of this cue can stimulate eating even when the rat is satiated. A recent study suggests that this phenomenon relies on direct pathways from orbitofrontal cortex and basolateral nuclei of the amygdala but not from Nc. accumbens (Petrovich et al. 2005). Furthermore, new learning induced by devaluation of the food with LiCL (lithium chloride) is abolished when the orbitofrontal cortex but not the amygdala is lesioned before the devaluation procedure (Pickens et al. 2003). Thus, the orbitofrontal cortex seems to be critical for learning about changes in the stimulus-reinforcement contingencies. Further differentiation among the contribution of neural structures of the motive circuitry is suggested when considering the inhibition of the feeding response by fear. Specifically, inhibition of feeding by presenting a classically conditioned fear stimulus is abolished when leasoning the central (but not the basolateral) nuclei of the amygdala (Petrovich et al. 2009). Overall, an interconnected network of neural structures has been revealed which mediates reward perception and provides gateways to the engagement of feeding motivation and the organization of appropriate motor responses. In humans, a growing number of studies investigated the hypothesis that core structures of reward perception are sensitive to incentive value using functional neuroimaging (e.g., Arana et al. 2003; Killgore et al. 2003; Kringelbach et al. 2003; Beaver et al. 2006; Porubská et al. 2006; Schienle et al. 2009). Despite notable differences, the findings support the notion that incentive value modulates neural activity in core structures of reward processing.

142.3 Food Deprivation and Incentive Value

The understanding of the neural organization of reward perception provides a roadmap for the neuroscientific examination of deprivation effects in humans. Early studies investigating fasting and satiation effects on brain activity revealed that neural activity decreased among other regions in several structures of the motive circuitry including orbitofrontal cortex, insular cortex, basal ganglia, and hypothalamus in satiated as compared to hungry state (Tataranni et al. 1999; Delparigi et al. 2002, 2005). These findings imply that hunger may have profound effects on resting state activity of the motive circuitry in the absence of external stimulation.

More recent studies investigated the effects of food deprivation on food-related stimulus processing. Incentive motivation theory posits that incentive value of food items is modulated by physiological drive states (Toates 1981). According to this hypothesis, core structures of the motive circuitry are expected to show increased activity to food-related stimuli in deprived as compared to satiated state. To identify relevant studies, a literature research on public databases (PubMed, Web of Science) was conducted using a variety of key words (e.g., hunger, deprivation, eating, food). Nine studies were identified, which directly contrasted deprived and satiated state and measured brain activity in the motive circuitry to the presentation of food-related stimuli (Tables 142.1 and 142.2).

Hemodynamic measures were used in all studies with functional magnetic resonance imaging (fMRI) being more common than positron emission tomography (PET), in particular in most recent

This table summarizes the main findings of deprivation effects in structures of the motive circuitry and other brain regions

DEP deprivation, *CAL* calorie, *SAT* satiated, *L* left, *R* right, *ACC* anterior cingulate cortex, *DLPFC* dorsolateral prefrontal cortex, *Fusiform* fusiform gyrus, *Hipp* hippocampus, *MPFC* medial prefrontal cortex, *NAcc* nucleus accumbens, *PC* parietal cortex, *PCC* posterior cingulate cortex, *Parahipp* parahippocampal cortex, *Postcen* postcentral gyrus, *Thal* thalamus

studies. Accordingly, before considering empirical findings, basic principles of fMRI are briefly summarized. The technique is not measuring neural activity directly but associated epiphenomena, the local vascular response. Neuronal activation is associated with an increase in blood flow (cf., Logothetis 2008). For poorly understood reasons, the delivery of oxygenated hemoglobin is larger than local oxygen consumption. Oxygenated and deoxygenated hemoglobin have different magnetic properties and changes in their relative concentration can be revealed by magnetic resonance signals. Like other brain imaging methods assessing blood flow, temporal resolution is on the order of seconds as the changes in blood flow are relatively slow. However, spatial resolution is high as the brain is divided in small cubes (e.g., $1 \times 1 \times 1$ mm). The subtraction method is used to disclose deprivation effects on food cue processing in which the Blood Oxygenation Level Dependent (BOLD) signal to food cues under deprived versus satiated state is contrasted.

Three studies examined the processing of food and control pictures in deprived and satiated state. The first of these studies observed increased BOLD activity in the amygdala when viewing food pictures in a deprived state (LaBar et al. 2001). In contrast, Uher and colleagues (2006) observed no differential activity in the motive circuitry elicited by food pictures as a function of deprivation. A recent study revealed that deprivation effects in the motive circuitry may appear specifically to high-incentive food pictures (Goldstone et al. 2009). Pronounced increases in activation of orbitofrontal and insular cortex, amygdala, and striatum were observed when contrasting high- and low incentive stimuli during deprived but not satiated state. Presenting symbolic visual representations of food items, in particular of high incentive value, is accordingly sufficient to elicit motivational responding in humans. Two further studies relied to an even greater extent on the presentation of symbolic stimuli and mental imagery. Specifically, a restaurant-like situation was realized, in which participants' brain activity was measured while they read and chose between menus items consisting of entrée, dinner, and dessert which were tailored individually to be of low and high incentive value (Hinton et al. 2004; Piech et al. 2009). A PET-study revealed that food deprivation was associated with increased BOLD activity in several structures of the motive circuitry (see Table 142.2). Furthermore, regions in the orbitofrontal cortex were particularly activated when reading high incentive menu items in a deprived state (Hinton et al. 2004). Using an event-related fMRI design, a follow-up study revealed two regions in orbitofrontal cortex, which were similarly showing an interaction of incentive value and motivational state. In addition, irrespective of food deprivation, amygdala activation was increased for menu items of high compared to low incentive value (Piech et al. 2009). Overall, food deprivation increases the incentive value of visual representations of food-related stimuli in the motive circuitry, possibly specifically for high-incentive stimuli.

Deprivation effects on the processing of taste stimuli were investigated in two studies. The study by Uher and colleagues (2006) included a taste condition in which processing of chicken broth and chocolate milk was compared to a control condition (artificial saliva). Deprivation did not alter the activity in structures of the motive circuitry when processing these complex gustatory stimuli. Studying pure taste stimuli, a recent study revealed deprivation effects in the motive circuitry (Haase et al. 2009; see Table 142.2), which, however, were most pronounced for the highly pleasant sucrose and mildly unpleasant citric acid stimuli. Overall, these studies reveal a pattern of findings similar to studies examining visual processing.

From a theoretical perspective, these studies revealed deprivation effects on food stimulus processing either in passive viewing or in active attention conditions, which were low in processing demand. Recent research suggests that task focus may have pronounced effects on food processing even when comparing passive viewing with evaluative rating tasks (Bender et al. 2009). It is therefore interesting to consider studies in which deprivation effects were investigated while participants performed explicit tasks. The first of these studies (Morris and Dolan 2001) used PET to explore whether food deprivation specifically enhances the recognition of food pictures. Blocks of either

food or non-food pictures were presented and participants' task was to indicate whether the seen pictures was included in a memory set presented immediate before the scanning took part. Furthermore, participants were initially tested in a deprived state and fed to satiety in the course of the experiment. Hunger ratings were positively correlated with BOLD activity in the insular cortex, Nc. Accumbens, and hypothalamus, irrespective whether participants viewed food or object pictures. Specificity for food picture processing was seen in the right posterior orbitofrontal cortex, which showed a positive relationship to hunger ratings. Several regions in the brain showed a relationship to memory performance, category-independent (e.g., orbitofrontal cortex) and category-dependent (e.g., left amygdala, insula), which, however, was not modulated by the motivational state. A second study examined the effects of spatial attention and food deprivation (Mohanty et al. 2008). The attention task consisted of valid, invalid, and neutrally cued responses to laterally presented target stimuli (donuts or tools) and foils (danishes and screws). In a mixed event-related paradigm, food and nonfood pictures were shown in separate blocks. Deprivation increased BOLD activity in the amygdala to blocks containing food pictures in a deprived as compared to a satiated state (see Table 142.2 for other regions). This finding was specific to food picture processing and not observed in blocks presenting tool items. A further aim of this study was to examine the relationship of anticipatory activity in neural structures of the spatial attention network and speed of responding. Deprivation specifically modulated anticipatory activity in parietal and posterior cingulate cortex during blocks of food targets. Furthermore, medial sectors of the orbitofrontal cortex were related to the performance in the attention task when hungry and lateral orbitofrontal cortex during satiety. A third study examined deprivation effects on the processing of high and low caloric food and object pictures in the context of an explicit object-based attention task (Siep et al. 2009). In separate blocks, attentional focus was directed either toward food items, towards the color of the picture, or to bars positioned at lateral sites of the pictures. A strict analysis revealed no significant three-way interaction of picture type, attention focus and deprivation. Less stringent analysis revealed that regions in the insular cortex, medial and inferior orbitofrontal cortex, and striatum showed an interaction between picture type (low calorie, high calorie food, objects) and deprivation. In these structures, low compared to high calorie stimuli seemed to elicit increased activity in the satiated state, while high compared to low calorie stimuli elicit increased activity in the deprived state. Furthermore, these effects were independent from the attention task. With regard to the effects of paying attention to food, activity in amygdala and orbitofrontal cortex was increased when food pictures where task relevant, however, the effect was similarly pronounced for low- and high calorie stimuli. Overall, deprivation effects were investigated in active task contexts by several studies adapting established paradigms from cognitive neuroscience. Albeit preliminary, evidence for modulations of incentive value by food deprivation seems ambiguous. Embedding food items in the structure of cognitive tasks may diminish their salience. The use of a passive viewing condition is recommended in order to determine the activation of structures of the motive circuitry independent from explicit task demands. Furthermore, although food stimuli are task-relevant in these studies, there are striking differences to natural situations in which goal-relevance of food stimuli serves to support adaptive behaviors.

One reading of the information depicted in Table 142.2 is that core structures of the motive circuitry are sensitive to both incentive value of food stimuli and internal state. However, there is considerable variety in experimental findings across studies. No single structure received unanimous support and positive findings showed considerable variability with regard to hemispheric lateralization. Consideration of methodological variables might be particularly informative to identify issues, which need to be addressed in future research (see Table 142.1).

The number of participants pronouncedly varied across studies raising the concern that differences in findings may simply arise because of differences in statistical power. While hours of deprivation

greatly varied across studies (6–24 h), there seems no simple relationship to the observation of deprivation effects. However, considering also the great variance with regard to time of testing, circadian rhythm might moderate the effects of food deprivation on food-related stimulus processing. Overall, a paradigmatic approach seems valuable to empirically delineate appropriate sample sizes and hours of deprivation and to reveal circadian rhythm effects.

The majority of studies presented visual stimuli. Food pictures were presented in six studies with most recent studies varying caloric content of the stimulus materials. Written descriptions of menus (starter, entrée, dessert) were used in two studies, which individually varied preference for the menus. Obviously, the quality of stimulus materials is of great importance in revealing deprivation effects. The development of freely shared stimulus materials, calibrated according to major dimensions of eating and ingestion might facilitate progress in the field, similar to the development of the International Affective Picture Series (IAPS, Lang et al. 2008) in the domain of emotion research.

In summary, insights about the neural organization of the feeding system derived from animal research can serve as theoretical foundation to investigate the neural organization of the human feeding system in general, and regarding the effects of deprivation in particular. The rather small number of studies provides promising evidence for the hypothesis that core structures of the motive circuitry, associated with reward perception and adaptive behavior organization, are sensitive to variations in internal state. However, given the importance of deprivation, the widespread practice of voluntary restricting food intake by dieting and restrained eating, a much larger database is needed to realize the potential of the neuroscientific perspective on the understanding of both basic mechanism of food intake regulation and eating-related disorders.

142.4 Overfeeding, Satiation and Incentive Value

A complementary perspective on the effects of deprivation is provided by studies investigating sensory-specific satiety and overfeeding (see Tables 142.3 and 142.4). Several studies examined the phenomenon of sensory-specific satiety, which denotes that the incentive value and rated pleasantness decreases to food, which is eaten to satiety to a greater extent than for other foods. In an fMRI-study (O'Doherty et al. 2000), processing of vanilla and banana odors was investigated in two sessions (pre- and post-meal), which were identical with the exception that the second session took part after eating bananas to satiety. The orbitofrontal cortex was related to olfactory sensory-specific satiety showing a specific decrease in BOLD signal to banana odors in the post- as compared to the pre-meal condition. These findings are consistent with single cell recording in the orbitofrontal cortex of macaques, which revealed that olfactory neurons decreased responding to food odors eaten to satiety (Critchley and Rolls 1996). A further PET- study investigated changes in brain activity related to eating chocolate. Specifically, brain activity was measured while participants were given a single piece of chocolate immediately before the scanning period, tracking the hedonic experience of chocolate from being highly pleasurable to being highly aversive (Small et al. 2001). Among other regions (see Table 142.4), medial orbitofrontal cortex, insular cortex, and striatal regions showed a decrease in activity with increasing satiety. Of particular interest, lateral orbitofrontal cortex showed opposite effects, i.e., enlarged activity when chocolate was perceived as highly aversive. Accordingly, adding further evidence for the role of orbitofrontal cortex and sensory-specific satiety, medial and lateral orbitofrontal cortex appear to be selectively responsive during states in which approach and avoidance dispositions were dominant. Effects of sensory-specific satiety were furthermore investigated in the context of associative conditioning paradigm, in which odors were paired with task-relevant visual stimuli (Gottfried et al. 2003). Devaluation affected several structures of the motive circuitry

(amygdala, ventral striatum, orbitofrontal cortex, insular cortex, see Table 142.4). Furthermore, regions in the amygdala and orbitofrontal cortex showed decreased BOLD signals specifically to the visual stimuli associated with the devalued odor while other brain regions (ventral striatum, insular cortex) showed both decreases and increases to visual stimuli paired with devalued and nondevalued odors, respectively. Investigating children, Holsen and colleagues (2005) presented food and object pictures in two sessions (pre- and post-meal) with participants eating a meal (500 kcal) in between the sessions. Amygdala, orbitofrontal cortex, and insular cortex showed a selective decrease to food pictures when comparing pre- and post-meal sessions. Two further studies investigated the effects of overfeeding on the processing of food (low and high incentive) and control pictures (Cornier et al. 2007; Cornier et al. 2009). Towards this end, participants were tested even after 2 days of either eucaloric or overfed (30% above eucaloric) energy intake. Overfeeding attenuated responding to high as compared to low incentive food pictures in the hypothalamus and inferior visual cortex (Cornier et al. 2007). These results were extended in a recent study investigating thin and obese participants, which reduced weight by 8% (Cornier et al. 2009). Regarding thin participants, food compared to object pictures elicited increased BOLD signals among other structures in orbitofrontal cortex, insular cortex, and ventral striatum in the eucaloric state. Overfeeding for 2 days resulted in reduced activity in these structures reaching significance in the insular cortex and hypothalamus. These effects of overfeeding were attenuated in obese participants. Overall, core structures of the reward matrix, in particular regions of the orbitofrontal cortex, showed a decrease in activity when fed to satiety.

142.5 The Motivational Regulation of Attention

The feeding system controls the organization of ingestive behaviors. Internal state and the perception of food-related cues from the immediate environment prime unique sets of perceptual-motor units that increase sensitivity to relevant stimuli at the appetitive and consummatory behavioral stage. According to this perspective, food deprivation effects operate at multiple levels, by increasing incentive value of food stimuli, and by regulating attention processes.

However, attention is not a unitary phenomenon but refers to a collection of disparate functional processes. For instance, recent research has begun to detail food deprivation effects on spatial attention mechanisms and object-based attention, which imply distinct neural mechanisms (Mohanty et al. 2008; Siep et al. 2009). Furthermore, attention is not only regulated according to explicit instructions by varying the task relevance of food stimuli, but is also passively captured by stimuli according to their motivational and emotional significance (Öhman 1986). When related to current motivational needs, stimuli may reflexively capture attentional resources to facilitate efficient responding.

Support for the obligatory nature of the motivational regulation of attention processes has been obtained in a study, in which food pictures were passively viewed, and participants performed an easy control task (detecting an occasional flicker of the images). Food deprivation enhanced the activity in higher order visual-associative regions (fusiform gyrus) when processing food pictures (LaBar et al. 2001). Conceptually similar results were observed when pictures were evaluated according to their likeability after viewing the pictures (Uher et al. 2006), but not when ratings of appealingness were made during picture viewing (Goldstone et al. 2009). Accordingly, although not explicitly designed to address the issue, there is some evidence that deprivation enhances attention processes to need-related food stimuli.

Two recent studies explicitly assessed the hypothesis that deprivation (24 h) sensitizes the processing of food cues (Stockburger et al. 2008, 2009a). Event-related brain potentials (ERPs) were measured

in these studies, which provide a voltage measurement of neural activity that can be recorded non-invasively from multiple scalp regions. More specific, ERPs are considered to reflect summed post-synaptic potentials generated in the process of neural transmission and passively conducted through the brain and skull to the skin surface where they contribute to the electroencephalogram (EEG). Since ERPs are usually hidden in the larger background EEG activity, it is necessary to use multiple stimulus presentations and stimulus-locked signal averaging to extract the ERP signal from the background EEG activity. Biophysical considerations suggest that large-amplitude ERP components reflect widespread, synchronous sources in cortical regions. Brain activity locked to the processing of a stimulus becomes apparent as positive and negative deflections in the ERP waveform. The amplitude and latency of specific ERP components provide information regarding the strength and time course of underlying neural processes. Furthermore, given appropriate spatial sampling, the topography of ERP components can be used to estimate the neural generator sites by advanced analytic tools such as L2-Minimum-Norm-Estimate (L2-MNE; Junghöfer et al. 2006).

The first study was specifically designed to determine whether motivational state modulates early visual attention processes (Stockburger et al. 2008). A rapid serial presentation technique was used in which stimuli were presented for 330 ms without any perceivable interstimulus gap. Thus, this paradigm induces perceptually demanding conditions, which are deemed as necessary to reveal attention effects. Food stimuli were interspersed in a stream of pleasant, neutral, and unpleasant control stimuli drawn from various categories of human experience, which served as control stimuli to determine the specificity of deprivation effects on food picture processing. Results showed that deprivation specifically modulated the relatively early processing of food pictures. Between 170 and 320 ms, the ERP waveform revealed enhanced posterior positive deflections for food pictures in hungry compared to satiated state (Fig. 142.3a). MNE source calculations revealed that these deprivation effects on food processing were associated with primary activations in posterior perceptual representation networks. In addition, secondary activations were suggested over anterior brain regions (Fig. 142.3b). However, spatial resolution was insufficient to determine whether this finding

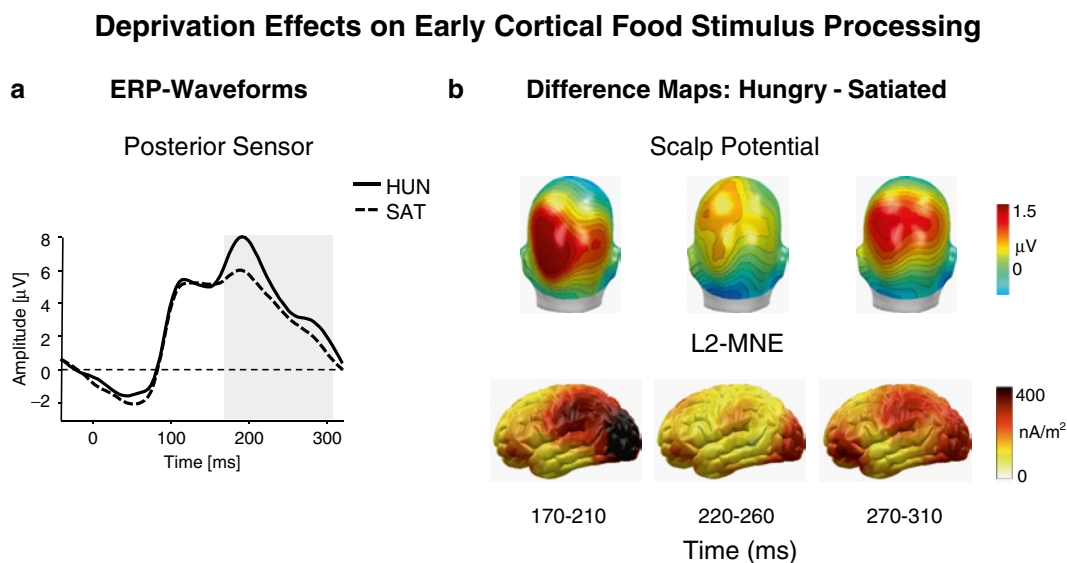
Deprivation Effects on Early Cortical Food Stimulus Processing


Fig. 142.3 (**a**) Representative ERP-waveforms for food pictures in the hungry (*red lines*) and satiated (*black lines*) states. (**b**) Scalp potential (*back view*) and L2-Minimum Norm estimates maps (right lateral view) show differences in processing food pictures in deprived and satiated state (Based on Stockburger et al. 2008)

relates to orbitofrontal activations, which were observed when comparing food cue processing in hungry and satiated state and food stimuli varying in their incentive value (O'Doherty et al. 2000; Morris and Dolan 2001; Arana et al. 2003). These findings suggest that perceptual stimulus processing is gated in specific ways according to motivational state. According to a functional perspective, ERP modulations in this time window have been considered to reflect a call for processing resources in later capacity-limited processing stages implicated in conscious stimulus recognition (cf. Öhman 1986; Schupp et al. 2006).

These later processing stages related to working memory and stimulus recognition were the focus of another study in which food and flower pictures were presented as rapid serial stream for 660 ms (Fig. 142.4a and b; Stockburger et al. 2009a). A consistent body of evidence revealed that emotionally relevant pictures elicit increased late positive potentials (LPP) between 350 and 700 ms post-stimulus (Schupp et al. 2006). Similarly, food deprivation specifically enhanced the LPP component to food pictures (Fig. 142.4c). The assumption that increased positive potentials to food pictures in a hungry state reflects enhanced processing is supported by L2-MNE analyses, which revealed increased dipole strength over extended posterior visual processing regions (Fig. 142.4d). Thus, consistent with its presumed relation to conscious stimulus recognition, the LPP is linked to widespread activation broadcasting stimulus information to many associative cortical regions rather than reflecting local processing (Del Cul et al. 2007). Overall, in a state of food deprivation, food pictures seem to elicit a state of heightened selective attention in a capacity-limited processing stage, which is a critical gateway for the stimulus representation in working memory and conscious stimulus recognition. Furthermore, these findings were observed while participants passively viewed the stimulus materials and the food images were not task relevant. Consequently, the motivational regulation of visual processing appears to be a spontaneous and involuntary phenomenon, important characteristics of automatic processes.

Overall, electrophysiological measures of brain activity allow delineating the regulation of attention processes at the level of distinct processing stages. Internal motivational state sensitizes responding to need-related stimuli in processing stages mandatory for stimulus recognition. This mechanism seems highly adaptive from a functional perspective. The selective responding and evaluation of need-relevant stimuli is critical for the efficient organization of food-related behaviors.

142.6 Food Deprivation and the Startle Reflex

To obtain reliable measures of brain activity related to stimulus processing, neuroimaging methods require repeated stimulus presentations. Accordingly, in the case of food deprivation, stimuli are presented while participants are denied access to food. Unfortunately, the motivational orientation elicited in these protocols is potentially ambiguous. On the one hand, viewing food-related stimuli in deprived state may prompt associated appetitive responses. Alternatively, a state of frustrative non-reward may be induced, if participants are denied the immediate consumption of food.

Studies utilizing the startle probe methodology (see Table 142.5) may help to resolve this issue (Drobes et al. 2001; Mauler et al. 2006). This research builds upon the notion that responding to emotionally and motivationally significant stimuli is organized by two basic brain circuits, one prompting appetitive responding and pleasant affects, and the other determining withdrawal and defense behaviors and unpleasant affect. The measurement of the defensive startle reflex allows inferring the engagement of basic motive systems, which is potentiated when elicited during an aversive state and inhibited during pleasant states. In their study, Drobes and colleagues (2001) presented a series of food pictures as well as emotional and neutral control pictures varying level

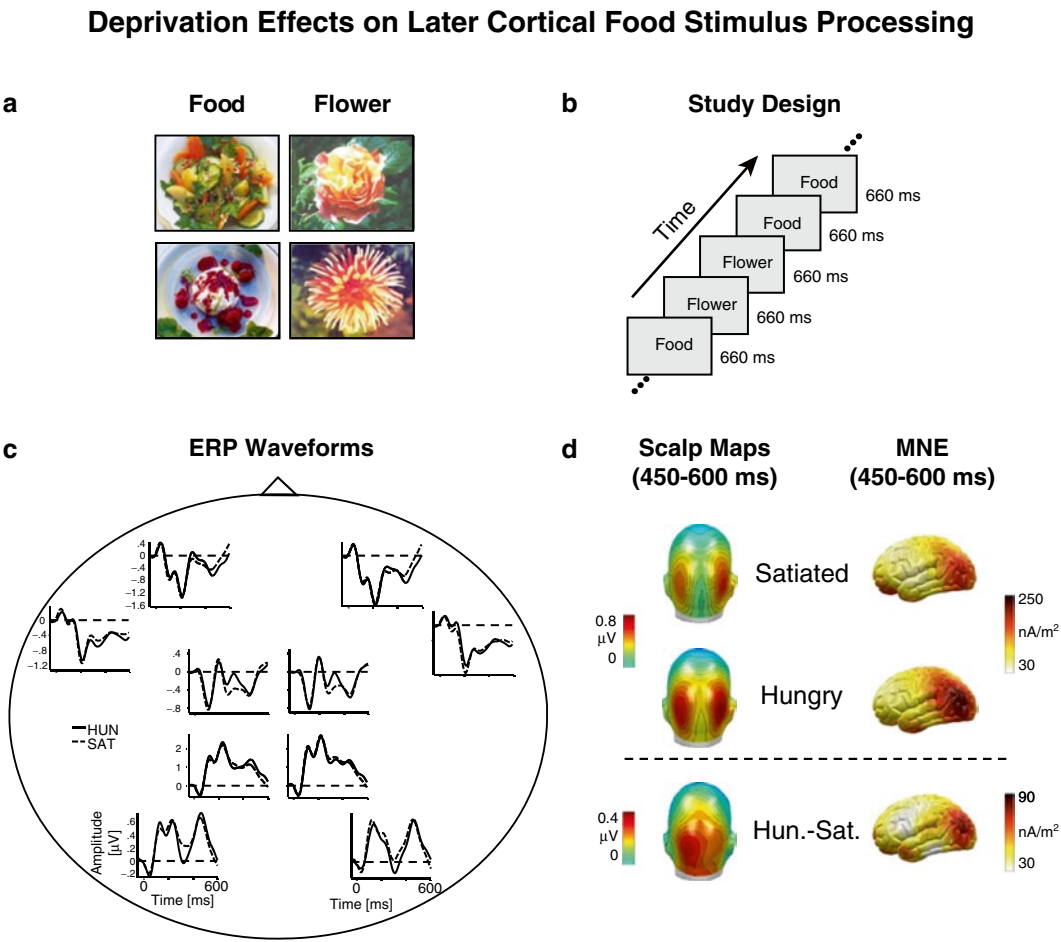
Deprivation Effects on Later Cortical Food Stimulus Processing


Fig. 142.4 (**a**) Representative examples of the food and flower stimuli. (**b**) Illustration of the rapid serial visual presentation paradigm. Food and flower pictures were presented for 660 ms without perceivable interstimulus gap. (**c**) Representative ERP-waveforms for food pictures in the hungry (*red lines*) and satiated (*black lines*) states. (**d**) Scalp potential (*back view*) and L2-Minimum Norm estimates maps (right lateral view) show the topography of the LPP component for food and the difference between the hungry and satiated states (Based on Stockburger et al. 2009a)

Table 142.5 Key features of the startle reflex

1. The startle reflex is a defense response that prevents organ injury and interrupts ongoing mental and behavioral activity
2. The startle reflex is a whole body response that consists of rapid flexor movements cascading throughout the body
3. The reflex is elicited by sudden, unexpected, and intense stimuli. In the laboratory, acoustic stimuli (e.g., 50 ms duration, 90–110 dB loudness, and instantaneous rise time) are often used to elicit the reflex
4. Rapid eye closure is among the most reliable components of the startle response in humans and measured by recording the electrical activity of the orbicularis oculi muscle
5. The acoustic blink reflex shows an onset latency of ~20–40 ms and usually peaks between 50 and 100 ms
6. While the startle reflex is an obligatory response, its magnitude varies as a function of emotional, motivational, and attentional processes

This table lists the key features of the startle reflex

of food deprivation across subjects (0, 6, 24 h). In a nondeprived state, food pictures revealed inhibited startle responses as compared to the other picture materials suggesting that these cues prompt an appetitive approach disposition. In contrast, startle reflexes elicited during food picture viewing were potentiated for both deprivation levels as compared to the nondeprived group. These findings were considered to reflect an aversive motivational reaction, which is attributed to a state of frustrative non reward, i.e., participants were not allowed immediate consumption (Drobes et al. 2001). However, another line of studies revealed that the active imagination of pleasant scenes triggered enhanced startle reflexes compared to neutral imagery contents (Miller et al. 2002). An alternative interpretation of the Drobes et al. (2001) and Mauler et al. (2006) findings is accordingly, that viewing food pictures elicited vivid imagination in the participants. Resolving the issue is of great theoretical importance and the startle probe methodology may serve as promising tool to disambiguate motivational orientation elicited by internal deprivation state and external food cue reactivity.

142.7 Applications to Other Areas of Health and Disease

Revealing the effects of food deprivation with regard to incentive value and attention processes provides highly relevant information for the obesity pandemic. The voluntary restriction of food intake for regulating body weight is an increasing phenomenon in many Western cultures. Such attempts in dieting and restrained eating are often accentuated towards foods considered as fattening (e.g., sweets, high-fat food). Specific food restrictions may be also due to moral and health concerns as is the case for instance in vegetarianism. It seems highly informative to determine the specificity of food restrictions on the processing of food stimuli with particular emphasis of affective attitudes and short- and long-term effects. For instance, a recent event-related brain potential study revealed the increased attention capture of meat pictures in vegetarians refraining from eating meat for several years (Stockburger et al. 2009b). Understanding food deprivation effects may be furthermore relevant in understanding eating disorders such as anorexia nervosa and bulimia.

Summary Points

- At the core of the feeding system are neural circuits that were laid down early during evolutionary history, in primitive cortex, sub-cortex, and midbrain.
- These motivational circuits are engaged by unconditioned food-related stimuli, determine general mobilization and approach behaviors of the organism, and mediate the shaping of the feeding system by learning and experience.
- Internal state variables exert a profound effect on the feeding system and neuroimaging methods appear promising to provide novel insights into the operation of food deprivation.
- Hemodynamic studies were reviewed providing some support for the notion that food deprivation increases the incentive value of food-related stimuli in core structures of the motive circuitry. There is evidence that these effects appear most robust for high-incentive stimuli.
- Furthermore, attention to need-related stimuli is regulated by motivational state. Event-related potential studies delineate motivated attention processes with high temporal resolution suggesting that deprivation effects facilitate perceptual processing in stages related to stimulus recognition and working memory representation.

- Guided by animal research about the neural organization of the feeding system, electrophysiological, hemodynamic, and reflex measures of brain activity provide a window to probe deprivation effects on food stimulus processing.
- Given the sparse number of relevant studies, a considerable research effort is needed to reveal consistent and reliable findings related to deprivation.
- Understanding these effects seems important when considering that attempts to regulate body weight and eating-related disorders often include the voluntary restriction of food intake.

Key Terms

Ingestive behavior: Ingestive behaviors are comprised by appetitive and consummatory phases which depend on the integration of information about internal state, cues from the environment, behavioral state, and cognition.

Incentive motivation: Incentives arouse motivated behaviors and form the target for goal-direct behaviors. Incentive motivation is determined by external stimuli and internal states.

Motive circuitry: Cortical, subcortical, and brainstem neural structures implicated in reward perception and activation of adaptive behaviors.

Functional magnetic resonance imaging: Neural activity is coupled with blood oxygenation level dependent (BOLD) signal changes that can be measured with MRI. Assessment of short-term changes can be used to infer functional neural activity associated with food stimulus processing in core structures of the motive circuitry.

Motivated attention: In natural environments, attention is dictated by motivational significance of salient stimuli and internal states.

Event-related brain potentials: Electrophysiological recordings of brain activity associated with food stimulus processing. Providing a high temporal resolution, event-related potential recordings allow measuring the motivational regulation of attention by food deprivation.

Chapter 143
Symptoms of Starvation in Eating Disorder Patients

Riccardo Dalle Grave, Elettra Pasqualoni, and Giulio Marchesini

Abbreviations

DSM   Diagnostic and Statistical Manual of Mental Disorders
NOS   Not otherwise specified

143.1 Introduction

The DSM-IV classification of eating disorders includes three main diagnostic categories: anorexia nervosa, bulimia nervosa, and eating disorders not otherwise specified (NOS) (American Psychiatric Association 1994). Underweight is a key diagnostic criterion for anorexia nervosa, but could be present in a subgroup of patients with eating disorder NOS (e.g., underweight patients that meet all DSM-IV criteria for AN except amenorrhea (Dalle Grave et al. 2008b) or the overevaluation of shape and weight (Dalle Grave et al. 2008c)). Severe weight loss and dietary restriction (i.e., a persistent caloric intake lower than energy expenditure) could also be present in a subgroup of not underweight eating disorder patients with bulimia nervosa or eating disorder NOS with an history of obesity.

Keys and his colleagues in their classic two-volume, 1,385-page text *The Biology of Human Starvation* (Keys et al. 1950) gave a detailed description of the symptoms of dietary restriction and underweight, traditionally called "starvation symptoms," reported by young male volunteers. The observation that many symptoms reported by the volunteers were similar to those found in patients with anorexia nervosa improved the understanding and the treatment of eating disorders (Garner 1997). Today, it is widely accepted that many symptoms, once attributed to the psychopathology of anorexia nervosa, are the mere consequences of severe weight loss and caloric restriction.

R. Dalle Grave (✉)
Department of Eating and Weight Disorder, Villa Garda Hospital,
Via Montebaldo 89, I-37016 Garda (VR), Italy
e-mail: rdalleg@tin.it

The chapter has three main aims: (1) to review the symptoms associated with underweight and dietary restriction; (2) to describe the role of underweight and dietary restriction in the maintenance of eating disorder psychopathology; (3) to analyze the clinical implications of these symptoms in the treatment of eating disorders.

143.2 Symptoms Associated with Underweight and Dietary Restriction (Starvation Symptoms)

The Minnesota study is considered the key reference on the effect of dietary restriction and weight loss in normal weight individuals. The study was carried out at the University of Minnesota between November 19, 1944 and December 20, 1945 (Keys et al. 1950). The study was designed to evaluate the physiological and psychological effects of severe and prolonged dietary restriction and the effectiveness of nutritional rehabilitation strategies. The principal aim of the study was to guide the assistance to famine victims in Europe and Asia during and after the World War II by using the data derived by a laboratory simulation of severe famine.

More than 100 men were ready to volunteer in the study as an alternative to military service. Of this initial sample, 36 men with the best physical and psychological health and with a high motivation to participate were selected (Keys et al. 1950). The participants were all white males in the age range from 22 to 33 years. Of the 36 volunteer individuals, 25 were members of the Historic Peace Churches (Mennonites, Church of the Brethren, and Quakers).

The study was divided in three phases: a control period of 12 weeks, 24 weeks of semistarvation, and 12 weeks of rehabilitation. During the control period the mean daily caloric intake of the participants was 3,492 calories, during the period of semistarvation the calories were decreased to a mean of 1,570, and during the period of rehabilitation they were re-increased to normal levels. In the semistarvation period, participants were fed foods most likely consumed in European famine areas and lost approximately 25% of their body weight.

Complete data are available only for 32 participants because 4 participants interrupted the study during or at the end of the second phase of semistarvation. The individual reactions to semistarvation and to the weight loss were heterogeneous, but in most cases the participants experienced dramatic effects (see Table 143.1).

143.2.1 Behavioral Effects

Toward the end of the starvation phase the participants spent almost 2 h to eat a meal that they previously consumed in few minutes. Many participants read cookbooks and collected recipes. Some increased coffee and tea consumption, drank large amount of water or soups to increase their fullness, and developed specific eating rituals (e.g., eating very slowly, cutting the food in small pieces, mixing the food in a bizarre way, ingesting hot food). The use of salt, spices, and gums increased, and also nail-biting and smoking. Many of these behaviors persisted also during the 12-week weight restoration phase.

During the semistarvation period, all participants reported a significant increase hunger. However, some were able to tolerate it, while others had bulimic episodes followed by self-criticism. In the weight restoration phase, when participants had access to a large amount of foods, some lost control eating, ingesting more or less than necessary. After 5 months of rehabilitation, most of the participants normalized their eating habits, but a subgroup continued to eat large amount of foods.

Table 143.1 Starvation effects reported by the Minnesota Study (Keys et al. 1950)

Behavioral effects

- Eating rituals (eating very slowly, cutting the food in small pieces, mixing the food in a bizarre way, ingesting hot food).
- Reading cookbooks and collecting recipes
- Increasing coffee and tea consumption
- Increasing the use of salt, spices, gums, hot soup, and water
- Nail-biting
- Increased smoking
- Bulimic episodes
- Increasing exercise to avoid the reduction of the caloric content of the diet
- Self-mutilation

Psychological effects

- Impairment of concentration capacity
- Poor insight and critical judgment
- Preoccupation about thought on food and eating
- Depression
- Mood lability
- Irritation
- Hunger
- Anxiety
- Apathy
- Psychotic episodes
- Personality changes

Social effects

- Social withdrawal
- Loss of sexual appetite

Physical effects

- Abdominal pain
- Gastrointestinal discomfort
- Sleep disturbances, vertigo
- Headache
- Strength reduction
- Hypersensitivity to light and noises
- Edema
- Cold intolerance
- Paresthesia
- Reduction of basal metabolism
- Reduce of heart and respiratory frequency.

Many participants reduced their habitual level of physical activity and complained that they had less energy. However, some individuals used intense exercise to be allowed a larger amount of food or to avoid a reduction in the caloric content of the diet.

143.2.2 Psychological Effects

Most of the participants showed marked cognitive and emotional changes. They reported a decreased concentration capacity, insight, and critical judgment, while no changes in intellectual ability were observed. The impairment in concentration capacity was probably due to the presence of recurrent thoughts on food and eating that were reported by most of the participants.

Some suffered periods of depression, while others had frequent periods of mood changes. A subgroup became irritated and developed episodes of hunger explosion. Anxiety and apathy were common, and in a subgroup of participants the emotional disturbances became so severe that the authors coined the term "starvation neurosis" to describe them. The emotional changes were confirmed by the Minnesota Multiphasic Personality Inventory that showed a significant increase in depression, hysteria, and hypochondria. Two participants developed psychotic symptoms and one self-mutilated three fingers of his hand to modulate his mood. In general, the emotional changes did not disappear immediately after rehabilitation, but persisted for many weeks. However, some participants did not show any psychological deterioration during the entire study period.

143.2.3 Social Effects

Starvation had also a large effect on social functioning. Participants become inward-looking and self-focused, which led to social isolation. In general, they also reported a loss of sexual appetite, another effect that could have contributed to social withdrawal.

143.2.4 Physical Effects

The most frequent symptoms reported by participants during the dietary restriction phase were abdominal pain, difficult digestion, sleep disturbances, vertigo, headache, strength reduction, hypersensitivity to light and noises, edema, cold intolerance, sight and hearing alterations, and paraesthesias. Participants showed a marked reduction in their basal metabolism (almost a 40% decrease), as well as in heart and respiratory frequency. During the weight restoration phase their basal metabolic rate increased proportionally to the increased caloric intake and they regained their baseline body weight after a weight loss of 25% or more of initial body weight.

143.2.5 Comments by Participants to the Minnesota Starvation Experiment

In 2003–2004, 18 of the 36 participants were still alive and were interviewed by researchers of The Johns Hopkins School of Medicine, Baltimore, MD (Kalm and Semba 2005). Participants were in their 80s when interviewed and each spoke passionately when discussing why they chose to be a conscientious objector and to participate in the experiment. Although the data of the study have been reported with scientific details in *The Biology of Human Starvation* book, participants painted a more vivid picture of their daily lives during the experiment (Kalm and Semba 2005). They reported that, after an initial enthusiasm, they suffered great changes in their personalities during semistarvation. They became increasingly irritable and impatient with one another and began to suffer the physical effect of caloric restriction. They also reported an increase of introversion, less energy, dizziness, extreme tiredness, cold intolerance, muscle soreness, hair loss, reduced coordination, ringing in their ears, and poor concentration. Food became an obsession for all the participants, and several men confirmed that interest in women and dating was lost soon after study began. Despite the difficulties of starvation, they reported a strong determination to continue the study, and suggested different reasons for their dedication, including religious reasons, discipline, and will power (Kalm and Semba 2005).

For some men, the rehabilitation period was considered the most difficult part of the experiment. They reported that symptoms of dizziness, apathy, and lethargy were the first to decrease, while feelings of tiredness, loss of sex drive, and weakness were much slower to improve. They reported not being back to normal by the end of the 3-month recovery period. Many overate after they left Minnesota and became obese. They estimated that the time to achieve a full recovery ranged from 2 months to 2 years (Kalm and Semba 2005). However, none of the participants believed they experienced any negative long-term health effects as a result of the experiment (Kalm and Semba 2005).

143.3 Starvation Symptoms in Eating Disorders

The starvation study had a fundamental role in improving our understanding of eating disorders because many symptoms observed in the volunteers are similar to those reported by underweight eating disorder patients. However, to date no study has evaluated the prevalence of starvation symptoms in eating disorder individuals. Table 143.2 reports the prevalence of starvation symptoms in the

Table 143.2 Prevalence of starvation symptoms in the last 28 days reported by 50 consecutive patients with anorexia nervosa (mean BM $15.3\,\text{kg/m}^2$ – range 11.7–$17.4\,\text{kg/m}^2$)

Symptoms	Percent (%)
Preoccupation with thoughts about eating and eating	90
Irritability	82
Anxiety	78
Depression	76
Mood changes	66
Sleep disturbance	66
Social withdrawal	56
Weakness	56
Gastrointestinal discomfort	56
Cold intolerance	56
Impaired concentration	54
Apathy	50
Heightened satiety	50
Low body temperature	38
Eating very slowly	38
Reduction in sexual interest	38
Heightened sensation of fullness	36
Heightened sensation of hunger	32
Cutting the food in small pieces	30
Collecting cookbooks and recipe books	28
Increasing the consumption of coffee or tea or spice	28
Personality changes	28
Hoarding food	24
Eating hot food	24
Noise intolerance	22
Tingling	20
Edema at the legs	18
Binge eating	16
Light intolerance	16
Hearing voices in the head	4
Hallucinations	0

last 28 days reported by 50 outpatients with anorexia nervosa consecutively assessed before starting treatment at the Department of Eating and Weight Disorder, Villa Garda Hospital. Starvation symptoms were assessed with the Starvation Symptoms Check List (see Appendix). About 90% of the patients reported preoccupation with thoughts about food and eating, and 82% irritability. Other symptoms reported by at least 50% of patients were anxiety, depression, mood changes, sleep disturbances, social withdrawal, weakness, gastrointestinal discomfort, cold intolerance, impaired concentration, apathy, and heightened satiety.

143.4 Interaction of Starvation Symptoms with Eating Disorder Psychopathology

The effects of starvation symptoms in individuals with eating disorders are different from those observed in subjects without these disorders. In the absence of eating disorder psychopathology, starvation symptoms lead individuals to focus their attention primarily towards food searching, and when food becomes available, they eat without being concerned about losing their control of body shape and weight. On the contrary, the presence of the eating disorder psychopathology (i.e., the overvaluation of shape, weight, and their control) (Fairburn et al. 2003) interacts with starvation symptoms maintaining the eating disorder (see Table 143.3 for the proposed general mechanisms).

In particular, it has been suggested that some symptoms of starvation stimulate further dietary restriction by undermining the person's sense of being in control over their eating, shape, weight, or themselves in general (Fairburn et al. 1999), while other symptoms exaggerate the tendency to use control over eating as an index of self-control in general (Shafran et al. 2003). It has also been proposed that some eating disorder individuals interpret the symptoms of starvation as a positive sign of being in control and as evidence that they are working hard to achieve their goal of controlling eating, shape, and weight (Shafran et al. 2003). Support for these hypotheses is provided by two studies. The first study found that patients with eating disorders were significantly more likely to interpret four symptoms of starvation (hunger, poor concentration, heightened satiety, and reduction in rate of weight loss) as a proof of control (Shafran et al. 2003). The second study found that a significantly higher proportion of inpatient eating disorder patients interpret the symptoms of hunger, heightened satiety, and dizziness in terms of control when compared to nonclinical participants (Dalle Grave et al. 2007) (see Table 143.4 for clinical examples).

Table 143.3 Proposed mechanisms through which starvation symptoms maintain the eating disorder psychopathology (Dalle Grave et al. 2007; Shafran et al. 2003; Fairburn 2008)

1. Underweight and dietary restriction symptoms increase the need to get control over their eating, shape, weight, or themselves in general.
2. Preoccupation with food and eating keeps the eating disorder mindset permanently "in place"
3. Social withdrawal and loss of previous interests prevent the development of other domains of self-evaluation
4. The maintenance of underweight requires the adoption of a hypocaloric diet that maintains the preoccupation with food and eating
5. Indecisiveness makes it difficult for patients to decide whether to change (procrastination)
6. Heightened need for routine and predictability interferes with change
7. Heightened feeling of fullness makes it difficult to increase the amount of food.

Table 143.4 Examples of how eating disorder patients may interpret some starvation symptoms

Symptoms	Dysfunctional interpretation of eating disorder patients
Hunger	I am controlling my diet
	I have to increase my attention to avoid losing control over eating
Sense of fullness	I eat too much, I have to reduce the calories of my diet
Binge eating	I am weak, I have to increase my control over eating
Reduction in the rate of weight loss	I am losing control over my weight. I have to reduce the amount of food I eat
Mood instability	I am not in control. I have to increase my control over eating, weight, and shape
Dizziness	It is a positive sign that I am losing weight
Poor concentration	I am losing control. I have to increase my control over eating

143.5 Clinical Implications

The knowledge of starvation symptoms and how they interact with eating disorder psychopathology have important implications both for the understanding and the treatment of eating disorders.

Clinicians should be informed that many psychosocial symptoms reported by underweight eating disorder patients are the consequences of dietary restriction and underweight and not the expression of their eating disorder psychopathology. These symptoms are not related only to food and eating, but extend to the whole range of psychosocial functions. Since many symptoms reported by eating disorder patients, often suggested to be the cause of their disorder, are indeed the consequences of underweight and dietary restriction, clinicians should be aware that the weight must be completely restored before a final assessment of the psychological functions and personality of their patients is accurately performed (Garner 1998).

Patients should be educated on the starvation symptoms and on the Minnesota study (Garner 1997; Garner et al. 1997). This recommendation is based on the assumptions that patients with eating disorders often have misconceptions about the cause of their symptoms and may be less likely to continue their efforts to maintain underweight if they informed about the scientific data on the maintenance of their disorder (Garner 1998). They also should be helped to change their dysfunctional interpretation of starvation symptoms, since a subgroup of patients tend to view some of these symptoms as a positive sign of being in control (Shafran et al. 2003; Fairburn et al. 1999). Finally, they should be helped to achieve a healthy body weight since the maintenance of caloric restriction and underweight is a mechanism maintaining their eating disorder psychopathology (Fairburn 2008). Educational material on starvation symptoms for underweight eating disorders patients (Garner 1997) and manuals for clinicians describing the procedures and the strategies to address underweight and caloric restriction in eating disorder patients are available (Dalle Grave et al. 2008a; Fairburn 2008).

143.6 Applications to Other Areas of Health and Disease

The dissemination of the knowledge about symptoms associated with underweight and caloric restriction could help to improve the assessment and the treatment of the following conditions associated with underweight and low calorie intake (the list is not complete):

• AIDS
• Alcoholism
• Alzheimer's disease

- Anxiety
- Cancer
- Celiac disease
- Chronic heart disease
- Chronic lung disease
- Chronic renal disease
- Clinical depression
- Cystic fibrosis
- Dementia
- Denture difficulties
- Dysphagia
- Infections
- Inflammatory bowel disease
- Lactose intolerance
- Malabsorption
- Poverty and lack of food
- Stomach ulcer
- Stomatitis
- Systemic lupus erythematous
- Schizophrenia
- Tuberculosis
- Uncontrolled diabetes mellitus

Summary Points

- Underweight is a key diagnostic criterion for anorexia nervosa, but could be present in a subgroup of patients with eating disorder NOS (e.g., underweight patients who meet all DSM-IV criteria for anorexia nervosa except amenorrhea or the overvaluation of shape and weight).
- Severe weight loss and dietary restrictions are also present in a subgroup of nonunderweight eating disorder patients with bulimia nervosa or eating disorder NOS with previous obesity.
- Underweight and dietary restrictions are associated with several physical and psychosocial symptoms ("starvation symptoms").
- Many psychosocial symptoms observed in underweight eating disorder individuals are the consequences of underweight and dietary restriction and not the expression of their psychopathology or personality.
- The most frequent starvation symptoms reported by eating disorder patients are preoccupation with thoughts about food and eating and irritability.
- Starvation symptoms interact with eating disorder psychopathology stimulating further dietary restrictions by undermining the individuals' sense of being in control over their eating, shape, weight, or themselves in general
- Some eating disorder individuals interpret the symptoms of starvation as a positive sign of being in control and as evidence that they are working hard to achieve their goal of controlling eating, shape, and weight.
- The treatment of eating disorder patients with underweight and/or caloric restrictions should include education on starvation symptoms, strategies to change their dysfunctional interpretation of starvation symptoms, and to favor weight regain

Definitions and Explanations

Dietary restriction: Persistent caloric intake lower than energy expenditure

Eating disorders: Persistent disorder of eating behavior and/or of behaviors aimed to modify or control the shape and weight, associated with an overvaluation of shape and weight and with significant physical and psychosocial impairment not secondary to any medical or psychiatric condition known.

Overvaluation of shape and weight and their control: Judging themselves predominantly or even exclusively in term of weight, shape, and their control (it is considered the core psychopathology of eating disorders).

Starvation symptoms: Symptoms associated with dietary restriction and underweight.

Starvation neurosis: Emotional disturbances associated with dietary restriction and underweight.

Key Points

1. The presence of starvation symptoms should always be evaluated in eating disorder patients.
2. The weight must be completely restored before carrying out an accurate assessment of the psychological functions and personality of eating disorder patients
3. Eating disorder patients should be educated that the maintenance of dietary restriction and underweight is associated with severe physical and psychosocial impairment.
4. Since starvation symptoms are potent mechanisms maintaining eating disorder psychopathology, the treatment of underweight eating disorders should always address underweight and dietary restriction.

144.1 Introduction

B vitamin deficiency, namely B12, B9 (folate), and B6, is linked to hyperhomocysteinemia, to brain amyloid overproduction and to aging in one of the most devastating disease in the elderly: Alzheimer's Disease (AD).

Aging is a progressive decrease of the physiological capacity to react to stress arising from the environment, leading to increased susceptibility and vulnerability to disease. Although the activity of the brain and the individual psychology plays a major role for such phenomena through unknown mechanisms, the physiology of aging it appears must be controlled by epigenetic mechanisms that made it possible for evolution to increase our lifespan. When approaching the maximum potential lifespan humans have to face physiological modifications and diseases most likely due to alteration of those epigenetic mechanisms that enhance early survival but could be disadvantageous later in life (Egger et al. 2004; Troen 2003). One of these is evidently AD, which increases proportional to lifespan. The study of non-DNA sequence-related heredity, as epigenesis can be defined, is becoming the epicenter of modern medicine because it is beginning to clarify the relationship between genetic background, environment, aging, and disease. Although DNA sequence remains essentially the same, the epigenetic state may vary among tissues and during the lifetime; in other words, it may be responsible for phenotypic plasticity in age-related modifications. Vitamin deficiency, either due to defective nutrition or to pathology, is among the elements capable of modifying the epigenetic mechanisms in the direction of disease. The new fact is that alteration of these mechanisms is not measurable by genetic defect or pathogenic elements, but could result in the modification of gene expression regulation. Over-production of brain amyloid due to hypomethylation of at least one specific gene promoter has been shown in recent years in several publications (Fuso et al. 2007, 2009; Scarpa et al. 2003, 2006). In these papers, the authors demonstrated that B vitamin deficiency (B6, B12, and folate) may be responsible for amyloid overproduction, whether in brains of transgenic mice or in human cell culture. Widespread loss of DNA methylation was observed in colorectal cancers in 1983 and thereafter a large number of reports of either hypomethylation of oncogenes or hypermethylation of oncosuppressor genes, which may result in a variety of cancers. The most fascinating aspect of epigenesis is the possibility of reversing its changes, unlike sequence mutations in disease, which could lead to a host of new therapeutic tools.

In this review the impact of those nutritional elements – B vitamins and catabolites like homocysteine – that may influence epigenetic mechanisms by altering the metabolism of methyl donor, will be discussed.

144.2 DNA Methylation

The study of DNA methylation in aging is extremely topical because of its implication in tumorigenesis, since cancer onset increases with aging. The general decrease in total genomic methylcytosine during aging in various organisms and the apparently finite number of cell divisions, characteristic of most somatic cells, reinforces the view of overall methylcytosine loss as a cellular timing mechanism that triggers senescence. Nevertheless, it is important to underline the fact that the methylation status of the majority of examined genes seems to be intact during aging. The alterations in CpG island methylation are crucial to modulate binding of transcription factors and methyl-DNA binding proteins. Aberrant methylation of CpG islands in the promoter region may contribute to the progressive inactivation of growth-inhibitory genes during aging, resulting in the clonal selection of cells

with a growth advantage towards cancer development. Alterations in DNA methylation during aging can depend on alterations in dietary status. The great influence of nutritional components on health and lifespan is largely accepted. Among the various mechanisms by which nutritional elements could affect the progress of senescence, two pathways involve DNA methylation: the first concerns the supply of metabolites of the S-adenosylmethionine cycle (SAM, folic acid, and B vitamins), whereas the second refers to elements able to directly modify the DNA-methyltransferase (DNMT) activity (selenium, cadmium, and nickel). Clear indications of methylation alterations come from studies on aging, on various noncommunicable diseases (Prader-Willi, Angelman's, and Beckwith-Wiedemann syndromes) and on various diseases related to aging (Down's syndrome, Alzheimer's, Parkinson's, and Huntington's diseases). Changes in chromatin structure are related to epigenetic modifications that consist of DNA methylation, histone post-transcriptional modifications (methylation, acetylation, and phosphorylation) and ATP-mediated chromatin modifications. In proliferating cells, DNA is principally found as euchromatin in actively transcribed loci like the growth regulatory genes. Conversely, it has been proposed that reassembly of repressive chromatin domains (heterochromatin) may contribute to cellular senescence. The main tool of epigenetic control on gene expression seems to lie in the CpG sequence, irrespective of whether this sequence contains a methyl group bound on C (Razin and Riggs 1980). We should bear in mind that although most studies have been dedicated to DNA, methylation processes have to do also with RNA, proteins, and lipids (Chiang et al. 1996). Regulation of gene expression through DNA methylation consists of the methylation or demethylation of cytosines in CpG sequences that eventually present in the gene promoters of those genes whose regulation is controlled by methyl groups. There is a basic difference between sequences that are normally unmethylated (Bergman and Mostoslavsky 1998), like CpG islands (Cross et al. 1997), and the CpG moieties belonging to genes expressed during development that are silenced later by methylation for physiological reasons. The former may become methylated for a pathogenetic mechanism, for example in the inactivation of oncosuppressor genes in cancer, and the latter may gradually lose their methylation and therefore overexpress genes that should be downregulated.

144.3 Epigenetic Mechanisms

At the molecular level, the biochemical modifications of DNA and histone proteins are the major epigenetic mechanisms. Additional mechanisms, involving RNA interference and prion proteins contribute as well to epigenetic regulation (Levenson and Sweatt 2006), but will not be included here. Essentially, chromatin modifications comprise DNA methylation at cytosine–guanine dinucleotides and post-translational modifications of histone proteins. Post-translational histone modifications, because of their chemical properties, influence the condensation of chromatin and therefore modulate the accessibility of DNA to the transcriptional machinery. DNA methylation is functionally most relevant when present in sequences rich in CpG dinucleotides: the CpG islands. These regions with more than 500 base pairs in size and with a C+G density higher than 55% (Takai and Jones 2002) have been conserved during evolution because they are normally unmethylated. The completion of human genome sequencing revealed that about 50% of all genes contain CpG islands within their regulatory elements (Venter et al. 2001) and they are stably methylated in transcriptionally silenced genes. Epigenetic control of gene expression by cytosine methylation is made possible by the activity of DNA methyltransferases (DNMTs) (Hitchler and Domann 2007). These enzymes catalyze transmethylation of cytosines by transferring methyl groups from S-adenosylmethionine (SAM) to position 5 of the pyrimidine ring with production of 5-MeC in DNA. Cytosine methylation in mammalian genomes is mainly carried out by three DNMTs: DNMT1, DNMT3a, and DNMT3b. Maintenance
Fig. 144.1 Schematic representation of DNA methylation. DNA methylation and demethylation mechanisms: maintenance methylation, passive demethylation, de novo methylation, and active demethylation

methylation is catalyzed by DNMT1 and occurs rapidly following DNA replication. DNMT1 has the primary role of passing on epigenetic control of gene expression to daughter cells (Kautiainen and Jones 1985). De novo DNA methylation is catalyzed by DNMT3a and DNMT3b, which are primarily responsible for initiating new epigenetic events regulating gene expression. De novo methylation can occur anytime following DNA replication (Fig. 144.1). This epigenetic event can be passed on during future cell divisions. These enzymes were identified and cloned in 1998 (Okano et al. 1998, 1999; Xie et al. 1999).

144.4 DNA Demethylation

Soon after Holliday and Pugh proposed that DNA methylation could control gene expression (Holliday and Pugh 1975) it became clear that, besides the possibility of inhibiting DNA methylases (maintenance and de novo), to obtain demethylation, global demethylation known to occur during early embryogenesis has to rely on an active mechanism (Kapoor et al. 2005). The author of this chapter participated in the first study showing active demethylating activity in cell culture (Razin et al. 1986). Since then three active demethylation mechanisms have been proposed, none of which has been widely accepted (Kress et al. 2001). The first is direct replacement of the methyl moiety by a hydrogen atom. The other two both involve DNA repair processes: the second mechanism proposes the removal of methyl-C by nucleotide excision followed by replacement with an unmethylated one (Weiss et al. 1996; Weiss and Cedar 1997), the third one postulated the participation of RNA molecules and appears to have gained support by key experimental observations, although the demethylase involved has not yet been cloned. Having ascertained that DNA undergoes the establishment of an inherited methylation pattern in adult organisms (Fig. 144.2), with the formation of stably activated
Fig. 144.2 Schematic model of methylation-dependent gene expression

genes (mostly demethylated), stably silenced genes (mostly fully methylated), and genes with specific methylation patterns able to be induced by reassessment of methyl moieties, it should be explained what mechanisms control the donation of methyl groups.

144.5 Central Role of SAM

In the last fifty years SAM has been shown to be perhaps the most frequently used substrate, after ATP, and therefore occupies a central position in human health, disease, and aging. SAM is known to be the primary methyl-donor present in eukaryotes and it is involved in methylation of target molecules as DNA, RNA, proteins, lipids, and polyamines synthesis (Fontecave et al. 2004; Lu 2000). SAM is probably second only to ATP in the variety of reactions in which it is involved; the most important ones are transmethylation, transsulfuration, and aminopropylation, which occur due to the presence of the high-energy sulfonium ion, which activates each of the attached carbons toward nucleophilic attack. SAM was discovered in 1951 by Giulio Cantoni as an important molecule in methylation reactions (Cantoni 1951, 1953; Kresge et al. 2005). It is a conjugate of methionine at the sulfur atom with adenosine, a reaction catalyzed by methionine–adenosyltransferase. SAM appears to be altered in some neurological disorders, including AD (Bottiglieri and Hyland 1994). About 95% of SAM is engaged in methylation reactions. It is then transformed in S-adenosylhomocysteine (SAH) and further hydrolyzed into homocysteine (HCY) and adenosine. The reaction is strongly reversible and HCY, if not rapidly transformed in methionine or cystathionine, forms SAH, which is a potent inhibitor of methyl-transferases. These metabolic alterations may be responsible for the generalized reduction of DNA methylations observed in aging. HCY exerts a pathogenic effect, at very high concentrations, through the alteration of oxidative metabolism, but it can even generate a pathological situation at concentrations just above normal by modifying the methylation pattern. Remethylation of homocysteine to form methionine, along with the transsulfuration pathway prevents HCY accumulation. Accumulation of homocysteine has been a great concern for human health since

hyperhomocysteinemia is present both in cardiovascular diseases and dementia. Many clinical studies have been undertaken to verify whether supplementation of human nutrition with B vitamins to lower homocysteine would be beneficial for health (Mason et al. 2008; Refsum and Smith 2008; Smith et al. 2008; Smith 2008). There seems to be a growing consensus that lowering homocysteine with vitamin supplementation does not solve the problem. Probably not enough attention has been paid to SAM production and SAH accumulation. The SAM metabolism is strictly controlled by B12 and B9 (tetrahydrofolate), except when remethylation of homocysteine to methionine occurs through betaine reaction, in its transmethylation pathway. Betaine reaction though seems to be absent in the brain. The second pathway, derived from SAM catalytic reactions to form homocysteine, is trans-sulfuration where B6 vitamin plays a fundamental role in the transformation of homocysteine to L-cystathionine to finally produce glutathione (Fig. 144.3). To mention another SAM activity, it has been shown (Lichtenthaler et al. 1999) that it functions as an allosteric activator of cystathionine beta-synthase (CBS), by increasing the enzyme activity about threefold. Low SAM concentrations generate low CBS activity, with the result that HCY is directed toward the transmethylation pathway. The result is lesser glutathione production. This alteration is exerted by poor uptake of B6 vitamin.

The most common alteration of this metabolism is the decreased uptake of vitamin B (folate, B12, and B6) with consequent HCY accumulation and SAM/SAH alteration. Diminished uptake of B12 and folate can be determined by a number of nutritional events as well as by pathological ones. *Helicobacter pylori*, which is very common in the population and very hard to eradicate, is known to
Fig. 144.3 SAM metabolism. *Met* Methionine, *SAM* S-adenosylmethionine, *SAH* S-adenosylhomocysteine, *HCY* Homocysteine, *CYS* Cystathionine, *GSH* Glutathione, *THF* Tetrahydrofolate, *MTHF* methyltetrahydrofolate, *B12* Vitamin B12, *B6* Vitamin B6, (1) Methionine adenosyltransferase (MAT); (2) Methyltransferase(s); (3) SAH hydrolase; (4) Cystathionine-β-synthase (CBS); (5) Methionine synthase; (6) Methylenetetrahydrofolate reductase (MTHFR); (7) Betaine homocysteine methyltransferase (BHMT)
Fig. 144.4 Modifications of DNA methylation pattern with aging. DNA methylation pattern is established during embryonal development and tissue differentiation. Environmental stimuli occurring during the lifespan could generate abnormal modifications of the DNA methylation pattern in specific genes

have this effect. The result will again be the alteration of the SAM metabolism. Accumulation of amyloid protein in the brain is a clear example of this alteration. SAH increase affects SAM/SAH ratio; this is an important indicator of cellular methylation status and is usually indicated as Methylation Potential (MP) (Chiang et al. 1996; Fuso et al. 2008; Lee and Wang 1999). Although there is some disagreement about this parameter, biochemically, SAH concentration is an undiscussed indicator for appropriate methylation.

Aside of the physiological function, these epigenetic phenomena may be influenced by alterations of metabolites and of the enzymes part of the methyl-donor (SAM) metabolic cycle which may be responsible for reduced brain concentrations in elderly (Morrison et al. 1996). The consequent demethylation and overexpression of genes would not be regulated, but rather induced by reduced synthesis of the methyl-donor or by inhibition of methylases. Recent experiments on TgCRND8 mice seem to show the second hypothesis to be the most common. With the aging of an organism, the general decrease of DNA methylation can lead to overactivation of methylation-controlled genes (Fig. 144.4).

144.6 SAM and Brain Amyloid

Alzheimer's Disease (AD) is becoming one of the most common pathologies in the aging population, leading also to increased social cost and impact, because of the increase in life expectation. Besides a familial (genetic) form of the disease, which has an early onset, the higher percentage of cases is represented by the sporadic occurrence of AD with onset at an advanced age.. Whereas it is

becoming increasingly evident which is the pool of molecules involved in the pathogenesis, the causes of this form of AD are not yet well understood. Alzheimer's disease is neuropathologically characterized by the presence of amyloid plaques and neurofibrillary tangles in the brain. Amyloid plaques are extracellular deposits primarily composed of amyloid beta-peptide, which is derived from amyloid beta-precursor protein (APP) by sequential cleavages at beta-secretase and gamma-secretase sites. Neurofibrillary tangles represent intracellular bundles of self-assembled hyperphosphorylated tau protein. In recent years, hyperhomocysteinemia has began to be widely considered a risk factor in AD and this may be ascribed to alteration of the S-adenosylmethionine/homocysteine (SAM/HCY) metabolism (Seshadri et al. 2002). In fact, a frequently observed condition in AD-affected people is the increase of haematic HCY along with the decrease of B12, B6, and folate uptake (Bottiglieri 1996; Joosten 2001; Quadri et al. 2004; Selhub et al. 2000). In AD, the loss of precise control through gene methylation may alter a delicate equilibrium among the three enzymes (alpha-, beta-, and gamma-secretases) known to be involved in the production of either amyloid-beta or other nondangerous catabolites (De Strooper 2000). It is well established that alpha-secretase cleavage of APP does not produce the amyloidogenic peptides and that, on the contrary, they are produced by the activity of beta-secretases that generate an N-terminal soluble fragment and a C-terminal fragment that is sequentially cleaved by gamma-secretase to produce A-beta peptides (Tabaton and Tamagno 2007; Vassar et al. 1999; Vassar 2005). The alteration of SAM/SAH ratio is tightly related to the altered expression of two genes involved in APP metabolism, finally producing the accumulation of A-beta peptide in the senile plaque. Previous papers in cell culture showed that two of the genes responsible for amyloid-beta production (PS1 and BACE, i.e., gamma and beta secretases) are upregulated by vitamin B deficiency; exogenous SAM administration can restore the normal gene expression, thus reducing amyloid levels (Fig. 144.5) (Cavallaro et al. 2006; Fuso et al. 2005; Scarpa et al. 2003, 2006). Moreover, a study on mice carrying the transgenic beta-amyloid-protein precursor (APP) showed that vitamin B deprivation was able to induce PS1 and BACE upregulation and increased Abeta deposition (Fuso et al. 2008). Accumulation of HCY and DNA hypomethylation are metabolically related since the lack of transformation of HCY to methionine reverts the metabolism to SAH, which is a strong inhibitor of DNA methyltransferases, therefore inducing DNA hypomethylation (Chiang et al. 1996). Therefore, hypomethylation may be a mechanism through which HCY exerts its toxicity in AD and promotes amyloidogenesis.
Fig. 144.5 Effect of B vitamin deficiency and SAM supplementation in TgCRND8 Alzheimer mice. Vitamin B deficiency causes hyperhomocysteinemia, decrease of SAM/SAH ratio and PS1 methylation, and upregulation of PS1 mRNA expression. SAM treatment, although it cannot completely revert high HCY can normalize the other parameters

144.7 SAM and Oxidative Stress

Increasing evidence demonstrates that oxidative stress is implicated in a number of age-related disorders among which are AD, Parkinson's disease (PD), and atherosclerosis. Hyperhomocysteinemia is a risk factor for atherosclerotic vascular disease and AD as well, and it is associated with increased oxidative stress. The central nervous system is particularly vulnerable to free radical damage owing to high brain oxygen consumption, its abundant polyunsaturated fatty acid content, and its relative paucity of anti-oxidant enzymes compared with other tissues (Guidi et al. 2006; Migliore et al. 2005; Vitvitsky et al. 2006; Zafrilla et al. 2006). Increased concentrations of HCY in the plasma of AD patients are associated with an increase of asymmetric dimethylarginine (ADMA) and a decrease in nitric oxide (NO) plasma concentrations, through inhibition of DDAH (dimethylarginine dimethylaminohydrolase, the enzyme that converts ADMA into citrulline and dimethylamine). ADMA is an endogenous inhibitor of nitric oxide synthase (NOS), and it is synthesized during the process of protein arginine methylation by SAM and subsequent hydrolysis. ADMA accumulation impairs cerebral blood flow. Brain infarcts and atherosclerosis increase the incidence and the severity of symptoms of AD patients; therefore, accumulation of ADMA may contribute to the development of AD by increasing the incidence of atherosclerosis and stroke (Selley 2003; Siroen et al. 2006; Stuhlinger et al. 2001). Moreover, the toxic effect of HCY in atherosclerosis is mainly due to the stimulation of inflammatory response through oxidative reactions, since HCY is involved in the synthesis of GSH, the major cellular antioxidant.

144.8 SAM and Tau Protein

Microtubule-associated tau protein is a phosphoprotein whose phosphorylation is regulated. The main physiological function of tau is the promotion of the assembly and stabilization of the microtubular network, which is essential for normal axonal transport of vesicles within the neuron. In humans, tau protein undergoes several post-translational modifications, such as abnormal phosphorylation, which plays a significant role in the formation of neurofibrillary pathology. Phosphorylated tau has a reduced capability of binding to microtubules and hyperphosphorylation contributes to the formation of pathological tau filaments. This leads to destabilization of the microtubular network and subsequent impairment of microtubule-associated axonal transport. The modification of tau by phosphorylation is regulated by the equilibrium between kinase and phosphatase enzymes. Previous works suggest that a decrease in Phosphatase 2A (PP2A) activity, rather than an increase in kinase activity, is crucial for the elevated levels of aberrant protein phosphorylation in AD. PP2A is abundantly expressed in the brain and its abnormal function has been demonstrated to be associated with AD. Expression of a mutant form of PP2A in mouse brain causes a marked decrease in PP2A activity and induces AD-like hyperphosphorylation of tau at specific serine/threonine residues (Kins et al. 2001). In vivo, PP2A enzymes predominantly exist as heterotrimers containing a catalytic subunit (C), a scaffolding subunit (A), and a regulatory subunit (B). The highly conserved carboxyl-terminal sequence of the C subunit can undergo post-translational modifications like methylation on the Leu-309 residue by a specific methyltransferase (PPMT). This modification critically modulates the binding of regulatory B subunits to the (AC) core enzyme, thereby affecting PP2A substrate specificity, targeting, and cellular function (Evans and Hemmings 2000; Wei et al. 2001; Yu et al. 2001). It has been observed that PPMT expression and PP2A methylation become downregulated in AD (Sontag et al. 2004). Nicola et al. 2010 showed that alteration in the SAM/HCY cycle results in decreased PP2A methylation. Reduced PP2A methylation is associated with B subunit down regulation and accumulation of phosphorylated tau (Sontag et al. 2007;

Zhang et al. 2008). Moreover, other papers showed that PP2A mRNA expression levels were increased in AD fibroblast (Zhao et al. 2003). These data suggest a double regulation both at gene and protein level.

144.9 Conclusions

Amyloid-beta has erroneously been considered toxic, but although several functions have been recently postulated, it is not yet clear which is the main one. Abeta becomes dangerous only when abundant and in oligomeric or polymeric forms. Dimers and trimers of beta-amyloid are now considered the first cause of AD onset and memory loss. These observations have quite changed the diffused idea that assigned the onset of AD to senile plaques. Recently it was demonstrated (Fuso et al. 2008) that the two genes responsible for Amyloid-beta production, beta (BACE) and gamma (PS1) secretases, are regulated by vitamin B deficiency and by SAM supplementation. Moreover, we showed that feeding either neuroblastoma cells with culture medium deficient of B12, B6, and folate, or TgCRND8 transgenic mice with food deficient in the same vitamins increased Abeta production (Fuso et al. 2005, 2008). The administration of methyl-donor has the opposite effect: it reduced significantly Abeta levels by remethylating the genes (Fuso et al. 2010). It is evident that whereas genetic factors are clearly associated with early-onset form of AD, epigenetic factors could be more easily linked to late-onset AD, since the epigenome is prone to changes during development and also aging (Bird 2007; Dolinoy 2007). The gene control mechanism here described is being studied in vivo for therapeutic applications (Table 144.1).

Table 144.1 Key epigenetic mechanisms possibly involved in Alzheimer's disease

Gene	Epigenetic modification	Treatment suggested	References
APP	APP cleavage product (AICD) recruits HAT TIP60 suggesting potential hyperacetylation.	None	Cao and Sudhof (2001)
	APP-induced death of cortical neurons causes H3 and H4 hypoacetylation.	None	Rouaux et al. (2003)
PS1	PS1 mutations prevent CBP degradation resulting in abnormal gene expression, potentially through hyperacetylation.	Substitution of PS1-mediated enzymatic activity	Marambaud et al. (2003)
	PS1 conditional knockout mice have decreased CBP level and CBP-mediated gene expression.	None	Saura et al. (2004)
	Hypomethylation of PS1 promoter increases Abeta production.	SAM administration reverses hypomethylation silencing gene and reduces Abeta production.	Fuso et al. (2009); Scarpa et al. (2003)
BACE	Vitamin B deficiency increases BACE expression and induces Abeta production.	Treatment with methyl-donor reduces BACE expression by unknown mechanism, thus reducing Abeta production	Fuso et al. (2008)

This table lists three genes implicated in Abeta production. APP is the large protein (695 amino acids) originating the 39–42 polypeptide fragment (Abeta). PS1 is presenilin 1 enzyme involved in gamma-secretase cut of APP. PS1 is also involved with Notch1 control, a factor necessary for stem cells maturation; which is the reason why knock-out of this gene cannot be applied as therapy. Beta-secretase (BACE) operates the second cut to form Abeta fragment

Although it is not clear if specific vitamins could be used as preventive therapy in the pathologies treated in this chapter, since depending on the dosage they could become responsible of the development of subclinical tumors, it will be very interesting to test clinically the use of SAM for the prevention and arrest of AD. This is only one of the cases in which gene silencing could be induced to repair or prevent pathologic outcomes due to an epigenetic disorder.

144.10   Applications to Other Areas of Health and Disease

The epigenetic mechanism outlined in this chapter will have a large number of applications. Considering the number of genes that may be controlled by methylation and the possibility to silence them by supplying the methyl-donor, it is evident that several other diseases may be studied in this respect to identify a possible target. The most delicate field seems to be cancer, since DNA methylation involvement has been shown in a large body of publications, but with contrasting results.

Summary Points

- Homocysteine accumulation is one of the key features in two major pathologies: neurodegenerative diseases and cardiovascular diseases.
- Diminished uptake of vitamins, both for nutritional or pathological reasons (helicobacter pylori), may be the main cause of AD.
- Several recent trials have shown that administration of vitamins to patients is not a sufficient remedy to control AD.
- If the hypothesis of a general loss of methyl groups in the elderly is correct, few epigenetic mechanisms are involved in these pathologies.
- The main remedy for hypomethylation of genes responsible for beta-amyloid production could be the reestablishment of correct concentrations of the main methyl-donor (SAM).
- The best indicator of altered SAM metabolism in the brain is SAH and homocysteine accumulation.
- Since the main source of SAM in humans is the liver, prevention of AD should point to liver diseases.

Key Terms

Epigenetic: DNA methylation at cytosine–guanine dinucleotides, post-translational modifications of histone proteins, RNA interference, and methylation; lipid methylation and prion proteins contribute as well to epigenetic regulation.

Transmethylation: remethylation of homocysteine to methionine where the methyl-donor is methyl-tetra-hydrofolate.

Transsulfuration: transformation of homocysteine to cystathionine; final product will be GSH, the main antioxidant agent in the body.

Gene silencing in epigenetics: the remethylation of cytosines in CpG sites or CCGG belonging to a gene promoter inactivates gene expression. It may be reversed.

Abeta: beta amyloid protein. It may be composed of 39 to 43 amino-acids. The latter is most dangerous since it aggregates more easily to form senile plaques.

Tau protein: is a phosphoprotein whose phosphorylation is regulated. The physiological function of tau is the promotion of assembly and the stabilization of a microtubular network, which is essential for normal axonal transport of vesicles within the neuron.

Vitamin B12 and folate (B9): are cofactors in the transformation of homocysteine to methionine where methyltetrahydrofolate is the methyl donor.

Vitamin B6: is cofactor of cystathionine beta-synthase transforming homocysteine in cystathionine. The end product is GSH (glutathione).

Chapter 145
Reinforcement and Food Hedonics: A Look at How Energy Deprivation Impacts Food Reward

Jameason D. Cameron and Éric Doucet

145.1 Introduction

Why is it that amidst the plethora of seemingly conscious choices we make throughout our days that we often find it irresistible to reach for that next chip? After all, aren't *we* in control here? When asked such seemingly simple questions it appears as though problems such as helpless overeating – or just as germane, the command involved in dietary restriction – seems to be plainly a matter of psychological weakness and purposeful cognitive control. But, as will be discussed throughout this chapter, there is much more to feeding behavior and stable body energy reserves than self-control. In order to comprehend the physiological and psychological components involved in the uncomplicated act of eating (or not eating!) a bag of potato chips it is necessary to focus on the myriad of mechanisms that are in motion when anticipating, approaching, ingesting, and reflecting about food.

Upon closer investigation it will be argued in the following pages that a significant amount of the variation in the individual response to a similar food environment can begin to be explained not only at the gene level, but also by examining psychobiological differences in the evaluation of food *reward*. Specifically, by highlighting the potential differences in responding between lean and obese animals – spanning studies from rodents to primates (including humans) – both to the hedonic evaluation of food and to the reinforcing value of food, this chapter will attempt to describe some of the intricacies behind one the most integrated of all behaviors, feeding. Furthermore, another underlying theme will be the discussion of how energy deprivation, defined as either acute or chronic, can impact the two abovementioned components of food reward.

Beginning with the advent of agricultural practices and modernized with industrial production of food, modern-day humans are now unique to the animal kingdom in that feeding, for much of the affluent world, occurs for reasons other than sustained periods of energy deprivation. The pursuit of pleasure – or the hedonics (from the Greek word *delight*) of food – is what often guides feeding behavior. But what belies the physiology and psychobiology of what amounts to abhorrent feeding patterns still remains elusive. What is clear, however, is that when energy deprivation is prolonged there is a degree of disinhibition with respect to appetite: not only does palatable food become more salient but items that would normally not be selected can also become attractive. A plethora of research has since emerged on how homeostatic-like elements – states of nutritional need – can alter the pleasure of a sensation of food. This concept was coined as *alliesthesia* and has since received much attention.

University of Ottawa, Ontario, Ottawa, Canada, K1N 6N5
e-mail: eric.doucet@uottawa.ca

Often a combination of sight, smell, touch, and previous exposure to the food stimulus, the rewarding quality of food is therefore represented by an active process of the brain that is defined by a composite reaction to the food, and as a result is not simply a physical property of the taste stimulus itself (Berridge 1996). Furthermore, the actual reward corresponds to, and is divided by, what are believed to be three separate psychological concepts ("*wanting*," "*liking*," and learning) which are underpinned by distinct neurobiological mechanisms. Each of these dissociable components describes independent qualities that define a rewarding stimulus, and each will be elaborated on in the following sections.

As a final introductory note, it must be clarified that contrary to the view that obesity is only about behavioral control (or lack thereof), that feeding behavior is not entirely a conscious process. The *Milieu Intérieur* is constantly responding to the ebb and flow of blood-borne (chemical) and mechanical (distension) signals and their sensory afferents; incentive stimuli in the external environment along with learned associations both external and internal add salience to edible objects; genotypic variations amongst several hundred genes predispose behavioral outcomes in particular environments; and the whole of the hierarchy from blood to brain necessitates access to the basal motor system to coordinate the action of hand-to-mouth. In the end this chapter is guided by the unresolved questions regarding how each level of the aforementioned hierarchy impacts the rewarding characteristics of feeding. This chapter will also serve as an analysis of the degree to which reinforcement/"wanting" and palatability/"liking" may reflect underlying nutritional needs (e.g., chronic energy deprivation) or to what extent these components of food reward can be reflected independently of need state (e.g., weight-stable and energy replete).

145.2 Reinforcement

145.2.1 Episodic Nature of Feeding: Beyond Homeostasis

Prior to beginning a discussion about the intricacies of defining and describing the rewarding attributes of a food stimulus there is a need to introduce the physiology of feeding in relatively general terms. At the behavioral level food intake is episodic (i.e., not continuous). This indicates that there must be physiologically distinct messengers that bring an animal to begin and to end a meal. In fact, nearly half a century of research has shown that there are hormonal signals released by the gastrointestinal tract – peripheral short-term feeding signals – resulting from, or prior to, a single bout of eating. These short-term signals are divided into orexigenic signals (e.g., the peptide hormone ghrelin) that convey the overall message to eat, and this in contrast with anorexigenic signals (e.g., the peptide hormones cholecystokinin and peptide YY) that convey the message of fullness (see Table 145.1). These peripheral feeding signals released from the physical act of consuming foodstuffs are first processed within the nuclei of the hindbrain (primarily, the nucleus of the solitary track, NTS). In a reciprocal manner, these stimuli are transmitted and converge to the real-time processing stations of the hypothalamus and associated cortico-limbic structures eventually leading to goal-directed motor programs that either facilitate or impede the further ingestion of food. Furthermore, there is extensive evidence that these peripheral meal-to-meal signals act directly on the arcuate nucleus of the hypothalamus by crossing the highly selective blood brain barrier, or indirectly at the arcuate through second messenger signaling. It must also be noted that there are metabolic signals such as excursions in blood glucose that can act to promote feeding. Classic work on glycemia first demonstrated in rats was extended to humans and showed that arteriovenous differences (rate of utilization) of glucose correlated with hunger and energy intake (Van Itallie et al. 1953). Although there is continued controversy on the action and mechanism of glucose's role in feeding, it appears that this metabolic signal also has downstream effects at the hypothalamus. The hypothalamus

Table 145.1 A brief list of the peripheral feeding signals implicated in the short- and long-term modulation of energy intake (Modified from Cameron and Doucet (2007). With permission)

Feeding signal	Primary site of secretion	Effect on food intake
Long term		
Insulin	Pancreatic β cells	Decreased energy intake
Leptin	Adipocytes	Decreased energy intake
Short term		
CCK	Endocrine I cells of the proximal Small Intestine	Decreased energy intake
PYY$_{3-36}$	Enteroendocrine L cells of the ileum & colon	Decreased energy intake
GLP-1	Enteroendocrine L cells of the proximal Small Intestine	Decreased energy intake
Ghrelin	Oxyntic X/A cells of the stomach	Increased energy intake

Of all the feeding signals, ghrelin is the only peptide hormone that is an orexigenic feeding signal
CCK cholecystokinin, *PYY$_{3-36}$* peptide YY, *GLP-1* glucagon-like peptide 1

acts as a primary relay station that influences three major systems: the autonomic nervous system, the endocrine system, and the nested brain areas involved in motivational systems. As previously noted, when considering feeding behavior – on a very primitive level – this response can be deconstructed and thought of as motivational states (or drives) that are based upon bodily needs. More than this, whether it is to quench one's thirst or to eat in response to severe hunger pangs, these drives often force the body into action.

Overall, there are two main points to consider regarding the short-term regulation of energy intake: meal size and frequency. What is noticed in free-feeding laboratory conditions is that meal size predicts the interval until the following eating episode. This so-called "postprandial relationship" suggests that meal size is determined via adjustments to the interval to the next meal – not dependent on mere convenience or learned time cues. Conversely, and in most cases in the Western world, meals are scheduled at specific times of the day, resulting in no significant relationship between meal size and intermeal interval (de Castro 2000). In this so-called "preprandial relationship" there is however a relationship between the intermeal interval and meal size; what can be extrapolated is that under daily circumstances, the episodic quality of feeding is lead by associative learning. However, as the period of deprivation (intermeal) increases there may be a shift to respond in a drive-induced manner. What this indicates is that there need not be a deprivation or homeostatic signal in order to initiate a drive state or to continue consummatory behavior; once an animal learns simple stimulus–response relationships, stimuli that were once meaningless become powerful cues with the potential to initiate goal-directed motor programs. Simply put, humans *learn* how and when to initiate feeding: we discover very early that the general feeling of malaise created by the rumbling of a hunger pang or light-headedness of hypoglycemia are often associated with a lack of food. And humans, like snakes and snails, learn by reinforcement.

145.2.2 Reinforcement: Psychological Theory

Although there is no single definition of reinforcement, the concept at its most basic level – in a purely behaviorist sense – can be defined by an environment–behavior relation resulting in the strengthening of an association. As an example, a foraging animal may be experiencing some form of vitamin deficiency and randomly come across a *novel* food containing the deprived vitamin. Prior to having experienced the positive postingestive consequences of that food stimulus – without the

paired experience of assuaging the metabolic requirement for the vitamin – there existed no incentive value to the object. Without previous exposure there is no goal, or direction to behavior. This definition becomes inadequate (or incomplete), however, given the evidence that the taste of sweet or salty food can be innately rewarding (Berridge 1996), and therefore considered a "primary reward/primary reinforcer." As an example, newborn babies (and chimps and rats) demonstrate stereotypical responses of "liking" of sweet foods. In the above examples, then, sweet/salty foods are innate incentive stimuli, which are analogous to unconditioned stimuli, and the initially neutral food containing the vitamin (the conditioned stimuli) becomes a predictor of reward (Berridge and Robinson 1998).

In the field of psychology some of the most used descriptors for a *reinforcer* label it as a goal and an incentive, or a stimulus that is approached or attained (Salamone and Correa 2002). Furthermore, implicit in any definition of a reinforcer is the ability for a stimulus to motivate behavior once the stimulus reward association is imprinted. The motivation to obtain the goal object (e.g., food) is not merely an immeasurable psychological concept but can be categorized (e.g., anticipatory, appetitive, etc.) and the neurotransmitters mapped. In fact, the role of midbrain dopamine projections will be argued as being one avenue for explaining the neurophychology of motivation – and specifically the incentive contribution to food reward – in the etiology of what today me be considered maladaptive behavior.

145.2.3 Food as a Reward

The concept that food can serve as a natural *reward* is not hard to grasp in the subjective sense that many foods have the quality of inducing a sense of gratified pleasure. This is most easily measured in humans because an experimenter can simply ask a subject to rate this pleasure/palatability on an analogue scale, for example. But the first neurophysiological evidence for the role of food as a *reward* emerged from brain stimulation studies during the late 1960s and throughout the 1970s. These studies demonstrated that humans would work to obtain electrical stimulation of some sites of the brain (including the lateral hypothalamus (Olds 1977; Rolls 1975), which was by definition rewarding. What is more, the rewarding quality of the brain stimulation appeared to mimic the rewarding quality of food; interestingly, it was found that animals would work harder to obtain brain stimulation when hungry (Hoebel 1969), but when an animal was fed to satiety, it was later found that the group of lateral hypothalamic neurons under observation ceased to respond to food (Rolls et al. 1986). It must be noted that evidence offered with human brain *reward* stimulation suggested that while the experience was certainly rewarding – patients could be found compulsively self-stimulating over thousands of repeated presses – there was no evidence of self-described pleasure in either case (Heath 1972; Portenoy et al. 1986). Observations such as these helped to lay the framework that disentangled the concept that rewards must be pleasurable; it is part of the *incentive salience* hypothesis (described below) that attempts to verify that under various circumstances (e.g., addiction) a *reward* need not be both pleasurable and desired at the same time.

The work on brain stimulation was extended to psychomotor stimulants and eventually it was discovered that the rewarding effects of both of these sources of unnatural reward could be blocked by dopamine antagonists. Eventually it was later confirmed that food *reward* – a natural *reward* – could be similarly attenuated (Wise et al. 1978), and thus began the explosion of studies examining how dopamine modulates feeding and food reward. The following subsections will describe some of the theoretical views of dopamine's role in feeding and reinforcement. The focus will then shift to an examination of the potential role that reinforcement (and dopamine) plays in obesity and how peripheral signals of energy deprivation (e.g., the "hunger hormone" ghrelin and the adiposity-marker hormone leptin) may modulate reinforcement through altered dopamine function.

145.2.3.1 The Dopamine Hypothesis of Feeding: From Anhedonia to Incentive Salience

The accepted hypothesis that is now entrenched in fields spanning from neuroscience to clinical psychology is what has been termed the dopamine hypothesis, or applied to food intake, the dopamine hypothesis of feeding. In brief, via dopamine signaling arising from the ventral tegmental area of the midbrain there is downstream communication with limbic and prefrontal cortex brain areas that act to focus attention on salient environmental stimuli and to promote learning associations, thereby facilitating specific behavioral output such as feeding. The thesis is that dopamine neurons form the backbone of the network of the brain's natural reinforcement system. Indeed, food consumption, in likeness with drug consumption, increases brain dopamine levels in not only in animals, but also in humans (Wang et al. 2002). A more detailed account of the effects of altered levels of dopamine in the brain is presented in Fig. 145.1. The *exact* role that dopamine plays in reward is, however, still open to debate.

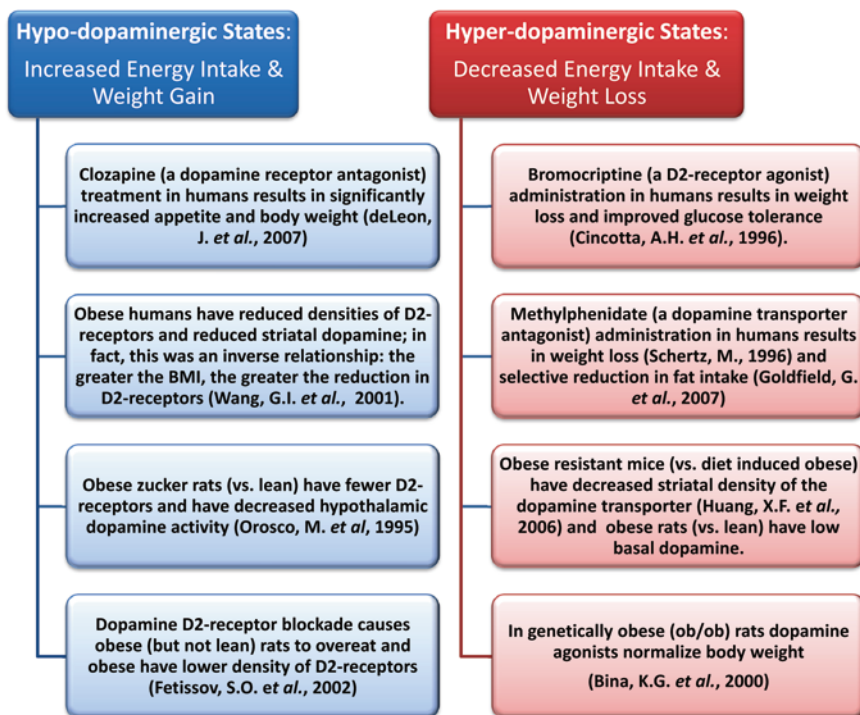
Dopamine is both a hormone and neurotransmitter that occurs in a wide variety of animals, including humans. It is one of the primary neurotransmitters in the mammalian brain, where it controls cognition, emotion, locomotor activity, food intake and endocrine regulation (Missale et al. 1998). In the brain there are three major dopaminergic pathways but the most relevant to this discussion is the reward related circuit – the mesolimbic pathway – originating in the midbrain ventral tegmentum and extending to several limbic structures, including the nucleus accumbens, the amygdala, and the hippocampus (Berthoud 2007). Part of the dopamine hypothesis of food intake is based on the initial


Fig. 145.1 Key points describing dopamine's role in feeding behavior. A look at how altered levels of the neurotransmitter dopamine, by pharmacological or genetic manipulation, can impact normal feeding behavior and body weight regulation in humans and in rodents. Note that a dopamine receptor antagonist *blocks* dopamine signaling by postsynaptic inhibition; oppositely, a dopamine transporter antagonist *promotes* signaling by flooding the synapse with dopamine (References are, from left side (de Leon et al. 2007; Fetissov et al. 2002; Orosco et al. 1995; Wang et al. 2001) and from the right side (Bina and Cincotta 2000; Cincotta and Meier 1996; Goldfield et al. 2007; Hauge et al. 1991))
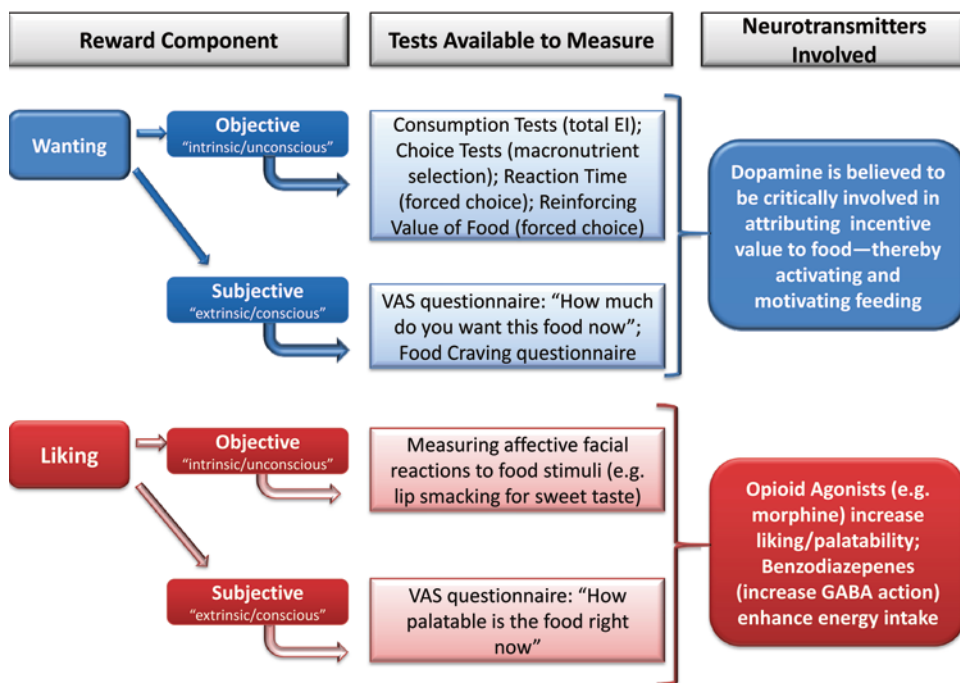

Fig. 145.2 A representation of the dissociable qualities of food reward according to the "incentive salience hypothesis" and the means by which each process can be quantitatively assessed in the laboratory. Note that EI is an abbreviation for energy intake.

work performed on animals subjected to the dopamine antagonist pimozide, which eventually led to the "Anhedonia (Greek for *without pleasure*) Hypothesis." This hypothesis stated, amongst other findings, that neuroleptics (specifically dopamine D2-receptor blockers) appeared to selectively blunt the rewarding impact of food stimuli by decreasing the pleasure of the reinforcer (Wise 1982). While other groups have arrived at many of the same conclusions – in that dopamine is required for *normal* motivation and reward – there appears to be some disagreement regarding the precise role of dopamine in reinforcement or reward. All of the intricacies of the various theories cannot be covered here; however, the view that appears most persuasive has been painstakingly developed (for review see (Berridge and Robinson 1998)) and asserts that dopamine is *not* necessary for 1) hedonic activation (i.e., normal affective reactions described as subjective/objective "liking") and, 2) for reward learning (i.e., relation between the conditioned stimulus and the unconditioned stimulus), but it *is* important for the attribution of the incentive salience of rewards. In fact, these three psychological processes are the foundation of the "incentive salience hypothesis," which offers a further description suggesting that these three processes are all dissociable qualities of reward that can be separated into components of "wanting" and "liking" (see Fig. 145.2)

145.2.3.2 "Wanting" and "Liking": Measuring Perceptual and Motivational Qualities of Food Reward

According to the "incentive salience hypothesis," there is a change at the neurological level that describes *perceptual* (e.g., cognitive) and motivational (e.g., unconscious) components that accompany the shift from a stimulus being neutral to something that is attractive and can energize and

motivate behavior (Berridge et al. 2009). The relevance for the study of feeding is that tools can be devised that measure the level of attraction to a stimulus/reinforcer and how much behavior it will support. One method that has been designed to examine *explicit* "liking"/ "wanting" and *implicit* "wanting" of food is the recent development of a forced choice computer-based procedure (Finlayson et al. 2007). This task presents photographic food stimuli of 20 different items varying along two dimensions – fat (high or low) and taste (savoury or sweet). From this computer task implicit "wanting" is measured by the speed with which one stimulus is chosen in preference to an alternative and is additionally measured by relative preference (e.g., fat vs. sweet).

In an attempt to determine whether acute energy deprivation influences food reward this forced choice paradigm was utilized at times pre- and post a standard lunch meal. The objective was to look for a state (hungry vs. satiated) dependent dissociation between "wanting" and "liking." The main findings noted that in a hungry state (3–4 h acute energy deprivation) subjects "wanted" fat (particularly high fat) and savoury food more so than fat and sweet food, but this trend was reversed and subjects "wanted" low fat sweet after the completion of an ad libitum pizza lunch. A separate study from the same group looked at the impact of meal-induced satiation on the dissociable qualities of food reward and discovered that once again implicit "wanting" for low fat sweet foods increased following a lunch meal and that "liking" for sweet foods did not decrease as much as that for fat foods (Finlayson et al. 2008). The general trend of decreased "liking" as one progresses from a hungry to satiated state is consistent with the notion of alliesthesia, a concept that will be discussed in greater detail in Sect. 145.3.

Under study designs similar to those just discussed (state-dependent), recent results from neuroimaging studies offer promising descriptions of what might be occurring in areas of the brain implicated in reward. With fMRI analysis, it was discovered that satiated normal weight women show a stronger BOLD response in the striatum and OFC – reward centers that can be viewed in Figs. 145.4 and 145.6 in Sect. 145.3 – when presented with images of low calorie foods. When hungry, however, these brain areas showed a stronger bold response to high calorie foods (Siep et al. 2009). In a separate fMRI study subjects were tested 3 h after the ingestion of a standardized meal by either infusing the "hunger hormone" ghrelin or a saline control prior to looking at food pictures (Malik et al. 2008). Ghrelin (and not saline) increased the response to food cues in the amygdala, the OFC, and the striatum. Consequently, as demonstrated by these fMRI data, the state-dependent results reported with the forced choice paradigm reported in the previous paragraph may be in part explained by a homeostatic-like influence on reward processing. To be sure, a study combining the "wanting/liking" computer task with fMRI neuroimaging and peripheral injections of ghrelin/leptin or neuropharmacological manipulation of dopamine would be of the highest impact. Unfortunately no such work has yet been performed.

145.2.3.3 The Relative-Reinforcing Value of Food & Energy Deprivation: Do Dopamine-Related Polymorphisms Impact Feeding?

In yet another definition of a reinforcing stimulus, one can describe a reinforcer as a stimulus that increases the rate of a behavior that it follows. The reinforcing value of a stimulus refers to how much behavior the stimulus will support (Epstein et al. 2007a). This can be objectively observed as the increased willingness – a quantitative measure – to work at a progressive ratio computer task to obtain a desirable food stimulus (vs. some alternative). As an example, a computer can be set up with a screen that alternates between two different choices (typically a healthy food and palatable snack food) that can be navigated with a mouse pad. It is called the relative-reinforcing value of food because the probability of earning food points varies across schedules and is contingent on performing

simple button presses on a computer joystick. The reinforcement schedule typically remains at a variable ratio (VR2) for all five trials for the healthy food, but increases progressively for the palatable snack food at VR2, VR4, VR8, VR16, and VR32 across the five trials. Thus, on average the reinforcement schedule for the healthy food is set to reinforce every second button push (VR2), and this remains the same across all trials; the reinforcement schedule for the snack food doubles across each trial, such that in the final trial (VR32) snacks were reinforced on every 32nd button press. Essentially, if subject 1 stops responding for the snack food at 16 button presses per point and subject 2 continues to respond for snack points at 32 button pushes per point, then the snack food is said to be twice as reinforcing for subject 2, as they must work twice as hard to obtain the reinforcer.

What is interesting is that comparing obese and lean individuals with this relative-reinforcing value of food paradigm, it was noted that not only did obese subjects work harder for palatable food items (vs. sedentary activities or healthy foods), but they also demonstrated an increased willingness to work for the reinforcer. In fact, this increase in the reinforcing value of food predicted ad libitum intake in the obese independently of rated pleasantness (Saelens and Epstein 1996; Temple et al. 2008). What this suggests is that the measure of motivation to work to obtain, i.e., implicit "wanting" as measured by button-presses, can in some instances be a better predictor of energy intake than explicit subjective accounts of "liking." It appears as though at the behavioral level the combination of consummatory and appetitive motivation can trump orosensory reward. Indeed a troubling finding is the observance that not only do the obese find food more reinforcing (they work more for food than for sedentary activity compared to lean) (Saelens and Epstein 1996), but obese persons also find high-fat foods more reinforcing than low-fat foods when compared to normal weight controls (Epstein et al. 1991). The reinforcing value of food, in turn, can influence how much food is eaten at an ad libitum buffet. What is more, individuals who are categorized as high in food reinforcement (i.e., spend more time at a variable ratio task working for palatable food vs. bland or nonfood items) eat more in an all-you-want-to-eat environment compared to individuals low in food reinforcement (Epstein et al. 2004a). It is unclear, however, whether these findings represent a cause or consequence of excess energy reserves.

One almost inescapable consequence of obesity is sustained periods of energy depletion or dieting. It is well known from psychological studies of reinforcement that food deprivation (and even drug deprivation) increases the reinforcing value of food. Obese and lean individuals alike pass through perturbations in body weight as a result of the prolonged interplay between energy intake, energy expenditure, and the overall involvement of gene and environment interactions. Indeed, results from an energy deprivation in lean individuals ranging in the time of ~13–20 h indicated that in this relatively short period of deprivation the reinforcing value of a palatable snack food significantly increased from the baseline measure in the fed state (Raynor and Epstein 2003). As an ecologically relevant example, if a lean person begins to regularly skip meals, then food is likely to become more reinforcing when it is finally approached. It is unknown if this phenomenon would persist with chronic periods of energy deprivation, but one could postulate that such behavior would lead to body weight gain according to the connection between the reinforcing value of food and energy intake (Raynor and Epstein 2003). Obese individuals experiencing the same feeding patterns theoretically would be even more vulnerable to weight gain, as food is already more reinforcing to begin with. What is fascinating is evidence suggests that polymorphisms of genes involved in the normal regulation of the neurotransmitter dopamine may be involved in a "high-food reinforcement" phenotype, or even related to excess energy reserves.

As a member of the catecholamine family, dopamine is synthesized from the amino acid tyrosine (produced in the liver from phenylalanine), mainly by nervous tissue and the medulla of the adrenal glands. Following the synthesis of dopamine (see Fig. 145.3) there is vesicle packaging in the nerve terminal that prepares this monoamine neurotransmitter for synaptic release. When a dopaminergic
Fig. 145.3 A stylized representation of midbrain dopamine neurons representing (**a**) a typical neuron with a normal propagation of action potential (AP) and (**b**) a neuron with impeded postsynaptic signaling (a "hypodopaminergic state") due to polymorphisms of the dopamine receptor and transporter. The dopamine transporter is responsible for the reuptake of dopamine and the 10/10 allele is hypothesized to result in decreased synaptic dopamine due to *increased* transporter density (i.e., increased reuptake). Also believed to be involved in impaired dopamine signaling, the Taq1A allele of DRD2 results in *decreased* density of dopamine D2-receptors (see **b**)

neuron is sufficiently excited, dopamine is released into the synaptic cleft where it interacts with the postsynaptic receptors causing the depolarization of the postsynaptic cell and initiating a new action potential. Dopamine availability is dependent on its metabolism, release, transport, and receptor binding. Consequently, by looking at the genes involved at any one of these stages there is an opportunity to indirectly investigate brain dopamine levels – in effect looking at markers of neurotransmitter activity (Epstein et al. 2007b) – and how behavior may be resultantly impacted.

The dopamine transporter gene (SLC6A3) codes for a membrane spanning dopamine transporter protein (DAT) that mediates reuptake of dopamine from the synapse into surrounding neurons. There are multiple alleles for this DAT protein and it appears that the 10-repeat homozygous polymorphism is associated with increased dopamine transporter density and transport (Fuke et al. 2001) when compared with the 9-repeat/10- repeat allele. The hypothesis posits that due to simple mendellian genetics, people who received the same 10-repeat allele (i.e., 10/10 genotype) from both parents have lower levels of postsynaptic dopamine. This is further evidenced from in vivo PET studies in humans showing that individuals with the 9-repeat/10-repeat genotype displayed a mean 22% reduction of DAT protein availability compared with 10-repeat homozygous individuals (Heinz et al. 2000). Individuals with the 10/10 genotype can also be at increased risk to obesity. It was found that African Americans with the 10/10 genotype had an odds of having BMI values ≥ 30 kg/m^2 that were 5.2 times greater than African Americans with the 9/9 or 9/10 genotype (Epstein et al. 2002).

Another polymorphism believed to result in decreased dopamine signalling occurs due to an alteration in the ANKK1 gene, known as the Taq1A restriction fragment length polymorphism. To remain consistent with existing literature–and due to the fact that ANKK1 is believed to be in linkage disequilibrum with DRD2–Taq1A will be acknowleged as being linked to DRD2. Specifically, there are three *Taq1* A variants (A1/A1, A1/A2, and A2/A2) and compared to carriers of the *Taq1* A2 allele, in vivo imaging had shown that people with the *Taq1* A1 allele have reduced brain dopamine signaling (Pohjalainen et al. 1998). With further in vivo (PET imaging) evidence, the mechanism of action is thought to be mediated primarily with the association of the *Taq1* A1 allele with decreased DRD2 receptor density (Noble et al. 1991). What this suggests is that carriers of the *Taq1* A1 allele experience reduced dopamine signaling in the brain; indeed, it has recently been demonstrated that decreased density of DRD2 is strongly associated with human obesity, in inverse proportion to BMI (Wang et al. 2001). Linking physiology with behavior, current research has revealed that the reinforcing value of food – analogous to the "wanting" component of food reward – can not only influence energy intake, but the presence of the *Taq1* A1 allele of the dopamine receptor can interact with obesity to influence food reinforcement (Epstein et al. 2004b, 2007b). Subjects identified as high in food reinforcement who were carriers of the A1 allele consumed more food than participants high in food reinforcement without the A1 allele and participants low in food reinforcement with or without the A1 allele (Epstein et al. 2007b). Although these data are preliminary, what this suggests is that using a behavioral genetic approach to understand the interaction between genotype, obesity, and food reinforcement can be viewed as a viable research venture.

Taken together, individuals with the *Taq1* A1 or the 10/10-repeat alleles are hypothesized to be less sensitive to stimulation of dopamine-regulated reward circuits – analogous to a reward-deficiency syndrome (Noble et al. 1994) – and by enduring a hypodopaminergic state are more likely to seek reinforcers, whether it be food or drug (Blum et al. 1996). In fact, this represents one view of dopamine's involvement in food reward and it fits well with much of the literature presented thus far. Although it is a very hedonistic view of feeding behavior, it is a tenable hypothesis that overeating has emerged as a compensatory mechanism to ameliorate a deficiency in the reward circuitry (Wang et al. 2002). Others contend a somewhat opposing view that focuses on an individual's sensitivity to reward, as measured by a psychobiological questionnaire. It is argued that individuals with high levels (hyperdopaminergia) of synaptic dopamine are more sensitive and have a greater capacity for reward, thereby making them more likely to engage in pleasurable behaviors (Davis and Fox 2008). In the end, it is not clear whether the dopamine hypothesis of feeding is best explained by hypodopaminergic states as described by a reward deficiency syndrome, or by hyperdopaminergic states as described by heightened reward sensitivity, or by both.

145.2.4 Peripheral Feeding Signals Impact Brain Dopamine: Evidence That Energy Deprivation Can Impact the Motivational Component of Food Reward

A promising path has been paved with respect to adiposity signals and their possible role in mediating food reward. When leptin is administered intraventricularly in rodents, it attenuates the rewarding impact of food-restriction-sensitive stimulation (Fulton et al. 2000), where animals significantly decrease rates of brain stimulation reward. What is interesting is that this rewarding effect is potentiated by chronic food deprivation and that the ability of this deprivation to enhance brain stimulation reward is proportional to the degree of weight loss (Carr and Wolinsky 1993). In effect, with greater weight loss animals will continue pressing the lever for ever smaller amounts of stimulation, which is translated into a leftward shift in the rate–frequency curve. Further, intracerebroventricular leptin

administration causes a rightward shift in this curve, restoring the reward value to predeprivation levels (Fulton et al. 2000), but to initially respond to the deprivation, an absolute weight loss of approximately 10% was required. It may be that long-term adiposity signals like leptin actively signal reward pathways of current body reserves, thereby intrinsically making food more attractive – more rewarding – when a significant loss of body energy reserves or a similar signal (decreased leptin) is detected.

New developments into the study of leptin and ghrelin – signals of energy surfeit and deficit, respectively – have indicated that these feeding signals may play complimentary roles in the dopamine hypothesis of feeding. Mesolimbic brain circuits have recently been shown to express the long form of the leptin receptor (the main leptin receptor, OB-Rb); more than this, it has been demonstrated that OB-Rb mediated signaling modified dopamine signaling and food intake. When leptin was administered directly to the ventral tegmental area (VTA) – the central hub of dopaminergic neurons – rats decreased food intake; oppositely, when the OB-Rb was knocked out in this area, feeding was increased, especially of highly palatable chow (Hommel et al. 2006). In contrast, but consistent with its role in feeding, when ghrelin is injected into the VTA rats show a robust dose dependent feeding response (Naleid et al. 2005). Taken together, what emerges is the neurological foundation that connects dopaminergic pathways of reward with short- and long-terms feeding signals. Leptin inhibits the firing of VTA dopamine neurons and ghrelin triggers tonic dopamine release, resulting in decreased and increased feeding, respectively. Food reward appears to be impacted by homeostasis and dopamine plays an integral role in the appetitive motivation to feed. Another possible role for dopamine that cannot be discounted is that it has indirect downstream action on another neurotransmitter. Indeed, there is evidence that ghrelin can impact the opioid system in the rat (Sibilia et al. 2006). The point here is that dopamine is only one piece of the grand puzzle that describes the intricate network underlying food reward.

145.3 Food Hedonics

145.3.1 Palatability: The Multimodal Representation of Taste

Taste perception is transmitted by cranial nerves, which propagate information about the touch, temperature and pain sensation on the tongue (Kringelbach 2004). The afferent taste signal progresses from cranial nerves to the NTS, continuing to the thalamus and then to the primary taste cortex; higher order taste assimilation is believed to be accomplished by the connections of the primary taste cortex with the secondary taste cortex (i.e., the orbitofrontal cortex) (Baylis et al. 1995). With respect to the pleasantness of the taste of foods, the responsiveness of the taste neurons in the NTS and in the primary taste cortex (see Fig. 145.4) do not seem to be affected by states of deprivation and repletion (Rolls et al. 1988; Yaxley et al. 1988). What this implies is that these areas do not reflect the hedonics of feeding, but instead represent sensory qualities of food independent of motivational state. Therefore the identity and intensity of food taste is made explicit in the primary taste cortex, but it is with the rich interconnectivities of the orbitofrontal cortex (OFC) that the hedonic component of the rewarding value of food finally is coded. In short, evidence from primates indicates that the identity of a taste and its intensity are represented separately from its pleasantness (Rolls 2007).

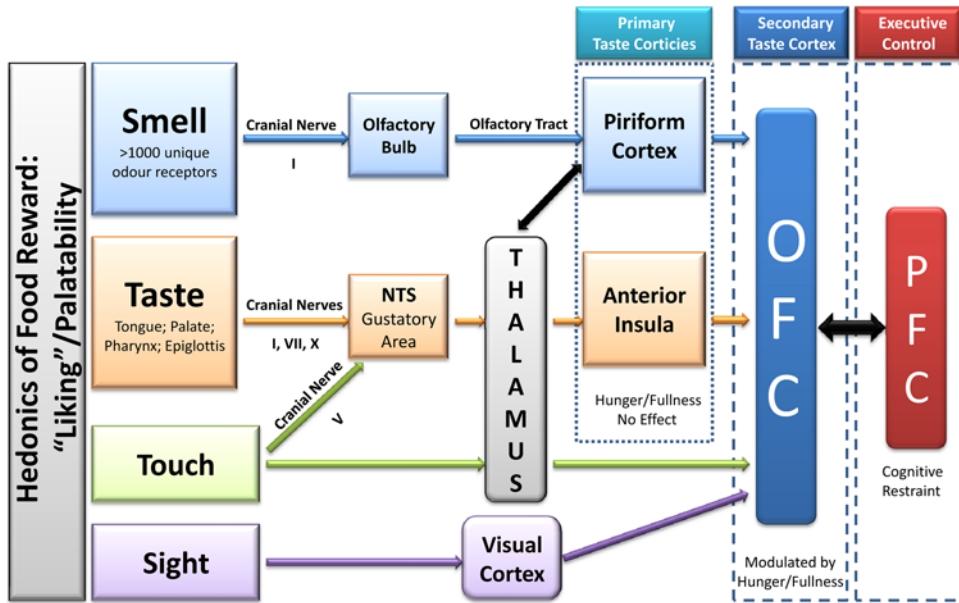
The OFC can be subdivided into two regions: the posterior region, restricted to the limbic functions and considered part of the limbic system, and an anterior region, restricted to inhibitory control over the amygdala (Borod 2000). In order for peripheral feeding related signals to influence food pleasantness – and by convention, food reward – this must occur from the processing of the stimuli


Fig. 145.4 A schematic diagram of pathways demonstrating the multimodal representation of taste and olfaction in the brain. Note that cranial nerve I is the olfactory nerve; cranial nerve VII is the facial nerve; cranial nerve X is the vagus nerve; and cranial nerve V is the trigeminal nerve (which transmits the mouthfeel of fats and oils); OFC is the orbitofrontal cortex; and PFC is the prefrontal cortex

at the level at or beyond the secondary taste cortex (Rolls et al. 1990). Efferent connections from the OFC include the amygdala, the hippocampus, the lateral hypothalamus, the striatum, and the ventral tegmental area (Kandel et al. 2000). What is interesting is that each of these brain areas is influenced by ghrelin, leptin, and dopamine. Interconnected within this network of neuromodulators and feeding-related signals lies what is believed to be a path toward describing reward signaling, or in the context of energy deprivation, *alliesthesia* (discussed below).

Pioneering work performed on primates indicated that responses from a group of OFC neurons to glucose taste decreased to zero when the monkey ate glucose to satiety; concurrently, over the course of administration of glucose the animal's behavior changed from positive to negative affective reactions (Rolls et al. 1989). Furthermore, it was demonstrated that this decrease in neural activity was specific to the ingesta, i.e., the authors discovered a piece of the neural foundation of *sensory specific satiety* (Rolls et al. 1989). What remains unclear is the role that information from the primary taste cortex and from adjacent limbic areas impacts the change in pleasantness of a food stimulus that occurs with continuous exposure over a meal or from refeeding after chronic energy deprivation.

Another area that requires clarification is to what degree the decisions regarding when, what, and with whom to eat are conscious. Indeed, much of the expression of appetite and eating is not explicit, and therefore outside of introspection. Studies from rats, to chimps, to human infants have demonstrated that "liking" of sweet foods can be implicit – and this was accomplished by measuring stereotypical facial reactions to the sweet stimuli (Steiner et al. 2001). Sweet tastes elicit a positive hedonic pattern of evaluation primarily described by tongue protrusions (licking/smacking of lips) and paw licking (Grill and Berridge 1985). Since "liking" is considered a basic evaluative reaction of the brain with objective behavioral indicators it can be implicitly measured by affective measures to the food *reward*; alternatively, the hedonic impact of "liking" can be explicitly measured in humans by describing their reaction to the food stimulus (e.g., analogue scales). A pleasant stimulus is a rewarding stimulus and for the most part feeding is a rewarding action. The "liking" component of food reward has its

biological underpinnings in at least two major neurotransmitter families defined by opioid, and endocannabinoid systems. The best studied in humans is the opioid modulation of palatability. Specifically, opioid receptor antagonists (e.g., naltrexone and naloxone) reduce the pleasantness of foods (Bertino et al. 1991; Drewnowski et al. 1992) and agonists (e.g., DAMGO and morphine) increase the pleasantness (Atkinson 1987; Levine and Atkinson 1987). This hedonic pleasure/palatability component of reward is represented in the brain mainly by pallidal circuits (Yeomans and Gray 2002) and by circuits within the shell of the nucleus accumbens (Pecina and Berridge 2005) (see *striatum* in Fig. 145.6).

145.3.2 Peripheral Feeding Signals and Taste Processing

There is limited data regarding the potential role of gut peptides (peripheral feeding signals) in taste processing. Studies on rats have indicated that PYY_{3-36}, a hormone released by L-cells of the distal colon, produced a dose-dependent conditioned taste aversion to a sweet solution (Chelikani et al. 2006; Halatchev and Cone 2005). Similarly, another peptide released by intestinal L-cells, GLP-1, also has the potential to produce a robust conditioned taste aversion to saccharine (Thiele et al. 1997). What is intriguing is that CCK, a "satiety hormone" like PYY and GLP-1, can actually produce a conditioned flavour *preference* at low doses in rats (Perez and Sclafani 1991). The authors interpreted this preference to the positive postingestive consequences of satiety. It is possible that the taste aversion with PYY and GLP-1 could be an artifact of nausea that has been reported in human subjects; nonetheless, there is evidence that these gut-peptide messengers are involved in taste-processing.

The hormone produced by the OB gene, leptin, has also been demonstrated to have a role in the hedonic evaluation of food. Specifically, leptin receptors were identified in taste cells and exogenous administration of leptin inhibited sweet taste responses in lean mice but not in db/db mice (lacking a functional leptin receptor) (Ninomiya et al. 2002). Evidence of a separate role for leptin in *olfactory processing* has also emerged from data on rats showing how nutritional status impacts olfactory perception. Specifically, intracerebroventricular leptin administration (mimicking satiety) dose dependently increases consumption of an aversive odorized drink, suggesting that leptin decreases odor sensitivity (Julliard et al. 2007). Taken together, leptin appears to play a role in *taste* and *olfactory* processing that is dependent on nutritional status. What this suggests is that when rodents are energy-replete and leptin levels are high there is a corresponding decrease in sensitivity to taste and to olfactory stimuli. Although there are limited data, human studies have also indicated that leptin is expressed and may play a functional role in the salivary glands and the oral cavity; the expression of the long form of the leptin receptor has also been discovered in the membranes of glandular cells and in the salivary ducts (Bohlender et al. 2003).

The role that *serum* leptin may play in food hedonics in humans has only been superficially investigated. In a group of six men and 20 women offered a standardized high carbohydrate breakfast, palatability was positively correlated to fasting serum leptin independently of BMI and body fat mass (Raynaud et al. 1999). One interpretation of these results is that palatability would be independent of need state, as those who had the highest leptin levels (indicating caloric surfeit) rated food as tasting most pleasant. Contrarily, these results could be demonstrative of the large variation in body composition in this study. With nearly half of the subjects being obese there could be a resistance to leptin that could not be easily detected.

In a study examining the impact of fasting leptin concentration on energy intake and macronutrient preference it was found that high fasting serum leptin was associated with lower preference for chocolate as well as lower energy intakes and specifically fat intake (Karhunen et al. 1998). These findings remained significant after adjusting leptin concentrations for body fat mass and dietary

underreporting. In a more recent study consisting of a chronic energy deprivation (8 week weight loss trial) and a repeated measure looking at food hedonics pre- and post weight loss, there was no significant relationship between serum leptin and rated pleasantness (Cameron et al. 2008). What this study did demonstrate, however, was that after the 8 weeks of caloric deprivation (−700 kcal/day) subjects rated the same foods as more pleasant to taste. Of note, both types of food presented to the subjects – vegetables and fruits vs. desserts – increased in hedonic valance. After weight loss both healthy food and "junk" food tasted better.

145.3.3 Energy Deprivation and Palatability: Evidence from Alliesthesia

A question that remains to be answered is the extent to which homeostatic components (a need-state) can impact the quality of orosensory reward, thereby enhancing food hedonics. Much of the research on this topic uses a preload paradigm that assesses the impact of a pretest snack on the subsequent ad libitum energy intake and rated palatability. The rationale behind this test supposes that if palatability is dependent on a need-state, then a preload of high energy density (vs. low) would have a greater impact on palatability of the ad libitum meal (i.e., meal becomes less pleasant following energy dense preload). There are conflicting data, but it appears that the short term manipulation of satiety does not reliably impact palatability. For example, subjects not only rated food as being less pleasant following a high energy preload (vs. low), but they consumed less total weight and calories in ad libitum feeding following the preload (Johnson and Vickers 1993) and similar findings were noted in a separate study (Booth et al. 1982).

On the other hand, several studies employing similar preload paradigms have demonstrated a lack of change in palatability with need state (Birch and Deysher 1986; Yeomans et al. 1998). Specifically, when a soup preload was covertly manipulated with maltodextrin and administered 30 min prior to ad libitum feeding, subjects did not rate the palatability lower than the trial where plain soup was consumed (Yeomans et al. 1998). However, with the added maltodextrin it was noted that subjects had lower hunger and higher fullness ratings prior to beginning ad libitum feeding. Similarly, a study of children aged 3–5 and adults 25–35 years old showed no change in pleasantness with respect to preload energy density, but both groups displayed sensory specific satiety during the lunch feeding (Birch and Deysher 1986). While the preload paradigm may be examining possible short-term signaling of need (free)-state, a far better manipulation that is unfortunately studied even less is increasing the deprivation state (e.g., chronic energy deprivation). As alluded to in much of this chapter, feeding repeatedly takes place without any measurable changes in body energy reserves, and most often according to learned cues (see Fig. 145.5). In order to truly examine how the "*internal milieu*" impacts food reward there most likely needs to be a prolonged perturbation in energy balance over days and weeks.

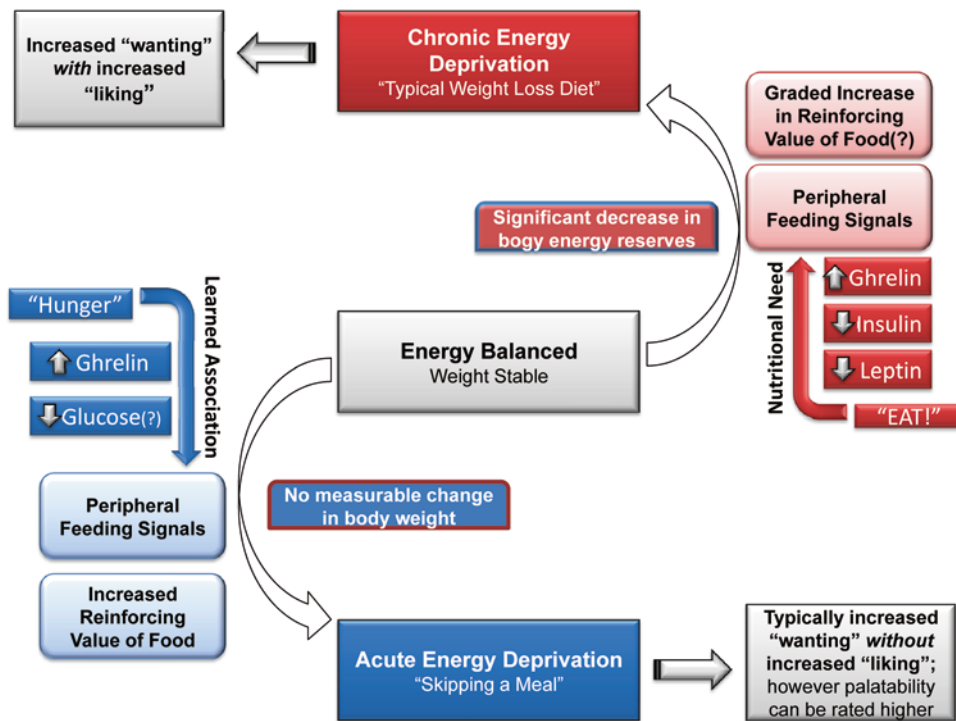
Some of the pioneering efforts examining energy deprivation and palatability were conducted by Michel Cabanac, the coiner of the term alliesthesia. In his seminal paper on hedonics (1971) he tested changes in gustative and olfactive perception at the subjects' normal weight, at 10% below this weight, and then again after the subject returned to normal weight. To reduce the body weight by 10% the energy intake was limited to 500–800 kcal per day until the weight was achieved, and this reduced weight was maintained for several weeks prior to the test day. In short, alliesthesia was measured by the change in subjective pleasantness ratings for multiple ingestions of sweet tasting sucrose solutions. When subjects were at their normal weight and after ingesting 200 ml of a 25% aqueous solution of glucose, these stimuli became unpleasant (negative alliesthesia). However, when subjects lost 10% of their body weight alliesthesia could no longer be demonstrated, and 50 g of glucose was insufficient to cause the negative affective ratings. Finally, the return to normal body weight restored the change in sensation from pleasant to unpleasant.


Fig. 145.5 Key Features representing the Ying and Yang of food reward as a function of energy deprivation. When there is no measurable change in body weight, it is believed that peripheral signals act as *cues* to feed, but chronic energy deprivation results in exaggerated responses from peripheral signals. It may be that significant changes in body energy reserves changes mere cues into powerful signals that motivate appetitive and consummatory feeding behavior

Corroborating these results are findings from deprivation periods of much shorter duration. By manipulating the period of energy deprivation with two separate test days, one day with a 3.5 h period of deprivation and another with an overnight fast of approximately 12–15 h, Spiegel et al. (1989) found that the deprivation period impacted palatability, consistent with alliesthesia. These results were consistent with obese and lean subjects. Germaine to this chapter are two major findings from this study: (1) the longer deprivation period resulted in increased palatability ratings and increased rate and quantity of food eaten ad libitum and (2) obese persons experienced a greater increase in palatability than lean persons, but lean individuals increased ad libitum feeding more than obese individuals.

145.4 Conclusions and Theoretical Integration

Food intake is the result of a multimodal representation of the sensory information about the food stimulus: in the brain there is a continuum consisting of the visual exteroreception of the sight of food, to the interoreception of primary and secondary taste corticies' evaluation of taste, temperature, texture, and viscosity. While energy deprivation can have an impact at several of these levels, humans also eat for reasons other than nutritional needs. For most of the developed countries meals are entrained to a schedule thereby eliminating what might be real signals of energy deprivation – this fact has raised to attention that such feeding may anticipate and prevent the development of significant

metabolic changes (Woods 1991). The study of feeding behavior, and in particular the study of subjective hedonic experience and objective measures of motivation, are central to understanding how appetite regulation can be compromised in certain individuals. Furthermore, with an integrated picture of physiological and behavioral changes that can occur as a result of caloric deprivation – particularly with regard to food palatability and reinforcement – what emerges is a better understanding of how palatable food can disrupt attempts at body weight regulation.

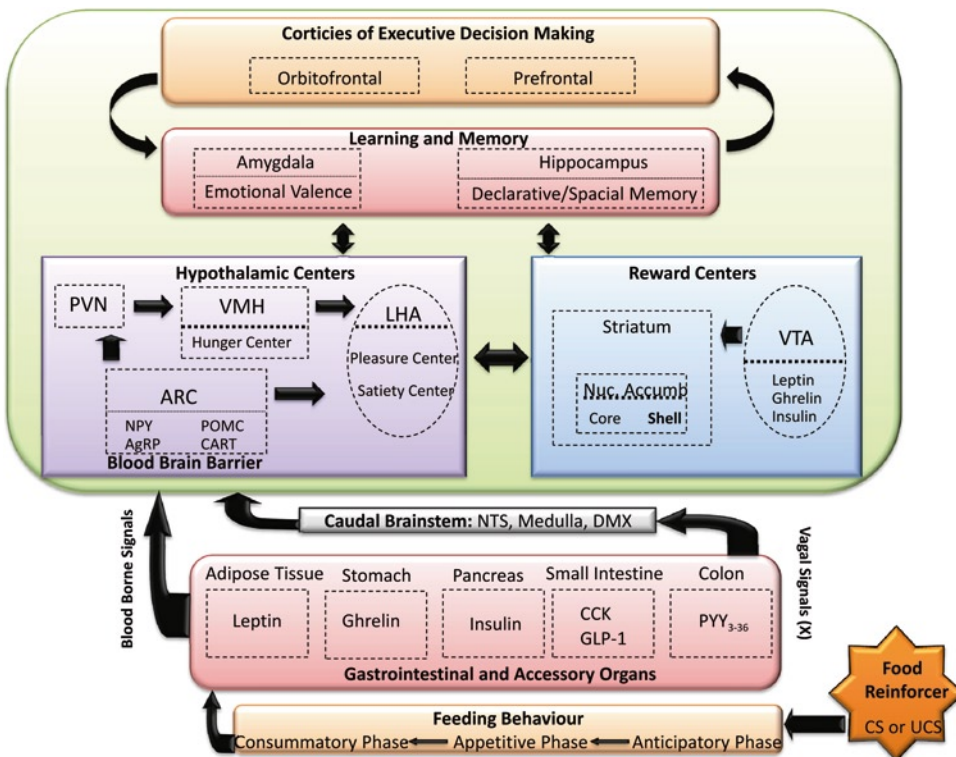
Epidemiological data suggests that some people are more susceptible to weight gain (Ravussin and Kozak 2004); this propensity to gain, maintain, or lose weight under similar environments has been attributed to various susceptibility levels such as metabolic, behavioral, psychological, physiologic, and genetic (Blundell et al. 2005). The fact that food intake is not merely based on nutritional or homeostatic requirements but is also very much influenced by its reinforcing properties presupposes a modulating role for dopamine in everyday feeding (Carr 2007) alongside with leptin and ghrelin (Figlewicz 2003) (see Fig. 145.6).


Fig. 145.6 An integrated summary of all the concepts discussed throughout this chapter: with the introduction of a food reinforcer begins the appetitive motivation to seek and finally to consume the food stimulus. When fasted for an extended period of time peripheral feeding-related signals from gastrointestinal and accessory organs are proposed to drive feeding behavior in a powerful manner via the ARC and the activation of neuropeptides that trigger hunger signals (e.g., NPY and AgRP). Conversely, when in the sated state, the nucleus accumbens and VTA may continue to promote consummatory behavior in the absence of hunger, i.e., as conditioned associations and learning interact with the reward pathways to increase implicit wanting. Equally as plausible, the palatability of food signaled by the Insular and Orbitofrontal corticies could also trigger eating in the absence of hunger. Abbreviations: *PVN* paraventricular nucleus, *LHA* lateral hypothalamic area, *ARC* arcuate nucleus, *NPY* neuropeptide Y, *AgRP* agouti-related peptide, *POMC* pro-opiomelanocortin, *CART* cocaine and amphetamine-related transcript, *Nuc. Accumb* Nucleus accumbens (Modified from Cameron and Doucet (2007). With permission)

If it can be shown with more fecundity that a biological basis exists for differences in the reward experienced in feeding, then as an example, individualized treatment and prevention programs for weight loss could differentially help those who are high in food reinforcement versus someone low in food reinforcement (Epstein et al. 2007a). Furthermore, there needs to be more data regarding the change in orosensory reward that may occur with chronic energy deprivation. One of the messages behind this chapter is that hedonic feeding results from discordance between appetitive motivation and inhibitory control. In order to help those trying to lose or maintain a specific level of body energy reserves, there needs to be a better understanding of the processes behind the rewarding qualities of food, both implicit and explicit. Behavioral strategies promoting dietary restraint – thereby shifting inhibitory control over appetitive motivation – may be what need to be promoted in a continual effort to inhibit weight gain in this modern obesogenic environment.

145.5 Applications to Other Areas of Health and Disease

Much of what has been described in this two part chapter was theoretical. Dissociating a psychological concept such as a reward into separable components of hedonic evaluation and motivation to obtain and consume does, however, have ecological validity. In particular, the tool described that measures the relative-reinforcing value of food can offer valuable information regarding the determinants of food choice. There are a lot of data showing that if access to a preferred food (such as cheesecake) is reduced, then people will choose a less preferred – although still enjoyable – alternative (such as yogurt). Applied in light of behavioral economics theory, if the price of a good that is typically purchased is increased, then as cost increases there will be a certain point where the consumer will *substitute* with something similar, though less expensive. A knee-jerk solution would be to tax foods with "empty calories" such as high fructose corn syrup, which in fact is occurring in some U.S. States. A better solution may be to promote the development of ready-to-eat healthy snacks such as the conveniently peeled and washed baby carrots, and to implement such foods across school cafeterias nationwide. At the very least, a goal should be to decrease the disparity in prices between fresh produce and the lower cost highly processed foods.

When considering the millions of people that start dieting each year, the fact that food reinforcement increases with energy deprivation has obvious concerns. The very thing that is supposed to help with weight loss (e.g., decreased energy intake) can act to increase the motivation to eat energy dense food. Although there are no definitive data to show that increased meal frequency (independent of energy intake) promotes weight loss, it may still be a good approach to prescribe such a diet in an attempt to control for overeating due to increased saliency of palatable food. To be sure, irregular meal patterns such as skipping meals can reinstate abhorrent binge-eating behavior in individuals recovering from bulimia nervosa. Nonetheless, a reduced calorie diet imposed with a greater frequency of meals may also leave individuals to choose a nonfood activity that is reinforcing (e.g., hiking) in the place of impulsively eating due to a perceived deprivation in energy and increased food reinforcement. The increased food reinforcement – and its predicting power of ad libitum feeding – experienced by the obese may also highlight the importance of limiting access to food in a strategic manner. Although there are no data about food reinforcement and success with weight loss, a valid hypothesis would be that for individuals high in food reinforcement (vs. low) a high meal frequency (e.g., six meals) diet of prepackaged meals would result in improved adherence to the diet and better appetite control vs. low meal frequency (e.g., three meals).

Regarding the forced-choice computer task that was developed in an attempt to measure *implicit* "wanting" and *explicit* "wanting" and "liking," there exists the potential to test the impact of various

forms of energy deprivation on these reward-related variables. Useful information will no doubt emerge on how relative (macronutrient) preference or reaction time – two quantitative measures of implicit "wanting" – can be impacted by not only reduced energy intake but also by increased energy expenditure. A recent study examined the impact of energy deprivation by means of exercise on food reward and ad libitum energy intake with two counterbalanced sessions, one at 50 min of high intensity exercise and then other without exercise (Finlayson et al. 2009). Although there was no significant difference in the amount of food eaten by test day for this group of lean women, it was found that after the exercise session there was a subgroup of "compensators" who ate more after exercise and also displayed a significant increase in *implicit* "wanting." After exercise there was an unconscious *implicit* desire for the "compensators" to eat high-fat sweet foods. What is interesting is that a separate study with similar exercise intensity (but longer duration) also demonstrated that lean female subjects overcompensated for the exercise session (vs. an equicaloric lower intensity exercise) when given access to an ad libitum for the remainder of the day (Pomerleau et al. 2004). In both studies there was evidence that performing intense aerobic exercise results in increased energy intake, thereby acutely promoting *positive* energy balance. It may be that some individuals are more sensitive to substrate flux and the mobilization and utilization of glucose, making them more likely to select energy dense foods following intense aerobic work. Elucidating who would potentially be "compensators" from the onset of an exercise prescription, as measured by increased implicit "wanting," could not only help with recidivism but also with weight loss success. Extending these findings to obese individuals could potentially identify those who would benefit from performing a lower intensity exercise to attain/maintain weight loss.

Summary Points

- Variation in the individual response to a similar food environment can begin to be explained not only at the gene level, but also by examining psychobiological differences in the evaluation of food reward.
- When energy deprivation is prolonged there is a degree of disinhibition with respect to appetite: not only does palatable food become more salient but items that would normally not be selected can also become attractive.
- Short-term feeding-related signals are divided into orexigenic signals (e.g., the "hunger hormone" ghrelin) that convey the overall message to eat, and this in contrast with anorexigenic signals (e.g., CCK and PYY_{3-36}) that convey the message of fullness/satiety.
- Leptin appears to play a role in taste and olfactory processing that is dependent on nutritional status: when energy-replete and leptin levels are high there is a corresponding decrease in sensitivity to taste and to olfactory stimuli.
- There need not be a deprivation or homeostatic signal in order to initiate a drive state or to continue consummatory behavior; humans *learn* how and when to initiate feeding.
- The dopamine hypothesis states that dopamine neurons form the backbone of the network of the brain's natural reinforcement system acting to focus attention on salient environmental stimuli and to promote learning associations. Leptin and ghrelin may play complimentary roles in the dopamine hypothesis of feeding.
- *Incentive salience theory* suggests that dopamine is *not* necessary for subjective/objective "liking") *nor* for reward learning, but it *is* important for the attribution of the incentive salience of rewards.
- The measure of motivation to work to obtain, i.e., implicit "wanting," can in some instances be a better predictor of energy intake than explicit subjective accounts of "liking."
- In vivo imaging suggests that individuals with the *Taq1* A1 (dopamine transporter) or the 10/10-repeat (dopamine receptor) alleles can be less sensitive to stimulation of dopamine-regulated reward circuits – analogous to a reward-deficiency syndrome – by imposing a hypodopaminergic state.

- The "liking" component of food reward has its biological underpinnings in at least two major neurotransmitter families defined by opioid and endocannabinoid systems.
- A question that remains to be answered is the extent to which homeostatic components (nutritional need-states) can impact the quality of orosensory reward, thereby enhancing food hedonics.

Definitions

Acute vs. Chronic Energy Deprivation: Acute energy deprivation will be defined as a complete fasting period of several hours (but otherwise being relatively weight stable), whereas, chronic energy deprivation will be defined as a prolonged reduction in energy intake below that would maintain body weight stability.

Alliesthesia: From the words esthesia (*meaning sensation*) and allios (*meaning changed*). It is the modification of conscious sensations by changes in internal signals, reflected by afferent actions of peripheral receptors; plainly, a pleasant or unpleasant sensation depending on the subject's internal state.

Appetite: An internal state or a specific disposition to act. Appetite as it pertains to feeding can be conceptualized as the hunger-stimulated response to a particular food and implies knowledge of the item(s) to which the actions should be directed

Incentive Salience: A motivational process that does not involve a pleasure/hedonic component, but is limited to a drive process that defines the "wanting" component of a reward. It is primarily believed to be influenced by dopaminergic neurotransmission.

Reinforcer: In a Skinnerian sense reinforcement can be viewed as behavioral measures of learning: it is the strengthening of an observed behavioral response (stimulus–response associations) or the strengthening of a learned behavioral response (stimulus–stimulus associations). A reinforcer can be a goal or a commodity.

Relative-Reinforcing Value of Food: Describes how hard an individual is willing to work for food by measuring responses at a predetermined reinforcement schedule. It is *relative-reinforcing* due to the fact that there are alternatives, albeit in a forced choice methodology.

Reward: A psychological process that is contingent on a reinforcing stimulus. Reward can be dissociated into two qualities of a food stimulus: (1) a hedonic component of "liking"/palatability and (2) a reinforcing component that is sometimes described as "wanting"/incentive motivational component.

1. "Liking": Divided into *implicit liking*, which is measured objectively by affective facial reactions to various food stimuli, and *explicit liking*, which is measured by the subjective hedonic rating of orosensory pleasure (e.g., visual analogue scales).
2. "Wanting": Divided into *intrinsic wanting*, which can be measured by choice tests, reaction time, or reinforcement, and *extrinsic wanting*, which can be defined by the intent or desire to consume a specific food and measured subjectively on a visual analogue scale.

Satiation/Satiety: Satiation refers to the processes that lead to the termination of feeding, e.g., a within-meal interval, whereas, satiety refers to the state of inhibition of feeding, e.g., a between meal interval.

Sensory-Specific Satiety: With continued exposure to the same food item there is a discernable and rather abrupt change in the overall hedonic rating, i.e., the perceived sensory qualities of the item are not absolute though the change in liking is specific to the unchanging sensory characteristics of the item itself.

Chapter 146
Nutritional Deficiencies and Spatial Memory Function

Sayali C. Ranade

Abbreviations

CNS	Central Nervous System
PUFA	Poly Unsaturated Fatty Acids
DHA	Docosahexanoic Acid
AA	Arachidonic Acid
EFA	Essential Fatty Acid
DNA	Deoxyribonucleic Acid
RNA	Ribonucleic Acid
CED	Chronic Energy Deficiency
BMI	Body Mass Index
PEM	Protein Energy Malnutrition
ID	Iron Deficiency
RAM	Radial Arm Maze
PD	Protein Deficiency
CA	Cornu Ammonis
IUGR	Intra Uterine Growth Retardation
BDNF	Brain Derived Neurotrophic Factor
DMT-1	Dimetallic Transporter 1
MMSE	Mini Mental State Examination
WMS-R	Wechsler Memory Scale-Revised
WAIS-R	Wechsler Adult Intelligence Scale-Revised
ERPs	Event Related Potentials
RA	Retinoic Acid

146.1 Overview

Food has classically been perceived as a means to provide energy and building material to the body. However, its role in development and maintenance of specific physiological systems has been suggested only recently. One such system which is sensitive to the effects of nutrition or lack of it is the nervous system. A healthy nervous system requires balanced intake of food. Nutrition is one of the major epigenetic factors that affects the development and functioning of the nervous system. It took long for the general acceptance of the concept that the food that you consume can have an effect on the structure and function of the brain.

The term "Nutrition" refers to the balanced intake of nutrients for proper functioning of all body systems. There could be either qualitative or quantitative deviation from this optimum food intake. The nervous system is extremely vulnerable to different types of nutritional insults. There is a wide range of defects induced by nutritional deficiencies on the nervous system. These include structural (brain size, hippocampal volume), cellular (cerebellar neurogenesis, oligodendrocyte maturation), biochemical (neurotransmitter synthesis and release), electrophysiological (excitation and inhibition levels of neurons), behavioral (antisocial/violent behavior), and cognitive (memory disturbances, learning impairment) defects. The deleterious consequences of malnutrition on the nervous system depend on various factors. The most important factors which affect the nature and severity of these defects are: type of deficiency, level of malnourishment, and timing of exposure. The interaction of these factors will decide the outcome of the nervous system's defects. There is an enormous amount of data available on the effects of nutritional deficiencies on CNS. These reports come primarily from case studies or experimentation done on children from several developing countries. In addition, animal models have also been used as they provide a great tool to study and understand the effects of malnutrition on the CNS and also the mechanisms involved therein.

146.2 Role of Different Nutrients in Normal Development and Function of the Nervous System

The role of optimum nutrition in the normal cognitive and psychological development of an individual was evidenced by studies carried out following the Dutch hunger winter of 1944–1945 and the Chinese famine of 1950. These natural experiments provide valuable information on the role of different nutritional factors in the normal psychological development of an individual. The strong evidence from these studies suggests a connecting link between neurodevelopmental disruption and increased risk of schizophrenia. Deficiency of several candidate nutrients has been implicated in the vulnerability of an offspring to different psychiatric disorders including schizophrenia. Although discussing the involvement of different nutrients in normal psychological development in detail is outside the scope of this chapter, these are perhaps initial evidences that confirm the role of optimum nutrition in the normal development of the nervous system.

The exact mechanism by which food and nutrients affect various aspects of brain development and functioning are not fully known. However, the voluminous literature available provides an insight on how specific nutrients could possibly affect various aspects of brain functioning.

The important nutrient groups that affect development and/or functioning of the nervous system are proteins, certain types of fatty acids, micronutrients like iron, zinc, certain vitamins, etc.

Several findings in humans support the hypothesis of links between n-3 polyunsaturated fatty acid (PUFA) status and psychiatric diseases. Essential fatty acids are an important component of nerve cell membranes and are also essential for neurotransmitter release (Arnold et al. 2000). The nutritionally

essential PUFAs, docosahexanoic acid (DHA), and arachidonic acid (AA) are critical for the proper development of brain structure and function during early development (Neuringer et al. 1986). EFAs provide nutrients and healthy fats necessary for the formation of myelin sheaths that cover axons, allowing faster conduction of nerve impulse.

Protein deficiency causes a variety of effects on the nervous system. In general, proteins are required by the brain for synthesis of DNA, RNA, structural proteins, growth factors, and neurotransmitters. They also play a role in synapse formation and extension of neurites, besides increasing the efficacy of neurotransmitters. Protein deficiency causes defects in the development and maturation of the nervous system, motor function, and major cognitive functions. Reduced brain size and impaired spinal cord histology are a few effects of protein deficiency on CNS.

The essential micronutrients, vitamin E, vitamin C, and selenium, affect the nervous system by virtue of their antioxidant functions. They protect the brain from oxidative insults by scavenging free radicals. Vitamin B complex is also essential for general health of the nervous system. Vitamin B12 helps in the formation of neurons, B9 is involved in synthesis of neurotransmitters, and vitamin B1 is involved in glucose metabolism of the brain.

The minerals calcium, magnesium, as well as manganese, iodine, potassium, silicon, sodium, and sulfur are all important for nervous system health. Calcium and magnesium also have an important role to play in nerve impulse conduction. There is considerable evidence that iron is important for neurological functioning and development (Lozoff 1987; Beard et al. 1993).Iron is a co-factor for several enzymes involved in neurotransmitter synthesis (Larkin and Rao 1990). It is also required for proper myelination of the spinal cord and white matter of cerebellar folds (Larkin and Rao 1990). Zinc is also an important co-factor involved in neurotransmitter synthesis. It is known to be indirectly involved in dopamine metabolism (Arnold et al. 2000)

146.3 The Factors Affecting Nature and Severity of Nervous System Defects

146.3.1 Extent of Nutritional Deficiency

The importance of the various nutrients in the development and maintenance of a healthy nervous system is well established. It can therefore be intuitively anticipated that anything less than the optimum requirement would be detrimental and induce deficits in the normal structure and function of the nervous system. The lesser the availability of the nutrient, the more severe the defects.

In a study of the effect of early long-term undernutrition on rat spatial cognition, the group with the highest level of dietary restriction showed the poorest performance on a water maze behavioral task. This effect however was significant in older rats. These findings demonstrate that the severity of the defects seen in the nervous system is directly proportional to the level of undernutrition. These findings also suggest that deficiency takes a longer time to exert its effects (Yanai et al. 2004). Rats undernourished (8% protein diet against normal 20% protein diet) during their lactational period were hyperactive to shock as adults (Vendite et al. 1985).Severe protein malnourishment causes reduction in brain size which is proportional to the degree of malnourishment. Children who are exposed to mild to moderate undernutrition are known to show varying degree of emotional instability, depending on extent of undernutrition.

However, any severity of malnourishment below a certain level exerts effects which are more general and are not limited only to the nervous system. In our own experience, female mice kept on a diet of low protein (less than 8%) had difficulty in becoming pregnant (unpublished observation).

146.3.2 Types of Nutritional Deficiency

Nutritional deficiencies are of different types. Undernutrition refers to insufficient caloric intake (chronic energy deficiency-CED, with BMI <18.5), while malnutrition implies imbalance or complete absence of one or more essential food constituents. However the term "malnutrition" is used in a more general sense, covering both under nutrition and malnutrition. The effects of malnutrition and undernutrition on nervous system development and functioning are often overlapping, but not always.

Undernutrition continues to be one of the major health hazards in developing countries and in certain sections of developed countries. Undernutrition affects several parameters of nervous system development and maintenance, including volumes of one or more brain regions (Ranade et al. 2008), their morphology, neurotransmitter metabolism, and even behavior.

Malnutritional deficiencies can be further divided into macronutrient and micronutrient deficiencies. Macronutrient deficiency is the complete absence or reduction in the amount of macronutrients in the diet.

Protein deficiency is one of the major macronutrient deficiency affecting millions of people worldwide. Protein energy malnutrition is a global problem. Nearly 20 million people worldwide suffer from various forms of PEM viz. marasmus, kwashiorkar. It is also known to induce several types of brain defects. Considerable evidence indicates that PUFAs like DHA and AA also cause some defects in visual and cognitive development (Uauy et al. 1990; Carlson et al. 1994). This can also be categorized under macronutrient deficiency.

Among the micronutrient deficiencies, iron deficiency has a significant effect on the nervous system. The brain is sensitive to dietary iron depletion and regulates iron flux homeostasis very tightly. Perinatal iron deficiency (ID) is known to produce learning and memory impairments as well as reduced psychomotor skills both in humans and animal models (Pollit 1989; Walter et al. 1989).Other micronutrient deficiencies include deficiencies of important vitamins (Vitamin A or vitamin E) and minerals (calcium, magnesium, zinc) which are essential for normal nervous system functioning.

Each of these deficiencies induces its own set of defects which could either be unique to that particular deficiency or may show common features with the defects induced by other malnutritional deficiencies.

146.3.3 Critical Period of Nutritional Deficiency

The effects of malnutrition and undernutrition are of great interest due to the widespread incidence of fetal and infantile nutritional deficiencies. There is a growing body of evidence which suggests that the effects of nutritional insult on the developing brain are long-lasting and lead to permanent deficits in learning and behavior (Van Gelder 1984; Strupp and Levitsky 1995; Galler 2001). These evidences mainly come from human studies as well as animal experimentation. The issue of timing of nutritional deficiency, therefore, is of great importance. It is generally seen that nutritional deficiencies early on in life tend to lead to permanent defects in the CNS as against nutritional inadequacies in the later part of life.

It has been observed that some nervous system defects remain irreversible even after complete restoration of optimum nutrition. This is a good indication of the presence of a "critical period" of nutritional deficiency. This "critical period" is a period during which nutritional deficiency causes maximum damage. Depending on the timing of exposure, any inadequacy during the critical period might interfere with basic developmental processes including cytogenesis, histogenesis, and functional maturation of the brain.

There is vast literature detailing the effect of perinatal malnutrition on the developing brain. "Perinatal" malnutrition refers to a large time window in terms of development. So it would be convenient to divide it further into smaller time frames in order to pinpoint specific brain defects occurring during particular developmental time points. Perinatal malnutrition can therefore be further divided into prenatal and postnatal malnutrition. Each of these can induce varying degree of defects in the developing nervous system, depending on the brain compartment involved during that particular time window. The brain compartment showing a high level of activity will be affected the most.

146.4 Spatial Memory: An Essence of Life

Yes! We all need it! We require it to go to our work place or movie theatre and get back home from there. We need it to locate objects around us and locate ourselves with respect to these objects. Grazing animals need it to locate food patches. Mice and frogs need it to save themselves from predators. What is it that is needed in all the above cases? It's spatial memory. Spatial memory is a highly specialized function of the brain that is vital for survival in all species, including humans.

Memory is the process of retention of acquired information. When this information is about the space surrounding you, it is considered as spatial memory. Literally, therefore, it means memory of the space around you. Spatial memory is an essential component of our daily life which helps us move around in our environment. It is remembrance of places visited and understanding your position with respect to your surrounding. The concept of spatial learning was first introduced by O'Keefe and Nadal. In their words "Spatial learning refers to the construction of a representation of the topographical layout of an environment, and enables goal-directed navigation on the basis of a cognitive map" (O'Keefe and Nadel 1978). In simpler words, it is the process of acquiring information related to the space around you and retaining it for future use. This process can be divided into three phases:

1. Acquisition: Wherein individuals gain information about their surroundings.
2. Retention: The acquired information is stored or retained in specialized compartments of the brain.
3. Retrieval: The stored information is retrieved or recalled for subsequent use.

Spatial memory has two components: one is "spatial" (the one related to space) while the other one is "mnemonic" (memory component). Both these components are equally important for proper spatial memory function. Impairment in any of these components significantly affects overall spatial memory function.

One of the most compelling problems in neuroscience today is to identify the mechanisms underlying memory function. The area of the brain which has been recognized to play a vital role in formation of spatial memory in particular is the hippocampus. The involvement of the hippocampus in spatial memory processes has been established in a variety of species such as birds and mammals, including humans.

The hippocampus is a cortical structure located deep in the temporal lobe. It is formed by two sheets of cortex interlocking each other and has a layered structure where rows of pyramidal cells are arranged along with these layers. The connections within the hippocampus generally follow this laminar format and are unidirectional. They form well characterized closed loops originating in the adjacent **entorhinal cortex**. The different cell layers and sections are defined by the series of connections made. The main pyramidal cell layers are the regions **CA1** and CA3 and the granule cell layer is the **dentate gyrus** (Figs. 146.1 and 146.2)
Fig. 146.1 A photograph showing human hippocampus, along with overlying temporal lobe. The hippocampus is one of the important structures involved in spatial memory function (Courtesy: Dr. Soumya Iyengar, National Brain Research Centre)
Fig. 146.2 A Nissl stained coronal section of rat hippocampus. Different subdivisions of hippocampus are seen viz. CA1, CA3 and Dentate gyrus (Courtesy: Dr. Shiv Kumar Sharma, National Brain Research Centre)

The hippocampus is a region of the brain which has both a prenatal and postnatal developmental window (Rice and Barone 2000). This course of development and the sequence of developmental processes are the same in both rodents and humans. There is a large increase in the size of the hippocampus during the first 4 postnatal weeks. The developmental processes occurring in the hippocampus during this period include neurogensis, myelination, proliferation of synapses, and dendritic remodeling (Altman and Bayer 1990). Normal progression of these processes is required for proper functioning of the hippocampus. Any deviation or disturbance in one or more of these processes can bring about defects in the normal functioning of the hippocampus, thereby affecting spatial memory function.

Although the initial knowledge about the involvement of the hippocampus in declarative memory came from patients with bilateral medial temporal lobe resection, further support and evidence indicating and confirming involvement of the hippocampus in spatial learning and memory (Witter and Amaral 1991) came from animal studies. Implication of the hippocampus in spatial memory function

Fig. 146.3 Radial arm maze. A photograph of Radial Arm Maze apparatus at the National Brain Research Centre. Radial Arm Maze is an apparatus first designed by Samuel and Olton (1976). The apparatus is used to study spatial memory in laboratory animals or human subjects. The picture shows radial arm maze used for studying spatial memory in mice. It consists of a central platform with eight arms radiating from it. At the end of each arm is food cup in which a reward (in this case a chocoflake or a small food pellet) is kept. Each arm is separated from the central platform by a Guillotine door. All the Guillotine doors are attached to common pulley. Both central platform and arms are covered with transparent plexiglass covers. Different temporal domains of spatial memory viz. reference memory, working memory can be tested by employing different experimental paradigms (Courtesy: Professor V. Ravindranath, former Director, National Brain Research Centre)

is supported by lesion, reversible inactivation, early gene expression, and electrophysiological studies (Frankland and Bontempi 2005).

There are well developed protocols available for studying, establishing, and confirming the role of the hippocampus in spatial learning. A variety of paradigms are available for investigation of spatial learning, and perhaps the most commonly used are the Morris water maze(Morris et al. 1982) and the Radial Arm Maze (Olton and Samuelson 1976) (Figs. 146.3, 146.4, and 146.5).

Another important brain area involved in spatial memory function in primates, including humans, is the prefrontal cortex. This area is also vulnerable to malnutritional insults. The effect of malnutritional insults on prefrontal cortex has been studied with respect to delay in development and maturation of cognitive function. However, its specific role in spatial memory function following malnutritional deficiencies has not been studied so far.

146.5 Malnutrition and Spatial Memory

As described previously, the effect of malnutrition on spatial memory or for that matter on any other brain function can be divided broadly into two groups:

(a) Perinatal malnutrition
(b) Malnutrition in later stages of life
Fig. 146.5 A schematic representation of Morris Water maze designed to study spatial memory function in rodents. The Morris water navigation task is another behavioral procedure used to study spatial memory of laboratory rodents. The apparatus was devised by Professor Richard Morris. It consists of a small water pool, which contains a small escape platform submerged few millimeters below the water level. The pool is theoretically divided into four quadrants. Conspicuous visual cues are placed around the pool in plain sight of the animal. The animal is placed in the pool and it swims around the pool in search of an escape. Various parameters like total distance traveled, the time spent in each quadrant of the pool, the time taken to reach the platform are recorded. The improvement of performance on all these parameters will be measured over the period of time

There is a distinct difference between the types and severity of deficits induced by these two different time windows, and each window will result in an entirely different profile of the defects on CNS. The reasons for these differences are as follows: In the first group, where the developing brain is especially malleable, malnutrition has a more pronounced effect on brain structures and systems supporting cognitive function. These effects are more severe and long lasting. These effects are therefore more likely to

be irreversible even after subsequent rehabilitation. In the latter group, because it is the developed brain that is exposed to malnutrition the effects are less severe and can be reversed at least to a certain extent with subsequent supplementation. It is thus logical and rational to consider both these groups separately.

146.5.1 Perinatal Malnutrition/Undernutrition and Spatial Memory

Malnutrition and/or undernutrition during infancy and childhood are problems prevalent in many parts of the world. Malnutrition neither produces gross anatomical abnormalities in the nervous system nor gross mental retardation or psychopathology. The effect of malnutrition shouldn't however be underrated for this reason. The malnutritional insults rather result in permanent suboptimal development leading to long-term learning and cognitive impairments. This is an equally serious problem. It is therefore important to study these effects. Animal studies provide a reasonable means of obtaining relevant information pertaining to the effects of malnutritional insults on the developing brain. These types of spatial memory defects have been studied at various levels of organization viz. structural, functional, biochemical, physiological, behavioral, and cognitive.

The defects underlying spatial memory function are best manifested at and therefore can be best studied at a behavioral level. Behavioral testing of rodents and primates are routinely done by using either the radial arm maze or the water maze paradigm. These behavioral protocols provide valuable insights into mechanisms underlying memory process. Behavioral defects are the manifestation of spatial memory dysfunction and the underlying cause could be a structural defect. Considering the involvement of the hippocampus in spatial memory function it is reasonable to study the hippocampus with respect to structural defects if any, followed by its functional implications.

Along with other areas of the brain which undergo rapid postnatal development, the hippocampus appears to be vulnerable to early undernutrition. This provides one more reason to study the hippocampus for possible defects. In spite of early undernutrition not producing brain lesions, deficits seen in the hippocampus by early undernutrition may show some related functional disability (Lynch et al. 1975). It is therefore important to study defects other than structural defects such as lesions, if any.

The type of deficiency one is subjected to, is one of the major deciding factors of the outcome of spatial memory deficits. Different types of deficiencies may or may not have similar effects on the system under consideration, in this case spatial memory function. Ranade et al. (2008) have shown that different types of malnourishment affect different domains of spatial memory function. Although these data have been shown with only three types of nutritional deficiencies; perinatal Chronic energy deficiency (CED), Protein deficiency (PD) and Iron deficiency (ID) and studied spatial memory function only at behavioral and gross anatomical levels, it is evident from this report that the type of deficiency has a significant role to play in deciding the specificity of defects seen. It is therefore important to study each type of deficiency specifically with respect to spatial memory function. Data from such studies will help in understanding the effects of specific types of malnutrition on spatial memory function.

146.5.1.1 Undernutrition and Spatial Memory Deficits

The effects of perinatal undernutrition on spatial memory or hippocampal function are inconsistent. Some studies, using radial arm maze or Morris water maze, report significant deficits in spatial memory function. However, others claim that spatial learning is completely unaffected by early undernutrition.

Jordan et al. (1981) have shown that perinatal undernutrition in rats affected their radial arm maze performance tested on an 8- and 16-arm apparatus, when tested at 90 days of age. Significant differences were seen on many parameters. Experimental animals showed less exploratory behavior and took more time to make choices when compared with control animals. Such deficits are similar to hippocampal dysfunction defects, which severely impair the performance of animals on similar spatial tasks.

Recent studies of the effects of developmental malnutrition in rats have suggested that hippocampal formation may be especially prone to irreversible neuroanatomical and neurophysiological alterations as well.

In another study, reduced cell numbers have been reported in the dentate gyrus and in the CA fields of the hippocampus proper (Lewis et al. 1979; Jordan et al. 1982) following perinatal undernutrition. In an altogether different paradigm of postnatal undernutrition it has been shown that lengthy periods of undernutrition affect the developmental growth curve of synapse formation and also alters the neuron: synapse ratio (Ahmed et al. 1987). Yanai et al. (2004) have reported the effect of different levels of dietary restriction on spatial cognition in rats. Animals were subjected to 80%, 60%, or 40% of free feeding and tested with Morris water maze place task throughout their lives. At a younger age, no significant difference was seen among the different experimental groups. However, at 9 months and thereafter, the 40% feeding group performed poorer than the other groups. This example also confirms the long-lasting nature of early undernutrition on spatial memory function.

On the other hand, Campbell and Bedi (1989) using Morris's test showed little evidence of any differences in the spatial learning abilities of rats previously undernourished from birth up to 60 days of age compared with well-fed age-matched controls. This is despite the fact that the same group had reported significant and persistent alterations in the morphology (viz. synapses per cell) of the dentate gyrus induced by undernutrition. The possible links between morphological and behavioral defects induced by perinatal undernutrition need to be established and confirmed.

146.5.1.2 Perinatal Protein Deficiency

It is well established that protein–calorie restriction, or protein malnutrition experienced during the early postnatal period leads to significant and often permanent changes in brain anatomy physiology, biochemistry, and behavior. The damages induced by protein deficiency include the damages to the maturation of the nervous system, motor function, and major cognitive functions. These effects have been observed in protein malnourished children all over the world. Exposure to protein deficiency even for a limited period may evoke permanent impairments of several brain functions. It has also been demonstrated (Ranade et al. 2008) that early protein malnourishment affects various aspects of hippocampal structure and function.

Protein deficiency can be induced in two ways.

(a) Protein malnourishment as a result of total undernutrition. Total reduced intake of food means reduced intake of proteins which culminates in protein deficiency.
(b) Protein malnourishment because of imbalanced diet i.e. diet doesn't contain the required amount of protein although there is optimum intake of food. That means there is no quantitative reduction in food intake.

The effects of both these conditions may sometimes have similar effects but sometimes may generate an entirely different profile of defects. Unless studied strictly under defined experimental conditions these two conditions are difficult to dissociate. So for this chapter these two conditions will not be explained separately. A series of studies have shown marked and lasting changes in the structure and function of the hippocampal formation in rats subjected to prenatal protein malnutrition.

The structural changes seen in the hippocampus include volume or area changes of the total hippocampus or certain subdivisions of it. Noback and Eisenman (1981) have reported a decreased width of the dentate gyrus as a result of protein–calorie restriction on the developing brain. Paula-Barbosa et al. (1988), in a study of long-term, postweaning undernutrition, reported a decrease in the width of the dentate gyrus and decreased granule cell packing density at 6, 12, and 18 months (Diaz-Cintra et al. 1991). Perinatal protein deficiency showed the highest reduction in hippocampal volume of F1-pups. This was in comparison with control as well as other deficiencies including CED and ID. This decrement was contributed maximally by the dentate gyrus and CA1 subdivisions of the hippocampus (Ranade et al. 2008).

These gross changes in the dimensions are a result of finer changes that occur at the cellular level. These changes include reduction in total cell number or decrease in certain population of cells. It could also be due to reduction in cell size of a certain population of cells. These changes at the cellular level either in isolation or in combination can bring about changes in the volume of the hippocampus.

Diaz-Cintra et al. (1991) have shown the effect of prenatal protein deprivation on the development of granule cells in rat at different ages. They showed significant reduction in the size of granule cells, a decreased number of synaptic spines, and reduced complexity of dendritic branching in the outer two thirds of the molecular layer. The effects persisted throughout the study period of 220 days.

The functional changes in hippocampus following early protein malnourishment include a reduction in the mean threshold to produce after discharge activity within the dentate gyrus. An even greater number of stimulations is required to elicit full convulsive motor seizures in response to perforant path kindling stimuli (Bronzino et al. 1991). Prenatal protein deprivation affected certain components of long-term potentiation (Austin et al. 1986) in the dentate gyrus of adult rats.

Taken together, these results suggest the vulnerability of the hippocampus to prenatal protein insults. An important question however is whether these structural and functional defects together lead to any behavioral impairment or not. Reports suggesting the effect of protein malnourishment on behavioral parameters are inconsistent.

Barnes et al. (1966) studied learning behavior in rats that were subjected to different forms of nutritional deprivation in early life. The performance of these rats was tested on visual discrimination performance in a Y-maze at 6–9 months of age. The rats that were deprived both before and after weaning made significantly more errors in their choices than the normal controls. Rats born to females fed on 8% case in throughout pregnancy showed lower visuo-spatial memory performance. The rats were deprived either preweaning or postweaning or both. On the Y-maze task, double-deprived rats performed the worst. When these rats were tested for position reversal performance in the water maze shortly after weaning the maximum number of errors were made by the double-deprived rats. The results also showed gender biases. Valadares and Almeida (2005) tested rats fed with 16% (well-nourished) or 6% (malnourished) protein diets during the lactation phase on the Morris water-maze in procedures of spaced trials (1 trial/day), intermediate density (4, 8, 12 trials/day), and condensed trials (24 trials/day). The results showed that protein malnutrition caused deficits in spatial learning and memory in spaced but not in intermediate and condensed trials procedure. When tested again 7 and 28 days after training, malnourished animals showed significantly higher latency compared with well-nourished controls. In another study, mice which were maintained on a protein-deficient diet during both gestation and lactation were tested on the radial arm maze. The results showed a specific and significant negative effect on working memory compared to other malnourished groups (viz. CED and ID) and controls (Ranade et al. 2008). These findings are inconsistent with previous reports by Tonkiss and Galler (1990), who reported no effect on working memory of rats which were prenatally protein deprived. This working memory was tested on two different behavioral protocols of learning and memory. The differences in experimental paradigms as well as in malnutrition protocols may account for the differences in results in this case.

Taken together these results very clearly suggest vulnerability of the developing hippocampus to gestational and/or lactation protein deficiency at various organizational levels. The discrepancies seen in the effect of PD on spatial memory function at the behavioral level could arise partially from the differences in the malnutritional paradigm used and partially due to differences in the design of the spatial memory task. There is also a possibility of the existence of species-specific differences.

146.5.1.3 Iron Deficiency and Spatial Memory

Iron deficiency is the largest single-nutrient deficiency affecting millions of new born babies worldwide. The several reasons for intrauterine iron deficiency include IUGR, anemia, alcoholism, maternal diabetes mellitus, and maternal nutritional iron deficiency either prior to or during pregnancy.

Several human studies report that anemic children show lower scores on various cognitive tests. Recognition memory at birth and at follow-up seemed to be affected in children who were at risk for brain iron deficiency (ID) during the late fetal/early neonatal period of the development (Siddappa et al. 2004). Although ID is associated with long-term cognitive abnormalities (de-Regnier et al. 2000; Nelson et al. 2000) its direct role in spatial memory is supported by only a few studies. Animal models have shown irreversible behavioral abnormalities resulting from diet-induced iron deficiency during early development. B.T. Felt and B. Lozoff (1996). View Record in Scopus Cited By in Scopus (107) ID is also known to delay myelination, thus leading to behavioral deficits. Therefore, behavioral defects seen as a result of iron deficiency cannot be attributed solely to hippocampal dysfunction.

Iron deficiency is known to affect some of the developmental processes related to the hippocampus, including myelination (Lozoff 2000), proliferation, and maturation of synapses (Jorgenson et al. 2005), and dendritic remodeling. It can therefore be speculated that some functions of the hippocampus may be compromised as a result of these underlying structural changes. Spatial memory could be one of them. The link between ID and spatial memory function is indirect and speculative at this point of time. Another possibility is that iron deficiency could potentiate these effects on the hippocampus through other adverse effects like oxidative stress.

The wide range of effects of iron deficiency on the hippocampus includes decrease in hippocampal energy metabolism (deUngria et al. 2000), altered hippocampal iron concentration (Felt and Lozoff 1996), altered neurotransmission by altering glutamate and GABA concentration (Rao et al. 2003), disrupted dendritic morphogenesis in CA1 pyramidal neurons (Jorgenson et al. 2003), and maturation of synaptic function and efficacy (Jorgenson et al. 2005). In addition there is an alteration in the pattern of neurochemical profiling (Rao et al. 2003), which also suggests changes in energy status, neurotransmission, and even myelination. Fetal or neonatal iron deficiency is also known to lower BDNF function, thereby impairing neuronal differentiation in the hippocampus (Tran et al. 2008). All or some of these changes may underlie spatial memory deficits seen in ID.

There are a few studies which report direct involvement of iron deficiency in spatial memory function.In their study of the effect of different types of malnutrition on spatial memory function checked by the radial arm maze test, Ranade et al. (2008) have reported that reference memory is selectively affected in the ID model. F1-pups born to mothers who were kept on an iron-deficient diet for 6 weeks prior to conception and also during gestation and lactation were checked for their spatial memory performance at 8 weeks of age. These animals showed selective impairment of reference memory function leaving other functions like working memory intact. In a recent report by Carlson et al. (2009), the importance of iron in neuronal development and memory function has been shown in the mouse hippocampus. Double mutants of mouse DMT-1(Slc11a2) were not able to perform

Effect of Different Types of malnutrition on Different subdivisions of Hippocampus
Fig. 146.6 Effect of different types perinatal malnutritional deficiencies on volumes of different hippocampal subdivisions. The *x*-axis shows different subdivisions of the hippocampus and *y*-axis shows a reduction in the volume of different hippocampal subdivisions with respect to control. This volume reduction was seen following perinatal malnutrition of different types viz. *CED* chronic energy deficiency, *PD* protein deficiency, *ID* iron deficiency. Results are expressed as mean ± SEM, *n* = 5 for each group (Reprinted from Ranade et al. 2007)

well on the difficult version of the spatial navigation task but were able to learn the easier version of it checked by the Morris water maze. No difference was found between the wild type and double mutant on learning of visual cued task.

From the above discussion it is clear that iron deficiency can cause a wide range of abnormalities in hippocampal structure and function. In addition, a strong correlation has been shown between iron deficiency and spatial memory dysfunction. However, a causal relationship between the two needs to be established. This can be achieved by suggesting a biologically plausible mechanism and studying it by using animal models. This will confirm the causal role of ID in spatial memory function (Fig. 146.6).

146.5.1.4   Other Perinatal Nutritional Deficiencies and Spatial Memory Function

Zinc deficiency occurs widely within the human population. In animal models, gestational or lactational zinc deficiency is found to produce various behavioral defects which include increased aggression (Halas et al. 1975.), increased food motivation (Halas et al. 1980), and impaired avoidance conditioning (Halas and Sandstead 1975). In their study carried out on rats Halas et al. (1985) showed the effect of perinatal zinc deficiency on learning and memory of young adult rats. Rats born to zinc-deficient mothers showed learning and memory deficits tested on the 17-arm radial arm maze. Pups which were born to zinc-deficient mothers showed significantly inferior working memory compared to the control group. No differences were seen in the reference memory of any of the experimental groups.

Choline is another important constituent which when deprived during fetal or neonatal development causes spatial memory deficits in addition to other nervous system defects. Choline is derived not only from diet but is also synthesized in the body. It influences cell proliferation and apoptosis, thereby altering brain structure and function. Choline supplementation in rats during pre- and postnatal development is known to enhance their spatial memory performance checked on the radial-arm maze (Meck et al.

1988) and water maze tasks (Schenk and Brandner 1995). Prenatally choline-supplemented and choline-deprived rats showed no difference in radial arm maze performance when the trials were spaced. Choline-deficient rats exhibited high levels of proactive interference as a function of mass trials suggesting that choline deprivation causes modification of discriminative abilities that distinguish between end of one trial and beginning of another and the capacity to remember location during a trial.

Transient vitamin D deficiency in rats is associated with subtle and discrete alterations in learning and memory. However, animals prenatally depleted of vitamin D showed impairment neither on spatial learning task in the radial arm maze nor on two-way avoidance learning in the shuttle box (Becker et al. 2005)

The initial evidence suggesting the importance of folate came from studies that established a link between increased risk of neurodevelopmental disorders and folate-deficient pregnant women (Smithells et al. 1976). Although cognitive defects following folate deficiency are well known, these defects do not pertain to spatial memory function. The mechanisms involved are also poorly understood.

Since the developing brain is an extremely transient system with its requirements very tightly regulated, any small modification or perturbation brings about a huge change in the outcome of this system at various levels. Nutritional factors which are major regulatory elements of this system have to be properly balanced in order to get the best out of it. It is therefore absolutely essential to strike the right balance of these nutrients to get the desired results of a normal functioning brain.

146.5.2 Late Age Nutritional Deficiencies and Effect on the Nervous System

In contrast to the developing brain the mature brain has long been thought to be resistant to malnutritional insults. Therefore, not much attention has been paid to the effect of nutritional deficiencies on the developed brain. But since it is evident from the literature that nutritional deficiencies not only affect development but also maintenance of the central nervous system, more efforts are being made to study the effect of nutritional deficiencies on the adult brain. A healthy diet is extremely important for the proper functioning of the developed nervous system as well. Exposure to nutritional deficiencies in adult life may not produce effects which are as severe as fetal or neonatal nutritional deficiencies. However, the adult nervous system is equally at risk to the hazardous effects of nutritional deficiencies.

A significant population of developing countries or certain socioeconomic groups of developed countries could very well serve as a model for adult malnutritional deficiency studies. However, there is a possibility that this is the same population which has also experienced fetal as well as neonatal malnutritional deficiency. So the results that one sees would be the cumulative effects of both perinatal as well as adult malnutritional insults. Population studies therefore don't offer much in terms of understanding the effects of malnutritional insults on adult brain. Once again, animal studies come as a great help. Most of our knowledge about these effects also comes from animal experimentation.

Two important deficiencies which are well studied with respect to their effects on the adult brain are protein deficiency and iron deficiency. However undernutrition is also known to have a significant effect on hippocampus-dependant cognitive function. A study carried out on 16 anorexia nervosa patients with same number of age-matched controls showed reduced hippocampal volume in anorexia nervosa patients (Connan 2006). This study did not report the link between the cause and consequence of hippocampal size and function. However, incorporation of endocrine, neuropsychological, and neuroimaging aspects in such studies would help in doing so.

In their study using a long-term low-protein diet model started in adult life, Paula-Barbosa et.al have shown that a low protein diet for an extended period of time in adult rats leads to a decrease in the numerical density of the dentate granule and CA3 pyramidal cells (Paula-Barbosa et al. 1988, 1989).The same group has further shown that the numerical density of synapses established by mossy fibers and the thorny excrescences of CA3 pyramidal cells was also decreased (Andrade et al. 1991). Paula-Barbosa further demonstrated that besides granule and CA3 pyramidal cells, the remaining neuronal populations of the hippocampal formation of the adult rat also show reduction in number as a result of long-term protein deprivation. This cell loss in the hippocampus proper, at this point of time, is a consequence of neuronal degeneration alone, as the process of cell acquisition of both CAl and CA3 pyramidal cells is accomplished before birth (Bayer1980). Therefore, the results may indicate an induction of neuronal degeneration as a result of adult protein deficiency. This study also demonstrated that rehabilitation from malnutrition does not lead to improvement in the morphological alterations induced by malnutrition. This also confirms the irreversibility of these malnutritional insults on the adult brain. Although there are no reports suggesting a direct role of adult protein deficiency in spatial memory function, the above mentioned correlation between protein deficiency and hippocampal defects can be extrapolated to establish a link between protein deficiency and hippocampus-dependant spatial memory function. The direct role of late protein deficiency in spatial memory function needs to be further investigated.

Women of reproductive age, and children, are at high risk for iron deficiency. While the effects of iron deficiency on mental function in children are well recognized, not much is known about how an iron shortage affects the adult brain. A number of investigators reported that iron deficiency anemia had a great influence on cognitive functions in infants and children. However, similar studies in adults are few and also controversial. Studies carried out on human subjects shows that reduced brain iron level or anemia in females induces attention deficits and learning and memory impairments (Murray-Kolb and Beard 2007). A study carried out by Khedr et al. on 28 young adults showed the possible influence of iron deficiency anemia and iron supplementation on cognitive function and intelligence. The patients in their study demonstrated lower scores on different cognitive tests like MMSE, WMS-R, and WAIS-R. Prolongation of ERPs and reduction in their amplitude were also seen. These performances however improved following 3 months of supplementation. There are quite a few reports suggesting the important role of iron in the normal functioning of the brain at any time in life, and several reports strongly suggest a link between ID and spatial learning and memory. However, not much data are available demonstrating the role of adult iron deficiency in spatial learning. Little evidence for this comes from the human studies, but more animal studies are needed to establish and confirm the role of adult iron deficiency, if any, in spatial learning and memory function.

The other malnutritional deficiencies known to affect the spatial memory function and hippocampus include vitamin A deficiency and folate deficiency.

Several animal studies have shown that vitamin-A plays a key role in brain development. Vitamin A deficiency exerts its effect on memory functions through retinoic acid hyposignaling (Lane and Bailey 2005; Bremner and McCaffery 2008). Long-term synaptic plasticity in hippocampal formation requires retinoids. Hypofunction of retinoid signaling is implicated in spatial memory dysfunction (Cocco et al. 2002). These types of effects can be reversed by either retinoid or vitamin-A supplementation. Long-term vitamin A deficiency is shown to decrease neurogenesis and leads to memory deficits. These effects were shown to be reversed with RA (retinoic acid) treatment which could be brought about by an upregulation of retinoid-mediated molecular events. Several reports suggest that the effects of vitamin A deficiency at the level of hippoccampal neurogenesis are reversible and that RA treatment also helps in the maintenance of the hippocampal plasticity and function.

Folic acid is another important nutrient whose deficiency has been associated with neurological diseases and mood disorders (D'Anci and Rosenberg 2004). A study which tested the effect of folate

deficiency on mice lacking uracil DNA glycosylase (*Ung_/_*) versus wild-type controls showed a clear effect on spatial learning. A hippocampus-dependant spatial learning task in the Morris water maze showed that escape latency and path length was significantly affected in folate-deficient mice. The same study also reported repression of neurogenesis in hippocampal progenitors following folate deficiency (Kronenberg et al. 2008). There is also increasing evidence of the beneficial effect of folate in protection against Alzheimer's disease and cognitive decline with age (Seshadri et al. 2002; Nurk et al. 2005).

146.5.2.1 Nutritional Deficiencies, Spatial Memory Function, and the Aging Brain

The relationship between nutrition and its brain effects become prominent during aging. The aging brain is vulnerable to various factors including malnutritional insults. A sharp decline in food intake accompanied by a slowdown in metabolism during aging contributes significantly to these effects. In addition to hampering cell function, this even weakens the cells' defenses against harmful free radicals, and also impedes the ability to grow new cells. Brain cells and neurons get affected due to free radicals generated through oxidation. All these reasons make the aging brain highly vulnerable to nutritional insults. Since these changes occur in almost all regions of the brain including the hippocampus it is possible that this in turn may contribute to memory loss.

Cognitive decline and memory loss are an inseparable part of natural aging process. So long as memory loss is not as serious as senile dementia or Alzheimer's disease, minor lapse of memory is nothing to worry about. Nutritional deficiencies contribute significantly to both general memory loss as a function of aging and more serious version of memory loss as seen in Alzheimer's disease.

As discussed, the effect of both prenatal and adult protein malnutrition or undernutrition on the brain includes a variety of dysfunctions. The hippocampus is one of the more severely affected brain compartments. Changes in the hippocampus include altered density of various important cell types, namely dentate granule or CA3 pyramidal cells. In addition there is also a reduction in dendritic spine density (Andrade et al. 1995). At the functional level, there seems to be a specific reduction of working memory checked on radial arm maze (Ranade et al. 2008). Since all these structural and functional deficits are manifested even as a function of normal aging, this decrement would be still stronger in aging brains subjected to protein malnutrition. Whether these age-dependant deficits are indirectly an effect of malnutrition by virtue of reduced food intake or not is debatable. Due to lack of experimental evidence, the effect of undernutrition or protein deficiency on the aging brain is purely speculative and needs to be studied in detail. There is growing interest in the role of nutrition in aging diseases such as dementia, in particular sporadic or late-onset Alzheimer's disease. Alzheimer's disease is the most prevalent form of dementia, characterized by significant memory loss. The nutritional deficiencies shown in Alzheimer's patients include a relative shortage of specific macro- and micronutrients. These include omega-3 fatty acids, several B-vitamins, and antioxidants such as vitamins E and C (Bourre 2004). Certain in vitro and in vivo studies also support the idea that nutritional components can compensate for specific defects of neurodegenerative disorders.

The role of iron deficiency in certain neurodegenerative disorders is also speculative at this point in time. The brain regions which accumulate iron in these disorders are the same as those compromised in early iron deficiency. The important questions that come up are: Does early life exposure to iron deficiency make one more prone to neurodegenerative disorders like Alzheimer's disease? If so, does this happen because the profile of iron-metabolizing proteins in the brain of these individuals is altered due to early iron deficiency? Also are these effects aggravated due to iron deficiency during aging? This is an idea that definitely needs to be explored in detail and supported by experimental observations.

The role of zinc deficiency is also suggested in the deterioration of learning and memory in senescence-accelerated mice. The report by Saito et al. (2000) suggests that age-dependent deficiencies of Zn in synaptic vesicles of the mossy fiber pathway induced by low expression of ZnT3 causes glutamatergic excitotoxicity in the hippocampal neurons and the deterioration of learning and memory in SAMP10 (Saito et al. 2000). An unbalanced copper metabolism and homeostasis (due to dietary deficiency) could also be linked to Alzheimer's disease.

Bourre explains the detailed role of different micronutrients on the aging brain (Bourre 2008). Vitamin B9 is known to preserve memory during aging. Vitamin B12 delays the onset of signs of dementia if administered in a precise clinical time window. Poor folate status is associated with cognitive decline and dementia in older adults.

Effects of malnutritional insults on the developing and adult brains are well known. These effects just become more pronounced on the aging brain. These effects need to be demonstrated empirically.

146.6 Applications to the Other Areas of Health and Disease

There is a strong requirement for efforts to be directed towards demonstrating the causal relationship of nutritional deficiencies and spatial memory dysfunction. A greater number of studies are needed to be carried out to demonstrate the specific involvement of a particular type of malnutritional deficiency on specific temporal domain of spatial memory function in detail. Studies which address the involvement of specific components of spatial memory function (either spatial or mnemonic) in overall compromised spatial memory dysfunction following malnutritional insults are also required to be carried out. This type of research will not only help delineate the mechanisms underlying spatial memory dysfunction but will also help us design new intervention strategies.

The information obtained from the above mentioned studies will have many added advantages and will also provide important insights into other areas of research.

A clearer and detailed understanding of the mechanisms involved in spatial memory function is valuable information that can be obtained from such studies, along with a better understanding of spatial memory function per se. The findings of these studies will help researchers link the behavior of an individual with the structural correlates of that particular behavior. This could be achieved by studying the affected brain area in detail at all levels of organization viz. structural, cellular, biochemical, and electrophysiological, and its behavioral manifestation. These studies will also offer valuable information about structural and functional development of the brain in general.

Deficiencies of certain nutrients are implicated in some neurodegenerative and psychiatric disorders. A detailed study in this context will help in finding a progression pattern of some of these disorders and may even shed some light on the detailed mechanisms involved in it. Various intervention strategies can be designed based on this knowledge. The studies will also suggest the critical period of vulnerability of the aging brain to various other insults and mechanisms involved. The mechanisms involved in brain aging can also be studied in detail by using such studies.

Thus, studying malnutritional insults with respect to spatial memory dysfunction will have several other added advantages and provide valuable information in other areas of research.

The age old saying, "You are what you eat," seems quite true even in the modern world. The advancement in techniques, expanding horizons of knowledge, availability of information put together also confirm that you are what you eat. Diet has a very strong influence not only on one's health but also on the outcome of disorders and diseases.

The nervous system is one of the systems that is highly vulnerable to nutritional insults. The effect of malnutrition on behavior and cognition are not usually life threatening but are still serious enough to demand special attention. Memory dysfunction is an issue of great concern. The types of behavioral or cognitive defects induced by malnutrition include reduced ability to learn certain tasks or inability to adapt to changes or inability to retain acquired information. Such defects do not allow an individual to make optimum use of one's own capability and to be the best that one can be in a demanding society. These types of defects deal mostly with "quality of life" issues.

The problem of fetal and neonatal malnutritional deficiencies is grimmer and also long lasting. It is almost the entire future generation which is at stake for suboptimal cognitive performance for the rest of their lives.

The increasing incidence of neurodegenerative and psychiatric disorders suggest a role of lifestyle changes due to modernization. The most obvious yet underrated factor influencing cognitive decline is the role of nutrition. Quite a few of these disorders have memory dysfunction as one of the important characteristics. Although normal decline and impairment in cognitive abilities as a function of aging is very common, increasing incidences of neurodegenerative disorders are alarming and may be blamed on unhealthy eating habits. The above discussion strongly confirms the role of nutrition as an important epigenetic factor influencing cognition and behavior.

The optimum physical, chemical, and physiological development of the brain and consequent behavior is the right of every individual irrespective of their social and/or economic background. Optimum nutrition should therefore be provided to each and every individual to ensure normal and healthy brain development. It is also imperative to employ multiple strategies at various levels to overcome the defects induced by malnutrition. Thus, a combination of economic, educational, behavioral, political, social, therapeutic, and rehabilitation strategies should be used to deal with this widespread and serious issue.

Summary Points

- Optimum nutrition is an essential factor that ensures normal structural and functional development of the brain. A change in even a single constituent of the diet can have a huge yet very specific effect on brain structure and function.
- Nutritional deficiencies affect development and maintenance of the central nervous system.
- Spatial memory function, which is a crucial function of the brain, is also compromised by nutritional deficiencies.
- Spatial memory is a memory of space around one. Spatial memory function involves processes like acquiring knowledge about the space around and retaining it for subsequent use.
- Early age nutritional deficiencies have more severe and long-lasting effects on spatial memory function as compared to late age nutritional deficiencies. The effects of fetal or neonatal nutritional deficiencies are irreversible.
- Although the adult brain is also vulnerable to nutritional insults the defects are mostly reversible at least up to a certain extent.
- Different types of nutritional deficiencies affect different domains of memory function, e.g., Protein deficiency selectively affects working memory, whereas iron deficiency affects reference memory leaving all other memory functions intact.
- Although a strong corelational link between nutritional deficiencies and spatial memory dysfunction is very well established, a causal link between the two needs to be demonstrated by suggesting a biologically plausible mechanism supported by well-designed experiments.

Definitions

Malnutrition: Reduction or complete absence of one or more food constituents in the diet.

Undernutrition: Reduction in total dietary intake or inadequate calorie intake.

Macronutrient deficiency: Reduction or complete absence of one or more macronutrients (e.g., protein or fatty acids) from the diet.

Micronutrient deficiency: Reduction or complete absence of one or more micronutrients (e.g., vitamins, minerals) from the diet.

Spatial memory: Memory of the space around an individual.

Spatial learning: The process of acquisition of information about the space around the individual.

Prenatal: Time period before birth, i.e., during pregnancy or gestation.

Postnatal: Time period just after birth, i.e., during lactation.

Perinatal: Time period covering both prenatal and postnatal periods.

Key Features of Spatial Memory Function

1. A balanced diet is important for the development and maintenance of a healthy nervous system. Imbalance in nutrition can affect various brain functions.
2. Spatial memory function refers to acquiring knowledge about the space around the individual, storing it, and retrieving it for subsequent use.
3. The hippocampus is the brain region important for spatial memory function.
4. Diet has a profound effect on spatial memory function. Any deviation from a balanced diet induces structural or functional defects either in the hippocampus or spatial memory function.
5. Human and animal studies contribute a lot to understanding the mechanisms involved in spatial memory dysfunction.
6. The effects of an imbalanced diet on the developing hippocampus are severe and long lasting.
7. The adult and aging hippocampus is also vulnerable to malnutritional insults.
8. More studies are required for a better understanding of spatial memory dysfunction. The findings of these studies will help design better interventional therapies for reversing these defects.

GABA	Gamma amino butyric acid
NMDA	*N*-Methyl-d-aspartate
PEM	Protein-energy malnutrition
PTZ	Pentylenetetrazole
PWE	People with epilepsy

147.1 Introduction

Malnutrition is a serious public-health problem. Approximately one billion people, essentially from developing countries, are affected by malnutrition (Elia et al. 2005). In developed countries, the prevalence of malnutrition is estimated around 5% of the 15 years and older population (Charles and Basdevant 2006). The term malnutrition usually refers both to undernutrition and overnutrition. Here, we will use the term malnutrition only for undernutrition. Malnutrition can be divided into two types: protein-energy malnutrition (PEM) and micronutrient deficiencies. Malnutrition produces adverse functional effects such as loss of muscle mass or alteration of the immune system, increasing the risk of infections that have clinical and public-health consequences or more typical diseases for micronutrients deficiencies (Stratton et al. 2003).

Epilepsy is a neurological disorder that affects 50 million people throughout the world. According to the epidemiological definition from the International League against Epilepsy (ILAE), it is characterized by the occurrence of at least two unprovoked seizures spaced over 24 h (ILAE 1993). An epileptic seizure is a transient occurrence of signs and/or symptoms due to abnormal excessive and synchronous neuronal activity in the brain (Table 147.1). This activity depends on membrane potential regulated by neurotransmitters, voltage-gated ion channels, and gap junctions. Synaptic transmission

Table 147.1 Key facts of epilepsy

- Epilepsy is a common chronic neurological disorder characterized by recurrent unprovoked seizures (at least two unprovoked seizures spaced over 24 h). It affects people whatever their age
- A seizure consists in the transient occurrence of signs and/or symptoms due to abnormal excessive and synchronous neuronal discharge in the brain. It can manifest as an alteration in mental state, tonic or clonic movements, convulsions, and various other psychic symptoms. Seizures can occur even in people who do not have epilepsy
- There are different types of epileptic seizures depending on the area affected by the seizures (generalized or focal), and the associated signs and the syndromes
- Epilepsy has many possible causes, including prenatal injuries, infectious diseases, head trauma, and abnormal brain development. In many cases, this cause is unknown.
- About 50 million people suffer from epilepsy all around the word, but about 80% of PWE are found in developing regions
- Drug-resistant epilepsy concerns 20–30% of PWE. This term is used when seizure control is not possible after 2 years, despite the use of at least two antiepileptic drugs from different pharmacological profiles adapted to the epileptic syndrome in a compliant patient
- PWE and their families can suffer from stigma and discrimination in many parts of the world. Stigma is a large part of the burden carried by individuals and occurs more often in developing countries

This table lists the key facts of epilepsy with regard to epidemiologic data, causes, mechanisms, and different types of seizures

is inhibited or excited according to the type of neurotransmitter, respectively gamma amino butyric acid (GABA) or glutamate. Epileptogenesis implies a local or diffuse modification of these mechanisms which are responsible for a loss of balance between GABA and glutamate. Seizure types are first organized according to whether the source of the seizure within the brain is localized (partial or focal onset seizures) or distributed (generalized seizures). The hippocampus plays a major role in partial temporal epilepsy. In these epilepsies, hippocampal modifications appear after an initial brain injury and then a latent period corresponding to epileptogenesis during which many changes occur. The limited nature of the hippocampus, the reproducibility of its reorganization during epileptogenesis made it as a preferred structure for the study of experimental models of epilepsy in animals and humans.

A relationship between nutritional status and epilepsy has been suspected for a long time. In this chapter, we will highlight the different interactions between malnutrition and epilepsy (Fig. 147.1).

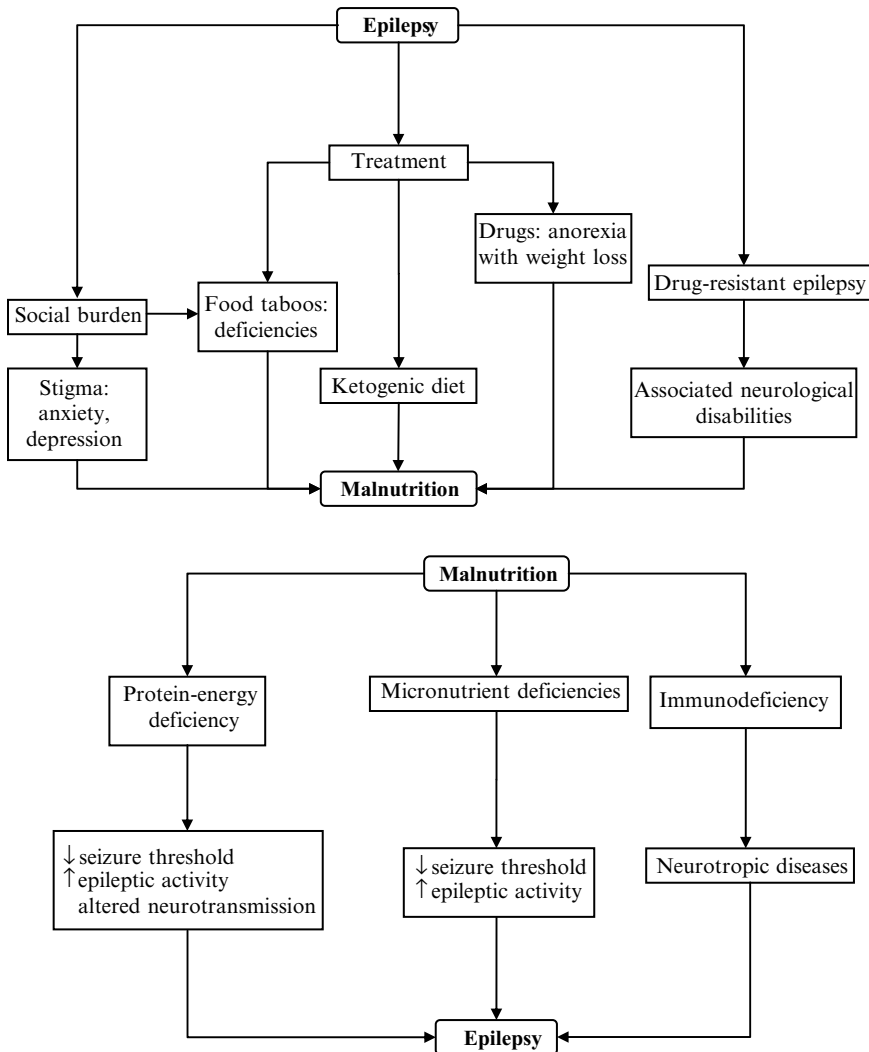
Almost 1,000 years ago, Avicenna recommended that people with epilepsy (PWE) avoid excessive eating, sheep meat, fish, onion, garlic, celery, cauliflower, and carrots (Asadi-Pooya and Ghaffari 2004). Several studies examine the relationship between malnutrition and epilepsy in humans (Hackett et al. 1997; Pal 1999; Nkwetngam Ndam 2004; Bertoli et al. 2006; Crépin et al. 2007; Volpe et al. 2007). The main results are summarized in Table 147.2. The studies were carried out essentially in developing countries and the results are divergent, in part due to methodological differences. But, in case-control studies with enough power, a link between malnutrition and epilepsy is found (Hackett et al. 1997; Crépin et al. 2007; Volpe et al. 2007). Prevalence of malnutrition in epilepsy in developing areas like Africa is high: 22.1% in a recent Benin study (West Africa) regardless of age (vs. 9.2% for the population without epilepsy, $p < 0.001$) (Crépin et al. 2007). Significant differences in consumption of cereals, tubers, vegetables, fish/meat and sweets, and several sociocultural factors (food taboos, stigmatization, etc.) are reported between PWE and controls (Table 147.3) (Crépin et al. 2007). In India, only one of two studies shows a link between epilepsy and body mass index (BMI) (Hackett et al. 1997; Pal. 1999). Two other studies performed in Italy and the United States, in children with refractory epilepsy, show existence of a risk of malnutrition, but no studies have been performed in non-drug-resistant PWE from developed


Fig. 147.1 Key facts of relationship between malnutrition and epilepsy. Links between epilepsy and malnutrition are bidirectional. Epilepsy can be responsible for the occurrence of malnutrition because of antiepileptic drugs (anorexic effect), food taboos (depending on the area in the world), and depression due to stigma. In the particular case of drug-resistance epilepsy, PWE can have other neurological disabilities (chewing problems, behavior problems or cerebral palsy, for example). Malnutrition is responsible for protein-energy malnutrition, micronutrient deficiencies, and immunodeficiency. Mechanisms implicated are decrease of seizure threshold, altered neurotransmission or increase of sensibility to infectious diseases as neurotropic diseases. In developed countries, we can speculate that malnutrition is unlikely lead to epilepsy whereas in developed countries the causal relationship is more likely. However, the relationship "epilepsy → malnutrition" is possible in any part of the world

countries. Many studies were performed in animals. The aim of these studies was to bring an assessment of the eventual role of malnutrition in seizure onset by exploring different avenues such as protein or micronutrient deficiencies, but in fact, there are two coexisting hypotheses to explain a link between malnutrition and epilepsy: on the one hand, malnutrition may contribute to the onset of epilepsy or at least seizures and on the other hand, epilepsy could be responsible for malnutrition.

Table 147.2 Studies about malnutrition and epilepsy performed in humans

Place	Study design	population	Age of subjects (years)	Results
Benin (Crépin et al. 2007)	Case-control study	131 PWE 262 controls	All ages	Risk of malnutrition higher for PWE (OR = 2.9, $p = 0.0006$)
Benin (Nkwetngam Ndam. 2004)	Case-control study	39 PWE 39 controls	All ages	No link between malnutrition and epilepsy ($p > 0.05$, lack of power)
Inde (Hackett et al. 1997)	Case-control study	26 PWE 1,146 controls	8–12	Mean BMI lower in PWE (OR = 0.74; $p = 0.023$)
Inde (Pal 1999)	Case-control study	61 PWE 59 controls	2–18	No link between BMI and epilepsy (OR = 31.3; $p > 0.05$, lack of power)
USA (Volpe et al. 2007)	Case-control study	43 PWE National Health and nutrition examination	1–9	Significant lower intakes for total energy and macro and micronutrients in children with drug-resistant epilepsy ($p < 0.05$)
Italy (Bertoli et al. 2006)	Cross-sectional study	17 PWE Standard chart	3–16	40% of children with drug-resistant epilepsy malnourished and 24% wasted ($p < 0.05$); unbalanced dietary intakes

Several studies concerning malnutrition and epilepsy are available. Most of them were performed in developing countries (4/6). Results are divergent because of methodological differences or lack of power. In case-control studies with enough power, malnutrition and epilepsy are linked

PWE people with epilepsy, *OR* odds ratio, *BMI* body mass index

Table 147.3 Factors linked with epilepsy in an African case-control study (Crépin et al. 2007)

Factors	Ajusted odds ratio (95% CI)	p
Mid arm upper circumference per unit	0.7 [0.6–0.9]	0.0020
Third party answering the questionnaire		
Yes (/no)	16.8 [3.1–90.3]	0.0010
Second occupation		
No (/yes)	7.1 [2.3–22.3]	0.0008
Cereal consumption		
≤1 time/day (/>1 time/day)	4.2 [1.8–10.0]	0.0010
Tooth decay		
Yes (/no)	2.9 [1.1–7.3]	0.0280
Food taboos		
Yes (/no)	25.0 [8.3–100.0]	<0.0001
Number of meals/day		
<3 (/≥3)	4.2 [1.6–10.9]	0.0037

In this case-control study performed in an African country, seven factors are significantly linked to epilepsy. These factors can be gathered in nutritional status factors (mid arm upper circumference, tooth decay), food consumption (cereal consumption, number of meal/day) or social factors (food taboos, second occupation, third party answering the questionnaire). Cases were people with epilepsy (PWE) and controls were people without epilepsy. In African countries, PWE don't usually answer directly to questionnaire or participate to study, a member of the family acts as a third party. It's one of the signs of stigma

CI confident interval

147.2   Effects of Malnutrition in Epilepsy

147.2.1   Protein-Energy Malnutrition

147.2.1.1   Protein Deficiency

Studies on animals show that if malnutrition is not considered a direct cause of epilepsy, it seems to favor the onset of epilepsy or seizures by various nutritional deficiencies. In rats, brain development occurs during the first 3 weeks of life. So, if this hypothesis is extrapolated to humans, it would mean that malnutrition during childhood could predispose someone to epilepsy. In humans, from the pre-natal period to third year of life is a time when the central nervous system (CNS) develops, and this is considered a sensitive period depending, in part, on protein, energy, and micronutrient availability. Malnutrition at this time adversely affects the developing brain in numerous ways, largely depending on its timing in relation to various developmental events in the brain and, to a lesser extent, on the type and severity of the deprivation. Many of the effects of prenatal malnutrition are permanent (Morgane et al. 2002). In animals, neuro-anatomical studies provide, for many years, evidences that the hippocampus and cortex are adversely affected by early malnutrition, which exerts its effects not only during the so-called brain growth spurt, but also during early organizational processes such as neurogenesis, cell migration, and differentiation in the cortex and hippocampus. Even if most of nutrients affect brain maturation, proteins seem to be the most important (Morgane et al. 2002; Georgieff 2007). In order to study the effect of malnutrition in the brain, the hippocampal neuronal model is widely used, particularly a study of the dentate gyrus, primarily because its anatomy and physiology are well-known and, secondly, because of its ideal internal geometry to study neuronal organization, reproducibility of the experiments, and its role in epilepsy. Stern et al. show that protein malnutrition during development leads to enhanced seizure susceptibility in adult rats reared on a diet containing inadequate protein levels (decreased seizure threshold and increased epileptic activity) (Stern et al. 1974). This effect is partially abrogated by restoring adequate dietary protein levels in adulthood, and seems to be specific to the type of stimulation used to induce experimental seizures (Forbes et al. 1978). Palencia et al. use a rat model of chronic malnutrition to study the possible influence of malnutrition at late stages of brain development with experimental seizures induced by pentylenetetrazole (PTZ), a $GABA_A$ receptor antagonist (Palencia et al. 1996). In this study, corn tortilla is the only solid food used. The dose of PTZ required to produce seizures is reduced in malnourished rats. This malnutrition model was used because corn and corn derivatives represent the most common food sources of undernourished people from Latin America. Histological studies of the brain show atrophic neurons especially in the hippocampus, cerebellar cortex, and cerebral cortex. In contrast with other studies, Nunes et al. find that malnourished neonatal rats (during the breast-feeding period) are not different from well-nourished rats in terms of flurothyl seizure susceptibility at postnatal day 15 or behavioral manifestations of seizures. But histological assessment shows that flurothyl-induced status epilepticus increases the expression of new cells in the dentate gyrus of malnourished immature rats compared to well-nourished rats; these results may be explained by a cumulative toxicity of malnutrition and status epilepticus (Nunes et al. 2000). However, the pathological function of these new cells has not been clearly established yet.

Protein malnutrition can affect cholinergic, GABAergic, serotoninergic, and glutaminergic transmission. Andrade and Paula-Barbosa randomly assign 2-month-old rats to three groups: (i) malnourished rats fed with an 8% low-protein diet for 12 months; (ii) recovery rats fed like the previous group for 6 months and then switched to a 17% protein standard laboratory diet for a further 6 months; and (iii) controls rats fed for 12 months with the standard laboratory diet (Andrade and

Paula-Barbosa 1996). Prolonged malnutrition lead to a substantial but reversible reduction in the cholinergic innervations of the hippocampal formation which could be explained by a lack of trophic factors, decreased synthesis, availability, and delivery of ordinarily existing neurotrophic substances or an altered ability of neurons to react to these factors. They also show irreversible loss of hippocampal cholinergic and GABAergic neurons.

We are also confronted with the problem of the mechanism leading to epilepsy from extrapolation of effects on hippocampal structures to more global alterations of the CNS explaining different types of epilepsy. Moreover, alterations of the hippocampal area play a key role in some focal epilepsy.

147.2.1.2 Neurotransmitters

Brain cells need certain amino acids and micronutrients to function normally. Several amino acids act as neurotransmitter precursors, such as tryptophan (for serotonin), and some neurotransmitters have amino acid bases, such as GABA or glutamate. Wood et al. show that malnourished rats have lower GABA concentrations in cerebral spinal fluid (CSF) than controls (Wood et al. 1979). For Steiger et al., modifications in $GABA_A$ receptors (variation of affinity or allosteric interactions between benzodiazepines and GABA receptors) are found in rats receiving a low-protein diet during gestation (Steiger et al. 2003). Schweigert et al. find that prenatal and postnatal protein-malnourished rats are more sensitive to picrotoxin ($GABA_A$ receptors antagonist) but there is no difference for quinolinic acid, which has an excitatory effect on neurons as *N*-methyl-d-aspartate (NMDA) receptor agonist. The authors also note an increase in GABA uptake in the hippocampus. In malnourished humans, GABA level is only measured in blood. The findings are contradictory. For Smith et al., this level is lower than in well-nourished humans (Smith et al. 1974) while for Agarwal et al., it is increased (Agarwal et al. 1981). When brain GABA concentration is increased by administration of antiepileptic drugs, blood and CSF GABA concentrations are also increased. But if GABA plasma concentration decreases no one knows whether CSF and brain GABA concentration is decreased as well.

Another hypothesis concerning the effects of changing cerebral concentration of GABA would be excitatory properties in connection with high intracellular concentration of chloride ($[Cl^-]_i$) due to modification of chloride transporter expression, as shown physiologically during the fetal stages and also in temporal epilepsy hippocampal pyramidal cells (Ben-Ari 2002).

We can speculate that chronic malnutrition in human induces alterations in the brain that decrease seizure threshold, facilitating epileptogenesis that occurs after cerebral injuries or disorders that are prevalent in inhabitants of developing areas.

147.2.2 Immunodeficiency

It is known that malnutrition is a major cause of immunodeficiency (Lesourd and Mazari 1997). PEM is associated with impairment of cell-mediated immunity, phagocyte function, complement system, secretory immunoglobin-A antibody concentration, and cytokine secretion. In tropical areas, poor sanitation and contaminated food or water contribute to alter immunocompetency and to increase risk of infections, especially intestinal infections, which themselves can lead to malabsorption and raise needs in order to adapt immune responses. Malnourished people are more vulnerable to infections, as for example infections known to be epilepsy risk factors, such as neurotropic viruses or cysticercosis, etc. One has to know that neurocysticercosis is the most frequent infectious cause

of epilepsy in developing countries (Preux and Druet-Cabanac 2005). Single nutrient deficiencies are also responsible for altered immune responses. This is observed even when the deficiency is mild. Zinc, copper, vitamins A, C, E, and B6 have important influences on immune responses (Lesourd and Mazari 1997).

147.2.3 Micronutrient Deficiencies

Malnutrition can be responsible for electrolyte deficiencies (calcium, magnesium, sodium, phosphorus, etc.), vitamin deficiencies (B1, B6, B12, D) or other elements (zinc or selenium). CNS homeostasis is essential for brain function. Micronutrient deficiencies can have direct or indirect effects on neuronal excitability and may facilitate epileptic activity (Table 147.4). Seizures can occur following hyponatremia, hypocalcemia, hypomagnesemia, or hypophosphatemia. There are usually tonic-clonic seizures but focal seizures are also possible (Castilla-Guerra et al. 2006). Electrolyte lab tests are recommended especially after a first seizure. Several seizure cases due to hyponatremia have been reported. A retrospective survey carried out in an American emergency department shows that hyponatremia (<126 mmol/L) is responsible for seizure occurrence in 56% of less than 2-year-old children and in 70% of children younger than 6 months old when there are no other obvious causes of seizure (Farrar et al. 1995). Seizures can be explained by a decrease in extracellular osmolality responsible for an osmotic gradient and water entry into cells. Several case-reports of seizures associated with hypocalcemia (essentially the neonatal stage, people with hypoparathyroidism or vitamin D deficiency) or hypomagnesemia are also reported (Leaver et al. 1987; Bushinsky and Monk 1998). In slices of human epileptogenic neocortex, a decrease in extracellular magnesium concentration always induces epileptiform discharges by eliminating its blocking effect on NMDA receptors (Avoli et al. 1991). Hypophosphatemia is a well known and possible cause of seizure during the refeeding

Table 147.4 Micronutrients deficiencies and seizure

Deficiencies	Hypotheses
Electrolytes	
Calcium (Bushinsky and Monk 1998)	Neuronal hyperexcitability
Sodium (Farrar et al. 1995; Castilla-Guerra et al. 2006)	Cerebral hypo-osmolality
Magnesium (Leaver et al. 1987; Avoli et al. 1991)	Neuronal excitability modulator
	Disinhibition of the complex sodium-channel- glutamate receptor NMDA-type
	Neuromodulation
Phosphorus (Sobotka 2004)	Unknown
Vitamins	
Vitamin B1 (Keyser and De Bruijn 2001)	Increase of irritative activity in predisposed people
Vitamin B6 (Kretsch et al. 1991)	Decrease of threshold seizure
Vitamin B12 (Biancheri et al. 2001)	Increase of glutamate sensitivity
Vitamine D (Johnson and Willis 2003)	Associated with consequences of calcium deficiency
Trace elements	
Zinc (Takeda 2000)	Genetic susceptibility
	Increase of cortical hyperexcitability
	Neuromodulation
Selenium (Schweizer et al. 2004)	Antioxidant effect

Micronutrient deficiency is a possible cause of seizures. Different types of micronutrients are involved (trace elements, vitamins, and electrolytes). Mechanisms implicated are various and depend on micronutrients. These data are essentially based on animal studies or human case series

syndrome (Sobotka 2004). The role of vitamin deficiencies in seizures has also been reported but mainly on case-reports (Keyser and De Bruijn 1991; Kretsch et al. 1991; Biancheri et al. 2001; Johnson and Willis 2003). For zinc and selenium, neurological effects have been studied in animal models (Takeda 2000; Schweizer et al. 2004). The hypothalamus contains high zinc levels, and is sensitive to deficiency. At a neuronal level, zinc acts as a neurotransmitter in glutaminergic and GABAergic transmission by decreasing the extracellular glutamate concentration and increasing the extracellular concentration of GABA. As selenium is an essential part of glutathione peroxidase involved in antioxidant defence, selenium deficiency can be implicated in oxidative stress (Schweizer et al. 2004). Oxidative stress seems to be implicated in occurrence of seizures. Animal models indicate that occurrence of seizures can increase the content of reactive oxygen species and superoxide generation in the brain. But also, free radicals can induce seizure activity by direct inactivation of glutamine synthase resulting in an abnormal build up of glutamate or inhibition of glutamic acid decarboxylase activity leading to a decrease of GABA. In a study performed in humans, the antioxidant status in the blood of PWE is low compared to controls (lower plasma concentration of vitamins A and C, erythrocyte glutathione reductase and high lipid peroxidation and hemolysis). This status is improved after antiepileptic treatment. Seizure activity may act directly on oxidant blood concentration and antioxidant may be useful to counteract the effect of free radicals (Sudha et al. 2001).

147.3 Effects of Epilepsy on Nutritional Status

147.3.1 Sociocultural Issues

Epilepsy is not only a clinical disorder but also a social label, especially, but not only, for PWE from developing countries. In developing countries, epilepsy is often wrongly considered a contagious disease, the transmission to bystanders being done through saliva, urine, feces, or flatus emitted during a seizure. This situation leads to a restriction on the normal life style and activities, stigma, and then social rejection (Nubukpo et al. 2003). Most African communities still view epilepsy as possession by the Devil or as a witchcraft act. As a consequence of these traditional beliefs, PWE are treated as outcasts. They can be excluded from their family, and not allowed to attend school. It can also be more difficult for them to get married. Seizure occurrence, as well as social rejection, can be responsible for anxiety, decreased food intake, and long-term malnutrition. Nubukpo et al. find that PWE are more anxious or depressed than people without epilepsy (Nubukpo et al. 2004). In developing countries, they have more food-related difficulties than controls: they frequently have fewer than three meals/day, consume cereals less often, and need family help more often (Crépin et al. 2007). Therefore, their nutritional status is worse than that of the control group.

In such countries, beliefs also dictate what PWE may eat. Indeed, food taboos can sometimes be the basis of epilepsy treatment. Nubukpo et al. report that food taboos is found in 63.9% of Benin PWE and 44.2% of Togolese PWE (Nubukpo et al. 2003). In another study performed in Benin, 64% of PWE have food taboos versus 22% for controls (Crépin et al. 2007). In France, food taboos are found in up to 19.5% of a studied population and in the United States, 6% of adults with epilepsy report food as a precipitating factor of seizure (Nubukpo et al. 2003; Asadi-Pooya and Sperling 2007). Eviction can include salty and/or spicy food, sweets, oil but also boiled meat or gummy sauces (with mucilaginous plants such as okra) depending on cultural beliefs and personal experiences (Asadi-Pooya and Sperling 2007; Crépin et al. 2007). If abstinence from certain foods is used, it is because they are considered as responsible for seizure occurrence or saliva secretion during

seizures and, in this way, can facilitate "the transmission" of the disease. For Asadi-Pooya and Ghaffari, 55.2% of parents of Iranian children with epilepsy think that there is a relationship between consumption of certain foods and seizure occurrence (Asadi-Pooya and Ghaffari 2004). In addition, this opinion is held by 58.4% of Iranian nurses and physicians (Asadi-Pooya and Hossein-Zade 2005). Almost 50% of the health care professionals and 31.2% of the family of children with epilepsy have experiences with seizure in their PWE after consumption of specific food (dairy products, sour food like vinegar, pepper, meat/fish, vegetables, or fruits) (Asadi-Pooya and Ghaffari 2004; Asadi-Pooya and Hossein-Zade 2005).

147.3.2 Specific Aspects of Drug-Resistant Epilepsy

Growth retardation is reported of children with epilepsy and this could be more prevalent in children with drug-resistant epilepsy. Several factors could explain this: frequent seizures and long post-ictal periods may lead to reduced times of alertness and may lead to decrease in total energy intake.

Two recent studies performed in developed countries suggest that drug resistance in children with epilepsy may favor malnutrition (Bertoli et al. 2006; Volpe et al. 2007). In Italy, 7 children from a cohort of 17 children with drug-resistant epilepsy are malnourished (weight < 80% compared with the reference weight for age) (Bertoli et al. 2006). Children with more severe neurological impairment have the lowest amount of fat-free mass and are hypercatabolic. In the United States, children with drug-resistant epilepsy were compared to healthy children of the same age from the National Health and Nutrition Examination Survey 2001–2002 and Dietary Reference Intakes (Volpe et al. 2007). Energy intake and macronutrients are substantially lower in the children with intractable epilepsy. About 47% of children have significantly lower intakes of total energy, protein, carbohydrate, fat, dietary fibers, certain vitamins, and trace elements compared with recommendations for sedentary healthy children. Drug-resistant epilepsy can be associated with several disabilities including metabolic diseases or cerebral palsy. However, in these two studies, all children for Bertoli et al. (2006) and 53% for Volpe et al. (2007) are at least mildly mentally retarded and, consequently, the risk of malnutrition seems to be partially linked to disabilities related to epilepsy (chewing and swallowing difficulties, anorexia, etc.).

147.3.3 Antiepileptic Treatment

Epilepsy is usually treated with drugs, but traditional treatments in developing countries and specific diets are also used. Because of cultural practices and limited access to medical care, traditional therapies are frequently used in developing countries. In Malawi, for example, treatments are often based on emetic and/or purgative preparations because Malawi people think that epilepsy originates from the stomach where insects can trigger seizures with their movements (Bernet-Bernady et al. 1997). Vomiting and diarrhea due to this type of treatment with long-term use may lead to various deficiencies and weight loss.

Numerous articles deal with the effect of antiepileptic drugs on weight: some can decrease bodyweight and others can increase it or are neutral on weight (Table 147.5). Topiramate, felbamate, zonisamide, and stiripentol induce weight loss due to loss of appetite (Biton 2003; Ben-Menachem 2007). Topiramate is one of the antiepileptics the most associated with weight loss. Weight loss depends on BMI (patients with a higher baseline BMI are more likely to lose weight), gender (females

Table 147.5 Effect of antiepileptic drugs on weight (Chiron et al. 2000; Biton 2003; Ben-Menachem 2007)

Weight gain	No effect	Weight loss
Carbamazepin	Lamotrigine	Felbamate
Oxcarbazepine	Levetiracetam	Topiramate
Gabapentine	Phenytoin	Zonisamide
Pregabalin	Tiagabine	Stiripentol
Sodium valproate	Lacosamide	
Vigabatrin		

Antiepileptic drugs are now known to have an effect on weight. This effect depends on the drug but also on risk factors linked to people with epilepsy (basal body mass index, sex…). The loss of weight is usually due to an anorexic effect of the drugs

are more likely to lose weight) and daily dose (>200 mg/J). Felbamate also significantly reduces the weight of PWE by 15–75%, with some losing up to 4% of their body weight within 6 months (Ben-Menachem 2007). Weight loss with zonisamide is reported in several clinical trials: almost 22% of PWE lose at least 2.3 kg versus 10.5% of PWE using placebo (Ben-Menachem 2007). Stiripentol is also responsible for weight loss: 7% versus 1% in placebo group (Chiron et al. 2000). Antiepileptic drugs can also be responsible for micronutrient deficiencies, such as that of vitamin D with phenytoin or phenobarbital, or taurine deficiency which seems to be responsible for the retinal toxicity of vigabatrin (Gissel et al. 2007; Jammoul et al. 2009). Even if in this chapter we only focus on under-nutrition, some antiepileptic drugs can, in contrast, be responsible for an increase of weight. The most well known weight-increasing drugs are: valproate, gabapentine, pregabalin (Biton 2003; Ben-Menachem 2007). Phenytoin, tiagabin, lamotrigine, and lacosamide are themselves considered weight-neutral antiepileptic drugs (Biton 2003; Ben-Menachem 2007).

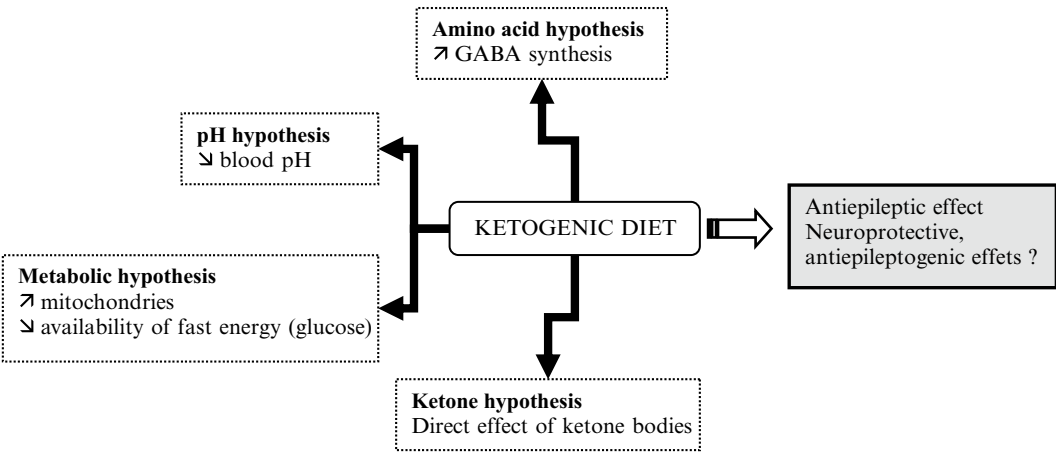
Dietary therapies are another option in epilepsy treatment. A ketogenic diet is the most often used, but it is not the only one (a modified Atkins diet with high fat, high protein, low carbohydrate, could be used, for example). A ketogenic diet is usually proposed for the treatment of children with drug-resistant epilepsy. It is a strict high fat, adequate protein, and low carbohydrate diet (Fig. 147.2). It decreases seizure frequency in more than 50% of children on the diet. After almost one century of use, the mechanism involved in the clinical efficacy of this treatment is still not clearly understood (Fig. 147.3). The pH hypothesis is based on the idea that the ketogenic diet makes the blood (and brain) slightly acidic because of the production of ketone bodies (acetoacetate, beta-hydroxybutyrate, and acetone). The pH change would be responsible for the antiepileptic effect. In the metabolic hypothesis, a ketogenic diet makes the brain switch from a glucose-based metabolism to a ketone-based metabolism. The antiepileptic effect is due to ketone bodies being more energetic than glucose. or an increase in mitochondrial number, and a decrease in availability of fast energy (glucose) necessary for the seizure. In the amino acid theory, the neurotransmitter balance is modified with an increased production of GABA. In the ketone hypothesis, ketone bodies themselves have antiepileptic properties. A ketogenic diet is efficient in many seizure types and epilepsy syndromes, especially in children who extract and utilize ketone bodies from blood more efficiently than older PWE (Kossoff and Rho 2009). The efficacy appears quickly in the first week of diet. It allows a decrease in seizure severity or duration and increases seizure threshold. In addition to the immediate effect of ketogenic diet, it could have long-term benefits with neuroprotective or antiepileptogenic effects. However, ketone bodies also have anorexigenic properties and other adverse effects as diarrhea and vomiting and can be responsible for growth retardation or weight loss especially in the youngest (Vining et al. 2002). Like the ketogenic diet, a calorie-restricted diet seems to be effective,
Fig. 147.2 Composition of ketogenic diet. A ketogenic diet is a high fat, adequate protein, and low carbohydrate diet. The ratio of lipid to nonlipid is usually 4:1 with a minimum of 1 mg/kg/day of proteins and a limited intake of carbohydrates (10–15 g/day). Vitamin supplementation is necessary. A nutritionally complete powdered product is available


Fig. 147.3 Mechanisms of ketogenic diet. A ketogenic diet, used in drug-resistant epilepsy, is one of the possible treatments in epilepsy. It consists in a strict high fat, adequate protein, and low carbohydrates diet resulting in a production of ketone bodies (acetoacetate, beta-hydroxybutyrate, and acetone). The ketogenic diet has at least an antiepileptic effect and probably neuroprotective and antiepileptogenic effects

on rodent models, in the decrease of seizure susceptibility by reducing the brain glycolytic energy (Greene et al. 2001). It leads to a global decrease in calorie intake without modification of proportions between different food groups and so differs from acute fasting and starvation. A calorie-restricted diet seems to have an additive effect when associated with a ketogenic diet in rodents, but this possible diet therapy has not been yet formally tried on PWE.

147.4 Conclusion

Links between malnutrition and epilepsy are complex. Malnutrition, via different mechanisms, could favor seizure onset and, perhaps, epilepsy. Conversely, epilepsy has consequences on the nutritional status of PWE because of sociocultural factors, severity of epilepsy, or antiepileptic treatments. Consequently, nutritional assessment of PWE appears to be important, as well at the first examination as during the follow-up. The use of simple tools as BMI or body weight variations measurement can be adequate. A better understanding of interactions between malnutrition and epilepsy might

prevent the genesis of certain types of epilepsy, especially in developing countries, and improve control of the consequences of epilepsy on nutritional status. Indeed, nutritional interventional studies to determine the best way to limit the occurrence of epilepsy or malnutrition in PWE are lacking. In the mean time, PEM and nutrient deficiencies have to be prevented, especially during pregnancy and childhood. Antiepileptic adverse effects have also to be prevented and treated. Global programs to fight against food taboos and stigmas are necessary.

147.5 Applications to Others Areas of Health and Disease

Neurological disorders are multifactorial. In developing countries, the risk factors for these disorders are numerous and could often interact, as is the case, for example, for infectious diseases, nutrition, and epilepsy. In some African countries, acute or subacute spastic paraparesis and degenerative neuropathy are linked to cyanide intoxication of dietary origin (consumption of large amount of cassava containing cyanogens) (Osuntokun and Monekosso 1969). So the knowledge and the monitoring of nutritional status of people could help to better prevent the occurrence of disorders or to manage existing ones. Other chronic neurological disorders have nutritional consequences, as in Alzheimer's disease. Weight loss is a common problem in Alzheimer's disease and it is associated with mortality, morbidity, disease progression, and poor quality of life (Smith and Greenwood 2008). Malnutrition could also be a prognostic factor in other diseases as in amyotrophic lateral sclerosis (Desport et al. 1999). The mechanisms by which nutrition and epilepsy interact could help to understand the physiopathological mechanisms of morbidity in other diseases, leading to better comprehension and, therefore to improved global public health.

Summary Points

- Malnutrition and epilepsy are two major public health issues. About 800 million people are malnourished and 50 million people have epilepsy all around the world. Both are much more prevalent in developing countries than in developed countries. About 90% of PWE live in developing countries.
- Malnutrition and epilepsy are linked in a two-way relationship. Malnutrition can probably cause seizure and epilepsy can, in turn, lead to malnutrition.
- Malnutrition corresponds to an imbalance between dietary needs and allowance. It can be subdivided in two types: PEM and micronutrient deficiencies.
- Epilepsy is a common chronic neurological disorder characterized by recurrent unprovoked seizures (at least two unprovoked seizures spaced over 24 h).
- Protein and nutrient deficiencies are probably the two most important deficiencies implicated in the occurrence of seizure and epilepsy.
- Protein deficiency acts on epilepsy in numerous ways: decrease of seizure threshold, increase epileptic activity, affecting neurotransmission or inducing the occurrence of atrophic neurons. It can also have an indirect effect by inducing the occurrence of neurotropic infectious diseases.
- Central nervous system homeostasis is essential for brain function. Micronutrient deficiency plays a role in neuronal and epileptic activity.
- Electrolyte lab test is necessary, especially after a first seizure.
- The period between conception to first years of life is considered a sensitive period for the brain. Malnutrition during this period can be responsible for damages.

- Epilepsy occurs essentially in developing countries, where, because of sociocultural issues, it is responsible for malnutrition. Stigma and food taboos are in part responsible for it.
- Food taboos concern various types of food groups as meat/fish, mucilaginous plants, oil, sweets, and vegetables.
- Antiepileptic drugs can be responsible for malnutrition. The nutritional status of PWE on antiepileptic therapies should be monitored.
- Ketogenic diets have proved to be efficacious as treatment for epilepsy. The exact mechanisms, however, remain unknown.

Key Terms

Malnutrition: corresponds to an imbalance between dietary needs and allowance. It can be subdivided in two types: protein-energy malnutrition (PEM) and micronutrient deficiencies.

Protein-energy malnutrition: corresponds to an inadequate protein intake. It is responsible for two types of malnutrition: kwashiorkor and marasmus.

Micronutrient deficiency: concerns deficiency of one of several essential nutrients required for normal body functioning as vitamins, electrolytes, or dietary minerals.

Epilepsy: is a common chronic neurological disorder characterized by recurrent unprovoked seizures (at least two unprovoked seizures spaced over 24 h).

A seizure: consists in the transient occurrence of signs and/or symptoms due to abnormal excessive and synchronous neuronal discharge in the brain.

Drug-resistant epilepsy: corresponds to the lack of control of the disease after 2 years of treatment, despite the use of at least two antiepileptic drugs from different pharmacological profiles adapted to the epileptic syndrome in a compliant patient.

A ketogenic diet: is one of the possible treatments for epilepsy. It's used when drug-resistance is established. It consists in a very strict high lipid diet.

Stigma in epilepsy: it is a mark of shame or discredit, a stain, and an identifying mark or characteristic.

Chapter 148
Cortical Spreading Depression: A Model for Studying Brain Consequences of Malnutrition

Rubem Carlos Araújo Guedes

Abbreviations

CNS	Central nervous system
CSD	Cortical spreading depression
EEG	Electroencephalogram
DC	Direct-current
GABA	Gamma-amino butyric acid
REM-sleep	Rapid-eye-movement sleep

148.1 Introduction: Malnutrition and Its Neurological Consequences

In the last decades of the twentieth century, the nutritional scenario in the world was characterized by a situation in which, due to the limited economic possibility of buying nutritionally adequate foods (which have higher costs than poor-quality foods), a large part of the human population was susceptible to the impact of inadequate feeding (Morgane et al. 1978). This situation still affects a considerable number of children, with an important influence on the morbidity and mortality indexes. In Brazil, as well in other developing countries, the poorest part of the population now experiences what has been called a rapid "nutritional transition," characterized by a simultaneous decrease of the prevalence of severe malnutrition and an increase of overnutrition (Monteiro et al. 2004). This nutritional transition has been accompanied by a diminution in the incidence of infectious and parasitic diseases and an increment of nontransmissible chronic diseases affecting homeostatic processes of the cardiovascular and renal systems, among others (Boubred et al. 2007; Ginter and Simko 2009; Popkin et al. 2001). However, the neurological impact of such conditions has not been the object of much investigation. Both the economic and social costs of that scenario are considerable, with regard to the health assistance required to be given to surviving individuals (Popkin et al. 2001). Considering the public health point of view, this situation can be characterized as a matter of great concern.

The biochemical and morphological organization of the brain can be disrupted by the dietary deficiency of one or more nutrients, especially if this deficiency occurs early in life, during the so-called "brain growth spurt" period (Grantham-McGregor 1995). Nutrition-dependent alterations in brain development and organization are usually followed by deleterious repercussions on its function and these can be more or less severe, depending on the intensity and duration of the nutritional disturbances (Morgane et al. 1978). The neural analysis of sensory information and perception, as well as the efficient production and control of motor activity, are basic neural functions that can be impaired by nutritional inadequacies. Malnutrition-induced neural impairment can also affect more complex brain functions such as those involving learning, memory, consciousness, cognition, and emotion. Such disturbances can sometimes also result in permanent effects in the nervous system, with the establishment of more or less disabling diseases (Grantham-McGregor 1995). All these social- and biological-related factors illustrate the great importance of studying the effects of malnutrition on the brain. Further, experimental evidence indicates that excessive food intake too can interfere with brain development and function (Davidowa et al. 2003). The systematic investigation of this condition started to increase in the last decade. These facts have motivated a number of clinical and experimental research laboratories to study the effects of early malnutrition on the developing and adult central nervous system, resulting in a considerable amount of data. In this chapter we present experimental results on the brain electrophysiological phenomenon known as "cortical spreading depression" (CSD), and demonstrate how CSD can be used in studies comparing their features in malnourished and well-nourished rats. In addition, the CSD effects of nutritional factors are confronted with those of non-nutritional variables.

148.2 Influence of Nutrition on the Electrical Activity of the Normal Brain

The brain exerts its diverse functions basically by producing electrical signals, which constitute the so-called electrical activity of the brain. This activity can be recorded in humans and in laboratory animals by different techniques and can thus provide valuable information about brain function. For this purpose, one of the most used techniques is the electroencephalogram (EEG), which consists in recording the differences of electrical potential between one or several pairs of electrodes placed at distinct regions on the skin over the skull. As a noninvasive technique, the EEG is extensively used in human patients to help in the diagnosis of certain neurological diseases. The initial human EEG studies (in the 1940–1950s) employed trained observers, who performed a visual analysis of the EEG tracings in order to detect and define normal and pathological EEG patterns. Using this technique, Nelson and Dean (1959) have studied 46 malnourished African children and found abnormal EEG discharges in 36% of the cases, localized predominantly at the temporal region, suggesting an enhancement of the cerebral excitability as also observed in human cases of epilepsy. It must be pointed out, however, that although visual examination of the EEG can be useful for qualitative analysis, it always contains an unavoidable subjectivity. Therefore, it is very difficult to adequately analyze quantitative parameters such as frequency and amplitude of the EEG waves by visual inspection (Morgane et al. 1978). This task was later properly achieved in the 1970s by employing computation science techniques, which allowed the use of spectral analysis and fast Fourier transform algorithms to quantify EEG features (see Morgane et al. 1978). This enabled studying the ontogeny of EEG patterns both in children (Schulte and Bell 1973) and in developing laboratory animals (Gramsbergen 1976). In the malnourished rat, the main EEG disturbance was characterized by an increased power in the theta range of frequencies (Morgane et al. 1978; Cintra et al. 2002).

The hypothesis that malnourished humans would be more prone to epilepsy, as compared with well-nourished controls, is supported by some of the above EEG findings. However, studies on this

subject involving human beings are very few and are not yet enough to definitely confirm the causal relationship between malnutrition and proneness to develop epilepsy (Hackett and Iype 2001). The acceptance of this hypothesis in humans requires further extensive investigations, as are already available in laboratory animals. In rats, under conditions of early nutritional imbalance, some brain electrophysiological alterations suggest disturbances in processes related to neural excitability. This includes a lower threshold to experimentally induced seizures (Palencia et al. 1996).

The evidence indicating nutrition-related changes in neural excitability, demonstrated by electrophysiological techniques, prompted us to investigate such changes by using, as a model, the phenomenon known as CSD as a result of brain electrical activity, and this is presented in the next section.

148.3 What is "Cortical Spreading Depression" of Electrical Activity?

In 1944, a young Brazilian PhD student at Harvard University, USA, described a new electrophysiological phenomenon in the anesthetized rabbit brain. The phenomenon was denominated "spreading depression" of the cerebral cortex activity (Leão 1944). Cortical spreading depression (CSD) was then described as being a "wave-like" response, produced as a consequence of electrical, chemical, or mechanical stimulation of one point of the cortical surface. The response consisted in a reduction (depression) of the spontaneous and evoked electrical activity of the stimulated point of the cerebral cortex. From that point, CSD concentrically propagated to remote cortical regions, while the eliciting point started to recover; it is thus a propagating and reversible phenomenon, which was later shown to be accompanied by a reversible negative slow potential change (also called DC-potential change) of the EEG-depressed tissue surface (Leão 1947). This negative slow potential change reaches maximum values after 1–2 min of onset, ranging in the rat from –5 to –20 mV and being completely reverted after a few minutes (Fig. 148.1). It can be measured, with a DC-coupled amplifier, against a remote point that presents an invariant potential, as, for example, the nasal bones. An average recovery time of about 5–10 min are usually required for the depressed cortical area to completely restore the predepression EEG pattern and the baseline DC level. The CSD slow potential change has an "all-or-none" feature, which makes it very useful to calculate the CSD velocity of propagation.

Some important key features of CSD are presented in Table 148.1.

In contrast to the propagation velocity of neuronal action potential (in the order of meters per second), the velocity with which CSD propagates is considerably lower, ranging from 2 to 5 mm/min in all vertebrate species so far studied (Guedes 2005). The remarkably slow CSD propagation velocity is compatible with a humoral mechanism of propagation rather than an ion-based mechanism, as in the action potential. It is widely accepted that CSD propagation would be based on one or more chemical factors that would be released from the neural cells under CSD (Martins-Ferreira et al. 1974). These factors, once in the "extracellular milieu," would "contaminate" the neighbor cells, which would become depressed and would also release the postulated CSD factors, generating a feedback loop that would maintain the CSD propagation in an auto-regenerative mode. A complete knowledge of CSD mechanisms has not yet been achieved, despite a very extensive body of information on CSD phenomenology that has been accumulated during the 65 years elapsed from the time of the initial description of CSD.

Three relevant human diseases are currently postulated to have some relationship to CSD, in terms of sharing at least some common mechanisms: migraine (Eikermann-Haerter et al. 2009; Lehmenkühler et al. 1993), epilepsy (Fabricius et al. 2008; Gorji and Speckmann 2004; Guedes et al. 2009; Leão 1944, 1972), and brain ischemia (Dohmen et al. 2008; Pezzini et al. 2009). This deserves some comments, considering that CSD has already been demonstrated in the human brain (Dohmen et al. 2008; Fabricius et al. 2008; Gorji and Speckmann 2004).
Fig. 148.1 Cycle of reversible electrophysiological events that occur during cortical spreading depression. Sequence of steps (A to F) that characterize the "cortical spreading depression cycle" in the rat cerebral cortex. In A, the normal cortical tissue is stimulated at the point marked with an "x" and one CSD episode is originated at this point. The white circle in B denotes the initially depressed area, from which CSD concentrically propagates to the entire cortex (steps C and D).The black circle in E indicates the area initially recovered after CSD. The recovery process then gradually attains remote areas (step F) and finally the entire cortex comes back to the pre-CSD condition, as in A. The square-lined area represents the post-CSD cortical *refractoriness* before full recovery. The central inset shows the electrocorticogram and the slow potential change of CSD (respectively upper and lower traces). The time-points corresponding to the conditions of the steps A to F are marked in the electrocorticogram with the respective letters]

Experimental evidence suggests that, under normal conditions, the neural tissue presents a certain degree of resistance to CSD propagation (Guedes 2005; Guedes and Do Carmo 1980). This resistance can increase or decrease as a result of experimental treatments, leading the brain to propagate CSD respectively with lower or higher velocities (Guedes 2005). In animals, the calculation of the CSD velocity of propagation along the tissue is an easy and useful way of estimating the brain's susceptibility to CSD. Therefore, animal studies under experimental conditions that either enhance or impair the brain's ability to initiate and propagate CSD may be helpful to understand both the CSD phenomenon and related diseases.

The appearance of epileptiform EEG waves during CSD at the time when spontaneous activity is depressed (Leão 1944; Guedes and Do Carmo 1980) led to the postulation of the "CSD–epilepsy link" (Leão 1944, 1972). The association between CSD and migraine has gained support from studies showing CSD-dependent brain vascular changes (Lehmenkühler et al. 1993), as well as from investigations on genetically modified animals (mouse models of familial hemiplegic migraine) showing genetic and hormonal modulation of CSD (Eikermann-Haerter et al. 2009). Data from

Table 148.1   Key features of relevant aspects of CSD

Aspect	Feature	Remarks
CNS cellular organization	Needs a minimal population of cell bodies for CSD to be generated and propagated	CSD is a "cell population", or "cooperative" phenomenon
Eliciting stimulus	Any kind of sudden energy variation (electrical, chemical, mechanical, etc.)	Eliciting stimulus does not need to be specific
Tissue condition after CSD	The depressed region recovers its electrical activity 5–10 min after depression.	It is a fully reversible phenomenon
Brain functional limits	CSD propagates equally from a sensory to a motor area and vice-versa	No evident relationship with regional functional limits
Phylogenetic aspects	Observed in all animal species so far studied, including the human species	CSD seems to be a very general phenomenon of the CNS
Velocity of propagation	In the order of a few mm/min	A paradoxically very slow propagating phenomenon (mm/min) in a tissue where action potentials propagate very fast (m/s)
Neocortical mammal structure	CSD propagates more easily in lisencephalic than in gyrencephalic brains	Cortical structural organization influences CSD propagation features.
Is CSD a physiological or a pathological phenomenon?	Some CSD features are found in certain neurological diseases	Understanding CSD mechanisms could help in understanding the mechanisms of some neurological diseases.

experimental models of brain ischemia, as well as from human ischemic patients, led also to the postulation of an important role for CSD in the physiopathology of brain ischemic disease (Dohmen et al. 2008; Pezzini et al. 2009). The following physiologic processes have been often postulated as possibly influencing CSD generation and propagation: (1) homeostasis of certain extracellular ions (Guedes and Do Carmo 1980), (2) homeostasis of free radicals produced in the nervous tissue (El-Bachá et al. 1998; Abadie-Guedes et al. 2008), and (3) neurotransmitter-dependent mechanisms (Gorelova et al. 1987; Amâncio-dos-Santos et al. 2006). These are neural processes that can be affected by nutritional and also by non-nutritional factors during brain development.

148.4 Nutritional and Non-nutritional Factors Influencing CSD Propagation

In early malnourished rats (Fig. 148.2), data from our laboratory have demonstrated a facilitation of CSD propagation, as judged by the higher CSD velocities, compared to well-nourished controls.

The maternal protein content of diet seemed to play an important role in determining the CSD effect in offspring: protein supplementation of the maternal diet abolished this effect provided the protein used in the supplementation was of high quality (casein). However, when the deficient diet was supplemented with low-quality protein (of vegetable origin), the CSD effect was not abolished (Andrade et al. 1990).

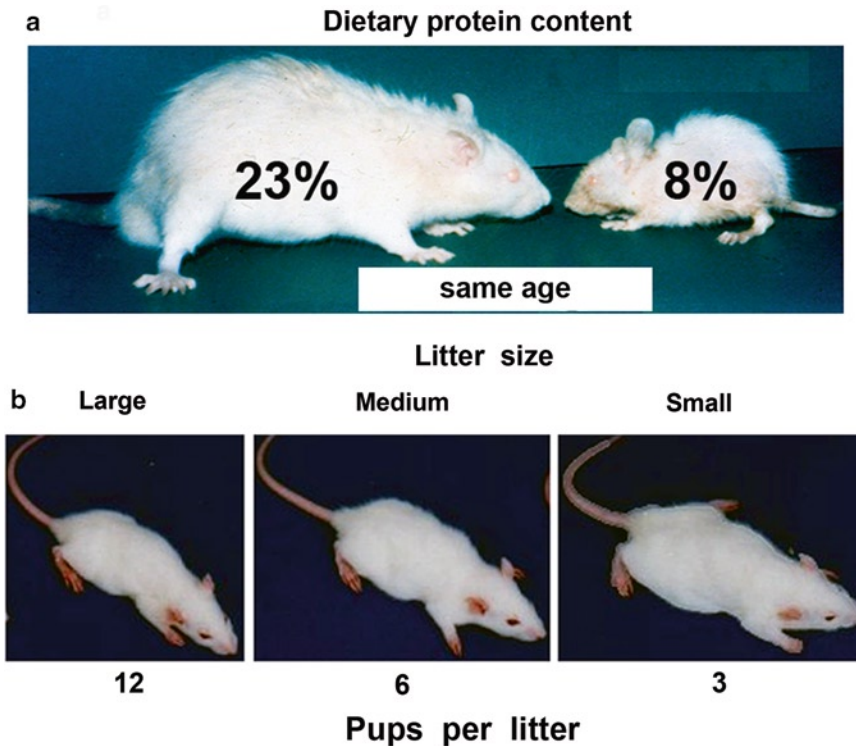
Considering that within the brain growth spurt period, the maximal intensity of various developmental processes (as, for example, neurogenesis, myelination, and gliogenesis) occurs at distinct time-points in different brain areas, we investigated if short episodes of maternal malnutrition, acting


Fig. 148.2 Impact of malnutrition and "overnutrition" on body dimensions. Photographs illustrating the physical aspect of malnourished, normally nourished (control) and "overnourished" rats. In part A, (adult animals) a case of severe malnutrition is confronted with a control rat. In this case, severe malnutrition was provoked by feeding a low-protein diet (containing 8% of protein, instead of the 23% of the control diet) during the whole life. The three young animals in part B (30 days-old) were suckled in litters of different sizes, classified as large, medium, and small-size litters, containing respectively 12, 6, and 3 pups. These three lactation conditions originate pups with moderate-malnutrition (*left*), normal nutrition (*middle*), and with moderate-overnutrition (*right*), respectively. The three pictures of part B were taken under the same magnification. Note the changes in the head size, which indicates alteration in brain size]

at a certain time point within the lactation period, could affect CSD in the progeny. We demonstrated that even a 7-day period of maternal malnutrition within the lactation period was sufficient to significantly enhance CSD propagation in offspring. This effect was shown to be long-lasting, since it was still detected when the pups became adults (Rocha-de-Melo and Guedes 1997). Moreover, the effect was more conspicuous when malnutrition was induced at the late phase of lactation – the third suckling-week, as compared to the groups malnourished in the two earlier weeks (Fig. 148.3), suggesting that with regard to the nutritional effects on CSD propagation, the brain developmental events occurring in this late phase of lactation would have a greater importance.

The mechanism by which early malnutrition results in enhanced CSD incidence and propagation still deserves detailed clarification. In the rat, malnutrition has been shown to reduce brain glutamate uptake (Feoli et al. 2006) and to increase the enzyme glutamic acid decarboxylase (Diaz-Cintra et al. 2007). Both conditions might in all probability increase the brain extracellular glutamate, which would facilitate CSD propagation (Peeters et al. 2007; Tottene et al. 2009).

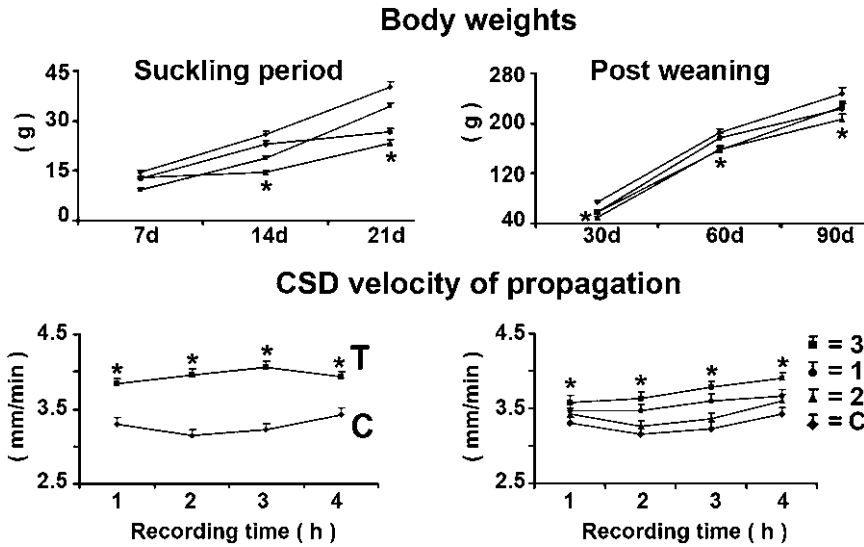
Three malnutrition-induced brain alterations, however, have been considered as probably involved in the CSD effects found in malnourished animals: (1) reduction in the brain myelin content, (2) impairment of glial function, and (3) increase in the cell packing density with reduction of the


Fig. 148.3 Effect of short episodes of early malnutrition on body weight and CSD propagation. Mean ± SEM of body weights (two *upper panels*) and CSD velocities (*lower panel*) of rats suckled by dams fed a low-protein diet (with 8% protein) for a small period (7 days), during the first (*ball-symbol*; $n = 13$), second (*triangle-symbol*; $n = 17$), or third (*square-symbol*; $n = 15$) week of lactation. The control group (C; *diamond-symbol*; $n = 19$) received a standard chow-diet with 23% protein. In the lower-left panel, the T group ($n = 17$) was malnourished during the total lactation period (3 weeks). Note in the lower-right panel the greatest increase in CSD velocity in the group malnourished during the third week of lactation]

extracellular space. Brain myelin has been considered as an obstacle to the humoral propagation of CSD; thus, the less myelin in the brain, the fewer obstacles to CSD propagation (De Luca et al. 1977). Glial impairment has also been demonstrated to facilitate CSD (Largo et al. 1997). Finally, compared with the well-nourished condition, the early-malnourished brain has reduced size and mass, with smaller cells packed in a denser manner and with a reduced extracellular space volume. Since a larger extracellular space volume in the brain hinders CSD elicitation and propagation (Lehmenkühler et al. 1993; Richter et al. 2003), the higher cell packing density and the smaller extracellular space volume, found in the malnourished brain, is thought to favor CSD propagation.

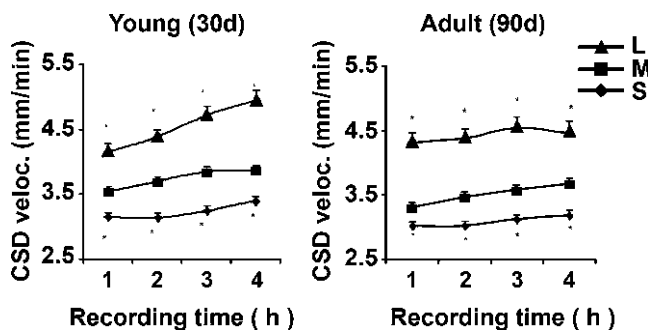
In contrast to malnutrition, the influence of early overnutrition on brain development and function had been almost not investigated at that time (Davidowa et al. 2003), and only a single short report was available concerning the effects of overnutrition on CSD (De Luca et al. 1977). To address this issue, we then used a simple and interesting method to positively influence the nutritional status of the pups during the lactation period. This method consists in diminishing the litter-size (i.e., reducing the number of pups to be suckled by a single dam), and inducing in the newborns a moderate degree of overnutrition (Davidowa et al. 2003). Considering that early malnutrition had facilitated CSD (Rocha-de-Melo and Guedes 1997), we hypothesized that the brain developmental influence of the favorable lactation condition (pups reared in small litters, with only three pups) on the CSD would be to impair CSD propagation, as compared to the control-size litter (six pups). By the same logic, the prediction was made that rat-pups suckled in litters much larger than the controls (litters with 12 pups instead of 6 as in the control) would display higher CSD propagation velocities, as this suckling condition induces a moderate degree of malnutrition; this has indeed been demonstrated (Rocha-de-Melo et al. 2006), and is here illustrated in Fig. 148.4.


Fig. 148.4 CSD effect of suckling rat-pups in litters of different sizes. Mean ± SEM CSD velocities of propagation in the cortical surface of young (30 days old; *left panel*; $n = 54$) and adult rats (90 days old; *right panel*; $n = 48$) that have been reared, during the suckling period, in large (L; $n = 21$ and 13 rats for the 30-day and 90-day old groups, respectively), medium (M; $n = 18$ and 17 rats) and small litters (S; $n = 15$ and 18 rats). The L, M, and S litters were composed respectively by 12, 6, and 3 pups. The asterisks indicate that the extreme groups (L and S) display CSD velocities of propagation significantly different from the age-matched control (M) group

Another interesting set of results came from testing how certain molecules of metabolic importance for the brain, like glucose, or pharmacological compounds with unequivocal effectiveness in influencing brain function, like the GABAergic compound diazepam, could influence CSD propagation, and how malnutrition would interfere with this possible effect. Data indicated that hyperglycemia reduces whereas diazepam and insulin-induced hypoglycemia facilitates CSD propagation. However, those effects were not found in rats that were previously malnourished (Guedes et al. 1992; Ximenes-da-Silva and Guedes 1991). In contrast, two other drugs that have an impairing action on CSD, the selective serotonin reuptake inhibitor fluoxetine and the cholinergic agonist pilocarpine produced in the malnourished brain respectively a more intense (Vasconcelos et al. 2004) and an equal (Amâncio-dos-Santos et al. 2006) CSD effect as compared to the well-nourished brain. Taken together, these experimental data suggest that malnutrition-induced changes in the brain responsiveness to pharmacological agents may vary depending on the neurotransmitter system under investigation. Concerning CSD, it appears for instance that, in contrast to the serotoninergic system, the responsiveness of the GABAergic and cholinergic systems were respectively decreased and increased by the nutritional deficiency imposed early in life on the malnourished rats. This raises some concerns, regarding the human use of therapeutical drugs acting specifically on a certain neurotransmitter system: if the above-described experimental observations were also to reflect what happens in the human brain, then this would imply that different classes of therapeutically employed drugs (as, for example, anti-epileptics and anti-migraine drugs) could present distinct degrees of effectiveness, eventually depending on the early nutritional condition of the patients. The medical implication would be a strong recommendation for the clinical investigation of this possibility in the human being.

Besides nutritional and the pharmacological variables, other clinically important hormonal and environmental factors have also been studied in several laboratories including ours regarding their significant influence on the brain's ability to generate and propagate CSD. Some of these factors were found to enhance CSD propagation, whereas some others impaired it. Conditions such as extracellular ionic alterations (Guedes and Do Carmo 1980), deprivation of REM sleep (Guedes and Vasconcelos 2008; Vasconcelos et al. 2004), ethanol consumption (Bezerra et al. 2005; Abadie-Guedes et al. 2008), treatment with gliotoxic drugs (Largo et al. 1997), genetic "knockin" manipulation in mice (insertion of the human hemiplegic familiar migraine gene; Eikermann-Haerter et al. 2009), and toxic and autoimmune induced cortical demyelination (Merkler et al. 2009) are some of the studied situations which enhance the CSD phenomenon. A summary of the studied conditions that enhance CSD is presented in Table 148.2.

Table 148.2 Experimental studies under some clinically important conditions that enhance CSD propagation. Pertinent bibliography is also provided

Conditions That Facilitate CSD

Animal	Reference	Condition	Effect
Rabbit	Guedes and Do Carmo (1980)	Low extracellular chloride (by gastric washing with distilled water)	Increased CSD propagation and EEG epileptiform activity; appearance of a second SD in the opposite hemisphere
Rat	Rocha-de-Melo et al. (2006)	Malnutrition early in life	CSD velocities higher than in well-nourished controls
Rat	Guedes and Vasconcelos (2008)	Deprivation of REM sleep (water-tank technique)	Increased CSD velocities, as compared with nondeprived or pseudodeprived controls.
Rat	Costa-Cruz and Guedes (2001)	Hypoglycemia [by (1) insulin or (2) food restriction + insulin]	CSD velocities higher than in normoglycemic rats
Rat	Guedes et al. (1992)	Increase of the GABAergic activity by diazepam	Higher CSD velocities after diazepam as compared with predrug values
Rat	Bezerra et al. (2005)	Administration of ethanol per gavage	Ethanol facilitated CSD as compared to water-treated or naïve controls.
Rat	El-Bachá et al. (1998)	Dietary deprivation of antioxidant vitamins	Higher CSD velocities; increased CSD-eliciting action of photoactivated riboflavin
Rat	Maia et al (2009)	Early in life treatment with l-arginine, per gavage	L-Arginine facilitates CSD as compared to water-treated or naïve controls.
Rat	Farias-Santos et al. (2009)	Daily sessions of heat exposure early in life	Increase in CSD propagation as compared to controls
Rat	Largo et al. (1997)	Treatment with the gliotoxic drug fluorocitrate	Glial impairment increased CSD propagation
Rat	Fregni et al. (2005)	1 and 20 Hz cortical electrical stimulation, 2x/d, for 2 days	Increase of CSD propagation measured 1 and 15 days after electrical stimulation.
Mouse	Eikermann-Haerter et al. (2009)	Genetic ("knockin") manipulation inserting the hemiplegic familiar migraine gene	Increased SD frequency and propagation speed; enhanced corticostriatal propagation
Mouse	Merkler et al. (2009)	Hypomyelination by dietary treatment with cuprizone	Accelerated CSD propagation, reverted after switching mice to the normal diet
Rat	Tenorio et al. (2009)	Unilateral early vibrissae removal	Facilitation of CSD propagation in well-nourished and malnourished rats.

CSD impairment has also been found in animals submitted to propylthiouracil-induced hypothyroidism (Guedes and Pereira-da-Silva 1993), aging (Guedes et al. 1996), peripheral electrical (Monte-Silva et al. 2007) or environmental stimulation (Santos-Monteiro et al. 2000), antioxidants (Bezerra et al. 2005; Abadie-Guedes et al. 2008), hypermyelination, (Merkler et al. 2009), and genetical proneness to audiogenic epilepsy (Guedes et al. 2009), among other conditions (Table 148.3).

148.5 Applications to Other Areas of Health and Disease

As an "excitable tissue," one of the main physiological properties of the nervous system is that it is capable of generating electrical activity and, through this activity, to execute its normal actions, including the highly complex ones. This is the main reason for using electrophysiologically based

Table 148.3 Conditions of clinical relevance, which have been shown to impair CSD propagation. For detailed information, bibliographic reference is provided

Conditions That Antagonize CSD			
Animal	Reference	Condition	Effect
Rat	Guedes et al. (1989)	Dietary treatment with lithium	Lower CSD velocities compared with controls
Rat	Costa-Cruz and Guedes (2001); Costa-Cruz et al., (2006)	Hyperglycemia (acute and chronic)	Lower CSD velocities compared with controls
Rat	Guedes and Barreto (1992)	Anesthetics	Lower CSD velocities under anesthesia, compared to waking state in the same rat.
Rat	Guedes and Pereira-da-Silva (1993)	Early hypothyroidism (by PTU)	Reduced CSD velocities in PTU-treated rats, compared with saline-treated controls
Gerbil and Rat	Guedes et al. (1996)	Aging	Inverse correlation between age and CSD velocity that is reduced by dietary antioxidant vitamin deficiency
Rat	Santos-Monteiro et al. (2000);Monte-Silva et al (2007)	Early peripheral electrical or environmental stimulation	Reduced CSD velocities compared with nonstimulated controls
Gerbil and Rat	Guedes et al. (1987)	Treatment with the opioid antagonist naloxone	Naloxone antagonizes CSD incidence and propagation
Rat	Guedes et al. (1988)	Topical cortical application of excitatory amino acid antagonists	MK-801 antagonizes CSD propagation.
Rat	Guedes et al. (2002); Amâncio-dos-Santos et al. (2006)	Pharmacological increase of brain serotonin activity	D-Fenfluramine, citalopram, and fluoxetine antagonize CSD propagation
Rat	Guedes and Cavalheiro (1997); Guedes and Vasconcelos (2008)	Single injection of convulsing and subconvulsing dose of pilocarpine	Dose-dependent blocking of CSD propagation.
Rat	Bezerra et al. (2005); Abadie-Guedes et al. (2008)	Treatment with antioxidants, per gavage	Both shrimp carotenoids and pure astaxanthin reduce CSD propagation in ethanol-treated rats.
Mouse	Merkler et al. (2009)	Hypermyelination (transgenic mice)	Lower CSD velocities in the hypermyelinated mice, compared to the wildtype controls
Rat	Guedes et al. (2009)	Genetically prone to audiogenic epilepsy	Gender-dependent impairment of CSD

animal models such as the present one that utilizes the CSD phenomenon in order to get information on normal brain function. These models could also help us to understand how the brain's physiology is altered under nutritional and non-nutritional conditions like those discussed here. In this chapter, we have presented CSD electrophysiological data from both laboratory animals and humans, documenting the importance and usefulness of this phenomenon in studying the nervous system. In the rat, brain structural and functional maturation is programmed to occur mostly during the lactation period. The malnutrition-induced brain alterations during this period probably resulted from the decreased number and/or size of cell elements, as well as from alterations in the events that cause neuronal maturation. Processes such as cell migration, dendrite development, synapse formation, and

myelination are certainly implicated in the neurophysiological alterations found when malnutrition occurs early in life (Morgane et al. 1978). This period of intense formation of synapses can be considered equivalent to the human synaptogenic stage, which starts at the third trimester of prenatal development and continues during the first year of child life (Morgane et al. 1978). The well-grounded extrapolation of data from one species (rat) to the other (humans) is a task that, despite some attempts, still needs to be further achieved and the increasing use of the here-described models and techniques is strongly desirable, as a supporting means to clarify the relationship between diet, nutrition, and neural development and function.

In the current world scenario of nutritional transition, experienced by a considerable part of the human population, it can be concluded that the electrophysiological analysis of CSD features constitutes a valuable experimental instrument to investigate the functional brain effects of different unfavorable nutritional as well as non-nutritional conditions that are often stressing and energy-demanding for the developing brain.

Since all the factors presented above in the Tables 148.2 and 148.3 are of clinical relevance, and also considering that they are known to affect the mammalian brain development and function, it is reasonable to assume that knowing the mechanisms by which they affect CSD propagation may shed light on the role of such factors in important human diseases, such as ischemia, migraine, and epilepsy. Furthermore, the complete understanding of CSD generation and propagation mechanisms might be very helpful in developing better treatment of those human neurological diseases.

Summary Points

- The malnourished organism suffers developmental and physiological alterations consequent to insufficient food intake during a certain period of its life. Depending on the intensity and duration of malnutrition, the physiological alterations can become permanent, usually with *neurological disturbances* involving sensory-motor activity, learning, memory, consciousness, cognition and emotion.
- Some data suggest that *malnourished humans would have higher propensity to epilepsy*, as compared with well-nourished controls, but further studies are needed to definitely confirm the causal relationship between malnutrition and proneness to develop the epileptic phenomenon.
- Animal studies under conditions that either enhance or impair the brain ability to initiate and propagate "Cortical Spreading Depression" (CSD) are helpful to understand both the CSD phenomenon and the human neurological diseases related to them, such as brain ischemia, migraine, and epilepsy.
- Besides malnutrition, *excessive food intake* early in life also affects the brain's ability to produce and propagate cortical spreading depression. This raises some concerns about the *impact of obesity on brain development and function*.
- If the findings in laboratory animals reflect what happens in the human brain, then this would imply that different classes of therapeutically employed drugs (as, for example, anti-epileptics and anti-migraine drugs) could present distinct degrees of effectiveness depending on the early nutritional condition of the patients.

Definitions and Explanations of Key Terms

Nutritional transition: It is the expression used to define the current epidemiological situation of a great part of the human population, mainly in developing countries. This epidemiological situation comprises an increasing human contingent with obesity, associated to a decreasing number of malnourished persons *in the same population.*

Electroencephalogram (EEG): It is the recording of the spontaneous brain electrical activity that all living mammals present, even when they sleep. This activity can be electronically recorded in chart-paper, ink-writer machines, or digitally in computer-based devices.

Epilepsy: It is a neurological disease resulting from an exacerbated and uncontrolled activity of a certain neuronal population in the brain. The main clinical signs of a generalized epileptic seizure are loss of consciousness and exacerbated and uncontrolled muscle contractions (motor seizure).

Cortical spreading depression (CSD): It is a reversible brain phenomenon provoked by an adequate stimulation of a point of the brain tissue. Current knowledge of the phenomenon leads to the postulation of a link between CSD and human neurological diseases like epilepsy, migraine, and brain ischemia.

Fast Fourier Transform: It is a mathematical technique that employs an algorithm to decompose a sequence of values into components of different frequencies. It is used to decompose the "spectrum of EEG-waves" into its distinct component frequencies, enabling the detection of nutrition-related alterations in one or more of such frequencies.

Extracellular milieu: It is the environment outside the cells. This environment is occupied by the extracellular fluid, the composition of which includes metabolites, ions, proteins, and many other substances that might affect cellular function. These substances are provided by the foods that we daily eat.

GABAergic compound: It is a substance that favors, promotes, or facilitates action, in the neurons or glial cells, of the neurotransmitter gamma-amino butyric acid (GABA). This neurotransmitter is believed to be inhibitory in the mammalian central nervous system.

Knockin mouse: It is a genetically modified animal, in the genome of which a gene has been inserted. The animal then expresses the characteristics coded by that gene (for example, a certain disease). The opposite genetic manipulation (deletion of a gene) originates the "knockout" mouse.

Chapter 149
Dietary Zinc and the Brain

Mohammad Tariqur Rahman

Abbreviations

AD	Alzheimer's disease
AMPA	α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid
ATP/ADP	Adenosine tri/di phosphate
BBB	Blood brain barrier
CSF	Cerebrospinal fluid
CNS	Central nervous system
ECF	Extracellular fluid
ER	Endoplasmic reticulum
MAPK	Mitogen activated protein kinase
MT	Metallothionein
RDA	Recommended daily allowance
UIL	Upper intake level
VGCC	Voltage-gated Ca^{2+} channels
(S)VZ	(Sub)Ventricular zone
ZIP	Zn^{2+} importing proteins
[Zn]	Concentration of Zn
ZnT	Zn transporter

149.1 Introduction

The physiological importance of zinc (Zn) was first recognized in 1940 when the Zn-containing enzyme, carbonic anhydrase, was described (Keilin and Mann 1940). Eventually, Zn was recognized as an 'essential' trace element found widely distributed in all human organs and tissues and required for the structure and functions of many cellular proteins (Table 149.1). Today, the importance of Zn in human health is well documented (Frederickson et al. 2005; Maret and Sandstead 2008). In the brain, Zn plays important roles both in its development and function.

Table 149.1 Key facts on zinc

Chemistry and physical properties

- Discovery: German chemist Andreas Sigismund Marggraf (1746) is normally given credit for discovering pure metallic Zn.
- Avaialability: the 24th most abundant element on the Earth's crust
- Empirical formula: Zn
- Position in the periodic table: 1st element in group 12
- Number of stable isotopes: five
- Atomic number: 30
- Atomic weight: 65.39 g

Uses

- Zinc plating for corrosion-resistance (e.g. on steel).
- Zinc alloys such as brass (alloy of zinc and copper) is used in batteries.
- Zinc chloride in deodorants
- Zinc pyrithione in shampoos
- Zinc sulfide in luminescent paints
- Zinc-carbonate, Zn-gluconate as dietary supplements

Biological importance

- Considered an essential mineral
- Structural component of many enzymes such as alcohol dehydrogenase in humans or other biomolecules important in cellular and molecular processes such as Zn finger transcription factors.
- Half of the total body's Zn is present in muscle. Other major organs of the body that contain zn includes bones, skin, kidneys, testes, and prostate glands
- Zinc deficiency causes growth retardation, delayed sexual maturation, infection susceptibility, and diarrhea, etc.
- Zinc excess is associated with ataxia, lethargy, and copper and iron deficiency.

This table includes the key facts on Zn including its chemical properties, uses, and biological importance

Zinc metalloproteins are the major (~80%) reservoir of the total brain Zn while the rest is free Zn^{2+} and are histochemically detectable by Timm's sulfide-silver staining method (Frederickson and Danscher 1990). In the brain, Zn is relatively concentrated in the hippocampus and amygdala (Takeda et al. 2004). Both regions are enriched with histochemically reactive Zn^{2+} which predominantly exists in the presynaptic vesicles. Zinc homeostasis in the brain is maintained by the blood brain barrier system and is not easily disrupted by dietary Zn deficiency. Nevertheless, histochemically detectable Zn in hippocampus are susceptible to dietary Zn deficiency.

Most of the cells in the human body including neuron maintain Zn homeostasis through the regulated expression of proteins for Zn- import, export, and sequestration. Specific Zn transporters are used in certain tissues and their expression may vary with dietary Zn status and time (Dufner-Beattie et al. 2003; Kelleher and Lonnerdal 2003). Thus Zn homeostatic mechanisms appear to be tissue specific.The mechanism of exact regulation of Zn uptake from extracellular fluids (ECF) into neurons and glial cells, however, is not completely known.

Large numbers of the world's population, an estimated total of about 50%, are at risk of Zn deficiency (Brown et al. 2001). Zinc deficiency in children is a nutritional and health concern in both developing and developed countries (Black 1998; Bryan et al. 2004). Zinc deficiency results in decrease in extracellular [Zn] in the hippocampus which subsequently causes abnormal glucocorticoid secretion from the adrenal cortex. As the hippocampus is enriched with glucocorticoid receptors, the abnormal glucocorticoid secretion alters its function. Abnormal glucocorticoid secretion in Zn deficiency is associated with neuropsychological symptoms affecting cognitive performance and aggravated glutamate excitotoxicity. The decrease in Zn^{2+} pool in the peripheral tissue in Zn deficiency can also change glucocorticoid action by triggering abnormal glucocorticoid secretion.

   Alterations in Zn homeostasis in the brain is observed in Parkinson's and Alzheimer's disease (AD) as well as in transient forebrain ischemia, seizures, and traumatic brain injury. There is much evidence to show that amyloid-beta deposition in AD is induced by Zn (see review Mocchegiani et al. 2005). An elevated concentration of Zn or an excess of Zn in the brain might play a role in such pathological conditions. Indeed the exact neuropathological mechanism of either the elevated level of Zn^{2+} or its deficiency has not been completely resolved (Colvin et al. 2003; Sensi et al. 2009).

   This chapter will elaborate on the physiological importance of dietary Zn in the brain. Emphasis will be given to the mechanism of Zn homeostasis, the role of dietary Zn in brain development, and the consequences of Zn excess and/or Zn deficiency in brain pathology.

149.2 Dietary Sources of Zn and Its Bioavailability

The richest food sources of Zn (Table 149.2) are sea foods (shellfish, shrimp, lobster, crab-meat), organs and flesh of mammals and fowls (liver, meat), whole grain cereals, and some beans (Brown and Begin 1993). The total Zn content of the diet and its bioavailability, solubility in particular, in the intestinal lumen determines the amount of Zn absorbed and which can be utilized or metabolized in different organs. This also is influenced by the chemical form of Zn and the presence or absence of specific enhancers or inhibitors of Zn absorption. Amino acids such as cysteine and histidine can increase the solubility of Zn. However, some proteins such as casein have an inhibitory effect on Zn absorption. Myoinositol hexaphosphate (phytate) reduces Zn bioavailability (Soto-Quintana et al. 2003), and therefore oils, fats, and sugar are not considered good sources of Zn. Meal proteins have a positive effect on Zn absorption. In humans without excessive intake of Zn, the body burden half-time of absorbed Zn has been observed in the range between 162–500 days. After parenteral administration, half-times of Zn may vary within the range of about 100–500 days (see review Lowe et al. 2009). In spite of its great importance in human health, the amount of zinc in the diet, however, needs to be maintained properly (Table 149.3).

149.3 Blood Brain Barrier and Permeability of Zn in Brain

Both the supply of the required nutrients for proper functioning of the brain and the control of harmful substances present in the bloodstream so as to prevent them from entering the brain are done by the specialized system of capillary endothelial cells of the blood brain barrier (BBB). The transport

Table 149.2 Zinc in human diet (From Brown and Begin 1993)

Category of foods	Example of edibles
Major dietary source of Zn	
Sea foods	flesh of shellfish, shrimp, lobster, crab
Organs and flesh of mammals and fowls	liver, meat, or muscle
Whole grain cereals, vegetables	chickpeas, kidney beans, almonds
Dairy products	yogurt, milk, cheese
Inhibitors of Zn absorption	Casein
Protein	Plant oil
Oils or fats	Sugar
Carbohydrate	

Zinc is available in various food and food products. This table includes a partial list of the dietary sources of Zn. The amount of Zn, however, may vary depending on type and species

Table 149.3 Recommended daily allowance (RDA) and upper intake levels (UIL) for human Zn consumption (From Institute of Medicine, Food and Nutrition Board. Washington, DC: National Academy Press, 2001)

Age	For male RDA/UIL	For female RDA/UIL	In pregnancy RDA/UIL	During lactation RDA/UIL
0–6 months	2 mg/4 mg	2 mg/4 mg		
7–12 months	3 mg/5 mg	3 mg/5 mg		
1–3 years	3 mg/7 mg	3 mg/7 mg		
4–8 years	5 mg/12 mg	5 mg/12 mg		
9–13 years	8 mg/23 mg	8 mg/23 mg		
14-18 years	11 mg/34 mg	9 mg/34 mg	13 mg/34 mg	14 mg/34 mg
19+ years	11 mg/40 mg	8 mg/40 mg	11 mg/40 mg	12 mg/40 mg

Both the recommended amount of dietary Zn or Zn supplement and upper tolerable levels vary depending on age, gender, or stage of growth and development. This table includes the amount of Zn recommended for daily consumption and the maximum or upper tolerable limit (UIL) for different ages or conditions to maintain optimum health
Fig. 149.1 The blood-brain barrier controls the exchange of ions including zinc, amino acids, peptides, and other substances between blood and brain. At the brain blood capillaries, the endothelium cells (i) are joined together at their edges by tight junctions (ii),which prevent water-soluble substances in the blood to enter the CSF. Most of the areas of the blood capillaries are enclosed by the astrocyte's "end-feet" (iii). Thus water-soluble substances can cross the BBB by passing directly through the walls of the cerebral capillaries made up of a lipid/protein bilayer. Fat-soluble molecules, including O_2 and CO_2, anesthetics and alcohol can pass straight through the lipids in the capillary walls (iv). Ions and amino acids can pass through using carrier proteins such as zinc import proteins (v), ion channels or pumps (vi) (Modified from Springer Image library accessed on 01 January, 2010 from http://www.springerimages.com/Images/Pharmacy/1-10.1208_s12248-008-9018-7-0)

of Zn into the brain parenchyma occurs via the BBB system (Kahn 2005). Entry of Zn into the brain is allowed through different kinds of proteins and channels on the BBB (Fig. 149.1). In other words the BBB system provides a strict regulation on Zn homeostasis in the brain and is not easily disrupted by dietary Zn (Franklin et al. 1992).

The presence of specific Zn transport sites on the brain capillary endothelial cells (Buxani-Rice et al. 1994) confirms the important regulatory role of the BBB in brain Zn homeostasis. The BBB-mediated control of Zn homeostasis in the brain is also supported by the enhanced transport of Zn across the BBB, as shown by an in vitro model of the BBB that was exposed to Zn-deficient conditions. The rate of Zn transport across the in vitro BBB model constructed using cultured porcine brain

capillary endothelial cells on porous membrane was observed to be slower when [Zn] was below 7 μmol/L and faster when it was above 30 μmol zinc/L (Lehmann et al. 2002). Notably, the zinc transport process is highly selective for Zn since none of the analogous minerals could effectively compete with zinc; besides, the zinc transfer process does not require much energy. Furthermore, metabolic inhibitors also do not influence the transport rate (Bobilya et al. 2008).

In order to maintain Zn homeostasis, brain capillary endothelial cells respond to changes in Zn status, increasing the uptake of Zn in the presence of low [Zn] in the blood and decreasing it in the presence of high [Zn] in the blood (Lehmann et al. 2002). Following its uptake, Zn can be transferred freely through the CSF and the brain ECF compartments. The reduced amount of histochemically reactive Zn in Zn deficiency suggests its reduced uptake in Zn deficiency (Takeda 2001).

149.4 Homeostasis of Zn in the Brain and Dietary Influence

The variation in the amount of Zn in different regions of the mammalian central nervous system (CNS) varies over about a fivefold range, with lower amounts generally in white matter (26–40 ppm in cortical white matter) and higher amounts in grey matter (60–90 ppm in cortical grey matter). On an average, the estimated amount of Zn in one gram of wet brain tissue is about 10μg corresponding to an average total intracellular [Zn] of about 150μM. This concentration is about 10-fold more than the serum [Zn]. On the regional distribution within the brain, the estimated total [Zn] in the hippocampus is more than 200 μM (see review Takeda and Tamano 2009), considered the highest compared to any other region (Frederickson et al. 2005). Notably, hippocampal [Zn] can be decreased significantly in dietary Zn deficiency. Among the other regions, the amygdala and neocortex contain the highest amount of Zn (Fig. 149.2).

In the ECF of the brain, Zn is either bound to low molecular weight ligands such as metalloproteins, or stay as free Zn^{2+} (see review Takeda and Tamano 2009). In the ECF, the estimated total [Zn] and
Fig. 149.2 Human brain-zinc map. The hippocampus belongs to the limbic system containing the highest concentration of zinc in the brain (*dark black area*). Other regions of the brain that contain relatively higher amount of Zn is the amygdala (*dark black area*) and grey matter neocortex (*black dotted area*)

free [Zn^{2+}] are 0.15–1 μM (Hershey et al. 1983; Weiss et al. 2000) and ~5–20 μM (Frederickson et al. 2006) respectively. About 80% of the total brain Zn is bound with Zn metalloproteins while the rest is histochemically detectable using Timm's sulfide-silver staining method (Frederickson and Danscher 1990). This is based on the observation that the removal of Zn transporter protein results in a 20% reduction of the total amount of Zn in the brain (Cole et al. 1999).

Within the brain, both the extracellualr and intracellular Zn are exchangeble. Extracellular Zn^{2+} in the brain may change because of its release from cells (Frederickson 1989; Qian and Noebels 2005), while changes in intracellular Zn^{2+} may result from oxidative stress (Frazzini et al. 2006). The concentration of rapidly exchangeable cytosolic free Zn^{2+} is estimated in the subnanomolar level. Such dynamic changes in Zn^{2+} gradients and the availability of specific Zn^{2+} binding domains suggest the importance of Zn^{2+} ions as signaling molecules. However, the signaling effects of Zn^{2+} may be mediated by intracellular or extracellular Zn^{2+} (Sensi et al. 1997).

In Zn deficiency, the level of serum Zn decreases which in turn leads to a decrease in CSF Zn. Although one week of Zn deprivation in young rats can decrease serum Zn level about 50% compared to control animals, a significant change (decrease) in extracellular Zn in the hippocampus is observed only after 4 weeks of Zn deprivation. Histochemically reactive Zn (Timm's stain) also decreases after 4 weeks of Zn deprivation. Thus only a prolonged period of Zn deficiency (4 weeks in contrast to 1 week) can cause a decrease in hippocampal Zn. Notably, extracellular Zn may lead to the decrease in histochemically reactive Zn. Extracellular Zn is also responsive to dietary Zn deficiency in other regions such as the amygdala, followed by a decrease in histochemically reactive Zn (Takeda and Tamano 2009).

The protein-bound Zn in intracellular compartments of the brain, on the other hand, may be resistant to Zn deficiency. It is possible that the response of hippocampal Zn to dietary Zn deficiency reflects that of peripheral Zn since the decrease in serum Zn may lead to the reduction of Zn^{2+} pool in peripheral tissues. It is possible that insufficient Zn^{2+} signaling in peripheral tissues is associated with activation of the hypothalamo-pituitary-adrenocortical system in Zn deficiency (Takeda and Tamano 2009).

149.5 Transport and Homeostasis of Zn in Neuron and Dietary Influence

Cells in different parts of the brain have different amounts of Zn which in turn contributes to the variable amount of Zn in different brain areas. The free [Zn^{2+}] in the cytosol from cultured neurons is estimated at subnanomolar (Weiss et al. 2000). However, Zn content in the synaptic vesicles of some neurons in the forebrain is found to be approximately >1 mM (Frederickson et al. 2005). Although intraneuronal cytosolic Zn^{2+} is in the subnanomolar or picomolar range, it is estimated to rise to micromolar levels in the proximity of axon terminals following release from synaptic vesicles that contain Zn^{2+} at millimolar range (Frederickson et al. 2005). This is most likely also the case in other intracellular compartments such as mitochondria, vesicles, and lysosomes that can take up cytosolic Zn^{2+} (Sensi et al. 2003; Colvin et al. 2006; Hwang et al. 2008; Dittmer et al. 2009).

Neurons that contain free Zn^{2+} in the vesicles of their presynaptic boutons are present both in forebrain areas (such as hippocampus, amygdala, and neocortex) and other areas of the brain (Fig. 149.2). Those neurons in the forebrain area are a subgroup of excitatory glutamatergic (or gluzinergic) neurons and in other areas they are termed Zn-enriched neurons (Frederickson and Danscher et al. 1990). Since the distribution of these neurons within the brain is not uniform, Zn distribution in the brain is also not uniform.

The exact mechanism that regulates Zn uptake from the ECF into neurons and glial cells is still not completely known. Most of the cells maintain Zn homeostasis through the regulated expression of proteins for Zn import, export, and sequestration (Table 149.4). Furthermore, Zn homeostatic

Table 149.4 Zn^{2+} transport and storage in neurons

Zn transporter(s) or storage protein	Important features
VGCCs and Ca^{2+}/Zn^{2+}-permeable AMPA receptors	Located at the plasma membrane the main routes Zn^{2+} entry into neurons
ZnT1	Located at the plasma membrane controls Zn^{2+} efflux interacts with the L-type VGCC that regulates Ca^{2+} and Zn^{2+} influx.
ZnT3	Located at the synaptic vesicles
ZnT5, ZnT6, ZnT7	Located at the golgi apparatus
ZnT5, ZnT6, ZnT7	Located at the lysozome
The Na^s/Zn^{2+} exchanger	Moves Zn^{2+} in or out of neurons depending on the Na^+ gradient
ZIP	H^+- or HCO_3-Zn^{2+} co-transporters and facilitates Zn^{2+} influx.
Ca^{2+} uniporter	Located at mitochondria
MT (MT-III)	Major Zn^{2+}-homeostatic proteins in neurons

AMPA, α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid; MT, metallothionein VGCCs, voltage-gated Ca^{2+} channels; ZIP, Zinc importing protein
This table summarizes the list of major zinc transporters involved in supply and homeostasis of zinc in neurons (for detail see Ohana et al. 2009)

mechanisms appear to be tissue specific. Specific Zn transporters are used in certain tissues and its expression varies with dietary Zn status and time (Dufner-Beattie et al. 2003; Kelleher and Lonnerdal 2003). A number of Zn^{2+} transporters (ZnTs), Zn^{2+}-importing proteins (ZIPs), and buffering proteins such as the metallothioneins (MT) bind cytosolic Zn^{2+} and mediate the complex intraneuronal cytosolic Zn^{2+} homeostasis. In addition, specific gated Zn-permeable membrane-spanning channels, such as voltage-gated L-type Ca^{2+} channels, Na^+/Zn^{2+} exchangers, N-methyl-D-aspartate (NMDA) receptor gated channels, and Ca^{2+} permeable AMPA/kainate channels can also mediate the neuronal uptake of Zn. Zinc transporter proteins too regulate the efflux of Zn from neurons as well as vesicular Zn uptake. Transporters of the Zip family, which are the main membrane Zn uptake transporters, also seem to be involved in this process (reviewed in Ohana et al. 2009).

ZnTs mediate Zn^{2+} transport from the cytosol to the lumen of intracellular organelles or out of the cell. There are at least ten members of the ZnT family, most of which are ubiquitously expressed, except ZnT3 which is neuron specific and present on synaptic glutamatergic vesicles. With the exception of ZnT1, ZnTs are present on intracellular organelles such as the Golgi and the secretory vesicles of many organs (Table 149.4). Zinc Transporter 1 is expressed, synaptically and extrasynaptically, on the plasma membrane of neurons and glia. Other ZnT family members, ZnT2, ZnT4, ZnT5, and ZnT6, are also expressed in several brain regions (reviewed in Sensi et al. 2009) such as in the hippocampus, cortex, and olfactory bulb (Lee et al. 2003), and in certain cerebellar GABAergic and dopaminergic neurons (Ruiz et al. 2004). Zin Transporter 7, which probably facilitates Zn^{2+} transport from the cytoplasm into the Golgi apparatus, is moderately expressed in the brain and ZnT2, ZnT5, and ZnT6, which are associated with vesicular Zn uptake and Zn efflux in many organs, should similarly play a minor role in the brain.

149.6 Biochemistry of Zn Binding with Proteins in Brain

The knowledge of the biochemical importance of Zn dates back to 1940 with the discovery of the Zn-containing enzyme, *carbonic anhydrase*, now known to contain 1 gram atom of the metal per mole (Keilin and Mann1940). Subsequently, more than 300 such Zn containing proteins with catalytic,

structural, and other functional roles have been described. This number is more than that of any other transition or Group IIB metal (Vallee and Falchuk 1993) that is involved in biomolecules. Specific binding sites for Zn^{2+} are present on numerous proteins, including Zn^{2+} fingers on transcription factors that bind it with high affinity, and metallothioneins, from which the Zn^{2+} is easily dissociable.

Zinc binds to many proteins involved in gene regulation. The Zn finger proteins as transcription factor, Zn twists in steroid receptors, and Zn clusters in the galactose metabolism activator are well known examples. Other metalloproteins tightly binding Zn include the RING finger protein family (Freemont 1993), the tumour suppressor p53, the human growth hormone-prolactin receptor complex, and metallothionein proteins (Ebadi 1986; Vallee and Falchuk 1993). Zinc also stabilizes the 3D structure of superoxide dismutase (Salguerio et al. 2007). A partial list of Zn finger transcription factors present in different areas and types of cells in the brain is given in Table 149.5. In the brain, Zn is structurally important for reelin, a large secreted protein, implicated in the cortical development of the mammalian brain. A 2.0-Å crystal structure from the fifth and sixth reelin repeats fragment revealed the presence of Zn^{2+} bound to them (Yasui et al. 2007).

The biochemical importance of Zn lies in its role as catalytic, coactive (or co-catalytic), structural (Vallee and Falchuk 1993; MacDonald 2000), and intracellular signaling factor such as the regulation of

Table 149.5 Zinc finger transcription factors in the brain

Transcription factor	Expression site and/or function
ATBF1	• Protein is highly expressed in the midbrain and diencephalon • mRNA is highly expressed in the brainstem, mostly in embryo and neonatal brain, postmitotic neurons in the brainstem • Expression is transient and weak in the precursor cells at early neurogenesis. • Expression decreases postnatally, but remains in mature neurons • Regulation of neuronal cell maturation or region-specific central nervous system differentiation
Bcl11A/Evi9/CTIP1	• Bcl11A-S/Evi9c is widely expressed in different regions of the rat brain • Bcl11A-L/Evi9a is expressed in the cerebral cortex, hippocampus, and olfactory bulb
DRRF (Sp1 family of transcription factors)	• Highly expressed in the neural ectoderm and neural groove • Moderately expressed in the mesoderm and endoderm at the early embryonic stage. • Highest DRRF mRNA levels in olfactory bulb and tubercle, nucleus accumbens, striatum, hippocampus, amygdala, and frontal cortex. • Regulates dopaminergic neurotransmission
Egr3	• Expressed in cortex and colocalized with zif268. • Important in defining long-term, neuroplastic responses.
FOG-2	• Expressed in developing and adult heart, brain, and testis • Important cofactor for GATA-mediated transcriptional activation in cardiac and neural cell lineages.
Ik-1 and Ik-2	• Positive regulators of enkephalin gene expression in the developing striatum • Participate in regulating enkephalinergic differentiation
Lot1	• High in cerebellar granule cells, a neuronal population undergoing postnatal neurogenesis
MOK2	• *PAX3* and *IRBP* (interphotoreceptor retinoid-binding protein) genes are two potentially important target genes for the MOK2 protein.
NSM1(IA-1)	• In mouse brain, *Insm1* is strongly expressed for 2 weeks after birth but shows little or no expression thereafter. • During embryo development Cbl-associated protein may enter the nucleus through its own nuclear localization signal or by binding to INSM1.

Table 149.5 (continued)

Transcription factor	Expression site and/or function
Plag1, Plag-l2	• In the CNS and PNS • In olfactory and neuroendocrine lineages. • Might control cell fate and proliferation decisions in the developing nervous system (Oncogenes)
REST/NRSF/XBR	• Highest levels in the neurons of hippocampus, pons/medulla, and midbrain • A negative regulator rather than a transcriptional silencer of neuronal gene expression and counteracts with positive regulators to modulate target gene expression quantitatively in different cell types, including neurons.
RP58	• mRNA at E 10 in the neuroepithelium, and subsequently in the VZ of the cerebral cortex in the E12 embryo. • Strong expression in the preplate in the cerebral cortex from this stage onward. High levels of expression continue to be detected in the cortical plate and SVZ of the neocortex, hippocampus, and parts of the amygdala
Sp8	• Expressed in neurogenic regions, which gives rise to olfactory bulb interneurons at embryonic and postnatal time points and remains expressed in the calretinin-expressing and GABAergic/nondopaminergic interneurons of the glomerular layer. • Contributes to olfactory bulb interneuron diversity by regulating the survival, migration, and molecular specification of neuroblasts/interneurons.
Wt1	• The developing olfactory epithelium
Zac1(Plag family)	• Abundantly expressed in many neuroepithelia during early brain development • Regulates both apoptosis and cell cycle arrest (tumor suppressors)
Zfp423	• Expressed within the cerebellum, both in ventricular and external germinal zones. • Loss of Zfp423 results in diminished proliferation by granule cell precursors in the external germinal layer, especially near the midline, and abnormal differentiation and migration of ventricular zone-derived neurons and Bergmann glia
Zic1–5	• Precursor cells of the granule neuron and the neurons in cerebellar nuclei • Neurulation, neuronal differentiation, neural crest specification, the establishment of left-right asymmetry, and regulation of cell proliferation
Zif268 (Egr1)	• Zif268 is constitutively expressed in several parts including the temporal lobe. • Zif268 regulates neurological genes and cellular growth and proliferation genes. • Expressed in mammalian neurons during visual and fear learning, as well as in song learning in birds. • Expressed in response to cellular growth and proliferation signals by enhancing the expression of TGFβ1
ZNF536	• Most abundant in the developing central nervous system and dorsal root ganglia and localized in the cerebral cortex, hippocampus, and hypothalamic area. • Negatively regulates neuron differentiation.

This table includes a partial list of Zn finger transcription factors expressed in different sites and/or cells of the brain. Related functions of the respective transcription factors at the expression site are listed as well

cell proliferation (Hershfinkel et al. 2007). The catalytic roles of Zn include participating in the transformation of substrates by facilitating the formation of OH^- at neutral pH, or through Lewis acid catalysis. The structural role of Zn is mostly in stabilizing active tertiary peptide conformation. Notably, Zn^{2+} interacts strongly with electronegative sulfur, nitrogen, and oxygen moieties in multiple coordination geometries, and yet unlike Fe or Cu, it is not redox active under physiological conditions and thus does not promote the formation of toxic free radicals. As an extracellular signal factor Zn is involved in synaptic neurotransmission (Frederickson 1989; Vallee and Falchuk 1993). It is generally accepted that an increase in free intracellular Zn^{2+} is associated with cell death. For example, release of intracellular Zn^{2+}, triggered by formation of reactive oxygen species or by nitrosilation, induces proapoptotic molecules, e.g., p38, and activation of K^+ channels leading to cell death (McLaughlin et al. 2001; Pal et al. 2003).

149.7 The Developing Brain and Zn Status in Diet

The impact of Zn supplementation or a Zn-deficient human diet on brain development and function has not been consistent. Various dimensions of research design and a broad range of subjects varying in racial background, age, and food habits might have contributed to the observed inconsistency. However, a growing number of studies have shown the influence of maternal Zn on fetal growth and development (Goldenberg et al. 1995; Georgieff 2007; Cole and Lifshitz 2008). Daily Zn supplementation in women with relatively low plasma [Zn] in early pregnancy is associated with greater infant birth weights and head circumferences, with the effect occurring predominantly in women with a body mass index less than 26 kg/m^2 (Goldenberg et al. 1995). Very low birth weight of Canadian infants scored improved motor development when given Zn supplement (Friel et al. 1993) while low birth weight infants in Brazil (Ashworth et al. 1998) and older infants and toddlers in Guatemala (Bentley et al. 1997) and India (Sazawal et al. 1996) did not show changes in motor development. However, Zn supplementation to Zn-deficient mothers is important for proper brain development in neonates (Gibson 1994; Georgieff 2007). An adequate Zn nutriture is essential for optimal neurological development (Takeda 2001; Prasad 1997). Additional Zn intake during pregnancy results in increased neuronal proliferation in the ventricular zone of the developing brain (Azman et al. 2009). Regular consumption of more than the recommended intake, on the other hand, can have adverse effects (Ronowska et al. 2007).

149.8 Neurogenesis and Zn Supplement

Neurogenesis is a process to generate postmitoitc neuronal and glial cells from neuroepithelial stem cells. Proliferation, cell-cycle arrest, differentiation, migration, and the natural developmental death of neural precursors are well coordinated during neurogenesis (Moskowitz and Lo 2003). Optimal development of the brain depends on strict co-ordination of these events during neurogenesis. Various cell-cycle genes and transcription factors including Zn transcription factors expressed in neurons (Table 149.5) govern neurogenesis, which also determines the correct positional identity of the neural cells from the stem/progenitor cells (Araujo et al. 1990; Edenfeld et al. 2002). In most brain regions, the generation and proliferation of neurons is normally restricted to a discrete developmental period with exceptions for the regions such as hippocampus, dentate gyrus, and the subventricular zone (SVZ) of several species (Caviness 1973; Gueneau et al. 1982; Cameron et al. 1993; Kuhn et al. 1996; Gould et al. 1998; Eriksson et al. 1998; Doetsch et al. 1999), and almost all neurons are generated before early postnatal life and are generally not replaced with new ones (Rakic 1982). The ventricular zone (VZ) is the major site of proliferation and presumably produces all the cell types. A second proliferative zone, namely SVZ, also contributes large numbers of neurons to the developing cortex (Nowakowski and Rakic 1981). In addition, granule neurons are generated throughout life from a population of continuously dividing progenitor cells residing in the subgranular zone of the dentate gyrus in the rodent brain (Stanfield and Trice 1988; Kuhn et al. 1996).

In neuronal cells, Zn deficiency induces oxidative stress, alters the normal structure and dynamics of the cytoskeleton, affects the modulation of several transcription factors and induces a decreased cell proliferation and increased apoptotic death. Thus, Zn deficiency affects critical developmental events of neurogenesis (reviewed by Mackenzie et al. 2007; Nakashima and Dyck 2009). Zinc supplement on the other hand results in increased number of proliferating neurons in the VZ of the developing neocortex. This was observed in the mouse pups delivered by the mother given oral Zn supplement in drinking water during pregnancy (Azman et al. 2009). Notably, Zn is involved in

activation of enzyme systems that influence cell division and proliferation (Varrault et al. 1998; MacDonald 2000; Valente et al. 2005; Ronowska et al. 2007). During DNA synthesis, Zn affects thymidine kinase, the activity of which increases dramatically during the G1 and early S phases of the cell cycle. Zinc also influences the hormonal regulation of cell division. Insulin-like growth factor-I and the pituitary growth hormone axis are responsive to Zn status (Root et al. 1979; Roth et al. 1994).

149.9 Neuronal Apoptosis and Zn Deficiency

Zn deficiency was found to increase the expression of Zn transporters in the brain, which facilitates increased brain Zn uptake and results in the conservation of brain Zn during Zn deficiency (Chowanadisai et al. 2005). In neuronal cells, Zn deficiency induces oxidative stress, alters the normal structure and dynamics of the cytoskeleton, affects several transcription factors, and results in decreased cell proliferation and increased apoptosis. These closely associated events affect neuronal function and critical developmental events of neurogenesis when Zn availability decreases (Mackenzie et al. 2007).

In human neuronal cell model IMR-32 cells, a decrease in cellular Zn triggers mitogen-activated protein kinases (MAPKs) both in H_2O_2-independent and dependent manner. Cells grown in low Zn-containing media showed increased cell oxidants and H_2O_2 release, increased c-Jun N-terminal kinase (JNK) and p38 activation, high nuclear activator protein-1 (AP-1)-DNA binding activity, and AP-1-dependent gene expression. Increase in cellular H_2O_2 can trigger the activation of JNK and p38, leading to AP-1 activation, events that are not involved in Zn deficiency-induced apoptosis (Zago et al. 2005).

149.10 Zinc Deficiency or Excess and Brain Pathology

The homeostasis of the free Zn^{2+} pool and the mechanisms involved in controlling that homeostasis are pivotal for proper brain physiology. Acute human dietary deficiency is accompanied by CNS related Zn-reversible symptoms such as anorexia, smell and taste dysfunction, emotional and cognitive disturbances, and loss of coordination (Fig. 149.3) (Ashworth et al. 1998; Bhatnagar and Taneja 2001). Perhaps this is because Zn as a neuromodulator at excitatory synapses plays an important role in stress response and in the functionality of Zn-dependent enzymes contributing to maintaining brain compensatory capacity. Dietary Zn deficiency was also reported to affect learning and memory. Deficiency in Zn is also associated with attention deficiency/hyperactivity disorder. Age-related decline in brain functions and impaired cognitive performances could be related to dysfunctions affecting the intracellular Zn^{2+} availability (Golub et al. 1995; Takeda 2000; Takeda et al. 2008).

Zn deficiency causes abnormal glucocorticoid secretion from the adrenal cortex, which is observed prior to the decrease in extracellular [Zn] in the hippocampus. The functions of glucocorticoid receptor-rich hippocampus are changed by abnormal glucocorticoid secretion that in turn aggravates glutamate excitotoxicity in neurological diseases. Thus Zn deficiency elicits neuropsychological symptoms and affects cognitive performance (Fig. 149.3). It is possible that the decrease in Zn^{2+} pool in the peripheral tissues triggers abnormal glucocorticoid secretion. In other words, the decrease in Zn^{2+} pool may cooperate with glucocorticoid action in Zn deficiency.

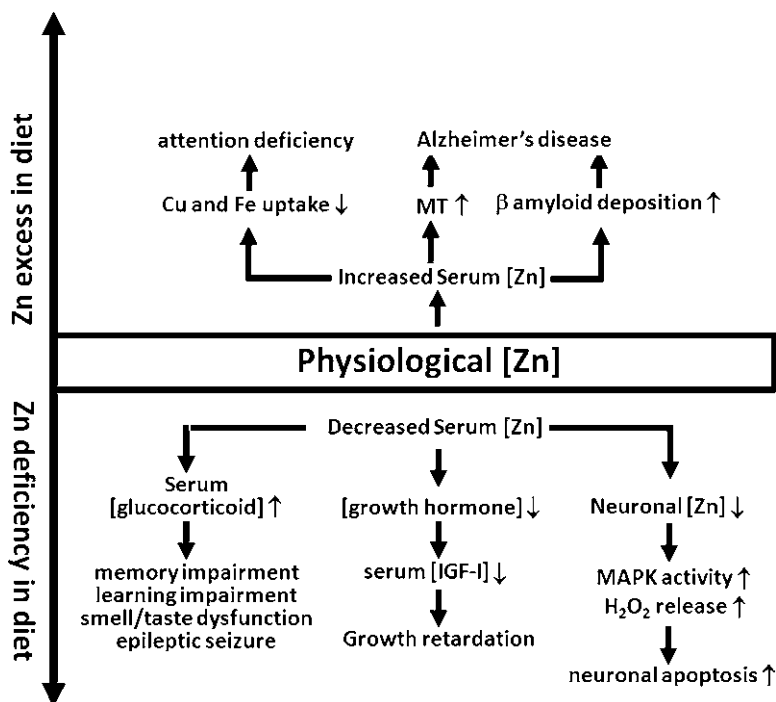
Again, elevated [Zn] or Zn excess in the brain has a profound negative effect on neurological cells, which are highly susceptible to extremes in extracellular [Zn]. The exact neuropathological mechanism of elevated level of Zn^{2+} is still unclear; however, it is found to be related to the progression


Fig. 149.3 Possible pathological consequences of dietary Zn-deficient or Zn-excess condition. In dietary Zn deficiency, serum [Zn] can be decreased leading to either increased serum glucocorticoid concentration or decreased growth hormone concentration or intracellular [Zn]. These conditions in turn may result in cognitive disturbances such as memory or learning impairment, growth retardation or neuronal apoptosis, respectively. In dietary Zn-excess condition, increased serum [Zn] can lead to decreased uptake of Cu and Fe in different organs, including the brain, or increased depositing of beta amyloid in the brain. *IGF* Insulin like growth factors I, *MAPK* mitogen activated protein kinase, ↓ decrease, increase

of AD and other neuropathologies (reviewed by Sensi et al. 2009). There is considerable evidence that amyloid-beta deposition in AD is induced by Zn, but the exact mechanism is still unclear (reviewd by Mocchegiani et al. 2005; Barnham and Bush 2008). An increased expression of MT-I and MT-II, and in some cases of MT-III (also known to be a growth inhibitory factor), is causally linked to such phenomena (Fig. 149.3). However, the protective roles of these proteins at a young age to maintain brain physiology and their functional ability in aging are not consistent. Alterations in Zn homeostasis have also been reported in Parkinson's disease as well as in transient forebrain ischemia, seizures, and traumatic brain injury. The altered Zn nutritional status of individuals with Down's Syndrome contributes to clinical complications that usually appear with their aging (Lima et al. 2010). Again, Zn metabolism is altered in the presence of Down's Syndrome (Licastro et al. 2001). Zinc supplement in diets has been tried to improve the patient's health albeit with conflicting results (Bucci et al. 2001; Blair et al. 2008).

149.11 Applications to Other Areas of Health and Disease

The importance of Zn in the biological system is remarkable and versatile. Zinc plays a pivotal role in gene expression involving cellular growth and differentiation; yet, unlike other transitional metals,

it does not cause any oxidative damage (Berg and Shi 1996). Enough is now known about the clinical and public health importance of Zn in human health and diseases. Community Zn supplementation programs among children in developing countries proved to have had a significant effect on the reduction of pneumonia (Bhutta et al. 1999). Zinc supplement has been beneficial for diarrhea prevention and childhood morbidity and mortality. Other than the brain (CNS), the epidermal, gastrointestinal, immune, skeletal, and reproductive systems are known to be affected clinically by severe Zn deficiency (Solomons 1998; Hambidge et al. 1986).

Summary Points

- The total Zn content of the diet and its bioavailability, especially its solubility in the intestinal lumen, determine the amount of absorbed Zn to be utilized or metabolized in the different organs including the brain.
- In the brain, Zn concentration is highest in the hippocampus which can decrease significantly in dietary Zn deficiency.
- The blood brain barrier system provides strict regulation on Zn homeostasis in the brain and is not easily influenced by dietary Zn.
- Zinc homeostasis is maintained through the regulated expression of proteins for Zn import, export, and sequestration.
- A multitude of Zn^{2+} transporters (ZnTs), Zn^{2+}-importing proteins (ZIPs), and buffering proteins such as the metallothioneins (MT) bind cytosolic Zn^{2+} and mediate the complex intraneuronal cytosolic free Zn^{2+} homeostasis.
- A number of Zn transcription factors are expressed in nerve cells and in different areas of the brain regulating genes involved in proliferation, differentiation, migration, and apoptosis of neurons and other cells of the brain.
- As an extracellular signal factor Zn is involved in synaptic neurotransmission.
- Additional Zn intake during pregnancy can increase neuronal proliferation at the ventricular zone of the developing brain.
- In neuronal cells, Zn deficiency induces oxidative stress, alters the normal structure and dynamics of the cytoskeleton, affects the modulation of transcription factors AP-1, NF-betaB, and NFAT and induces decreased cell proliferation and increased apoptotic death.
- Acute human dietary deficiency is accompanied by symptoms such as anorexia, smell and taste dysfunction, emotional and cognitive disturbances, and loss of coordination. Dietary Zn deficiency also has been reported to affect brain functions, including learning and memory defects.

Key Terms

Apoptosis: A form of cell death (or cell suicide) in which a programmed sequence of events leads to the elimination of cells without leaving or releasing harmful substances into the surrounding area of the dying cell(s). Apoptosis also refers to the structural changes that the cells undergo before the programmed death. Apoptosis is crucial in developing and maintaining health by eliminating old, unnecessary, and unhealthy cells. Hyperactivation and inactivation of apoptosis may result in pathological conditions. Hyperactivation may kill too many cells and inflict grave tissue damage, leading to such neurodegenerative disorders as Alzheimer's, Huntington's, and Parkinson's diseases.

Astrocyte: Astrocytes (collectively known as astroglia) are characteristic star-shaped glial cells in the CNS. Three forms of astrocytes exist in the CNS: *fibrous* (located in white matter and that physically connect the cells to the outside of the capillary wall when they are in close proximity to them), *protoplasmic* (found in grey matter tissue; they possess a larger quantity of organelles and exhibit short and highly branched cellular processes), and *radial* (disposed in a plane perpendicular to the axis of ventricles). Their functions include: biochemical support to the endothelial cells at the BBB, controlling of nutrient supply to the nervous tissue, maintenance of extracellular ion balance, and aiding in repair mechanisms of the brain and spinal cord injuries.

Blood brain barrier (BBB): The BBB is a protective network of blood vessels that filters blood flowing to the brain and separates circulating blood and cerebrospinal fluid (CSF) maintained by the choroid plexus in the CNS. Endothelial cells of the blood vessels restrict the diffusion of microscopic objects (e.g. bacteria) and large or hydrophilic molecules into the CSF, while allowing the diffusion of small hydrophobic molecules (O_2, hormones, CO_2).

Central nervous system (CNS): The CNS is one of the two major divisions of the nervous system and consists of the brain and the spinal cord. The CNS connects to sensory organs (such as the eye and ear) and other organs of the body, muscles, blood vessels, and glands through the peripheral nervous system. The CNS consists of the brain in the cranial cavity and the spinal cord in the spinal cavity.

Hippocampus: The hippocampus is named for its shape like a seahorse (From the Greek *hippos* = horse and *kampos* = a sea monster). It is a closely associated, paired structure with mirror-image halves in the left and right sides of the brain. In humans and other primates, the hippocampus is located inside the medial temporal lobe, beneath the cortical surface. The hippocampus is part of the olfactory cortex essential to the sense of smell and also helps to regulate emotion and memory. Hippocampus also plays important roles in long-term memory and spatial navigation.

Homeostasis: (from Greek: *homoios*, "similar"; and *histēmi*, "standing still"). Generally refers to the property of a system, either open or closed, that regulates its internal environment and tends to maintain a stable, constant condition. When applied to living organisms, homeostasis refers to a property of cells, tissues, and organisms that allow the maintenance and regulation of the stability and constancy needed to function properly and is maintained by the constant adjustment of biochemical and physiological pathways.

Metallothionein (MT): Metallothionein is a family of cysteine-rich, low molecular weight (3.5–14 kDa) proteins. The thiol group of MT contains cysteine residues, which represent ~20–30% of its total amino acidic residues. Both essential (such as Zn, copper, selenium) and toxic (such as cadmium, mercury, silver, arsenic) heavy metals can bind the thiol groups through the cysteine residues. MT has high affinity for Zn (1.4×10^{-13} M). There are four major isoforms (MT-I, MT-II, MT-III, MT-IV) expressed primarily in the liver and kidneys. MT expression is also evident in other tissues and organs such as blood, skin, and heart. In the brain, MT-III is known as the growth inhibitory factor. Expression of MT in different organs and tissues depends on the availability of the dietary minerals, such as Zn, copper, and selenium, and the amino acids histidine and cysteine. MT distributes intracellular Zn as Zn undergoes rapid inter- and intracluster exchange.

Neurogenesis: The process by which new nerve cells are generated i.e., production of new neurons, astrocytes, glia, and other neural lineages from undifferentiated neural progenitor or stem cells. Neurogenesis is most active during prenatal development and inactive in most areas of the adult brain.

Neuron: Neurons are cells in the nervous system including the brain, spinal cord (vertebrate), the ventral nerve cord (invertebrate), and the peripheral nerves that process and transmit information by

electrochemical signaling. A typical neuron has a cell body (soma), branching processes specialized to receive incoming signals (dendrites), and a single process (axon) that carries electrical signals away from the neuron toward other neurons or effectors. Electrical signals carried by axons are action potentials. Different types of neurons are named after their specialized structure and functions: for example, *sensory neurons* respond to touch, sound, light, and numerous other stimuli affecting cells of the sensory organs that then send signals to the spinal cord and brain; *motor neurons* receive signals from the brain and spinal cord and cause muscle contractions and affect glands; *interneurons* connect neurons to other neurons within the same region of the brain or spinal cord.

Dopaminergic neuron: Neurons that produce dopamine, a neurotransmitter produced in several areas of the brain, including the substantia nigra and the ventral tegmental area in either vertebrates or invertebrates. Dopamine is a neurohormone released by the hypothalamus mainly to inhibit the release of prolactin from the anterior lobe of the pituitary.

GABAergic neuron: Neurons that produce γ-aminobutyric acid (GABA), the chief inhibitory neurotransmitter in the mammalian CNS. It plays an important role in regulating neuronal excitability throughout the nervous system. In humans, GABA is directly responsible for the regulation of muscle tone. GABA acts at inhibitory synapses in the brain by binding to specific transmembrane receptors in the plasma membrane of both pre- and postsynaptic neuronal processes. This binding causes the opening of ion channels to allow the flow of either Cl^- ions into the cell or K^+ out of the cell. Two general classes of GABA receptor are known: $GABA_A$ in which the receptor is part of a ligand-gated ion channel complex, and $GABA_B$ metabotropic receptors, which are G protein-coupled receptors that open or close ion channels via intermediaries.

Reelin: Reelin is a protein expressed in different tissues of the body including brain, spinal cord, and blood. In the developing brain it helps to regulate neuronal migration and positioning. In the adult brain, it modulates synaptic plasticity by enhancing the induction and maintenance of long-term potentiation. It also stimulates dendrite and dendritic spine development and regulates the continuing migration of neuroblasts generated in adult neurogenesis sites like subventricular and subgranular zones.

Subventricular zone (SVZ): The subventricular zone is a paired brain structure situated throughout the lateral walls of the lateral ventricles. Along with the subgranular zone of the dentate gyrus, the SVZ serves as a source of neural stem cells in the process of neurogenesis. It harbors the largest population of proliferating cells in the adult brain of rodents, monkeys, and humans.

Synaptic vesicle: Synaptic vesicles or neurotransmitter vesicles are 40–100 nanometers in diameter, and made up of a lipid bilayer, store various neurotransmitters (NT) that are released at the synapse for synaptic transmission. The release of NTs is regulated by a voltage-dependent Ca^+ channel. At synapses, the junctional complexes between presynaptic membranes (synaptic knobs) and postsynaptic membranes (receptor surfaces of recipient neurons or effectors), synaptic transmission process signal transfer (communicate) from one neuron (affector) to other neurons (effectors).

Zinc finger transcription factor: Zinc finger transcription factors are the DNA-binding proteins, containing Zn finger domain. Zinc fingers are small protein domains, folds of which are stabilized by one or more Zn^{2+}. They coordinate Zn^{2+} with a combination of cysteine and histidine residues. Different families of Zn finger proteins can bind DNA, RNA, proteins or small molecules involved in transcription, nucleic acid polymerization, and histones.

Chapter 150
Dietary Copper and the Brain

Helma Antony and Ian G. Macreadie

Abbreviations

Aβ	β-Amyloid Protein
AD	Alzheimer's Disease
AI	Daily Adequate Intake
ALS	Amyotrophic Lateral Sclerosis
APP	Amyloid Precursor Protein
ATP	Adenosine Tri-Phosphate
BACE	Beta-Site APP Cleaving Enzyme
BBB	Blood–Brain–Barrier
BSE	Bovine Spongiform Encephalopathy
CJD	Creutzfeldt-Jacob Disease
CSF	CerebroSpinal Fluid
Cu	Copper
CWD	Chronic Wasting Disease
EC	Enzyme Commission number
ETIC	Endemic Tyrolean Infantile Cirrhosis
Fe	Iron
HD	Huntington Disease
ICC	Indian Childhood Cirrhosis
ICT	Idiopathic Copper Toxicosis
OHS	Occipital Horn Syndrome
PD	Parkinson's Disease
RDA	Recommended Dietary Allowance
ROS	Reactive Oxygen Species
SOD	Superoxide Dismutase
TSE	Transmissible Spongiform Encephalopathy
UL	Daily tolerable Upper intake Level

150.1 Introduction

Copper is essential for life. It is vitally important for the body as it forms a critical component of various fundamental enzymes in the cells. These cuproenzymes (see Table 150.1) are absolutely dependent on copper for its enzymatic activity. At the molecular level, copper is required as a catalytic cofactor or prosthetic group for these metalloenzymes. The cuproenzymes include cytochrome oxidase (EC 1.9.3.1), superoxide dismutase (EC 1.13.11.11), tryptophan-2,3-dioxygenase (EC 1.13.11.11), lysine oxidase (EC 1.4.3.12), monoamine oxidase (EC 1.4.3.4), tyrosinase (EC 1.14.18.1), and dopamine-β-hydroxylase (EC 1.14.17.1).

In humans, these enzymes are required in various organs or sites and indeed some are essential in all cells. Cuproenzymes like cytochrome oxidase are an essential component of cellular respiration and are required in all cells. Other cuproenzymes are involved in iron oxidation, connective tissue formation, nerve cell function, hormone production, and pigmentation (Table 150.1). Cuproenzymes are also important for the synthesis, development and normal functioning of several physiological systems like hemopoietic, cardiovascular, nervous, skeletal, reproductive, and integumentary systems. In addition, copper plays a role as a free metal ion in some nonenzymatic activities like angiogenesis, nerve myelination, and endorphin action.

150.2 Copper in the Diet

Given that copper is essential for normal health, the dietary intake of copper is important. However, increased copper levels in the body can lead to toxicosis resulting in serious consequences (see below). Hence, it is important to consume safe and adequate amounts of copper. The previous recommended dietary allowance (RDA) of 1.5–3.0 mg of copper/day has now been reduced to 0.9 mg/day for adult men and women and 1.0–1.3 mg/day for pregnant and lactating women. For infants up to 1 year old, the daily adequate intake (AI) level is 0.2–0.22 mg/day. To avoid copper toxicity from excessive dietary intake, it is desirable not to exceed the tolerable upper intake level (UL). The UL of copper for adults is 10 mg/day. A comprehensive list of specific AIs, RDAs, and ULs for all ages can be found in Table 150.2 (Klevay 2005).

Table 150.1 Copper-containing proteins (Balamurugan and Schaffner 2006; Zatta and Frank 2007)

Enzymes/Proteins	Function
Cytochrome *c* oxidase	Energy production (electron transport chain)
Superoxide dismutase (Cu–Zn–SOD)	Protection against free radical damage
Lysyl oxidase	Strengthening connective tissue (cross-linking of collagen and elastin)
Dopamine β mono-oxygenase	Neurotransmission (catecholamine formation)
Peptidyl α amidating mono-oxygenase	Neurotransmission (pituitary peptide hormone maturation)
Amine oxidase	Hormone removal
Mono-oxygenase	Melanin formation
Ascorbate oxidase	Oxidation of ascorbate
Ceruloplasmin	Copper and iron transport (oxidation of Fe^{2+} to Fe^{3+})
Galactose oxidase	Oxidation of primary alcohols to aldehydes
Tyrosinase	Pigmentation (oxidation of phenols)

Enzymes and proteins that require copper and their biological functions are listed

Table 150.2 Dietary copper (Klevay 2005)

Age group	AI	RDA (in mg)	UL (in mg)
Infants			
0–6 months	0.20 mg or 30 μg/kg		
7–12 months	0.22 mg or 24 μg/kg		
Children			
1–3 years		0.34	1.00
4–8 years		0.44	3.00
9–13 years		0.70	5.00
Adolescents			
14–18 years		0.89	8.00
Adults			
19–70 years		0.90	10.00
Pregnant women		1.00	8.00
Lactating mothers		1.30	8.00–10.00

Recommended levels for safe and adequate copper nutrition for the different age groups are listed

AI daily Adequate Intake, *RDA* Recommended Dietary Allowance, *UL* daily tolerable Upper intake Level

150.2.1 Dietary Sources of Copper

Figure 150.1 shows some of the dietary sources of copper. High-copper containing foods such as nuts (0.2–0.5 mg/tablespoon), seeds, seafood – particularly shell fish, lobster, etc. (1.0–3.7 mg/serving), organ meats – like liver (3.8 mg/serving of beef liver) and legumes (0.2 mg/serving) are good dietary sources of copper. Substantial amounts of copper are also present in whole grains, grain products, and chocolates. Other foods like tea, milk, chicken, and potatoes contain low levels of copper. Cooking in copper vessels and drinking water from copper pipes may also offer trace amounts of copper via leaching.

150.2.2 Factors Affecting Copper Nutrition

Adequate copper nutrition also depends on the bioavailability of copper in foods and the influence of other dietary components or nutrient partners. In spite of the higher copper content of vegetarian diets compared to nonvegetarian diet, copper is less efficiently absorbed from a vegetarian diet (Hunt and Vanderpool 2001). Nevertheless, total apparent copper absorption is greater in vegetarians owing to the greater copper content of the vegetarian diet (Hunt and Vanderpool 2001). There are several other factors that affect the intestinal absorption of copper and its bioavailability. Physical and chemical food processing treatments often alter the mineral content of foods (Wapnir 1998). Long-term cooking can reduce the copper content of food considerably. Dietary components like ascorbic acid (vitamin C), zinc, calcium, molybdenum, ferrous iron, stannous tin, etc. are found to reduce copper absorption due to their copper antagonistic, chelating or copper-binding nature; whereas sodium is found to enhance copper absorption (Wapnir 1998). It has also been observed that an increased consumption of saturated and trans fats along with increased copper diet can accelerate brain aging and deteriorate cognitive function (Morris et al. 2006).
Fig. 150.1 Dietary sources of copper. Copper-containing foods are shown in decreasing order of their copper content. Foods in the upper row are rich in copper, while those in middle row contain substantial amounts of copper. Foods in the bottom row contain low levels of copper

150.3 Physiology of Copper

The physiology of copper involving its dietary intake, absorption, distribution to various tissues, and organs and its excretion is summarized in Fig. 150.2.

150.3.1 Absorption of Copper

Dietary copper uptake has been reviewed by (Linder and Hazegh-Agam 1996). Copper absorption occurs primarily via the brush border cells of the small intestine into interstitial fluid and blood (Linder and Hazegh-Agam 1996), where the copper binds to plasma proteins that carry copper. A small fraction of copper absorbed by the stomach is nutritionally insignificant (Wapnir 1998). Thus the primary site of copper absorption is considered to be the small intestine. At the level of the whole person, it is desirable for copper levels to be neither increased nor decreased. About 4 mg of copper excreted into the bile each day is mostly reabsorbed by the intestines, which in combination with dietary absorption of 0.6–1.5 mg copper, leads to a relatively constant level in the body.
Fig. 150.2 Pathway of copper in the body. The main organs involved in copper uptake, absorption, and excretion are shown

150.3.2 Copper Transport

Copper in blood is transported in a protein-bound form to all tissues and organs (Fig. 150.2). Radiolabeled copper studies have shown that labeled copper disappeared from plasma within 2 h (Weiss and Linder 1985). The plasma-protein carriers of copper are ceruloplasmin, albumin, transcuprein, and some low molecular weight small peptides and amino acids. Of these, ceruloplasmin constitutes the nonexchangeable pool while the rest binds copper in a removable fashion to facilitate easy exchange with tissues.

(i) *Ceruloplasmin* – The major copper binding protein in blood is ceruloplasmin, which is synthesized in the liver where it binds copper. Almost 90% of the serum copper is bound to ceruloplasmin, but it is not utilized for copper transport as the bound copper is in a nonexchangeable form. Ceruloplasmin is a multicopper oxidase that requires copper for its function in the iron transport system. Ceruloplasmin oxidizes Fe^{2+} to Fe^{3+}, which then is bound by transferrin for transport. The equivalent protein in yeast is Fet3, a protein that also functions as a multicopper oxidase (see Table 150.1) (Askwith et al. 1994; de Silva et al. 1997; De Silva et al. 1995; Yuan et al. 1995). People with a total deficiency of ceruloplasmin (aceruloplasminemia) have an iron metabolism disorder and midlife dementia (Harris et al. 1995).

(ii) *Albumin* – Albumin is one of the most abundant plasma proteins. Although albumin can carry ~40 mg copper per litre of blood, it usually carries less than 1% of this amount at a time. Albumin binds copper with high-affinity via three amino acid residues at its N-terminus (Linder 2002).

(iii) *Transcuprein* – Transcuprein is a macroglobulin and is another high-affinity copper carrier found in the serum of mammals, including humans, rats, and dogs (Liu et al. 2007; Hyun and Filippich 2004; Linder 2002; Montaser et al. 1992). Both albumin and transcuprein carries 12% each of the total plasma copper and also rapidly exchanges copper with each other (Linder 2002).

(iv) *Low molecular weight fraction* – Trace amounts of copper are found bound to small peptides and amino acids in blood (Linder 2002). They are less tightly bound and increase copper content in blood directly after a meal (Zatta and Frank 2007).

150.3.3 Distribution of Copper

A healthy man of 70 kg is estimated to contain 110 mg of copper, which is constituted by 10 mg in the liver, 8.8 mg in brain, 6 mg in blood, 26 mg in skeletal muscles, and 46 mg in skeleton and bone marrow (see Fig. 150.3) (Linder et al. 1998).

 (i) *Copper in the brain* – Copper enters the brain from the bloodstream as free Cu ions via the blood–brain–barrier (BBB) and the entry is regulated by the blood-CSF barrier (Choi and Zheng
Fig. 150.3 Regional distribution of copper in the human body. Distribution of absorbed copper in different organs of the body is shown. Units are expressed in mg and the amounts are based on a healthy man with a total copper of 110 mg (Source of values: Linder et al. 1998)
Fig. 150.4 Regional distribution of copper in the brain. Distribution of copper in different regions of (**a**) human brain and (**b**) rat brain are shown. Units are expressed as μg/g dry weight (Source of values: Prohaska 1987)

2009). While the brain contains greater amounts of copper than the blood, the concentration varies between different regions of the brain depending on age, species, environment, and genetics (see Fig. 150.4) (Zatta and Frank 2007). Compared to other animal species, the human brain has the highest copper content (Zatta and Frank 2007). The highest metal ion concentration in the adult human brain is found in substantia nigra, nucleus dentatus, putamen, and nucleus caudatus (reviewed by Speziali and Orvini 2003).

(ii) *Copper in other organs* – Most of the absorbed copper is mainly transported to the liver via enterohepatic circulation and some to the kidneys via systemic circulation. Radiolabelled copper studies show that 40% of the absorbed copper localizes in the liver by 6 h of ingestion (Weiss and Linder 1985). Though only a small amount of copper is taken to the kidneys in normal conditions, excess dietary intake can result in high levels of copper in kidneys and urine.

150.4 Copper in Cells

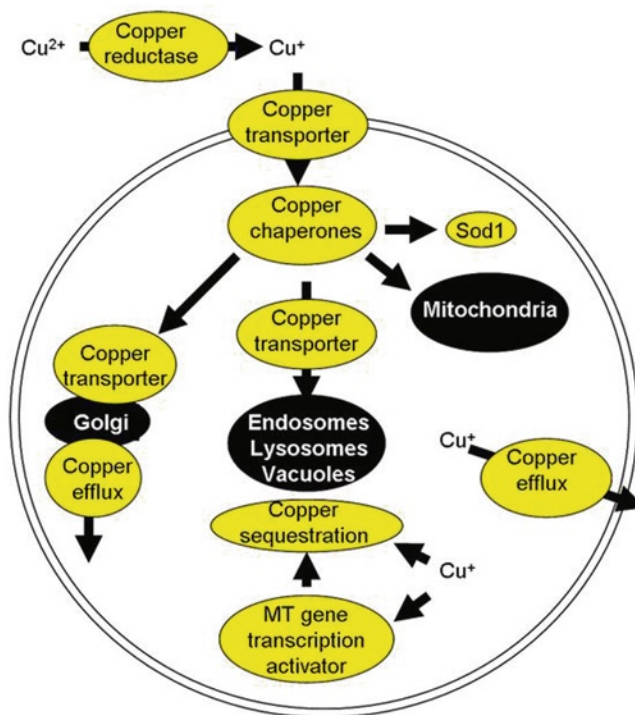
At the cellular level, much has been learned about the destiny of copper through basic studies of yeast genetics and cell biology. Yeast has been ideal for such studies because it is the best understood eukaryote and because it is readily genetic manipulated. In addition, gene knockouts are available for all yeast genes enabling easy and direct study of their functions. The high-level of similarity and homology between yeast and human genes aids functional identification and also often allows human gene complementation to be achieved. In the case of copper, it appears that both yeast and humans share the same pathway for the destiny of copper (shown in Fig. 150.5). The human proteins involved


Fig. 150.5 Schematic representation of the cellular destiny of copper in eukaryotes (adapted from Macreadie 2007). The shaded ellipses represent the classes of proteins described in Table 150.3. Exogenous Cu^{2+} is reduced by a copper reductase to Cu^+ which can be transported into the cell by a membrane-spanning copper transporter. Specific chaperones carry Cu^+ to specific locations, including to Sod1, the mitochondrion and the *trans*-Golgi network. Another copper transporter delivers Cu^+ to late endosomes and lysosomes in mammals, or vacuoles in yeast. Efflux pumps and metallothionein remove or sequester excess copper. Levels of metallothionein are tightly controlled at the transcription level by a copper-sensing transcription factor that is itself a copper apothionein

in the intracellular handling of copper and the yeast equivalent proteins are summarized in Table 150.3. Several human diseases involving copper metabolism (e.g., Menkes and Wilson's disease), have also greatly aided in understanding the copper metabolism. The sections below examine copper homeostasis and the fate of copper at the cellular level.

150.4.1 Cellular Copper Homeostasis

Copper homeostasis is critical for the well-being of all organisms. Although copper is essential for the survival of many enzymes and biochemical processes that are dependent on copper for activity, excess free copper can lead to cellular toxicity. Copper toxicity is mainly brought about by the generation of aggressive free radicals via the Fenton reaction catalyzed by copper and the structural disruption of proteins via the ectopic binding of copper (Balamurugan and Schaffner 2006). Hence, all organisms, from bacteria to yeast to humans, possess complex pathways and regulatory mechanisms to control cellular uptake, transport, distribution, detoxification, and efflux of copper in order to maintain cellular homeostasis of copper (further explained below).

Table 150.3 Copper proteins in the cell (Macreadie 2007)

Function	Human proteins	Yeast proteins
Cu reduction	Steap1, Steap2, Steap3, Steap4	Fre1, Fre2
Multicopper oxidase/ Fe transport	Ceruloplasmin, Hephaestin	Fet3
Cu uptake	hCtr1, hCtr2 (late endosomes, lyzosomes)	Ctr1, Ctr3, Ctr2 (vacuoles)
Cu chaperone	Atox1, formerly called Hah1 ($\rightarrow$ ATP7A and ATP7B)	Atx1 ($\rightarrow$ Ccc2 $\rightarrow$ Fet3)
	Ccs1 ($\rightarrow$ Sod1)	Ccs1 ($\rightarrow$ Sod1)
	Cox17 ($\rightarrow$ Sco1 and Cox11)	Cox17 ($\rightarrow$ Sco1 $\rightarrow$ Cox11)
	Sco1 ($\rightarrow$ Cco)	Sco1 ($\rightarrow$ Cox2)
	Cox11 ($\rightarrow$ Cco)	Cox11 ($\rightarrow$ Cox1)
Internal Cu transport/efflux	Atp7A ($\rightarrow$ secretory pathway)	Ccc2
	Atp7B ($\rightarrow$ ceruloplasmin)	Ccc2
Cu sequestration	Metallothioneins	Metallothioneins
MT transcription factor	Mtf-1	Ace1

Major human and yeast proteins involved in copper homeostasis are listed

The arrows indicate the transfer of copper and its target proteins

150.4.2 Cellular Copper Uptake

The handling of copper in eukaryotic cells is depicted in Fig. 150.5. In the diet, copper occurs in its most oxidized form (Cu^{2+}) and requires reduction by a cell-derived copper reductase (to Cu^+) to enable transport into cells. In yeast the copper transporters, Ctr1 and Ctr2, utilize the same metalloreductase, Fre1 (Rees and Thiele 2007) which is also a ferric reductase. Another ferric reductase, Fre2, appears to have an equivalent role to Fre1. The human counterparts of Fre1, the Steap proteins, function as both cupric and ferric reductases (Ohgami et al. 2006).

The transport of copper through the plasma membrane requires a membrane-localized copper transporter which delivers the Cu^+ to a copper chaperone. In yeast, this transport occurs through a high affinity copper transporter Ctr1 (Dancis et al. 1994a, b). Human equivalents of Ctr1 and hCtr1 were identified by yeast complementation studies (Zhou and Gitschier 1997). Yeast with a defective *ctr1* gene exhibited defects in respiratory growth, iron transport, and Sod1p, all of which were rescued by the human gene, hCtr1. The overproduction of hCtr1 led to copper overload (Zhou and Gitschier 1997). A similarity search of the human proteome identified additional gene, hCtr2 (Zhou and Gitschier 1997), that is expressed in late endosomes and lyzosomes where it facilitates cellular copper uptake (van den Berghe et al. 2007). An equivalent copper transporter in yeast, Ctr2, is found exclusively on the vacuolar membrane where it controls vacuolar copper levels (Kampfenkel et al. 1995; Rees et al. 2004). It appears that Ctr2 is a nonessential vacuolar copper transporter (Portnoy et al. 2001).

150.4.3 Metallochaperones for Copper Trafficking

Unlike chaperones, metallochaperones (e.g., copper chaperones) do not facilitate protein folding. Instead, they protect the cell by binding copper with high affinity and deliver it to specific target proteins within the cell. Each copper chaperone is highly specific for its ultimate destination. Functional identification of the copper chaperones, or metallochaperones, was first made in yeast. Later studies indicated that copper chaperones were conserved from yeast to humans as three functional groups depending on their ultimate destination (reviewed by Balamurugan and Schaffner

2006). Ccs1 chaperones copper to the eukaryotic antioxidant enzyme, Cu/Zn superoxide dismutase (Sod1) in the cytosol (Culotta et al. 1997); while three copper chaperones, Cox17, Cox11 and Sco1, works together to deliver copper to cytochrome *c* oxidase (Cco) in the mitochondria (Glerum et al. 1996; Amaravadi et al. 1997; Horng et al. 2004). Atx1 is the chaperone responsible for delivering copper to the secretory pathway for cuproenzymes at the cell surface or for release (Klomp et al. 1997; Lin et al. 1997; Pufahl et al. 1997). In the Golgi, the copper from Atx1 is utilized by the copper-transporting ATPases, ATP7A and ATP7B in humans and Ccc2 in yeast. Though only yeast chaperones have been mainly cited above, the human homologs of these chaperones are described in Table 150.3.

150.4.4 Internal Copper Efflux

Internal copper efflux is accomplished by ATP-dependent transporters of the ATP7 family, also known as P-type ATPases. Insights on cellular copper efflux in humans are mainly derived from studies of Menkes disease and Wilson's disease, the two major genetically-inherited disorders of copper homeostasis (further detailed under "copper-associated diseases" below). Human cells contain two isoforms of ATPases: ATP7A (or MNK transporter) that is expressed in the mucosal cells of intestinal epithelium and most other tissues other than liver, and ATP7B (or WND transporter) which is primarily expressed in liver and certain areas of the brain (Linder 2002; Balamurugan and Schaffner 2006). Both ATPases contain six copper binding sites at the N-terminus (Zatta and Frank 2007) and are functionally stimulated by copper for trafficking (Balamurugan and Schaffner 2006). At normal or low copper, ATP7A delivers intracellular copper to enzymes in the *trans*-Golgi network (Yamaguchi-Iwai et al. 1996) but at high copper levels, ATP7A moves to the plasma membrane to perform copper efflux (Petris et al. 1996). ATP7A also plays an important role in systemic copper absorption, reabsorption of copper in kidneys and adequate copper supply to the brain (reviewed by Balamurugan and Schaffner 2006). ATP7B is functionally related to ATP7A and they also share 54% sequence similarity. At normal or low copper, ATP7B is found only in the liver where it delivers intracellular copper to apoceruloplasmin in the *trans*-Golgi network (Yamaguchi-Iwai et al. 1996); but at high copper levels, ATP7B moves copper to vesicles for delivery to the biliary caniliculus, performing copper efflux into the bile for excretion (Petris et al. 1996). Yeast cells have an equivalent pump, Ccc2, which facilitates cation transport, including copper (Yuan et al. 1995). Ccc2 is also an ATPase and it translocates copper into the trans-Golgi vesicles, where copper is then packed into the multicopper containing protein ferroxidase Fet3 (Arnesano et al. 2001).

150.4.5 Copper Sequestration and Detoxification

Since excess and free copper are toxic to cells, it is imperative that cellular mechanisms exist to sequester free intracellular copper. Healthy yeast cells maintain free copper levels at less than one free copper ion per cell (Rae et al. 1999).

Metallothioneins (also known as copper scavengers) are the cellular copper binding proteins that provide significant protection against elevated copper levels. Yeast metallothionein (Karin et al. 1984; Winge et al. 1985) is highly regulated by Ace1, a constitutively produced transcriptional activator of the yeast metallothionein gene (Buchman et al. 1989; Szczypka and Thiele

1989). In the presence of copper, Ace1 binds copper and activates transcription. In the converse situation of copper starvation, another yeast transcription factor, Mac1 acts as an intramolecular autoinhibitory domain. In human cells, heavy metal load and copper excess is handled by the transcription factor, MTF1. MTF1 is the functional analog of yeast Ace1; but they are neither related to each other nor similar in their binding sites (reviewed by Balamurugan and Schaffner 2006). In the absence of metallothionein, superoxide dismutase (SOD) plays a major protective role against copper toxicity. It is significant that some cases of amyotrophic lateral sclerosis (ALS) have defects in Cu–Zn SOD, suggesting some linkage between this form of motor neurone disease and copper metabolism. Despite the capacity of metallothioneins to store copper, they cannot perform copper efflux. For pumping out excess copper, cells depend on the afore-mentioned ATPases.

150.5 Copper-Associated Diseases

Deficient or excess copper can lead to serious disorders in many organs of the body, including brain. Depending on the origin, human disorders associated with copper can be classified into three: hereditary, chronic deficiency, and overload.

150.5.1 Hereditary Copper Diseases

Menkes disease and Wilson's disease are the two major genetically-inherited disorders of copper homeostasis resulting from mutations in the copper transporters, ATP7A (MNK transporter) and ATP7B (WND transporter) respectively. Menkes disease, an X-linked recessive disorder, is effectively a copper deficiency disease that presents with growth failure, skeletal defects, degeneration of the central nervous system, and early death (Danks 1995). Contradictorily, despite the copper deficiency in Menkes disease, the kidneys and intestinal epithelial cells in affected individuals accumulate copper, owing to the defect in copper efflux (Mercer 2001). On the other hand, Wilson's disease, an autosomal recessive disorder, is effectively a copper toxicosis disease that presents with copper accumulation in the liver and brain, leading to liver cirrhosis and neurological problems including behavioral disturbances and movement disorders. Menkes and Wilson's disease are similar in that they utilize a similar pump, but they use it in different tissues. The MNK transporter (ATP7A) is also known to be involved in placental copper transfer. Hence, abnormal gestational development and copper-deficient phenotype in fetus and newborn is observed in Menkes disease (Linder 2002). In contrast, Wilson's disease occurs only gradually after birth. Occipital Horn Syndrome (OHS), an X-linked connective tissue disorder, is a mild variant of Menkes disease caused by mutations in the Menkes gene ATP7A and presents with mild neurological disease (Mercer 2001). Another hereditary copper-associated disease is aceruloplasminemia which is caused by mutations in the ceruloplasmin gene, but it manifests as an iron accumulation disorder and does not affect copper metabolism probably due to the presence of other plasma-protein carriers for copper (Mercer 2001; Linder 2002).

Menkes disease can be treated by administering copper histidine, but success rates depend on residual Menkes protein activity. In Wilsons's diseases, treatment by Cu-chelation therapy or use of oral zinc (to reduce copper absorption from diet) is promising if disease is diagnosed prior to irreversible tissue damage (Mercer 2001).

150.5.2 Copper Deficiency Diseases

Clinical copper deficiency is rare in adults (Mercer 2001), but it can occur due to genetic predisposition, malnutrition, marginal intake of copper, reduced bioavailability (caused by excess consumption of zinc, molybdenum, chelating agents, compounds that interfere with copper absorption, etc.), patients with gastrointestinal disorders or surgical treatment such as removal/bypass of a large portion of intestine, peritoneal dialysis, etc. (Zatta and Frank 2007). At the molecular level, copper deficiency reduces the activity of SOD and other components of the oxidant defense system resulting in increased lipid peroxidation and oxidative damage to DNA and proteins (Uriu-Adams and Keen 2005). Deficiency of copper also affects the function of cuproenzymes, thereby leading to anemia, neutropenia, changes in ossification, and elevated plasma cholesterol (Zatta and Frank 2007). Severe cases display seizures. In the brain, deficiency of bioavailable copper plays a major role in the pathogenesis of many neurodegenerative diseases like Prion disease, Alzheimer's disease (AD), Huntington disease (HD), Parkinson's disease (PD), etc. (further explained in "role of copper in neurological diseases" below).

150.5.3 Copper Toxicosis

As mentioned earlier, increased amounts of copper can cause excessive oxidative stress and significant tissue damage. The oxidative stress is a consequence of the redox reactivity of copper via the Fenton reaction, i.e. production of free radicals by catalysing the reaction between superoxide anion and hydrogen peroxide. Tissue damage is caused by the structural disruption of proteins by copper and also as a result of oxidative stress (Uriu-Adams and Keen 2005). Copper toxicosis can occur as a result of copper poisoning, increased dietary intake or genetic defects. Copper poisoning reports indicate instances of accidental or deliberate ingestion of beverages contaminated with copper. Symptoms in these cases progress from abdominal pain, nausea, vomiting, headache, lethargy and diarrhea to tachycardia, respiratory difficulties, hemolytic anemia, gastrointestinal bleeding, liver and kidney failure, finally resulting in death (Hyun and Filippich 2004). Genetic copper toxicity disorders include Wilson's disease, Idiopathic copper toxicosis (ICT), Indian childhood cirrhosis (ICC), and endemic Tyrolean infantile cirrhosis (ETIC), all of which have an autosomal recessive mode of inheritance (Mercer 2001; Hyun and Filippich 2004; Balamurugan and Schaffner 2006). ICT, ICC, and ETIC are all fatal hepatic diseases. Copper contaminated milk feeds have been implicated in ICC and ETIC (Hyun and Filippich 2004; Balamurugan and Schaffner 2006). Copper toxicosis also contributes toward some neurodegenerative diseases like ALS and Creutzfeldt-Jakob disease (CJD) (Uriu-Adams and Keen 2005). In liver, copper accumulation can also occur as a consequence of chronic cholestatic liver diseases like primary biliary cirrhosis and chronic hepatitis.

150.5.4 Other Diseases Associated with Copper

Although metallic copper is insoluble, inhalation of copper dust from industrial processes can cause "copper fever" that presents with sweetish taste in mouth, dry throat, burning eyes, followed by severe headache, leukocytosis, fatigue, and catarrhic symptoms (Balamurugan and Schaffner 2006). Altered copper metabolism has also been reported in inflammation, infection, and cancer (reviewed by Linder 2002).

Key Points of Copper

- A number of essential enzymes in the cell require copper for their normal function.
- Copper is a trace element that is essential for life.
- Too little or too much is bad, but exquisite handling at the level of the cell and organs, ensures the desired homeostasis.
- We require less than 1 mg of copper per day.

150.6 Copper and the Brain

Copper contributes positively to brain development and function. Besides cytochrome *c* oxidase, which is essential for energy generation in brain, copper is utilized by dopamine β mono-oxygenase and peptidyl α amidating mono-oxygenase, both of which are important for the biosynthesis of neurotransmitters. Transport of copper across the BBB and distribution within the brain is regulated by ATP7A, the mutation of which leads to severe deficiency of copper in the brain. Bioavailability of copper is also important for normal functioning of the brain. While chronically high or low copper levels lead to major abnormalities such as Menkes or Wilson's disease, some evidence suggest that even more subtle changes in copper homeostasis have an impact on the brain, leading to some of the major late onset neurological diseases. However, more work is required to decipher the exact mechanisms of these relationships.

150.6.1 Role of Copper in Neurological Diseases

PD is the second most common neurodegenerative disorder after Alzheimer's disease, affecting both men and women over 50. PD is characterized by abnormalities of movement, such as tremor, muscular rigidity, and postural instability brought about by the degeneration of neurons in a region of the brain that controls movement. Copper affects the oligomerization of α-synuclein (Paik et al. 1999), a key protein implicated in PD. Furthermore, dopamine that is strongly associated with PD may become more toxic when it interacts with copper (Paris et al. 2001; Snyder and Friedman 1998; Spencer et al. 1994).

Prions are infectious protein particles involved in transmissible spongiform encephalopathies (TSEs), which includes CJD, scrapie, chronic wasting disease (CWD), and bovine spongiform encephalopathy (BSE). These fatal neurodegenerative diseases are caused by the misfolding of cellular prion protein PrP^c to the infective disease causing isoform, PrP^sc. Brain copper has been reported to be low in TSEs (reviewed by Legleiter et al. 2007). Furthermore, some studies indicate that human prions have copper binding sites (Brown et al. 1997; Hornshaw et al. 1995). It is speculated that the binding of copper to PrP^c may serve to stabilize the protein and allow normal function (Legleiter et al. 2007). However, this requires further research.

ALS is a progressive neurodegenerative disease that affects upper and lower motor neurons resulting in muscle weakness and atrophy. Death due to respiratory failure occurs within a short time from the onset of symptoms. The familial form of ALS is found to have a mutation in Cu–Zn SOD gene. Though one group has reported severe copper depletion of spinal cord in copper-deficient SOD, contradictory results have been reported by others (reviewed by Zatta and Frank 2007). Hence, further investigation is warranted to understand the molecular mechanism.

HD is another progressive neurodegenerative disease characterized by glutamine expansion within the N-terminus of huntingtin protein. Affected individuals undergo progressive motor, cognitive, and psychiatric deterioration. HD brain has shown an accumulation of copper and iron in the

striatum (Dexter et al. 1991). Recent studies indicate a pro-oxidant interaction between copper and huntington protein (Fox et al. 2007).

150.6.2 Copper and Alzheimer's Disease

AD is a fatal and highly debilitating progressive mental disorder that generally affects people over 65 or as young as 40–50 years. It is the most prevalent form of dementia and is characterized by severe cognitive impairment due to degeneration of brain cells that handle speech, memory, and thought. The most important protein implicated in AD is the Alzheimer's Precursor Protein (APP) from which the Aβ peptide, or β-amyloid is derived. APP has two copper binding sites, including one in the Aβ peptide sequence (Atwood et al. 1998; Hesse et al. 1994). In transgenic mice, the overexpression of APP appeared to reduce levels of copper in brains (Bayer et al. 2003; Maynard et al. 2002; Phinney et al. 2003) suggestive of APP being a copper transporter (White et al. 1998). Although APP has no yeast equivalent, it performed copper efflux in yeast (Treiber et al. 2004) as it does in brains. Two other proteins, Aplp1 and Aplp2, may also perform copper efflux since they have copper binding domains and structural similarity (Hesse et al. 1994; White et al. 1998, 1999a, b).

APP is unique among the APP/Aplp1/Aplp2 family because it is cleaved by the BACE protease (Vassar et al. 1999) and γ secretase protease to produce Aβ. Aβ exhibits neurotoxicity and is a major component of the extracellular Aβ plaques associated with AD. The extracellular plaques are a reservoir for a number of metals, including copper, and it is has been considered that the copper in these plaques may be available for the production of reactive oxygen species (ROS) which could cause neuronal loss and brain damage (Bush 2000). However, in view of the overall decline in copper levels as brains age, the alternate possibility of a build up of Aβ causing a copper shortfall, should also be considered.

150.6.3 Manipulation of Brain Copper Levels

The possibility of manipulating neuronal copper levels may lead to rational approaches to the treatment of neurological diseases. Clioquinol, a metal chelating compound, and some related compounds represent some of the most promising drugs that have been trialled to date. Clioquinol reduces plaque in mouse AD models and it appears to alter copper levels (Cherny et al. 2001). In a treatment of APP 750[SL] transgenic mice, clioquinol was shown to improve survival (Schafer et al. 2007). While clioquinol reduced serum copper levels from around 800 to around 500 μg/l, even with added copper in the diet, brain copper significantly increased, from 3.9 to 4.2 μg/g with added dietary copper. The treated mice also exhibited normal survival and improved memory, suggesting that clioquinol enabled brain copper levels to increase, and this in turn gave the positive benefit. Clioquinol also increased copper levels in yeast producing APP (Treiber et al. 2004).

Interesting results from Sparks and Schreurs show that in cholesterol-fed rabbits, increased copper led to increased deposits of Alzheimer's Aβ brain plaque (Sparks and Schreurs 2003). Plaques were induced at levels of 0.12 ppm copper in drinking water (much lower than the levels of 1.3 ppm permitted by water supply agencies). We suggest that conversely, lower cholesterol levels could lead to lower copper levels, reducing Aβ plaques. Interestingly the statins, blockbuster cholesterol-lowering drugs, appear to be the best drug to lower the incidence of AD. One particular statin, simvastatin, is

unique with respect to reducing AD (Wolozin et al. 2007). Unlike many other statins, simvastatin is lipophilic and crosses the blood–brain–barrier (BBB), so it may be expected that simvastatin would reduce cholesterol synthesis in the brain.

Finally, vaccine approaches may have some merit in animal models of AD by clearing Aβ plaque. Whether this affects brain copper has not been considered but presumably metals associated with the plaque would be removed along with plaque.

It is clear that much is now known about copper homeostasis, but there is still some way to go before we conquer neurological diseases that involve copper. It is likely that an increased understanding of copper homeostasis may help in unravelling the many important neurological diseases involving copper metabolism.

Key Points of Copper in Brain

- Copper contributes positively to brain development and function.
- Most of the major neurological disorders are due to the disruption of copper homeostasis caused by abnormal copper interactions or irregular copper metabolism.
- Manipulation of brain copper levels with compounds like clioquinol or statins could be a rational solution.

150.7 Applications to Other Areas of Health and Disease

The importance of copper in nutrition and copper homeostasis has been emphasized in this chapter. This knowledge has implications for the animal husbandry, crop management, biological control strategies, and possibly the treatment of human diseases. For example, upsetting the copper homeostasis by increasing copper levels is a strategy in antifungal control in agriculture, where copper sulphate can be applied to prevent the growth of mould, mildew, and rust fungus in crops. Likewise copper sulphate performs effectively as an algaecide in domestic swimming pools. The converse strategy, lowering copper levels, may also be a strategy to consider for impeding cell growth. Specific copper chelators such as bathocuproine sulphate can effectively inhibit the growth of cells.

Copper-deficiency in soils may also adversely affect agricultural outputs. In Australia, copper deficient soils were associated with lower wool yields in sheep. Recognizing the deficiency of copper and other trace elements in many soils have led to remedial practices such as the use of salt licks.

Detailed knowledge of copper homeostasis also provides the insights required in engineering super microbes that may help in bioremediation. For example, copper is a significant pollutant at mining sites and its removal requires novel strategies such as organisms that have increased ability to sequester copper. Metallothioneins are not limited to copper sequestration; they can sequester other metals as well.

Potentially copper homeostasis could also be altered to control cell proliferative diseases; however, lack of specificity is likely to be an issue.

Summary Points

- Copper is essential for all cells. Depletion of copper leads to loss of growth and survival.
- Copper is a cofactor for a number of cuproenzymes involved in diverse reactions.
- Excess copper can be toxic. Thus all biological systems have complex mechanisms to maintain correct copper levels.

- The fate of copper, its roles, and its biological functions has been strongly supported by studies in yeast.
- The brain may be very sensitive to copper levels which change with aging.
- Copper is a significant factor in neurodegenerative diseases, including Alzheimer's Disease.

Definitions and Explanations

Bioavailability: The amount of substance that is absorbed by the body and becomes available at the site of biological activity.

Blood–brain–barrier: A membrane barrier that separates many compounds from the brain, including various drugs, biochemicals, and macromolecules.

Copper Efflux: Outward flow of copper from the cell in the event of excess copper.

Cuproenzymes: Enzymes that require copper for their normal function.

Homeostasis: The maintenance of a constant state. Cells require homeostasis for survival, as well as for growth.

Statins: The world's largest selling prescription drugs. Although prescribed for lowering cholesterol levels they also lower the incidence of AD and PD.

Yeast studies: The yeast Saccharomyces cerevisiae is a model organism for human studies. Resources pertaining to the yeast genome can be found at www.yeastgenome.org.

Chapter 151
Fetal–Neonatal Iron Deficiency Affects Neurotrophic Factor Expression, Neural Differentiation, and Neuroplasticity in the Rat Hippocampus

Michael K. Georgieff and Phu V. Tran

Abbreviations

BDNF	Brain-Derived Neurotrophic Factor
CNTF	Ciliary Neurotrophic Factor
Dcx	Doublecortin
Dusp4	Dual Specificity Phosphatase 4
Egr1 and 2	Early-Growth-Response-Gene 1 and 2
EGF	Epidermal Growth Factor
ERK1 and 2	Extracellular-Signal Regulated Kinase 1 and 2
FID	Formerly Iron-Deficient
GDNF	Glial-Derived Neurotrophic Factor
Hif1α	Hypoxia Inducible Factor 1α
HMGCR	3-Hydroxy-3-Methylglutaryl Coenzyme A Reductase
ID	Iron-Deficient
IS	Iron-Sufficient
LTP	Long-Term Potentiation
Mbp	Myelin Basic Protein
mTOR	Mammalian Target of Rapamycin
NGF	Nerve Growth Factor
p75^{NTR}	Neurotrophic Receptor p75
P	Postnatal Day
PARV	Parvalbumin
qPCR	Quantitative RT-PCR
TrkB	Tyrosine-Receptor Kinase B
TUNEL	TdT-Mediated biotin-dUTP Nick End Labeling

151.1 Introduction

151.1.1 Fetal and Neonatal Iron Deficiency Impairs Cognitive Development

Iron deficiency is one of the foremost early-life micronutrient deficiencies, affecting approximately 30–50% of preschool age children and pregnant women worldwide (WHO 2008). Late gestational and neonatal (perinatal) iron deficiency arises from four common maternal gestational conditions: severe iron deficiency anemia (IDA), placental vascular insufficiency resulting from maternal hypertension, diabetes mellitus, and cigarette smoking (Chockalingam et al. 1987; Petry et al. 1992; Sweet et al. 2001). The adverse neurobehavioral effects of early-life iron deficiency in humans and animal models are considerable and long-lasting (Lozoff and Georgieff 2006). For example, iron-deficient (ID) human newborns exhibit deficits in cognitive development that last beyond the period of iron deficiency (Nelson et al. 2000; Siddappa et al. 2004; Riggins et al. 2009). While certain developmental deficits recover with iron treatment, cognitive deficits following neonatal and early postnatal iron deficiency in humans persist up to 10 years after iron treatment (Tamura et al. 2002; Lozoff et al. 2006). Fetal and neonatal ID rodents and monkeys showed similar adverse neurobehavioral effects (Golub et al. 2006; Felt et al. 2006; Schmidt et al. 2007). The potential neural basis of these cognitive deficits continues to be an active research area; however, these effects imply an impaired hippocampus, a brain region responsible for learning and memory.

151.1.2 Fetal–Neonatal Iron Deficiency Alters Hippocampal Structure, Function, and Gene Expression in the Rat Model

In rats, fetal–neonatal iron deficiency resulted in abnormal hippocampal CA1 dendritic structure, impaired synaptic transmission, and increased susceptibility to deleterious infarction (Jorgenson et al. 2003, 2005; Rao et al., 2007). These findings support the hypothesis of an abnormal hippocampus in ID rats. The possibility of early-life ID leading to dysregulation of genes necessary for proper hippocampal development was investigated with a microarray mRNA profiling analysis (Carlson et al. 2007). This work identified alterations in salient molecular pathways involved in neuronal differentiation with most notably the Alzheimer-related gene network centered on amyloid precursor protein and the mammalian target of rapamycin (mTOR) pathway (Carlson et al. 2007, 2008). The amyloid precursor protein gene network has been implicated in cytoskeletal remodeling, cell motility and growth cone formation during hippocampal development (Guenette et al. 2006; Ikin et al. 2007). The mTOR pathway integrates external stimuli such as nutrients and growth factors and gene expression necessary for the synaptic maturation and plasticity in the hippocampus (Tang et al. 2002; Schratt et al. 2004).

151.1.3 Neurotrophic Factors Mediate Hippocampal Development and Function

Neurotrophic factors such as nerve growth factor (NGF) and brain-derived neurotrophic factor (BDNF) regulate multiple aspects of neuronal differentiation and plasticity in the hippocampus (Hennigan et al. 2007). Fetal and neonatal environments affect the expression of these neurotrophic

factors. For example, an enriched environment has beneficial effects on hippocampal function and is accompanied by increased NGF and BDNF levels, whereas an adverse environment impairs memory function and lowers NGF and BDNF expression (Pham et al. 2002; Branchi et al. 2004). In addition, neural activity such as induction of long-term potentiation (LTP), a cellular phenomenon associated with memory formation, in the rodent hippocampus rapidly increases NGF and BDNF mRNA levels (Patterson et al. 1992; McAllister et al. 1999).

The role of BDNF in mediating hippocampal function is well established, as exemplified by deficits of learning and memory in rodents with BDNF suppression or gene targeted-deletion (Korte et al. 1995; Heldt et al. 2007). BDNF is a complex gene with multiple mRNA variants containing a common protein-encoding region (Timmusk et al. 1993). BDNF signaling is mediated by tyrosine-receptor kinase B (TrkB) and p75 neurotrophic receptor (p75^{NTR}) (Chao 2003). Full-length TrkB (TrkB$_{FL}$) contains the intracellular kinase signaling domain, while several short (truncated) isoforms (TrkB$_{S}$) lack this signaling domain (Klein et al. 1990). The p75^{NTR} is a low affinity receptor that binds promiscuously to BDNF as well as other known neurotrophic factors. BDNF binding of TrkB promotes neurite outgrowth and synaptic plasticity in part through regulation of activity-dependent immediate early genes c-fos, early-growth-response-gene 1 and 2 (Egr1 and Egr2) (Alder et al. 2003; Calella et al. 2007). In contrast, BDNF binding of p75^{NTR} reduces neurite outgrowth and mediates long-term depression (Woo et al. 2005; Zagrebelsky et al. 2005).

151.1.4 Fetal–Neonatal Iron Deficiency and Hippocampal Expression of Neurotrophic Factors

The effects of fetal–neonatal iron deficiency on the expression of neurotrophic growth factors critical for hippocampal neurogenesis, differentiation and plasticity have remained unresolved. However, the abnormal hippocampal dendritic morphology and impaired neurotransmission observed in fetal–neonatal ID rats led to the hypothesis that iron deficiency would result in dysregulation of neurotrophic factors involved in hippocampal differentiation and neuroplasticity. Moreover, the persistent deficits of hippocampal-dependent tasks in formerly iron-deficient (FID) rats, that were ID during fetal–neonatal period (Felt et al. 2006; Schmidt et al. 2007), imply a long-lasting change in regulation of neurotrophic factors including BDNF. Indeed, we found evidence of diminished BDNF signaling during and after a period of iron deficiency in the rat hippocampus (Tran et al. 2008, 2009).

151.2 Fetal–Neonatal IDA Acutely Alters Expression of Neurotrophic Factors and Delays Hippocampal Neuron Differentiation

151.2.1 Increased Expression of Neurotrophic Factors During Peak Normal Neuronal Differentiation in Rat Hippocampus

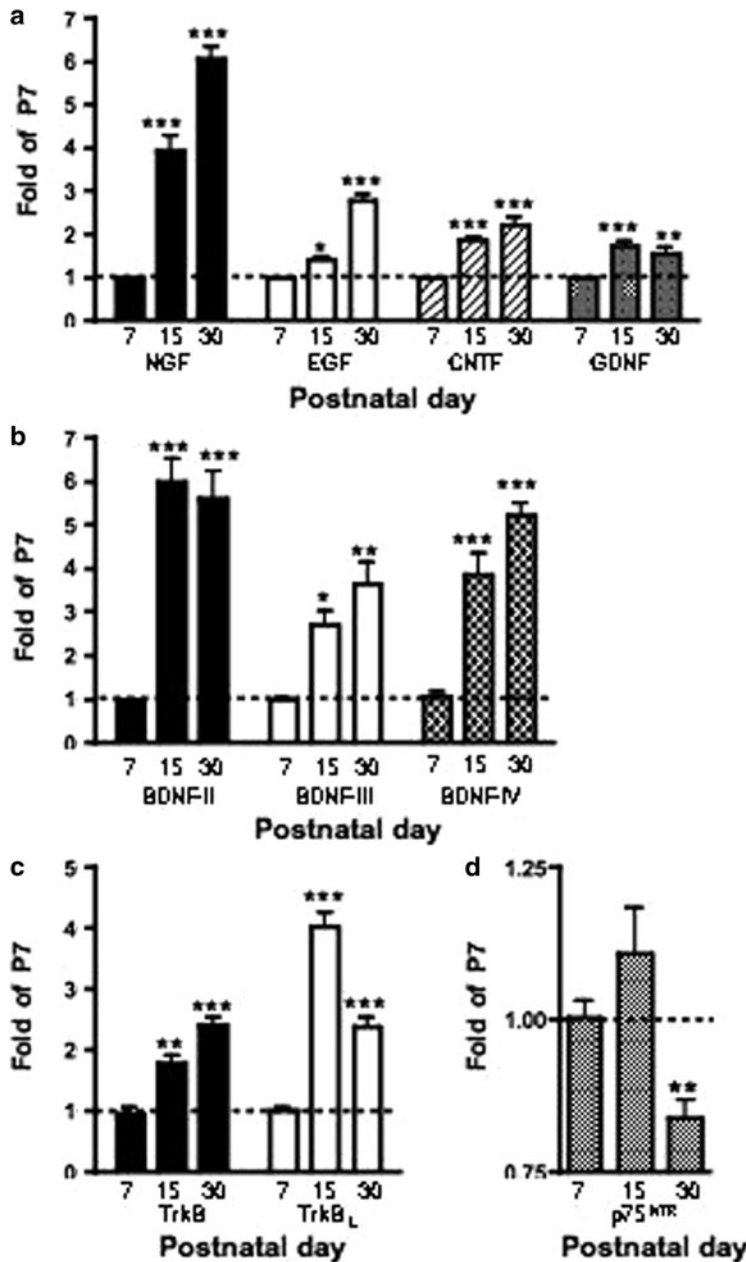
Differentiation of hippocampal neurons occurs rapidly during P15 and P30 in rats (Pokorny and Yamamoto 1981; Steward and Falk 1991) with a corresponding increase in iron uptake (Siddappa et al. 2002). Quantitative measurement (real-time PCR) of messenger RNA (mRNA) for ciliary neurotrophic factor (CNTF), epithelial growth factor (EGF), glial-derived neurotrophic factor (GDNF),


Fig. 151.1 Expression of neurotrophic factor mRNA levels at P7, P15, and P30 in the male rat hippocampus. Levels of messenger RNA (mRNA) were compared to P7, demonstrating the developmental expression of neurotrophic factors. (**a**) Nerve growth factor (NGF), EGF, CNTF, and glial-derived neurotrophic factor (GDNF), (**b**) BDNF -II, -III, and -IV, (**c**) total TrkB and TrkB full-length (TrkB$_L$), and (**d**) p75 neurotrophic receptor (p75^{NTR}). Values are means ± SEM, n = 4–6. Asterisks denote P-values as follows: *$P < 0.05$, **$P < 0.01$, ***$P < 0.001$ (Modified and printed with permission from American Society for Nutrition)

and NGF showed higher levels at P15 and P30 compared to P7 (Fig. 151.1a). Likewise, BDNF-II, III and IV transcripts were greater at P15 and P30 compared to P7, with BDNF-II mRNA being at a negligible level compared to BDNF-III and IV in the developing rat hippocampus (Fig. 151.1b). Similar findings were also observed for BDNF receptors, TrkB and p75^{NTR} (Fig. 151.1c). Taken

together, peak expression of NGFs and their cognate receptors occurs during periods of rapid differentiation in the rat hippocampus (Tran et al. 2008). These findings are consistent with the role of neurotrophic factors in promoting neuronal differentiation and dendritic outgrowth.

151.2.2 Increased EGF, GDNF, NGF and p75^{NTR}, and Deceased BDNF Expression During Fetal–Neonatal ID in the Hippocampus

While CNTF levels were unaffected, levels of EGF, GDNF and NGF were greater in the ID compared to IS rats at P15 (Table 151.2). In contrast, iron deficiency decreased BDNF transcripts across development with a significant reduction of BDNF-III at P7 and BDNF-IV at P7 and P15 (Table 151.2). The difference was less significant between groups at P30, suggesting a normalization of expression with iron therapy. Despite lower BDNF levels, expression of its high affinity receptor TrkB was similar between ID and IS groups, suggesting an absence of an expected compensatory upregulation (Table 151.2). However, iron deficiency increased p75^{NTR} levels at P7 and P15. Collectively, iron deficiency dysregulates neurotrophic factors and associated receptors during the period of iron deficiency (Tran et al. 2008).

The reduced BDNF during periods of neural proliferation and differentiation (P7 and P15) may account for the 14% reduction in hippocampal size (Rao and Georgieff, unpublished data) and abnormal CA1 dendritic structure in older FID rats (Jorgenson et al. 2003). The effect of iron deficiency on proliferation and cell number remains unresolved with preliminary findings of increased neuronal turnover in a late gestational embryonic ID hippocampus (Lehman and Georgieff, unpublished data). Increased EGF, GDNF, NGF, and p75^{NTR} expression in the ID hippocampus suggest utilization of alternate pathways to compensate for the lower BDNF expression. Upregulation of EGF might facilitate neurogenesis and differentiation in ID hippocampus (Wong and Guillaud 2004). Likewise, GDNF could synergize with BDNF to promote neuronal survival (Erickson et al. 2001), minimizing the adverse effects of reduced BDNF. It is worthwhile to note that both EGF and GDNF mediate astrocyte proliferation and differentiation (Wong and Guillaud 2004; Chen et al. 2005). The effects of fetal–neonatal iron deficiency on astroglia development have not been fully investigated, albeit metabolomic evidence suggests increased astroglia in the ID hippocampus (Rao et al. 2003). Increased EGF and GDNF levels may affect the astroglia number as well as regulation of glutamine synthase activity (Yamada et al. 1997), in line with increased glutamine levels observed in the ID hippocampus (Rao et al. 2003). However, it is less clear what effects increased NGF and p75^{NTR} may have in the ID hippocampus. ProNGF/p75^{NTR} signaling induces neuronal apoptosis contrasting the survival effect of the mature-NGF/TrkA sig-

Table 151.1 Key facts of neurotrophic factors

1. A family of proteins classically includes nerve growth factor (NGF), BDNF, neurotrophin-3 (NT-3), and neurotrophin-4/5 (NT-4/5). These factors each bind a specific tyrosine receptor kinase (Trk) with high affinity (i.e. NGF/TrkA, BDNF/TrkB, NT-3, 4/TrkC). All bind p75 receptor with low affinity.

2. The non-classical members of neurotrophic factors include glial-derived neurotrophic factor (GDNF), CNTF, cardiotrophin-1 (CT-1), interleukin-6 (IL-6), and leukemia inhibitory factor (LIF). With the exception of GDNF, which initiates intracellular signaling by binding to the RET receptor tyrosine kinase, other factors bind and signal via G-protein coupled receptor (GPR130).

3. The role of neurotrophic factors is to regulate differentiation, growth, survival, and plasticity of both central and peripheral nervous systems.

This table describes general key facts of neurotrophic factors and their receptors. The binding of the neurotrophic factor to its cognate receptor initiates a signaling cascade that results in increased transcription and/or translation of downstream effectors

Levels of transcript (messenger RNA) for relevant neurotrophic factors and BDNF receptors were compared between iron-sufficient (IS) control and iron-deficient (ID) hippocampi. Data were standardized to P7 value to demonstrate changes in transcript level across postnatal ages. Values are means ± SEM, $n = 4$–6. Means in a row without a common letter differ, $P < 0.05$ (a < b < c). *Asterisk denotes the difference from IS at a time, $P < 0.05$ Post-hoc Bonferroni corrected t-test

naling (Friedman 2000; Lee et al. 2001). Elevated NGF and p75[NTR] transcripts in the ID hippocampus would have predicted an increase in neuronal apoptosis. However, the observed reduction in apoptosis in postnatal ID hippocampus (Tran et al. 2008) suggests that increased NGF and p75[NTR] likely have a survival effect as seen in other studies (Bui et al. 2002; Culmsee et al. 2002). In addition, p75[NTR] is known to promote high-affinity ligand/receptor binding (e.g., BDNF/TrkB) and ligand/receptor retrograde transport (Chao 2003). The upregulation of p75[NTR] might act in a compensatory manner to promote BDNF/TrkB signaling, facilitating synaptic formation and LTP (Minichiello et al. 2002).

151.2.3 Reduced Doublecortin (Dcx) Expression is Associated with Delayed NeuN-Nuclear Accumulation in the Developing ID Hippocampus

The persistently immature form of electrophysiology (Jorgenson et al. 2005) combined with reduced NMDAR (NR2B) expression (Jorgenson and Georgieff, unpublished data) suggest an abnormal development of hippocampal glutamatergic neurotransmission in fetal–neonatal ID rats. Consistent with this effect, the level of Dcx, a microtubule-associated protein expressed in differentiating neurons (Francis et al. 1999), was reduced by 40% in the ID hippocampus at P15 (Fig. 151.2a). Dcx localization was similar in P15 IS and ID hippocampi with prominent expression in the dentate gyrus proper (Fig. 151.2b). ID rats also showed a failure of NeuN, a nuclear neuronal marker, localization to the nucleus of pyramidal neurons by P30 as seen in IS rats (Fig. 151.2c,d) (Tran et al. 2008). These findings imply a delay of neuronal maturation in the ID hippocampus during a period of rapid differentiation. Based on the increase demand of iron uptake during this developmental period (Siddappa et al. 2002), we propose that iron deficiency results in deferment of neuronal differentiation, perhaps leading to an extension of this rapid growth period, until sufficient iron replenishment. This developmental brake hypothesis is in agreement with the observed NeuN-nuclear localization in the hippocampus of iron-repleted P65 rats (Fig. 151.2e,f).
Fig. 151.2 Reduced P15 doublecortin (Dcx) expression and abnormal NeuN localization in the ID rat hippocampus. (**a**) Expression of a neuronal differentiation marker, doublecortin (Dcx), showed a significant reduction in the postnatal day (P)15 ID hippocampus compared to the IS control. Values are means ± SEM, $n = 4$–6. *$P < 0.05$, Mann-Whitney U-test. (**b**) Localization of Dcx protein in the dentate gyrus (DG) of the P15 ID rat. There was no apparent difference in Dcx localization between the IS and ID hippocampus. (**c–d**) NeuN staining in the dentate gyrus of P30 IS (**c**) and ID (**d**) hippocampi. Note the absence of NeuN in nuclei of ID neurons. Similar observations were seen in CA1 and CA3 hippocampus (data not shown). (**e–f**) NeuN staining in CA1 of P65 IS and FID rats. Note the presence of NeuN in cell nucleus. Scale bar = 50 μm

151.3 Long-Term Reduction of BDNF Activity in Adult Rats That Experienced Iron Deficiency During Fetal–Neonatal Period

The etiology of long-term the learning impairment seen in fetal and neonatal ID humans and rodent models remain largely unknown. The possibility of long-term dysregulation of neurotrophic factors and their downstream targets that regulate a cascade of molecular mediators of synaptic plasticity in FID rats was investigated (Tran et al. 2009).

151.3.1 Decreased Hippocampal BDNF and TrkB Expression in P65 FID Rats

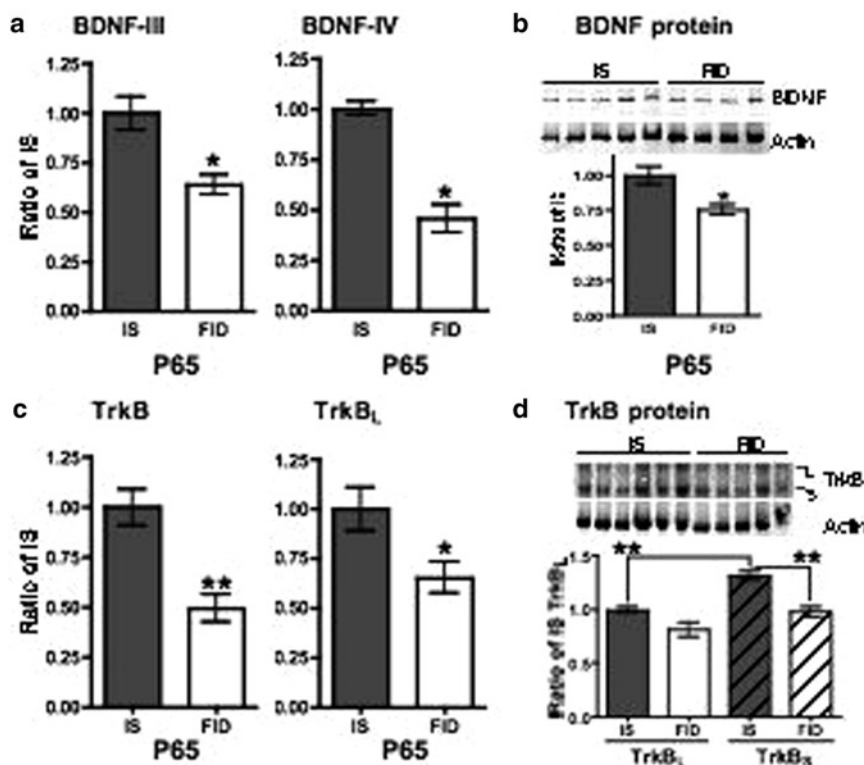
Levels of p75^{NTR}, CNTF, CTGF, EGF, GDNF, and NGF were not different between the always IS control and FID P65 rats. However, P65 FID rats had lower levels of BDNF and its high affinity receptor TrkB (Fig. 151.3). Interestingly, truncated TrkB (TrkB$_S$) is expressed at a higher level than TkB$_{FL}$ in the control hippocampus, but not in the FID hippocampus at P65 (Fig. 151.3d). This finding


Fig. 151.3 Reduced BDNF and TrkB expression in the P65 FID hippocampus. Hippocampal expression of BDNF and TrkB receptor were compared between the control (always IS) and the formerly iron-deficient (FID) rats. Data were normalized to IS control. FID rats showed a reduced expression of BDNF and its cognate receptor TrkB. BDNF mRNA (**a**) and protein (**b**). TrkB mRNA (**c**) and protein (**d**). Values are means ± SEM, $n = 4$–6. *$P < 0.05$ and **$P < 0.01$, Mann-Whitney U-test (Modified and printed with permission from Wolters Kluwer Health)

suggests that the P65 FID hippocampus retains immature characteristics compared to the IS control hippocampus (Silhol et al. 2008). Despite having limited signaling capability, TrkB$_S$ has been implicated to negatively affect BDNF/TrkB signaling (Eide et al. 1996; Pillai and Mahadik 2008). Thus, the lower level of TrkB$_S$ in the FID hippocampus might have a compensatory effect by increasing the signaling capability of the available full-length receptor. Even with lower levels of BDNF and TrkB expressions, protein localization appeared similar in the hippocampus of both groups (Tran et al. 2009). While further ultrastructural analysis of protein localization is needed to ascertain these findings, preliminarily they imply an overall lower BDNF signaling in the hippocampus of FID rats without compromising their localization. The specific reduction of BDNF expression in FID rats suggests a more permanent change in its regulation induced by early iron deficiency. The precise mechanism awaits further investigation. One possibility may involve epigenetic modification (e.g., DNA methylation) at the BDNF gene, which was hypermethylated in rats exposed to adverse early-life environment (Roth et al. 2009).

151.3.2 Reduced Hippocampal Expression of BDNF-Activity Dependent Gene Cascades

In the postnatal brain, BDNF regulates neuronal HMGCR, the rate-limiting enzyme in cholesterol synthesis that facilitates synaptic vesicle formation (Suzuki et al. 2007). Consistent with lower BDNF activity, the level of HMGCR was decreased in P65 FID hippocampus (Fig. 151.4a), suggesting that vesicle formation may be compromised (Tran et al. 2009). Combined with a lower level of synaptobrevin I (Carlson et al. 2007), a protein involved in vesicle fusion (Schiavo et al. 1997), this finding may underlie the impaired paired-pulse facilitation and reduced synaptic efficacy seen in adult hippocampal slice preparations following recovery from fetal–neonatal iron deficiency (Jorgenson et al. 2005). Paired-pulse facilitation and LTP are important indices of neuroelectrophysiologic events during neurotransmission and LTP is widely accepted as a cellular substrate for learning and memory (Malenka 2003).

BDNF also induces the expression of c-fos, Egr1, and Egr2, which are activity-dependent immediate early transcription factors that facilitate LTP in the hippocampus (Alder et al. 2003; Rossler and Thiel 2004). Expression of these genes was also decreased in FID rats (Fig. 151.4b–d) (Tran et al. 2009). Lower c-fos expression may not only lead to a reduction in expression of genes necessary for LTP (Miyamoto 2006) but may also contribute to further reduction of BDNF expression (Dong et al. 2006), thereby leading to lesser plasticity in the hippocampus of FID rats. As expected, reduced expression of Egr1 was accompanied by lower expression of its known target genes, hif1α and Dusp4 (Berasi et al. 2006; Sperandio et al. 2009), in the hippocampus of FID rats (Fig. 151.5a,b) (Tran et al. 2009). Hif1α is an oxidative-state-dependent transcription factor that regulates chemokine (C-X-C motif) ligand 12 (Cxcl12), an important modulator of synaptic formation (Klein and Rubin 2004). Cxcl12 mRNA expression is reduced in FID rats (Carlson et al. 2007). Combined with similar long-term reductions in post-synaptic density 95 (PSD95) and calmodulin-dependent kinase IIα (CamKIIα), these changes may account for the abnormal apical dendritic length and branching in FID hippocampal neurons (Jorgenson et al. 2003; Carlson et al. 2007). DUSP4 (protein) is a dual specificity phosphatase targeting phosphorylated extracellular signal-regulated kinases 1 and 2 (ERK1 and ERK2), factors phosphorylated during formation of memory (Guan and Butch 1995; Kelly et al. 2003). Reduction of DUSP4 activity and the consequential increased level of phosphorylated ERK1/2 in FID compared to IS rats (Fig. 151.5c) could further contribute to impaired synaptic
Fig. 151.4 Reduced expression of BDNF activity-dependent genes in the P65 FID hippocampus. Hippocampal expression of (**a**) HMGCR, (**b**) c-fos, (**c**) Egr1, and (**d**) Egr2 were compared between the IS control and the FID rats. FID rats showed a lower expression of these factors, consistent with a decrease in BDNF signaling. Values are means ± SEM, n = 4–6. *P < 0.05, **P < 0.01 Mann-Whitney U-test (Modified and printed with permission from Wolters Kluwer Health)

plasticity by dampening neuronal responsiveness to stimulation (Tran et al. 2009). Alternatively, sustained phosphorylation of ERK1/2 may reflect the compensatory state of the already lowered neural plasticity in FID rats. Reduced Egr2 expression resulted in lower expression of its target genes (Fig. 151.5d,e) (Tran et al. 2009), insulin-like growth factor 2 (IGF-II) and myelin basic protein (Mbp) (Gillian and Svaren 2004; Jang et al. 2006), which are important for myelin health and glial contributions to plasticity. In the adult brain, IGF-II is expressed in astroglia (Rotwein et al. 1988) and regulates myelin associated protein genes (Ye et al. 2002). Mbp is a complex gene with multiple splice variants, encoding a major component of the myelin sheath of oligodendrocytes. Decreased IGF-II and Mbp expression together may contribute to the impairment of myelination and the compromised neural transmission seen in the P65 FID hippocampus (Jorgenson et al. 2005). While whole brain Mbp expression is acutely reduced during iron deficiency (Beard et al. 2003; Clardy et al. 2006), these findings in the hippocampus of FID animals provide evidence for a long-term effect of fetal–neonatal iron deficiency on the health and function of astrocytes and oligodendrocytes.
Fig. 151.5 Reduced expression of Egr1- and Egr2-target genes and parvalbumin in the P65 FID hippocampus. Assessment of Egr1 target, Hif1a (**a**) and Dusp4 (**b**), showed a lower expression in FID rats. (**c**) The increase of phosphorylated-ERK1/2 (P-ERK1/2) suggests a decrease in Dusp4 activity because Dusp4 converts P-ERK1/2 to ERK1/2. Lower transcript levels of Egr2 target, Igf2 (**d**) and Mbp (**e**), indicate a decrease in Egr2 transcriptional activity in FID rats. Together with Igf2 and Mbp, reduced parvalbumin expression (**f**) suggests impaired astroglia function in FID rats. Values are means ± SEM, $n = 4$–6. *$P < 0.05$ and **$P < 0.01$, Mann-Whitney U-test (Modified and printed with permission from Wolters Kluwer Health)

BDNF also mediates interneuron differentiation in rodent hippocampus (Marty et al. 1996; Grosse et al. 2005). More research is needed to determine comprehensively the effect of early-life iron deficiency on interneuron development. However, mRNA level of parvalbumin (PARV), a calcium-binding protein expressed in a subset of interneurons, was lower in the FID rat hippocampus (Fig. 151.5f). Whether the lower parvalbumin transcript in the FID hippocampus reflects a decrease in gene expression or a fewer number of PARV-positive (+) cells remain to be determined. It is unclear if lower BDNF expression would lead to a decrease in PARV+ cell number. Study of BDNF knock-out mice suggested a decrease of hippocampal PARV+ cell (Grosse et al. 2005); however, exogenous administration of BDNF showed no such effect in cultured rat hippocampal slice preparations (Marty et al. 1996). Nonetheless, lower parvalbumin expression might contribute to impaired plasticity in the FID rat by reducing synaptic efficacy (Jiang et al. 2004).

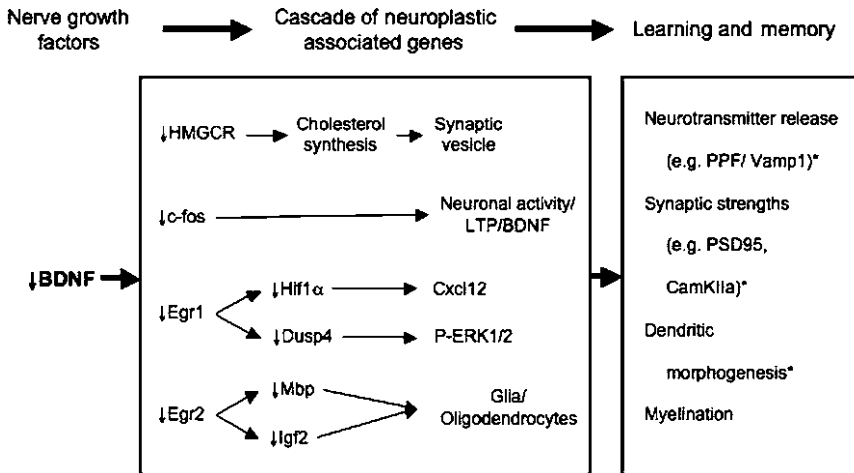
In summary, these findings reveal an overall diminished BDNF-mediated neural development and plasticity during and beyond iron deficiency periods. We propose that this specific effect may serve as molecular basis for the electrophysiological, morphological, and ultimately behavioral abnormalities that persist beyond the period of fetal–neonatal iron deficiency (Fig. 151.6) (Lozoff et al. 2006).


Fig. 151.6 Proposed mechanism. A possible molecular mechanism underlying a reduced BDNF activity leading to decreased neuroplasticity in FID rats. BDNF signaling regulates a cascade of factors that modulate neural plasticity, a basis of learning and memory. *Asterisk denotes previously altered factors contributing to lower synaptic plasticity (Modified and printed with permission from Wolters Kluwer Health)

151.4 Applications to Other Areas of Health and Disease

Fetal–neonatal iron deficiency is a common clinical sequela in offspring of pregnancies complicated by maternal diabetes mellitus, maternal hypertension causing intrauterine growth restriction (IUGR), maternal smoking, and severe maternal anemia. These risk groups are characterized by poorer long-term neurodevelopmental outcomes particularly in the cognitive domain suggesting that the developmental trajectory of neural circuits that support these behaviors are compromised. Long-term compromise in spite of prompt neonatal iron treatment suggests the possibility of long-term changes in regulation of the salient genes, perhaps by epigenetic mechanisms.

The lower BDNF activity induced by fetal–neonatal iron deficiency during periods of rapid neural differentiation may underlie the delay of neuronal differentiation in the developing ID hippocampus. It may also serve as the molecular basis for the morphologic and functional abnormalities seen during the period of iron deficiency. Whether these alterations are consequences of the deficit of neuronal iron or to other confounding factors in this anemia model, such as hypoxia at systemic and/or cellular levels, remain unresolved. IUGR models are also characterized by both hypoxia and iron deficiency, however, our ID model differed in terms of compensatory expression of TrkB receptor. Whereas a pig model of chronic placental insufficiency showed an obligatory increase of TrkB expression due to lower BDNF expression (Dieni and Rees 2005), we did not find such effect in ID rats. Thus, difference in TrkB finding may be attributed to the effect of ID rather than hypoxia. Despite an absence of upregulation, a greater $TrkB_L$/BDNF ratio suggests an increased availability of this TrkB isoform for BDNF binding in the ID hippocampus. This finding may be important in terms of understanding the early antecedents of adult neurological disorders characterized by reduced hippocampal function or early hippocampal degeneration. For example, Alzheimer and Parkinson's diseases are characterized by reduction of BDNF levels without compensatory increases in TrkB expression (Siegel and Chauhan 2000). The altered expression of genes involved in the pathogenesis of Alzheimer's disease as well as an increased susceptibility of brain injury in this same model supports this possibility (Carlson et al. 2007, 2008; Rao et al. 2007).

The long-term dysregulation of BDNF suggests that iron treatment alone is insufficient to attenuate the effects of iron deficiency during sensitive periods of hippocampal development, providing a role for iron in long-term programming of hippocampal BDNF. The underpinning mechanisms of this long-term effect are unknown but may be similar to those involved in the developmental origins of health and disease (Gluckman et al. 2008), including epigenetic modifications. This possibility is supported by a recent report of early-life negligence resulted in long-term down regulation of BDNF that is associated with hypermethylation of its regulatory region (Roth et al. 2009). Our results also emphasize the concept that provision of nutrients alone is inadequate to maintain optimal brain function. We propose that proper regulation of growth factors is also essential to ensure optimal utilization of nutrients. Long-term dysregulation of these growth factors may thus account for persistent abnormal function despite nutrient repletion.

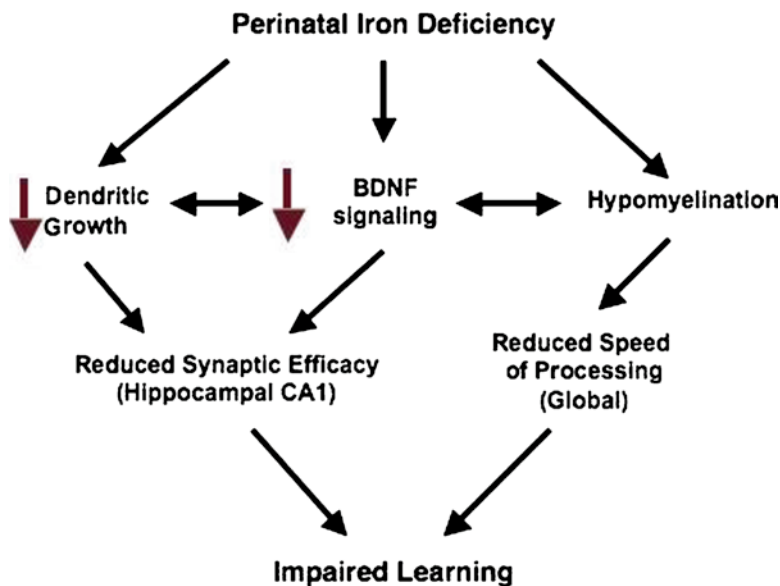
In summary, our findings provide insights into a possible molecular mechanism underpinning acute and long-term cognitive deficits in fetal–neonatal iron deficiency model (Fig. 151.7). Further research is needed to determine precisely how iron regulates the expression of BDNF and its downstream effectors. While the long-term effect may be accounted by potential epigenetic modification (i.e., DNA methylation), the acute effect remains virtually unknown. We speculate that iron may have a direct role in modulating the binding of transcriptional machinery/complex at the BDNF regulatory region (Tsuji et al. 1999; Wong et al. 2005). Our data suggest that interventions that enhance BDNF activity such as exercise or selective serotonin reuptake inhibitors (Russo-Neustadt et al. 2000) may be useful as therapeutic approaches to treat long-term effects of fetal–neonatal iron deficiency, complementing iron therapy.


Fig. 151.7 Proposed working hypothesis. A proposed model accounting for learning impairments induced by fetal–neonatal iron deficiency. BDNF signaling affects both neuronal maturation (e.g., dendritic growth) and myelination. In turn, these processes alter synaptic efficacy and speed of neurotransmission, which ultimately contribute to learning impairments

Summary Points

- Peak expression of neurotrophic factors and their cognate receptors occurs during periods of rapid differentiation in the rat hippocampus are consistent with the role of neurotrophic factors in promoting neuronal differentiation and dendritic outgrowth.
- Fetal–neonatal iron deficiency dysregulates neurotrophic factors with specific reduction of BDNF and is associated with a delay of neuronal maturation during a period of rapid differentiation, which may reflect an extension of this rapid growth period in ID hippocampus.
- The specific reduction of BDNF expression in formerly-iron-deficient (FID) rats that were ID during early life suggests a more permanent change in its regulation. A possible underlying mechanism may involve epigenetic modification (e.g., DNA methylation) at the BDNF gene.
- Despite an absence of compensatory upregulation, an increased $TrkB_L$/BDNF ratio may maximize available BDNF signaling in the ID hippocampus. This may be important in terms of understanding the early antecedents of adult neurological disorders (e.g., Alzheimer and Parkinson's diseases) characterized by reduced BDNF and hippocampal function or early hippocampal degeneration.
- The overall diminished BDNF activity accompanied by reduced expression of a cascade of downstream factors during and beyond iron deficiency periods may serve as molecular basis for the electrophysiological, morphological, and ultimately behavioral abnormalities that persist beyond the period of fetal–neonatal iron deficiency.
- The long-term dysregulation of BDNF suggests that iron treatment alone is insufficient to attenuate the effects of iron deficiency during sensitive periods of hippocampal development, emphasizing the concept that the provision of nutrients and proper regulation of growth factors are essential to ensure optimal utilization of nutrients for brain function.

Definitions and Explanations of Key Terms

BDNF: A member of neurotrophic factors that plays critical roles in mediating neuronal proliferation, differentiation, and survival.

Dendritogenesis: A process of neural differentiation in which dendrite grows and branches into a complex pattern specifically unique to each neuronal type.

FID rats: Refers to rats that experienced iron deficiency during fetal–neonatal period, but are no longer bodily or brain ID.

Hippocampus: A brain region responsible for learning and memory that is classically organized into three subregions: CA1, CA3, and dentate gyrus.

LTP: A sustained electrophysiological activity resulting from a long-term increase of synaptic strength between two neurons, which is widely accepted as a cellular form of memory formation.

Microarray gene expression analysis: A molecular genetic technique that simultaneously assesses expression levels of thousands of genes.

Neural plasticity (neuroplasticity): The ability of neuron to adapt to its environment by altering its intracellular properties.

Quantitative (real-time) PCR: A molecular technique to measure levels of gene expression by simultaneously amplify and monitor RNA/cDNA per each thermocycle over the course of the polymerase chain reaction (PCR).

Key Points

1. Fetal–neonatal iron deficiency and cognitive development – Fetal–neonatal iron deficiency is a common clinical sequela in offspring of pregnancies complicated by maternal diabetes mellitus, maternal hypertension causing intrauterine growth restriction (IUGR), maternal smoking, and severe maternal anemia. These risk groups are characterized by poorer long-term neurodevelopmental outcomes particularly in the cognitive domain suggesting that the developmental trajectory of neural circuits that support these behaviors are compromised. According to a recent W.H.O estimate (2003), the prevalence of IDA among pregnant women and preschool age children ranges between 30% and 50% of global population worldwide.

2. Fetal–neonatal iron deficiency reduces BDNF expression and signaling – Early life iron deficiency diminishes acute as well as long-term BDNF-mediated neural development and plasticity. In turn, expression of molecular factors downstream of BDNF signaling is reduced, contributing to decreased neural maturation and plasticity. These effects may serve as molecular bases for the electrophysiological, morphological, and ultimately behavioral abnormalities during and beyond the period of fetal–neonatal iron deficiency.

ICCIDD	International Council for the Control of Iodine Deficiency Disorders
UI	Urinary iodine
ADHD	Attention deficit hyperactivity disorder

152.1 Introduction

The role of iodine in brain metabolism and development has been recognized since the first half of the twentieth century. Its ability to prevent and even cure goiter was described in 1918 by Marine et al. (Marine and Kimball 1990). Soon afterwards, substantial evidence arose for its role in preventing cretinism and the deterioration of brain development (Table 152.1). It is estimated that 5–30% of the people suffering from iodine deficiency eventually suffer from neurological impairment. The latest reports on iodine deficiency published by WHO (Benoist de et al. 2004; Andersson et al. 2007). make it clear that 2 billion people continue to suffer from iodine deficiency, with Europe having the biggest proportion of people who are iodine-deficient (Andersson et al. 2007) (Table 152.2).

[a]192 WHO Member States

[b]Based on population estimates in the year 2002

Thus far, iodine and its relation to brain development have been considered from a thyroid hormone point of view. Despite research during the last 40 years in this area several questions still wait for answers. In this chapter we provide a different point of view and relate iodine deficiency to the basic nutrients that are involved in iodine and thyroid metabolism. We focus on iodine, selenium, tyrosine, and vitamin D and point out their interactive relationships. By looking at the same problem from a different point of view new research and solutions could arise.

Iodine is available in the soil and recently the iodine cycle has been described in more detail. This availability in soil is probably reduced in countries with a young geographical background and in areas suffering from the latest ice age, repeated flooding, and elevated regions subject to glaciations and higher rainfalls.

152.2 Iodine and the Thyroid Hormone

152.2.1 Thyroid Hormone

Iodine is known for its role in the production of thyroid hormones. The thyroid hormone consists of two tyrosine molecules and four or three iodine molecules. The brain is known for its selectivity for thyroxin. After uptake in the brain, thyroxin is deiodinized by selenium-dependent selenodeiodinase enzymes (Kvicala and Zamrazil 2003; Kohrle 2005; Beckett and Arthur 2005).

The thyroid hormone is not only a source of iodine and tyrosine but is also a source of 3-iodothyronamines, their deiodinated products (Scanlan et al. 2004; Scanlan 2009). It is known that these 3-iodothyronamines are trace amines that overlap with classical biogenic amines, such as catecholamines and serotonin. They are capable of increasing catecholamine release.

Theoretically, this could mean that the production of 3-iodothyronamines will lead to a greater availability of the classical catecholamine. In that respect, iodine is necessary for the production of these 3-iodothyronamines and/or the binding of tyrosine.

152.2.2 Deiodination

Deiodination is a process in which deiodination enzymes are involved (Table 152.3 Iodine and brain development, Berber and Morales). As mentioned above, it is clear that the first deiodination is performed by selenium-dependent selenodeiodinase enzymes (Kohrle 2005; Beckett and Arthur 2005). These enzymes are influenced by the availability of thyroxine and triiodothyronine. In case of iodine deficiency there are several up- and downregulating mechanisms. By increasing selenodeiodinase

Table 152.3 Benefits from iodine supplementation programs (From Andersson et al. 2007; Hetzel and Maberly 1986; Levin 1987; Levin et al. 1993)

Physiologic benefits		Benefits to society
Humans	Reductions in: • Mental deficiency • Deafmutism • Spastic diplegia • Squint • Dwarfism • Motor deficiency • Goitre • Birth defects	• Higher work output • Reduced costs of medical and custodial care • Reduced educational costs (because of less absenteeism and grade repetition)
Livestock	Increases in: • Live births • Weight and meat yield • Strength for work • Health (less deformity) • Wool coat in sheep	Higher output of meat and other animal products and hence: • Profits • Higher work output of animals

Beneficial effects of iodine supplementation. Important are the effects for society as well. Noteworthy is the beneficial effect on the livestock; certainly in developing countries an important additional effect if supplementation is extended to livestock.

proteins in the brain it is, at least in the earlier stage, relatively protected from the lower T4 production (Obregon et al. 2005).

However, in the last few years it has become clear that other deiodinase proteins play an important role in the deiodination of diiodotyrosine (DIT) and monoiodotyrosine (MIT). These iodotyrosine dehalogenases (DEHAL1) have been studied only in relation to the deiodination of MIT and DIT in the thyroid. However, several studies show that their presence is not limited to the thyroid but can be found in human kidney, trachea, liver, and colon. The enzymatic deiodination is a reductive process leading to the formation of iodine and tyrosine, increasing both levels. Tyrosine itself is a known inhibitor of the process (Gnidehou et al. 2004). Since the research on the expression of the DEHAL1 in several tissues is very young it cannot be excluded that DEHAL1 is expressed in the (developing) brain. During metamorphosis in frogs, the presence of the DEHAL1 has been described in the olfactory epithelium, the nucleus infundibularis ventralis, the ventricular lining, cerebellum, in the pituitary gland, and in the mucus glands of skin (Gaupale et al. 2009). The same expression could be possible in the developing fetus. Neither studies on the effects of iodine deficiency on the expression of the gene, nor studies on the influence of iodine deficiency on the activity of the enzyme itself have been performed.

By this two-step deiodination, not only 3-iodothyronamines are formed but delivery of iodine and tyrosine into the tissues is provided as well. It is known that tyrosine is the precursor of dopamine and adrenalin, both highly important in the development and metabolism of the brain. Thyroid hormones may therefore be seen as a targeted on-demand system for catecholamine metabolism by increasing their release and also by providing the precursor itself.

152.2.3 Sodium Iodine Symporter (NIS)

In the last 10 years much research has been done on iodine uptake. The presence of the NIS was revealed in 1996. Since its discovery, many researches have been performed, predominantly related to medication development. Some interesting observations have been made. First of all, the distribution pattern of the NIS reveals that NIS is not located in the brain. Most of the NIS is present in tissues that have a direct contact to the outside world, such as the skin, salivary glands, and the stomach (Levy et al. 1998; Riesco-Eizaguirre and Santisteban 2006). Given the known interaction between bacteria and viruses and iodine it could provide a first line of defense against microorganisms. It is unlikely that the NIS is not present in the brain given the dependency of the development of the brain on iodine. Moreover, iodine uptake has been demonstrated in the ventricle system and choroid plexus, although the precise effect on the concentration of iodine in the cerebrospinal fluid and the brain tissues has not been studied thus far (Welch 1962). It could mean we have to look at the role of iodine from another perspective. By looking at iodine from a thyroid

The NIS has also been also located in the kidney, in Henle's loop. Even more important is the fact that the uptake of iodine in the kidney is dependent on the plasma sodium concentration (Spitzweg et al. 2001) (Fig. 152.1). Furthermore, the NIS could be blocked by thiocyanate and perchlorate (Fig. 152.2), the first present in cigarettes (Sande van et al. 2003; Groef de et al. 2006). This could mean that in case of strict sodium restriction or presence of per- or thiocyanate, iodine reabsorption could be impaired, leading to a high iodine excretion in the urine, but to a low presence in the body. This has implications for the availability of iodine during pregnancy and the development of the child in the smoking mother. Smoking is known to increase stillbirths, slower fetal growth, and infertility and could have a negative effect on intelligence capabilities. It may be hypothesized that these effects can be deduced to iodine deficiency.
Fig. 152.1 Sodium dependency of iodide uptake by human kidney cells. Sodium dependency of iodide uptake by human kidney cells. Optimal iodide uptake is related to higher sodium levels in the kidney. The relationship with sodium restriction diets has not been investigated thus far, but could attribute to iodine deficiency (From Spitzweg et al. 2001)
Fig. 152.2 Time course of iodine uptake by kidney cells and influence of perchlorate. Figure a shows that iodide uptake by human kidney cells is rapid and reaches maximum levels after 40 min. This is in line with the rapid iodide uptake in the stomach. Perchlorate inhibits iodide uptake by a factor of eight as can be seen in figure b. Lane 1 is normal uptake by kidney cells, lane 2 represents the same kidney cells incubated with 10 μmol/L perchlorate. Lane 3–6 are control cell lines known not to be able to take up iodine. This observation is in line with another study, which shows a similar inhibitory pattern in case of thiocyanate, abundantly present in cigarettes (From Spitzweg et al. 2001)
Fig. 152.3 The activating type III deiodinase (D2) catalyzes the conversion of T4 into T3. D2 also transforms rT3 into T2. Inactivating D3 transforms T4 into rT3, and T3 into T2. D3 is found in the plasmatic membrane (pm) of neurons while D2 is found in the endoplasmic reticulum (er) of astrocytes and tanycytes

152.2.4 Keypoints of Iodine Uptake by Sodium Iodide Symporter

- Iodine uptake takes place by the NIS. Its presence is not limited to the thyroid but widely distributed throughout the body.
- This observation should lead to reconsidering the recommended daily allowances (RDA), a line of thought consistent with the grounds to change the vitamin D RDA.
- Iodine uptake is negatively influenced by low sodium concentration, perchlorate, and thiocyanate. Because thiocyanate is present in cigarettes, smokers are more at risk for iodine deficiency.

152.3 Iodine and Diseases

152.3.1 Cretinism

The most dramatic effect of iodine repletion is the disappearance of cretinism and the neurological impairments in severe iodine deficiency. Before the introduction of iodine it was considered to be a disease without understanding of the mechanism. Even today the role of iodine in the development of cretinism is not fully explained. Most research concerns the measurable changes in behavior or development but not the unraveling of the mechanism itself.

The clinical manifestation depends on the degree of iodine deficiency and varies widely. Early clinical recognition is made by subnormal temperature, slow heart rate, wide fontanelles, dwarfism, and submature and sluggish behavior. Other signs include slow dentition, slow reaction time, constipation, dystonia, thick tongue and skin, and a delay in sexual development.

One of the most striking pathophysiological discrepancies is the fact that in observed cretinism there is no difference in urinary iodine excretion when compared to individuals in the same region. Moreover, a clear relationship between mental retardation and thyroid hormone levels does not seem to be present.

In the previous century some aspects of the mechanisms involved in iodine deficiency have become more apparent. In case of iodine deficiency, selenodeiodinase enzymes in the brain are upregulated, and the brain is protected against the lower production of thyroxin. The fetus is protected by upregulation of the NIS in the placenta and thus the embryo is protected at the cost of the mother. After birth too the child is protected by upregulation of the NIS in the breast in case of breastfeeding. Of course this protection is not present in the case of baby formula being used.

So it could be possible that other factors are contributing to the development of cretinism. As mentioned above, with thyroxin, tyrosine and 3-iodothyronamine are also delivered to the brain. In the process of dopamine formation out of tyrosine, tyrosine hydroxylase (TH) is the most rate-limiting step. Its activity is upregulated by vitamin D and vitamin A (Puchacz et al. 1996; Jeong et al. 2006; Gelain et al. 2007). In research we have to take other known cofactors into account, especially if it concerns widespread deficiencies, such as that of vitamin D.

If tyrosine is influencing the development of cretinism and neurological deterioration there should be clinical overlap with tyrosine–dopamine-related deficiency disorders.

152.3.2 Attention Deficit Hyperactivity Disorder (ADHD)

Recently, Vermiglio et al. showed that mothers with iodine deficiency had a greater chance that their offspring would get ADHD (Vermiglio et al. 2004). Given the fact that during pregnancy there is an upregulation of the NIS in the placenta, it is logical to suppose that the child is protected from the mother's deficiency. It would also mean that the mother will become more deficient post partum. Not only the child's iodine but also the recirculating iodine pool from the child will vanish. Given the child's protection for iodine deficiency by the upregulating NIS it is more logical to suppose that the real ADHD development takes place after birth at the moment the child starts to eat the same (iodine deficient) food the whole family takes. Just as was the case with cretinism, it is highly questionable if syndromes like ADHD have a genetic base or are just micronutrient (and thereby family) related, with the highest impact during childhood and adolescence.

It is known that iodine deficiency leads to less development of intelligence capabilities. Given the reports it could mean a decrease of IQ of 10–15 points (Bautista et al. 1982; Tiwari et al. 1996; Briel van den et al. 2000; Andersson et al. 2007). Even more important are the observed changes in social behavior (Table 152.3). Several studies point out that iodine repletion leads to a more social behavior, higher working capacity. and higher initiative level (Tiwari et al. 1996; Briel van den et al. 2000; Andersson et al. 2007).

152.4 The Role of Iodine in Brain Metabolism

Despite the fact that much literature does not concern the physiological mechanism itself we now try to explain the role of iodine. One should realize that some parts are hypothetical.

Iodine is known to be a potent antioxidant (Polley 1971; Kupper et al. 2008). It is the most simple antioxidant compared to the vitamins we know. It finds its way into the brain mostly by T4, but also by iodine uptake in the choroid plexus. Given the fact that the thyroid increases the production of T3 during iodine deficiency at the cost of T4 it means a lower iodine influx in the brain. This lower influx is counteracted by increasing the selenodeiodinase proteins.

As pointed out above, the role of iodine on the brain has thus far been discussed from the thyroid hormone perspective. It is difficult to distinguish between effects of iodine and the thyroid hormone and between thyroid hormone and tyrosine effects. In this respect, it is impossible to unravel the underlying physiological processes that account for the beneficial effects of iodine and/or tyrosine or thyroid hormones.

152.4.1 Tyrosine Effects

Studying the role of the thyroid hormone one must account for the effects of its deiodinization metabolites, iodine, 3-iodothyronamine, and tyrosine. In earlier days, thyroid hormone was, at least in part, considered a tyrosine delivery hormone. However, the idea was finally rejected based on the observation that tyrosine was widely available in the proteins present in all tissues.

It can be questioned whether that rejection was evidence-based. The fact that tyrosine is available in proteins does not have to mean that there is no need for a second delivery system. It can be even quite advantageous to have a second system, especially as we know that tyrosine is the precursor of dopamine and (nor) adrenaline. These are short-lived monoamines that have to be instantly available on several demands from several tissues. So next to a basal slowly adapting system provided for by proteins, which cannot react to individual tissue demands, it could be very ingenious to have a second swift acting system.

In this respect, it is known that the deiodination time for T4 is longer than for T3. This could explain the greater metabolic effects of T3 compared to T4. Second, the system is a post translation system and thereby a quickly adapting system. Third, by having several deiodination products, there is a buffer level within the cells, all with their own deiodination response times. T4 is slower deiodinated than T3, which in turn is slower deiodinated than DIT, which at its turn is slower deiodinated than MIT. It is even known that these products themselves can influence the thyroid-stimulating hormone (TSH) and TH (Nakano and Danowski 1959; Lutsky and Zenker 1968; Groot de and Jaksina 1969). In this way, there is an intelligent regulating system, which is not only regulated by T4 or T3 but also by its other metabolic products, next to the effectors themselves such as dopamine and adrenaline. The final metabolic reaction will depend on the total product of stimulatory and inhibitory signals.

There are not many publications about the role of tyrosine and the development of the brain. However, as being the precursor of dopamine and the amino acid thyroid hormones are made of, it could play a crucial role in brain development.

152.4.2 Tetrahydrobiopterin Deficiency

Tetrahydrobiopterin (BH4) is a crucial cofactor in the biosynthesis of catecholamines. It is encoded by the 6-pyruvoyltetrahydropterin (Pts) synthase gene. Pts knockout mice die after birth, although they develop with normal morphology in utero. However, when the mice are fed BH4, L-Dopa, and 5-hydroxyptryptophan, they survive. The mice were sacrificed and studied at 6 weeks. Qualitative

characteristics showed dwarf mice with reduced activity, dystonia, tremor, no signs of sexual maturation, hair loss, and hypothermia (Elzaouk et al. 2003). These characteristics show great overlap with the clinical features of cretinism and interestingly develop after birth. Chemical analysis showed normal serotonin and phenylalanine levels as well as normal nitric oxide synthase activity in the brain. However, the dopamine levels in the brain appeared to be only 3% of normal.

152.4.3 Tyrosine Hydroxylase Deficiency

TH is a rate-limiting enzyme involved in the synthesis of dopamine out of tyrosine. TH deficiency is a relatively rare disorder, with the severest form called infantile parkinsonism, which is mostly related to an insufficient dopamine metabolism. In the case of enzyme deficiency, the development of the syndrome is faster than in the case of a nutrient-related insufficiency, because of the compensating mechanisms occurring in the latter. Clinical symptoms of TH deficiency are lack of motion, dystonia, irritability, lack of speaking development, decreased intellectual development, low body temperature, and constipation (Eiduson 1971; Eisenhofer et al. 2003; Giovanniello et al. 2007). As with cretinism, the clinical presentation can vary greatly but there is some striking overlap with the clinical pattern of cretinism.

Given the fact that TH plays a crucial role in dopamine and adrenaline synthesis, the factors that are known to influence this enzyme have to be taken into account if we study the effects of iodine deficiency on brain development. Vitamin D is known to increase TH and vitamin D deficiency is widespread. It therefore could negatively affect the fetus if the mother is severely vitamin D deficient. Of course it will also have a negative effect on the development of the child after birth although most countries advice vitamin D supplementation, but only until the third year. Given the new insights in vitamin D, optimal levels of vitamin D supplementation are a point of discussion nowadays (Puchacz et al. 1996; Holick 2007).

152.5 Micronutrients Contributing to Iodine Deficiency

In short, the interactions between the nutrients known for their role in the iodine–tyrosine metabolism have to be mentioned. Even the earliest study on iodine and goiter by Marine et al. showed only a 60% positive effect. In those days, other nutritional influences were not known, but might account for the 40% nonresponders. The role of those other nutrients follows in brief.

Iron is crucial in the forming and functioning of peroxidases, in this case thyroid peroxidase. Thyroid peroxidase is crucial for the iodination of tyrosine (Zimmermann and Kohrle 2002).

Vitamin A is known to play an important role in the uptake of iodine by the NIS. It is known to be capable of increasing this uptake (Schmutzler 2001; Zimmermann et al. 2007).

Selenium is necessary for the formation and functioning of selenodeiodinase, which is essential for the deiodination of the thyroid hormones. It is advised not to start supplementation of selenium in case of iodine deficiency, since it can worsen or cause hypothyroidism. Nevertheless, it is widely used, not only in reform stores but also in the animal food industry. This could be harmful and give rise to increasing thyroid problems in countries with iodine deficiency. But even in countries considered to be iodine sufficient a negative effect can be expected since a median urinary iodine excretion of 100 microgram per liter could still mean a large proportion of the population being iodine deficient (Zimmermann et al. 2008).

Finally, tyrosine itself is essential for an optimal metabolism, being the precursor of catecholamines and crucial for thyroid hormone synthesis. Several studies mention the relationship between tyrosine

levels and thyroid functioning (Melmon et al. 1964; Malamos et al. 1966; Tahara et al. 1988). Optimal nutrition levels are not known.

Also, vitamin D could influence thyroid functioning. Although not widely studied, a few studies showed an interaction between vitamin D and thyroid hormones levels (Zofkova et al. 1981; Smith et al. 1989). The exact mechanism is unknown but could be related to the influence of vitamin D on TH. However, other influencing factors such as deiodinase upregulation should be studied.

In conclusion, it is clear that in our search for an optimal iodine-related metabolism all known other factors have to be taken into account as well (Verheesen and Schweitzer 2009).

152.5.1 *Keypoints of Tyrosine Metabolism in Relation to Diseases*

- Mono- and diiodotyrosine are reduced by iodotyrosine dehalogenases to iodine and tyrosine. Iodotyrosine dehalogenases are widely distributed. In developing frogs they are upregulated in the brain. Other animals have not been investigated.
- Dopamine deficiency diseases are related to a clinical picture with great similarity to cretinism.
- ADHD is treated with dopamine increasing medication. Instead of increasing dopamine by blocking its conversion, deficiency of nutrients such as iodine, tyrosine, and vitamin D leading to lower dopamine production capabilities should be investigated.

152.6 Alternative Solutions to Fight Iodine Deficiency

More than 90 years after the discovery of iodine as an essential mineral in the prevention of cretinism and hypothyroidism, 2 billion people still suffer from iodine deficiency. It is hard to believe that the strategy followed thus far will finally lead to eradication of iodine deficiency, especially if we take into account the numerous programs that have been implemented and billions of dollars that have been spent in the last decades.

Given the fact that iodine is naturally taken up by animals and plants it would be logical to increase iodine content in the soil (Steinnes 2009). Thereby it enters the natural food chain and increases the recirculation of iodine. This could lead to various profitable effects.

First, it is a far more natural way to provide enough iodine in the food chain and we are no longer dependent on one single iodine source, as in iodized salt. This single route prevention strategy is very vulnerable and depends largely on diet choices and requires a continuous very active policy. When the complete food chain is soaked with iodine many alternatives are present even when people choose to eat a very invariable diet.

Second, it has been proven that organic selenium gives rise to fewer side effects than inorganic selenium and that inorganic selenium can easily be transformed into organic selenium by plants (Broadley et al. 2006). The same phenomenon could be true for iodine. Iodine is organically bound to tyrosine, its natural partner, as is the case of iodine in seaweed. Deiodinase activity has to be present to release this bounded iodine. Furthermore, the conversion of MIT and DIT into tyrosine and iodine is inhibited by the product tyrosine itself (Gnidehou et al. 2004),thereby reducing overdose and side effects. On the other hand, the presence of thyroid antibodies could very well be related to other contributing micronutrients, especially selenium deficiency (Xu et al. 2006; Duntas 2008). Before addressing iodine as the main cause of side effects, other factors have to be taken into account

and need further investigation. In this respect, organic iodine in the form of iodotyrosine or diiodo-tyrosine could also be an attractive biomarker for individual longstanding iodine status, since it represents net iodine uptake. Measuring iodotyrosine or diiodotyrosine means that factors negatively influencing iodine uptake by the NIS have been taken into account. This is in contrast to the situation where iodine excretion in the urine is established.

Despite several reports from the WHO about increasing iodine deficiency levels, especially in developed countries, politics either do not or are slow in responding. Most countries do not follow the advice of the WHO concerning iodine supplementation in case of pregnancy and breastfeeding. Even recent advice reports from health care government agencies do not include this 6-year-old WHO directive (Health Council of the Netherlands 2008). Moreover, these countries also do not implement the directives on monitoring iodine supplementation. The case becomes worse if we are aware of the limitations of the population indicator used to define iodine sufficiency. Although some countries are regarded as iodine sufficient, up to 50% of their population can, in fact, be regarded as iodine insufficient (Zimmermann et al. 2008; Verheesen and Schweitzer 2008). However, most of these countries interpret sufficient as no deficiency at all and are not motivated to erase iodine deficiency completely. A better way to present deficiency data is by showing prevalence figures, even if they are estimated statistically. For instance, 10% of a population being deficient sounds like a good achievement, but if it means that still 27 million people are suffering from iodine deficiency (USA) it sounds like work needs to be done (Benoist de et al. 2004).

In this chapter, we chose to look at iodine and the brain from an unconventional point of view. By doing this we might find new solutions for old unresolved problems and physiological and medical questions. By studying how to nurture nature we could find a way to prevent or even change the course of diseases and syndromes without changing nature itself, and without gene therapy or by medication alone.

152.6.1 Keypoints of Alternative Strategies on Solving Iodine Deficiency

- Given the large number of children affected, the pregnancy and lactation supplementation directive from WHO should be implemented by all countries who signed the United Nations-sponsored "Declaration for the Survival, Protection and Development of Children" in 1990, before 2012.
- New iodine supplementation strategies must be considered, such as enrichment of soil.
- Iodotyrosine or diiodotyrosine could be attractive biomarkers for the individual longstanding iodine status.

152.7 Application to Other Areas of Health and Disease

Deficiencies are, even in developed countries, still widespread. History has taught us that solving severe deficiency leads to solving diseases that were thought to be heritable and untreatable, like cretinism. It showed us that genetic polymorphism is not to be blamed for diseases but environmental factors are the cause. Also mild deficiency will lead to related health problems, although not as obvious as in severe deficiencies. Iodine deficiency is by far the most widespread deficiency worldwide. It will lead to unbalanced thyroid metabolism, which theoretically, depending on the genetic polymorphism, can cause related health problems such as hypercholesterolemia, heart disease, infertility, depression, and health problems related to a disturbed tyrosine or iodine metabolism. Before changing the genetic blueprint we have to study the influence of nutrients on the expression of genes and finally diseases.

152.8 Conclusions

Based on the literature available on the role of iodine and tyrosine on the development and metabolism of the brain, several conclusions can be drawn, although some could be seen as hypothetical until more specific research on the topic is undertaken.

It is remarkable that in the case of the Pts knockout mice, the development of the fetus in utero is normal and problems begin only after birth. It could be assumed that during pregnancy the maternal delivery of catecholamines and iodine is more essential than the producing possibilities of the fetus. This could have consequences for the way we look at iodine deficiency disorders and their development. In contrast to the assumption nowadays, developmental problems could occur mainly after birth.

As with the knockout mice this could mean that the developmental disorders could very well be reduced by providing adequate levels of the required tyrosine, iodine or thyroxin. This is in line with the observations that iodine supplementation can improve the deteriorated intelligence and social behavior because of iodine deficiency. Furthermore, it is in line with the observation of the upregulated NIS in the placenta and in the breast feeding breast, the first one to prevent fetal deficiency at the cost of the mother, the second to provide optimal iodine nutrition after birth, again at the cost of the mother.

In the case of ADHD, the most effective medicine is methylphenidate. As stated, it is known to increase dopamine levels in the brain. Instead of focusing on ways to increase dopamine levels by blocking its degradation, one should focus on the possibility that essential elements in the synthesis of dopamine are lacking. Several micronutrients need to be investigated. Given the widely distributed deficiency, iodine is the most important one to investigate. In addition, the following also have to be investigated: tyrosine as being the precursor, vitamin D as being a stimulator of TH, tetrahydrobiopterin as being the cofactor for biosynthesis, vitamin A as being a second stimulator of TH, and selenium as being essential for the deiodination of thyroxin by selenodeiodinases. Since studies never focus on these specific micronutrients, no literature is available on the presence of deficiencies, let alone combinations of even very mild deficiencies that could become more relevant because of their combined existence (Verheesen and Schweitzer 2009).

The sodium symporter in the brain has not been studied, so no data are available on its presence in the various parts of the brain. Furthermore, no data are available on the effects of iodine deficiency at the NIS level. We know, however, that the distribution of the selenodeiodinases differs significantly throughout the body.

Finally, the most important concern is the fact that today iodine deficiency is still widespread. The fact that countries are characterized as developed does not guarantee that iodine deficiency has been solved, as the latest report on Europe shows (Table 152.4). Governments not only need to sign declarations, but need to execute them with the greatest efforts possible. Given the few experts involved in specific deficiencies, governments need to be willing to request for expertise from the WHO or International Council for the Control of Iodine Deficiency (ICCIDD) when they formulate

Table 152.4 Proportion of population, and number of estimated individuals with insufficient iodine intake in school-age children (6–12 years) and in the general population (all are groups) in Europe,[a] 2004

Insufficient iodine intake (UI <100 mg/l)			
School-age children		General population	
Prevalence (%)[a]	Total number (millions)[b]	Prevalence (%)[a]	Total number (millions)[b]
47.8	24.9	46.1	272

[a]Based on data from 40 countries

[b]Based on population estimates in the year 2002

and publish national guidelines. An authorization for the guidelines by the very few experts in cooperation with the leading authorities like the WHO or ICCIDD would be even more preferable. Unfortunately, national politics are very protective and have not reached that level of openness yet.

By studying the effect of iodine on the development and metabolism of the brain only as part of the thyroid hormone we could very well be missing the real effectors, tyrosine and iodine. In addition, interacting nutritional factors could be missed and not studied in relationship to each other.

Summary Points

- Iodine deficiency is the most widespread micronutrient deficiency worldwide since 1918, with 2 billion people affected anno 2007.
- To make governments better aware of the extent of the problem, the estimated number of individuals affected should be the first priority and not the overall classification based on the median urinary iodine excretion.
- Europe has the largest proportion of people affected of all WHO regions; South East Asia has the highest absolute number of individuals affected of all WHO regions.
- A biomarker for the longstanding individual iodine status is crucial to present solid prevalence data. Iodo- or diiodotyrosine could be attractive candidates since they represent the iodine level after uptake by the NIS.
- In our understanding of the physiological mechanisms of iodine deficiency, other micronutrients have to be taken into account. Most relevant nutrients are vitamin A, selenium, tyrosine, and vitamin D.
- To eliminate iodine deficiency after 90 years it is important to search for other strategies. The most logical strategy is to enrich the soil with iodine.
- To understand the side effects of iodine other contributors, especially selenium, need to be investigated since it is known for lowering thyroid peroxidase antibodies.

Explanation of Key Terms

Iodine: Member of the halogens, soluble in water, with the greatest concentrations in seawater. Seaweed and some plants are known for their high uptake of iodine.
Iodine deficiency: Iodine deficiency is characterized by a median urinary iodine excretion less than 100 microgram per liter. Goiter and elevated TSH should be regarded as a sign for longstanding inadequate iodine intake.
Deiodination: Deiodinaton of thyroid hormones is regulated by three selenodeiodinase isoforms. Deiodination of mono- and diiodotyrosine takes place by iodotyrosine dehalogenase, which is upregulated in the brain of developing frogs. In humans, selenodeiodinase and iodotyrosine dehalogenase are widely distributed.
Cretinism: Cretinism is the most severe clinical feature of iodine deficiency or congenital hypothyroidism. It leads to seriously impaired physical growth and mental development.
Sodium Iodide Symporter: The sodium iodide symporter is widely distributed throughout the body and not limited to the thyroid. In pregnancy and lactation, it is upregulated in the uterus and breasts. Iodine uptake is inhibited by perchlorate and thiocynate, next to the other halogens, bromide, and fluoride.

Chapter 153
Riboflavin Deficiency, Brain Function, and Health

Rita Sinigaglia-Coimbra, Antonio Carlos Lopes, and Cicero G. Coimbra

Abbreviations

BBB	Brain-blood barrier
BH4	Tetrahydrobiopterin
CADCase/CSADCase	Cysteine and sulfinic acid decarboxylase
CBS	Cystathionine β-synthase
cGMP	Cyclic guanosine monophosphate
CL	Cystathionine-γ-lyase, or cystathionase
CNS	Central nervous system
CO	Carbon monoxide
CSF	Cerebrospinal fluid
EGRAC	Erythrocyte glutathione reductase activation coefficient
eNOS	Endothelial nitric oxide synthase
FAD	Flavin adenine dinucleotide
FMN	Flavin mononucleotide
GABA	γ-aminobutyric acid
GAD	Glutamic acid decarboxylase
γ-GCS	γ-glutamylcysteine synthetase
GMP	Guanosine monophosphate
GR	Glutathione reductase
GSH	Reduced glutathione
GSSG	Oxidized glutathione
GSTs	Glutathione S-transferases
H_2S	Hydrogen sulphide
HO	Heme oxygenase
HPLC	High-performance liquid chromatography
iNOS	Inducible nitric oxide synthase
MADD	Multiple acyl coenzyme A dehydrogenase deficiency
MPTP	1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine
MS	Methionine synthase

NADPH	Nicotinamide adenine dinucleotide phosphate
nNOS	Neuronal nitric oxide synthase
NO	Nitric oxide
NOS	Nitric oxide synthase
PD	Parkinson's disease
PLP	Pyridoxal-5′-phosphate
PPO	Pyridoxine(pyridoxamine)-5′-phosphate oxidase
Rbf	Riboflavin
SHMT	Hydroxymethyltransferase
VDR	Vitamin D receptor

153.1 Introduction

Vitamin B2 (Rbf) is an essential micronutrient playing a key role in energy production (Hendler and Rorvik 2008). The active forms FAD and FMN act as either coenzymes or prosthetic groups in a wide diversity of biochemical reactions. Rbf deficiency has been also related to developmental abnormalities, altered iron status (ferritin iron mobilization, iron absorption and loss), cancer, visual abnormalities, neurodegeneration, and high plasma homocysteine (Powers 2003).

Nevertheless, clinical and experimental evidence compiled in this chapter support the view that the significance of Rbf deficiency for the pathophysiology and treatment of human diseases (of CNS disorders in particular) has been largely underestimated. First, current views merely consider low vitamin B2 status as a component of multiple vitamin deficiencies associated with malnutrition related to either poverty or alcoholism, because Rbf and other vitamins of the B complex share similar food sources such as whole grains, leafy green vegetables, eggs, meat, and milk (Powers 2003). Allegedly, deficiency of vitamin B2 could not occur as an isolated nutritional disorder, and the clinical consequences of multiple nutrient deficiencies would inevitably veil the specific manifestations of restricted availability of Rbf active metabolites.

Second, such views neglect the epidemiological studies by Anderson and coworkers who provided direct evidence showing that a substantial part of the world population (10–15%) carries an inherited restriction of Rbf absorption. Such restricted absorption is only balanced with a relatively high dose of Rbf (Anderson et al. 1994) repeated three to four times a day to stabilize circulating levels within the normal range throughout the 24 h (Coimbra and Junqueira 2003), suggesting increased urinary loss due to limited tubular reabsorption of Rbf from glomerular filtrate. The fundamental importance of these findings for human pathologies has been long neglected, possibly for being initially confined to the literature related to the epidemiology of malaria, against which Rbf deficiency seems to provide resistance. The data reviewed here suggest that a critical pathophysiologic role for Rbf deficiency is clearly feasible and likely, and worth research attention, particularly due to immediate implications in the prevention and therapeutic control of a wide range of prevalent human disorders like Parkinson's disease, arterial hypertension, fetal malformation and spontaneous abortion, migraine, and the full range of autoimmune diseases.

Third, a single inherited polymorphic gene disturbing cellular uptake of Rbf could explain all data related to poor absorption at the proximal ileum, low transport into red blood cells, and reduced reabsorption by proximal tubules. Anderson and coworkers provided evidence showing that the highly prevalent low vitamin B2 status is genetically determined, and suggested a polymorphic flavokinase, which catalyzes the conversion of Rbf to FMN, as a possible inherited feature responsible for the impaired cellular

uptake and trafficking of Rbf (Anderson et al. 1994). Regardless of whether or not Rbf phosphorylation is the metabolic step to blame, the polymorphic gene involved may simultaneously affect the homeostatic system reported by Spector (1980), which privileges the brain tissue with normal vitamin B2 concentrations during severe systemic deficiency. Due to the evident pathophysiologic relevance of disrupted Rbf homeostatic mechanisms in the CNS, neurologic disorders are particularly likely to develop in genetically affected individuals. Conversely, experimental attempts to replicate human neurologic disease requiring disruption of CNS mechanisms of vitamin B2 homeostasis by submitting genetically intact animals to dietary Rbf restriction may comprehensibly fail (DalPai et al. 2007).

Fourth, a wide range of metabolic pathways requires other essential micronutrients that are dependent on Rbf status, including vitamins B6 (PLP), B9 (folate), B12, and D3, which are similarly involved in numerous additional metabolic routes. Some other pathways (such as NO synthesis, HO activity, and the activity of the whole cytochrome P-450 enzyme superfamily) are doubly dependent on vitamin B2, for requiring both flavin active forms (FMN and FAD) for constant switching of critical heme enzymes to the reduced state. Furthermore, heme synthesis and degradation are also primarily or secondarily dependent on vitamin B2 status. The metabolic interdependency of these bioactive molecules significantly amplifies the spectrum of pathophysiologic phenomena potentially related to vitamin B2 deficiency, while creating direct and indirect pathways and positive feedback loops that further enhance several disease mechanisms.

153.2   Riboflavin and Its Bioactive Forms – FAD and FMN

Rbf is a water soluble light sensitive vitamin chemically named 7,8-dimethyl-10-(1′-d-ribityl-isoalloxazine), molecular formula: $C_{17}H_{20}N_4O_6$, and molecular weight: 376.4 Da (Hendler and Rorvik 2008). Originally isolated from milk in the ninth century by Wynter Blyth as a bright yellow pigment, Rbf was later recognized as a member of the vitamin B complex. Richard Kuhn in Heidelberg (1934) and Paul Karrer in Zurich (1935) almost concurrently succeeded in determining the chemical structure, and the name "riboflavin" was given to replace the variety of previous names. Soon after, Hugo Theorell (1937) and Otto Warburg and Walter Christian (1938) identified the two Rbf active forms, FMN and FAD, respectively (Massey 2000) (Fig. 153.1).
Fig. 153.1 Structure of riboflavin and its bioactive forms. Riboflavin, also known as vitamin B2, is the core of its bioactive forms – flavin mononucleotide (*FMN*) and flavin adenine dinucleotide (*FAD*). It contains a so-called "flavin ring system," an isoalloxazine ring methylated at the 7 and 8 positions, having also a d-ribityl moiety at the position 10. FMN is generated by phosphorilation at the 5′ position of ribityl group, and the addition of adenosine-5′-monophosphate yields the second bioactive form, the FAD.

153.3 Sources, Dietary Requirements, and Pharmacokinetics

Humans are not able to synthesize Rbf, and must thus obtain the vitamin from their diet. Dietary vitamin B2 is scarcely available as free Rbf, but rather mostly as FAD and FMN integrated into proteins (flavoproteins). The dietary sources of vitamin B2 are similar to those of other B vitamins. The main specific sources are milk and dairy products, which contribute to 51% of the overall intake in preschool children, 35% in schoolchildren, 27% in adults, and 36% in the elderly (Powers 2003). To a lesser extent, meat, green vegetables, and grains are also good sources of vitamin B2. UV light exposure is the most important factor impairing the bioavailability of vitamin B2 (Foraker et al. 2003).

The daily intake recommended by the World Health Organization varies from 0.3 mg for infants to 1.3 mg for adult males, being the highest requirements reserved for pregnant and lactating women (up to 1.6 mg/day). However, those recommendations do not take into account the possibility of hereditary malabsorption that may affect an average of 10–15% of the general population as suggested by Anderson and coworkers (1994), nor pathological conditions like celiac disease, malignancy or resection of the small bowel (WHO/FAO 2009). The maximal amount of Rbf that can be absorbed from a single dose is 27 mg (Zempleni 1996), which represents approximately 20 times the recommended daily dose. Therefore, humans tolerate large doses (multiple grams) given orally without toxicity – limited intestinal absorption affords protection at high intakes (Bates 1997).

The dietary bioactive forms of the vitamin (FMN and FAD) undergo hydrolysis to Rbf for absorption. Enterocytes at the proximal ileum can take up only free Rbf, which is rapidly absorbed (1.4–2.0 h) and further metabolized by specific enzymes. FAD-pyrophosphatase converts FAD to FMN, and FMN-phosphatase converts FMN to Rbf. Once within the intracellular compartment, Rbf accumulates in tissues after the resynthesis of FMN and FAD. Rbf flavokinase turns Rbf into FMN, and the enzyme FAD synthetase converts FMN to FAD (Rivlin and Pinto 2001). Intracellular FMN is either converted to FAD or integrated to flavoenzymes as a prosthetic group (covalent bounds), while FAD is mainly (covalently) incorporated into apo-flavoenzymes. Interestingly, thyroid and adrenal hormones regulate the consecutive conversions of Rbf to FMN and FMN to FAD, as well as the covalent binding of flavins to their apo-flavoenzymes (Zempleni et al. 1996).

Rbf absorption occurs through two distinct mechanisms: (1) active transport, which is dominant under low or physiologic concentrations of Rbf within the proximal ileum, and (2) passive diffusion, which becomes prominent at intraluminal Rbf concentrations above the physiological range. In addition, Ca^{++}/calmodulin, protein kinase A and G may regulate Rbf absorption (Foraker et al. 2003). The role of binding proteins in Rbf absorption and transport requires further investigation (Fig. 153.2). Several drugs (including psychotropic agents, antidepressants, chemotherapeutic and antimalarial medicines) may reduce Rbf absorption by impairing Rbf conversion into bioactive forms. It is worth noticing that all these drugs share structural similarities to Rbf. Alcohol may also impair Rbf utilization due to inhibition of both digestive and absorptive processes (Pinto et al. 1987).

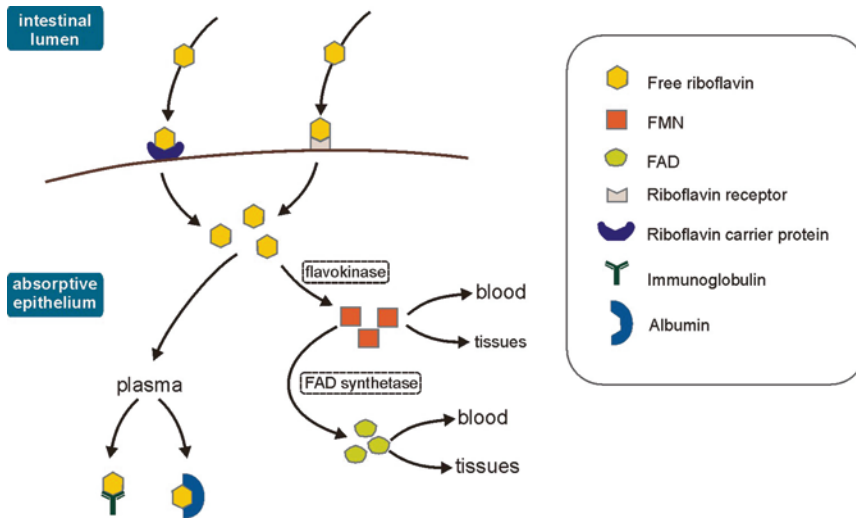
Mammals have a variety of tissular and circulating Rbf binding-proteins, including albumin, immunoglobulins, and pregnancy-specific Rbf-binding proteins and Rbf kinase (White and Merril 1988), all of them endowed with high potential clinical significance. The literature has scarce information about Rbf homeostasis in the brain. Spector (1980) showed that Rbf rapidly crosses the rabbit BBB and accumulates in the brain tissue by a saturable system after phosphorylation. CSF Rbf either accumulates in brain cells or crosses the choroid plexus into the blood by a saturable, probenecid-sensitive mechanism. Rbf excretion is mainly renal, and several flavin metabolites are detectable in the urine (Zempleni et al. 1996). Further studies should address the identification of proteins


Fig. 153.2 Riboflavin absorption at the proximal ileum. Free riboflavin can be uptaken by either a receptor or a carrier protein. After uptake, riboflavin may have two possible fates: (**a**) phosphorylation to FMN by flavokinase, and then converted to FAD by FAD synthase, or (**b**) transportation to plasma. Note that small amounts of FMN may be found in blood and scarcely in tissues, while FAD is the most abundant bioactive form of vitamin B2 in blood and tissues. Part of free riboflavin is transported through the cell into the bloodstream in the unphosphorylated form, and then bound to riboflavin-binding proteins, such as albumin and immunoglobulins. *FMN* flavin mononucleotide, *FAD* flavin adenine dinucleotide

(and related gene polymorphisms) involved in uptake, trafficking, and cellular homeostasis of Rbf in humans, including at the levels of renal tubules and the BBB (Foraker et al. 2003).

153.4 Vitamin B2 Status Assessment

Although all forms of vitamin B2 (free Rbf, FMN, and FAD) are present in measurable concentrations, FAD is the main form of the vitamin found in tissues and whole blood (Powers 1999) and is therefore, most representative of total body flavin content. Although HPLC with fluorometric detection may accurately detect FAD, a functional test (EGRAC) is the method of choice for assessment of vitamin B2 status (Powers 1999). EGRAC measures saturation of the enzyme GR with its coenzyme (FAD). When vitamin B2 stores are significantly low, the addition of FAD to a sample of erythrocytes in vitro produces a percentage increase in measured enzyme activity (activity coefficient) that exceeds 15–20% (EGRAC = 1.15–1.20, respectively). Therefore, EGRAC is the ratio between enzyme activity determined with and without the addition of FAD. The larger the increase in EGRAC noted after the addition of FAD in vitro, the greater the degree of unsaturation of the apoenzyme with its cofactor and the more severe the deficiency of vitamin B2. The loss of erythrocyte FAD at an early stage in vitamin B2 deficiency makes EGRAC a sensitive method for the diagnosis of vitamin B2 deficiency (Bates 1993). EGRAC is an index independent of any uncontrolled denominator, and hence is robust as well as sensitive in practice (Bates 1987). Following bloodsampling, 31.5–84.8% of plasma FAD is hydrolyzed to FMN within 10–40 mm at 37°C (Zempleni et al. 1996). Therefore, blood should be immediately processed after sampling, and erythrocytes stored at 4.0°C for early EGRAC assessment.

153.5 Riboflavin Functions

Many key enzymes require FAD and/or FMN to catalyze a wide range of different types of reactions, particularly oxidation–reduction reactions, dehydrogenation, and oxidative decarboxylation. Most importantly, FAD and/or FMN is involved in the respiratory chain, lipid metabolism, the cytochrome P-450 system, and drug metabolism. Monoamine oxidase, sarcosine dehydrogenase, and succinate dehydrogenase are flavoproteins. Vitamin B2 also plays a role in the metabolism of essential fatty acids in brain lipids (Ogunleye and Odutuga 1989).

Complexes I and II are respectively FMN- and FAD-dependent (Nelson and Cox 2009), while flavoproteins are also responsible for oxygen reduction to hydrogen peroxide (Rivlin and Pinto 2001). Upon reduced vitamin B2 bioavailability, ATP production is selectively preserved, while the less critical FAD- or FMN-dependent metabolic pathways are impaired (Anderson et al. 1994).

Another critical feature is the influence of vitamin B2 on the glutathione system. Glutathione is a tripeptide occurring in reduced (GSH) and oxidized (GSSG) states. GSH is the major endogenous cellular antioxidant, which not only directly neutralizes free radicals, but also deactivates hydrogen peroxide molecules that result from the action of superoxide dismutase on superoxide ions. GSH is the most abundant form of glutathione under physiological conditions, and increased GSSG-to-GSH ratio becomes evident under oxidative stress. Following inactivation of free radicals or peroxides, GSH is regenerated from GSSG by the FAD-containing enzyme GSSG reductase (Hustad et al. 2002) (Fig. 153.3).

The two alternative pathways of deoxynucleotide synthesis primarily or secondarily require FAD at the expense either of FAD or GSH, respectively (Nelson and Cox 2009) (Fig.153.4), and decreased bioavailability of vitamin B2 should therefore affect DNA synthesis. Not surprisingly, the activity of the glutathione system affects the pathophysiology of cancer, regulation of apoptosis, and DNA repair (Hall 1999; Berwick and Vineis 2000; Locigno and Castronovo 2001). Vitamin B2 deficiency may affect the mitochondrial pool of GSH which in turn may affect the activities of the flavoenzymes NADPH-cytochrome P-450 reductase and NADPH-cytochrome b reductase (Hustad et al. 2002).

The GSTs comprise a super family of multifunctional enzymes widely expressed in mammalian tissue cytosols and membranes that play a pivotal role in electrophile detoxification, while protecting cells from the consequences of oxidative stress. They catalyze the conjugation of GSH with a wide
Fig. 153.3 The role of FAD on the glutathione antioxidation system. Glutathione peroxidase (*GPx*) neutralize free radicals and peroxides. The FAD-dependent enzyme glutathione redutase (*GR*) regenerates oxidized (*GSSG*) to reduced (*GSH*) glutathione. *FAD* flavin adenine dinucleotide, *SOD* superoxide dismutase, *NAD$^+$* oxidized nicotinamide adenine dinucleotide, *NADH* reduced nicotinamide adenine dinucleotide, *NADP$^+$* oxidized nicotinamide adenine dinucleotide phosphate, *NADPH* reduced nicotinamide adenine dinucleotide phosphate, *ADP* adenosine diphosphate, *ATP* adenosine triphosphate

Fig. 153.4 The role of riboflavin bioactive forms (FAD and FMN) on the cytochrome P-450 system. The microsomal cytochrome P450 receives electrons from a FAD- and FMN-containing enzyme – the NADPH-dependent cytochrome P450 reductase, where both FMN and FAD operate as prosthetic groups. *FAD* flavin adenine dinucleotide, *FMN* flavin monophosphate, *NADPH* nicotinamide adenine dinucleotide phosphate, *NADP+* nicotinamide adenine dinucleotide phosphate
variety of exogenous and endogenous chemicals with electrophilic functional groups (e.g., products of oxidative stress, oxidized DNA and lipid molecules, environmental pollutants, xenobiotics, and carcinogens). By neutralizing the electrophilic sites, the process prevents these products from attacking macromolecules and renders them more water-soluble (Parl 2005). The impairment of GR activity by abnormally low vitamin B2 status should plausibly limit the availability of GSH required for GST activity, thereby increasing the oxidative stress.

The cytochrome P-450 is a superfamily of hemeproteins (comprising 57 human genes) that catalyze the oxidation of a wide array of lipophilic compounds such as drugs and carcinogens or endogenous compounds such as prostaglandins, fatty acids, and steroids (Nebert and Russell 2002). The microsomal cytochrome P-450 receives electrons from a FAD- and FMN-containing enzyme – the NADPH-dependent cytochrome P-450 reductase, where both FMN and FAD operate as prosthetic groups (Wang et al. 1997) (Fig. 153.4). Therefore, the whole spectrum of cytochrome P-450 reactions is impaired with vitamin B2 deficiency. That includes the metabolism of drugs, foreign chemicals (carcinogens as well), arachidonic acid and eicosanoids, cholesterol metabolism and bile acid biosynthesis, steroid synthesis and metabolism, vitamin D3 metabolism, retinoic acid hydroxylation, and the activity of other enzymes of unknown function (Nebert and Russell 2002).

The microsomal NADPH-dependent cytochrome P-450 reductase is also required to provide the reducing equivalent necessary for heme oxidation through the HO enzymatic activity (Maines 1997). HO is the only enzyme that can degrade heme (iron protoporphyrin-IX, hemin) to biliverdin, free iron, and CO. Maintaining cellular heme homeostasis, HO protects tissues against hemin-triggered oxidative stress, thereby limiting damage in diverse in vitro and in vivo models of cellular and tissue injuries. HO consists of two major isozymes: the inducible HO-1, known as heat shock protein-32 (HSP-32), and the constitutively expressed HO-2, which is highly concentrated in the brain and testes. HO-1 under basal conditions is barely detectable in the brain, but is induced in numerous conditions, such as hyperthermia, Alzheimer disease, transient and global ischemia, and subarachnoid hemorrhage (reviewed by Kim et al. 2005). By impairing the activity of the biflavin

(FMN- and FAD-dependent) enzyme NADPH-cytochrome P-450 reductase, vitamin B2 deficiency may conceivably compromise HO-dependent cytoprotective effects.

To date, tens of thousands of publications and three Nobel Laureates have unveiled and emphasized the fundamental biological importance of NO for both normal cellular and whole body physiology, and also in the pathology of many diseases, especially those related to inflammation and long term degenerative disorders. Enzymes known as NO synthases (without ATP utilization) synthesize NO from l-arginine in mammalian tissues. The activity of the three isoenzymes (eNOS, iNOS, and nNOS) requires l-arginine and NADPH, and results in the formation of citrulline and NO. NO synthesis requires not only these substrates but also the presence of calmodulin, as well as four other coenzymes/cofactors: BH4, NADPH and, particularly relevant for this discussion, the active flavins FMN and FAD (Bruckdorfer 2005). Vitamin B2 deficiency therefore, may affect the whole spectrum of metabolic pathways, physiologic and pathophysiologic phenomena related to NO.

153.6 Rbf Interactions with Pyridoxine, Folic Acid, Cobalamin, and Vitamin D

FMN and/or FAD are required for maintenance of pyridoxine (vitamin B6), folic acid (vitamin B9), and cobalamin (vitamin B12) statuses, so that vitamin B2 deficiency may lead to secondary impairment of all B6-, B9-, and B12-dependant enzyme activities. Such metabolic relationships largely amplify the spectrum of pathophysiologic implications and diseases potentially related to vitamin B2 deficiency. They provide likely explanations for the relation of vitamin B2 availability to plasma homocysteine levels, which is associated with cardiovascular disease, pregnancy complications, and cognitive impairment (Hustad et al. 2000; Skoupy et al. 2002).

A number of folate-dependent pathways related to methionine and nucleotide biosynthesis explain how folic acid may prevent neural tube and other birth defects like spina bifida, lower homocysteine and risk of cardiovascular disease, prevent several types of cancer, dementia, affective disorders, Down's syndrome, and serious conditions affecting pregnancy outcome. FAD is the cofactor for MTHFR (Fig. 153.5), which catalyzes the formation of 5-methyltetrahydrofolate – a methyl donor for homocysteine remethylation. The MTHFR C677T (cytidine to thymidine substitution at position 677) polymorphism causes alanine to be replaced by valine in the catalytic domain. This genotypic alteration affects the FAD binding and destabilizes the quaternary structure of the enzyme, making it thermolabile with approximately half-normal activity (Joshi et al. 2009), and increasing total plasma homocysteine concentrations, particularly in association with low folate status (Moat et al. 2003). Therefore, low vitamin B2 status should further impair folate-dependent pathways in individuals carrying MTHFR polymorphisms and potentiates this and other genetic susceptibilities to folic acid deficiency. Folate-dependent key physiologic roles potentially impaired in vitamin B2 deficiency, include maintenance and repair of the genome, regulation of gene expression, amino-acid metabolism, neurotransmitter synthesis, and the formation of myelin (Djukic 2007).

FMN serves as a cofactor for PPO, which catalyzes the terminal and rate-limiting step of the biosynthesis of PLP (the biologically active form of vitamin B6) from pyridoxine, the main dietary and therapeutic form of vitamin B6 (Powers 2003). PLP is a coenzyme in the catabolism of carbohydrates, fats, and proteins, and in the synthesis of hormones, red blood cells, neurotransmitters, and enzymes. PLP is a coenzyme for more than 100 enzymes involved in amino acid metabolism, including aminotransferases, decarboxylases, racemases, and dehydratases. PLP is a coenzyme for CBS (unique in having both PLP and heme as cofactors) and CL, the two enzymes involved in the transsulfuration pathway from homocysteine to cysteine (Fig. 153.5).

Fig. 153.5 FAD interactions with pyridoxine, folic acid, cobalamin. For maintenance of normal metabolism (*left panel*), the folic acid/methylcobalamin cycle needs FAD as a coenzyme for methylenetetrahydrofolate reductase (*MTHFR*) and methionine synthase (*MS*) activities. The synthesis of pyridoxal 5′-phosphate (PLP, the active form of vitamin B6) from pyridox(am)ine 5′-phosphate requires FMN, while serine hydroxymethyltransferase (*SHMT*), cystathionine-γ-lyase (*CL*, cystathionase) and cystathionine β synthase (*CBS*) are PLP-dependent enzymes and therefore, secondarily depend on FMN. Glutathione reductase (*GR*) activity requires FAD, while cysteine synthesis from homocysteine requires the consecutive activities of two PLP enzymes (CL and CBS). Hence, the levels of reduced glutathione (*GSH*, an antioxidant molecule with multiple essential metabolic functions) are doubly dependent on vitamin B2 status. The role of GSH in deoxynucleotide production (required for DNA synthesis) is explained in Fig. 153.7 and text. Upon vitamin B2 deficiency (*right panel*) all B6-, B9-, and B12-dependent enzyme activities may be impaired. "X" and "X inside the circle" respectively indicate enzyme activities primarily and secondarily inhibited under low vitamin B2 status (secondary to low PLP or methylcobalamin availability). Associated reductions of FMN-dependent SHMT activity, DNA methylation (CH$_3$DNA), deoxynucleotide production, and purine synthesis contribute to impairment of DNA repairing mechanisms under low vitamin B2 status. *GSSG* oxidized glutathione, *MT* metallothionein, *AdoHcy* adenosylhomocysteine, *SAHH* S-adenosyl homocysteine hydrolase, *Ado* adenosine, *BHMT* betaine-homocysteine methyltransferases, *Met* methionine, *MAT* methionine adenosyltransferase, *AdoMet* S-adenosyl-methionine, *MS* methionine synthase, *DHFR* dihydrofolate reductase, *TS* thymidylate synthase, *DHF* dihydrofolate, *CHTHF* methenyltetrahydrofolate, *CHOTHF* formyl tetrahydrofolate, *THF* tetrahydrofolate, *dUMP* deoxyuridine monophosphate, *dTMP* deoxythymidine monophosphate, *CH$_3$DNA* methylated DNA

PLP is also a coenzyme for δ-aminolevulinate synthase – the rate-limiting step in the biosynthesis of heme, which is incorporated as a prosthetic group to a wide variety of proteins with biologically diverse critical functions. Heme proteins include:

(a) Oxygen transport and storage proteins – hemoglobin and myoglobin;
(b) Heme redox enzymes – the cytochrome P-450 superfamily; peroxidases, catalases, and catalase-peroxidases; the dioxygenases indoleamine 2,3-dioxygenase and tryptophan 2,3-dioxygenase; the three NOS isoforms;
(c) Electron transfer proteins – cytochromes b and c;
(d) Heme sensor proteins – heme-responsive heme sensor proteins, such as the HRI system which regulates the translation of genes required for globin synthesis in red blood cells; gas-responsive heme sensor proteins such as guanylate cyclases.

The classical clinical symptoms of B6 deficiency are seborrheic dermatitis, microcytic anemia, epileptiform convulsions, insomnia, depression, and confusion (Mooney et al. 2009). By limiting the conversion of pyridox(am)ine 5′-phosphate to PLP, vitamin B2 deficiency may impair the whole wide range of PLP-dependent vital metabolic pathways (Fig. 153.5).

The enzyme MS (also known as methionine synthase reductase), which converts homocysteine to methionine, is dependent on 5-methyltetrahydrofolate as a methyl donor and on vitamin B-12 (as methylcobalamin). Vitamin B-12 plays an essential role in the methyl transfer reaction by acting as an intermediate methyl carrier between methyltetrahydrofolate and homocysteine. MS also contains both FMN and FAD as coenzymes, which are essential for maintenance of proper redox state of cobalt ions in the methylcobalamin molecule, thereby preventing inactivation of the enzyme (Olteanu and Banerjee 2001) (Fig. 153.5).

The dependency of vitamins B6, B12, and folate on FAD and/or FMN availability largely amplifies the metabolic importance of vitamin B2. For instance, Rbf deficiency may both limit the activation of vitamin B6 to PLP and inactivate methylcobalamin. Metabolic derangement of methionine and folate metabolism in this circumstance may result not only primarily from reduced MTHFR and SHMT activities, but also from oxidation of methylcobalamin secondary to Rbf deficiency.

Likewise, rather than solely resulting from decreased coenzymes (FMN and FAD) required for NOS activity, diminished NO synthesis and reduced NO-mediated biological effects in vitamin B2 deficiency may also be secondary to low PLP production by FMN-dependent PPO, which limits the synthesis of prosthetic heme to be incorporated during the assembly of NOS isoenzymes and GC (Fig. 153.6). Similarly, oxidative stress in vitamin B2 deficiency would not merely result from decreased GSH regeneration from GSSG by the FAD-dependent enzyme GSSG reductase: decreased prosthetic heme incorporation during the assembly of catalases may further aggravate oxidative stress.
Fig. 153.6 The importance of vitamin B2 for NO production. Dependency of endothelium-derived nitric oxide (*NO*) function on vitamin B2 status. Endothelial nitric oxide synthase (*eNOS*) activity requires both active forms of vitamin B2, flavin adenine dinucleotide (*FAD*), and flavin mononucleotide (*FMN*). The vasodilatatoy effect of NO depends on guanylate cyclase (*GC*) for cGMP synthesis within smooth muscle cells. Both eNOS and GC are hemeproteins, and prosthetic heme synthesis requires the activity of pyridoxal 5′-phosphate (*PLP*)-dependent δ-aminolevulinate synthase. The synthesis of PLP (the active form of vitamin B6) from pyridox(am)ine 5′-phosphate requires FMN. Therefore, vitamin B2 deficiency may impair the vasodilatatoy effect of NO at multiple biochemical steps, including depressed eNOS activity and low availability of prosthetic heme for posttranslational incorporation into the expressed proteins eNOS and GC. *Arg* arginine, *O₂* oxygen, *Fe⁺⁺* ferrous iron, *Ca⁺⁺CaM* calcium/calmodulin complex, *BH4* tetrahydrobiopterin, *GTP* guanosine triphosphate, *cGMP* cyclic guanosine monophosphate
Fig. 153.7 FAD and FMN interactions with vitamin D. The deficiency of vitamin B2 bioactive forms may secondarily affect the activity of vitamin D hydroxylases. Note that enzymes 25-hydroxylase and 1α-hydroxylase are members of the cytochrome P-450 superfamily and require the activity of the flavo-enzyme NADPH-dependent cytochrome P450 reductase. *FAD* flavin adenine dinucleotide, *FMN* flavin monophosphate, *NADPH* reduced nicotinamide adenine dinucleotide phosphate, *NADP*⁺ oxidized nicotinamide adenine dinucleotide phosphate

In addition, vitamin B2 deficiency may significantly affect the activity of vitamin D hydroxylases. The enzymes 25-hydroxylase and 1α-hydroxylase are members of cytochrome P-450 superfamily. The consecutive syntheses of 25(OH)D3 (calcidiol) from cholecalciferol and 1α,25(OH)2D3 (calcitriol, the active form of Vitamin D) from calcidiol are expected to be reduced vitamin B2 deficiency. This may occur because of both decreased prosthetic heme incorporation (secondary to reduced heme synthesis due to low PLP production) to hydroxylases and limited prosthetic FMN/FAD incorporation to NADPH-dependent cytochrome P-450 reductase (Fig. 153.7).

153.7 Deficiency Consequences in Both Human and Experimental Studies

Rather than restricted to developing countries, vitamin B2 deficiency may be widespread in industrialized countries as well, where it affects both the elderly and young adults rather than occurring only in patients suffering from chronic conditions such as celiac disease, cancer, and alcoholism (Powers 2003). The importance of the work by Anderson and associates – showing that low vitamin B2 status may result from defective absorption in a relatively large number of otherwise well-nourished individuals – cannot be overemphasized. In spite of an adequate dietary intake, 10–15% of the inhabitants of London and Florence showed a low activation coefficient of two vitamin B2-dependent enzymes – GR and PPO. High doses of Rbf (24–30 mg/day for 5–8 weeks) corrected the activity of both enzymes in the affected individuals. The dependency of both FMN and FAD levels on Rbf absorption, and the normalization of the activities of both FMN- and FAD-dependent enzymes only at a high Rbf intake, taken together, are consistent with the expression of polymorphic genes related to Rbf absorption such as the flavokinase gene. The similar number of persons affected in different ethnic groups

(10–15%) indicates that these percentages may be representative of the world prevalence of genetic polymorphisms impairing Rbf absorption in the proximal ileum (Anderson et al. 1994).

Normal vitamin B2 body homeostasis also depends on a renal saturable uptake system that reabsorbs almost all the filtered micronutrient in the proximal tubule epithelial cells (Jusko and Levy 1970). Moreover, maintenance of normal EGRAC levels in vitamin B2 deficiency unrelated to dietary restriction requires the administration of high doses of Rbf at least three times a day (Coimbra and Junqueira 2003). This finding suggests an increased urinary loss of vitamin B2 in the affected individuals, implying a general impairment of uptake, trafficking, and cellular homeostasis of Rbf. In other words, a single genetic polymorphism may cause widespread changes in Rbf transport in several cell types, and underlie both malabsorption of Rbf by proximal ileum cells and impaired Rbf uptake from glomerular filtrate by proximal tubule cells. This issue has major implications for neurologic disorders as explained ahead.

The classical signs of vitamin B2 deficiency are cheilosis, angular stomatitis, glossitis, seborrheic dermatitis (Hendler and Rorvik 2008), and cataract (Powers 2003). Experimental studies in vitamin B2 deprivation in rats demonstrated disruption of iron metabolism (Powers 2003). Other studies on vitamin B2 deprivation during fetal development showed a reduction of the terminal electron transport system, increased fetal mortality and decreased fetal growth, mental retardation, and complete cessation of growth (Bates 1997; Powers 2003).

153.8 Vitamin B2 Deficiency and Neurological Diseases

The wide array of metabolic functions of FMN and FAD and their interactions with pyridoxine, folic acid, cobalamin, and vitamin D exceedingly amplify the range of human diseases potentially associated with Rbf deficiency. Additionally, the high prevalence of Rbf deficiency (probably secondary to polymorphisms of genes related to uptake, trafficking, and cellular homeostasis of vitamin B2 in humans) highly emphasizes the pathophysiologic and epidemiologic relevance of the issue.

The issues related to a highly prevalent genetic mechanism impairing cellular trafficking of Rbf in multiple tissues, possibly involving the flavokinase gene (Anderson et al. 1994), are particularly relevant for the CNS. A very efficient homeostatic system for Rbf renders the brain tissue privileged in circumstances of low dietary Rbf availability in genetically normal individuals, so that the total CNS content of vitamin B2 is preserved in contrast to other tissues (Spector 1980). The concentrations of total Rbf in plasma, CSF, and brain were 0.2, 0.1, and 8.8 2 M, respectively, in genetically normal adult rabbits (Spector 1980). Conceivably, polymorphisms of genes related to cellular uptake mechanisms may also impair the transport of Rbf across the choroid plexus epithelial cells, the main transport locus of the blood-cerebrospinal fluid barrier (Spector and Johanson 2006), thereby disrupting the activity of those powerful homeostatic mechanisms.

153.8.1 Parkinson´s Disease

Genetically impaired CNS Rbf homeostasis may underlie the predisposition to PD by enabling the activity of pathophysiologic mechanisms related to degeneration of dopaminergic nigral cells (Coimbra and Junqueira 2003). These homeostatic mechanisms would be intact in genetically normal rats and prevent the activity of similar pathophysiologic phenomena in the experimental setting (DalPai et al. 2007).

Several pathophysiologic issues related to PD may be related to disturbed Rbf homeostasis in the CNS. GSH depletion – considered an early key event in the pathogenesis of PD (Jenner et al. 1992; Schulz et al. 2000) may occur as a consequence of impaired FAD-dependent GR activity. Because humans lack efficient iron excretory mechanisms, iron excess is dealt with by increasing the synthesis of the iron-storage protein ferritin (Casey et al. 1988). Disturbed systemic (Logroscino et al. 1997) and brain (Dexter et al. 1990) iron metabolism has been reported in PD, suggesting that a selective decrease in the levels of ferritin may result in an increase in intracellular free iron, thereby enhancing free radical production (Mann et al. 1994). Indeed, vitamin B2 deficiency in rodents is associated with low circulating iron concentrations, increased iron turnover, and excretion into the intestinal lumen, which may occur in response to impaired ferritin synthesis (Powers 2003). Therefore, the consistent finding of an abnormal Rbf status in PD (Coimbra and Junqueira 2003), may help to explain the disturbed iron metabolism found in PD patients, with the underlying mechanisms possibly involving (1) impaired hemin catabolism by HO secondary to low activity of FMN- and FAD-dependent cytochrome P-450 reductase, and (2) reduced neuronal ferritin synthesis. Free iron concentrations in the cytosol increase due to impaired ferritin synthesis and/or reduced hemin catabolism associated with hydrogen peroxide accumulation due to glutathione depletion, thereby triggering the Fenton reaction, and ultimately leading to the selective formation of the potent neurotoxin 6(OH)DA in dopaminergic neurons.

Moreover, because FAD is required in both alternative pathways of deoxynucleotide synthesis (Nelson and Cox 2009) (Fig. 153.8), DNA repair and replication are expected to be disturbed by decreased Rbf bioavailability, and abnormal Rbf status may also explain the cumulative mitochondrial DNA mutations reported in PD (Di Monte 1991). In addition to mitochondrial DNA mutations, the reduced bioavailability of FMN and/or FAD required for the activity of mitochondrial complexes I and II, respectively, may further explain the impaired oxidative metabolism of PD patients (Schapira et al. 1990; Mytilineou et al. 1994; Mizuno et al. 1994).

Emotional stress may cause PD (Smith et al. 2002; Sipetic-Grujicicl et al. 2007) in individuals turned susceptible to stress-induced nigral degeneration by polymorphic genes that disturb cellular uptake and trafficking of Rbf and affect the homeostatic preservation of the vitamin stores in the CNS. Excessive dopamine concentrations in nigral cells under prolonged stressful situations (Kim et al. 2005) may cause accumulation of dopamine-derived salsolinol (Naoi et al. 2002), a potent endogenous aromatic heterocyclic amine similar to MPTP (Speciale 2002) capable of covalent binding to DNA (DNA adduct formation) and inducing degeneration of nigral cells. Additionally, exogenous aromatic heterocyclic amines absorbed from ingested meat cooked at high temperatures may contribute to Parkinsonian neurodegeneration (Collins and Neafsey 2002). Both the synthesis and catabolism of heterocyclic amines require the participation of cytochrome P-450 enzymes (Sinha and Caporaso 1997). The metabolism of (endogenous or exogenous) heterocyclic amines by cytochrome P-450 enzymes is secondarily altered in vitamin B2 deficiency due to impairment of NADPH-cytochrome P-450 reductase. Simultaneously, the vulnerability of the nervous tissue to DNA adduct formation is increased due to this and other FMN of FAD-dependent metabolic pathways, such as impaired mitochondrial DNA repair (Figs. 153.5 and 153.8), low GSH levels (Fig. 153.3), and diminished local synthesis of calcitriol (Fig. 153.7).

153.8.2 Migraine

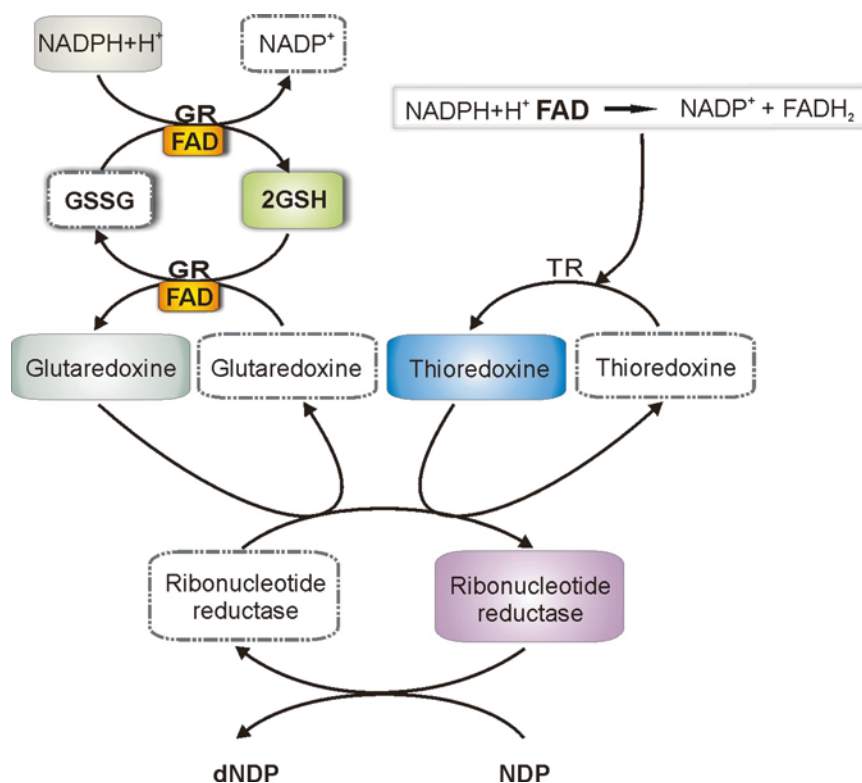
Endothelial NO production has been implicated in the pathophysiology of migraine. This short-lived free radical is responsible for cerebral blood vessel relaxation activating guanylate cyclase and increasing cGMP in smooth muscle (reviewed by Murad 2008). Migraine-like headache is induced


Fig. 153.8 The role of FAD in deoxynucleotide biosynthesis. *NADPH* reduced nicotinamide adenine dinucleotide phosphate, *NADP+* oxidized nicotinamide adenine dinucleotide, *FAD* flavin adenine dinucleotide, *GR* glutathione reductase, *GSH* reduced glutathione, *GSSG* oxidized glutathione, *dNDP* deoxyribonucleoside diphosphate, *NDP* ribonucleoside diphosphate

by i.v. infusions of glyceryl trinitrate (an exogenous NO donor) and histamine (which liberates NO from the vascular endothelium). Furthermore, the i.v. infusion of eNOS inhibitors effectively controls migraine attacks. These data suggest that the release of NO from blood vessels, perivascular nerve endings or from brain tissue may trigger spontaneous migraine. By reacting with superoxide, NO forms peroxynitrite, which is a highly reactive free radical that exerts noxious effects on tissues. Following interaction with superoxide, NO may cause the headache through variations of cerebral blood flow (Olesen 2008).

The synthesis of guanylate cyclase requires the incorporation of prosthetic heme, while the production of heme depends on the availability of PLP (from FMN-dependent PPO) for δ-aminolevulinate synthase activity, as mentioned elsewhere. Therefore, both adequate synthesis of NO by FMN/FAD-dependent eNOS and the triggering of intracellular signaling events by NO ultimately rely on normal vitamin B2 status. On the other hand, abnormally low vitamin B2 status with secondary impairment of GR activity should limit the availability of GSH required for elimination of peroxides, direct inactivation of reactive oxygen species, and activity of GSTs. Therefore, increased production and decreased inactivation of reactive molecules, with the consequent increase in peroxynitrite formation may enable the variations of cerebral blood flow that underlie migraine attacks. The polymorphisms of enzymes involved in FAD-dependent metabolic pathways (GSTs) and polymorphic flavo-enzymes (C677T mutation of MTHFR), respectively, correlate with susceptibility to migraine with (Kowa et al. 2000) and without (Kusumi et al. 2003) aura, supporting the relevance of vitamin B2 status for the pathophysiology of migraine.

Accordingly, several studies, including randomized control trials demonstrate that high-dose (200–400 mg) Rbf taken once a day is a well-tolerated, effective, and low-cost prophylactic treatment in children, adolescents, and adults suffering from migraine (Schoenen et al. 1998; Boehnke et al. 2004; MacLennan et al. 2008; Condo et al. 2009). Current views regard the benefits of Rbf in migraine prophylaxis as the result of a pharmacological effect, due to the high doses employed. However, the authors have not assessed the pretreatment status of vitamin B2 nor taken into consideration the seminal series of studies by Anderson and coworkers (1994) who have demonstrated a high prevalence of genetically determined Rbf malabsorption in the general population. As reviewed above, Rbf deficiency facilitates multiple pathophysiologic mechanisms of migraine; conceivably, migraine and Rbf malabsorption (with disruption of the homeostatic system for CNS flavin content) may be co-morbid conditions in a potentially large number of individuals. Furthermore, the authors have neither considered that a single dose of 27 mg saturates absorptive mechanisms, so that any excess to that dose is not actually absorbed (Zempleni 1996). Multiple daily doses of Rbf may be required for a steadily normal status of vitamin B2 (Coimbra and Junqueira 2003) that may conceivably occur in a potentially large number of migraine sufferers who could concomitantly bear genetically disturbed flavin uptake by renal proximal tubule cells increasing urinary loss of vitamin B2. A therapeutic paradigm rationalized according to current knowledge of the altered vitamin B2 dynamics may enhance the effectiveness of Rbf therapy not only in migraine prophylaxis, but also in other disorders potentially related to that genetically determined and highly prevalent metabolic defect.

153.8.3 Multiple Sclerosis, Guillain-Barré Syndrome, Myasthenia, and Other Autoimmune Disorders

Vitamin D activation requires two sequential biosynthetic steps (25-hydroxylation in hepatocytes and 1α-hydroxylation in immune cell) by mitochondrial/microsomal cytochrome P-450 enzymes, respectively 25-hydroxylases (CYP2R1, CYP27A1) and 1alpha-hydroxylase (CYP27b), yielding calcitriol, which plays a central role in maintaining immune tolerance. Vitamin D-induced immune tolerance is therefore, critically dependent on vitamin B2 status, as the activities of all cytochrome P-450 super family members require continuous restoration of their prosthetic heme to the reduced state by FAD- and FMN-containing, NADPH-dependent cytochrome P450 reductase (Wang et al. 1997) (Fig. 153.7).

During the last decades, epidemiologic studies unequivocally demonstrated a strong negative correlation between the prevalence of autoimmune diseases and the bioavailability of vitamin D, from either consumption of fish oil or sunshine exposure. Both experimental and clinical data provide evidence that the concentration of circulating 25(OH)D3 (calcidiol), which best reflects vitamin D status, critically affects the outcome of autoimmune diseases such as multiple sclerosis, systemic lupus erythematosus, rheumatoid arthritis, insulin-dependent diabetes mellitus, and inflammatory bowel disease (Correale et al. 2009; Cutolo 2009).

The active form of vitamin D (calcitriol) synthesized from circulating calcidiol by the enzyme 1alpha-hydroxylase within the immune cells maintains immunologic tolerance to self-antigens upon interaction with nuclear VDR (Bikle 2009). The expression of 1alpha-hydroxylase and VDR has been described in dendritic cells, macrophages, B cells, and activated T cells, which are, therefore, both producers and targets of calcitriol. Calcitriol changes the phenotype and the activity of the very calcitriol-producing cell (autocrine effect) and the nearby cells (paracrine effect), thereby effectively inducing tolerance to auto-antigens without causing significant immune-suppression or endocrine effects (hypercalcemia and/or hypercalciuria) (Vieth 2004).

Predisposition to autoimmune diseases due to low sunlight exposure and poor ingestion of fish oil is conceivably more prominent in individuals bearing 1alpha-hydroxylase or VDR gene polymorphisms, which respectively impair the efficiency of the enzyme and/or the affinity of VDR for its agonist (calcitriol). Accordingly, the development of auto-immune pathology related to polymorphic changes of 1alpha-hydroxylase (Pani et al. 2002) or VDR (Smolders et al. 2009), and both polymorphisms of the VDR (Smolders et al. 2009) and vitamin D metabolite levels (Smolders et al. 2008) have been linked to multiple sclerosis susceptibility and disability.

Conceivably, the administration of cholecalciferol in doses much higher than those currently recommended has a remarkable therapeutic potential in multiple sclerosis (Vieth 2004; Kimball et al. 2007; Niino et al. 2008). High levels of calcidiol may compensate for the higher Michaelis–Menten constant of a polymorphic 1alpha-hydroxylase. Similarly, a high calcidiol-to-calcitriol conversion rate provided by the effect of optimized substrate provision (to a genetically normal 1alpha-hydroxylase within the immune cells) may increase intracellular ligand levels and counteract the low binding affinity of a polymorphic VDR. However, the effect of high-dose cholecalciferol therapy in either of these circumstances may be significantly compromised by low FMN and FAD incorporation to NADPH-dependent cytochrome P-450 reductase in altered vitamin B2 status.

A low vitamin B2 status may significantly impair vitamin D metabolism for two reasons: (1) the two sequential steps of calcitriol biosynthesis require the activity of the NADPH-dependent cytochrome P-450 reductase, which (2) is doubly dependent on vitamin B2 as it uses the two active flavins (FMN and FAD) as prosthetic groups. In addition, vitamin B2 deficiency may further dysregulate the immune system by at least two other ways. First, the immune function seems to be exquisitely sensitive to changes in the intracellular GSH:GSSG ratio (Fidelus and Tsan 1987; Droge and Breitkreutz 2000), and low availability of FAD diminishes both GR activity and intracellular concentration of GSH, while increasing GSSG levels. Second, a wealth of evidence now supports the existence of extra-adrenal production of corticosteroids, particularly in the cardiovascular system and CNS, where the full array of enzymes required for the de novo synthesis of corticosteroids from cholesterol has been identified (Davies and MacKenzie 2003). The synthesis of endogenous steroids requires the activity of cytochrome P-450 enzymes (Nebert and Russell 2002), and therefore, altered vitamin B2 status could credibly favor local inflammatory and autoimmune responses in these sites.

Vitamin B2 and vitamin D statuses may similarly affect other autoimmune neurological disorders, including Guillain-Barré syndrome (acute inflammatory demyelinating polyradiculoneuropathy), myasthenia, and optic neuritis. These disorders may also respond to therapy with high doses of cholecalciferol and Rbf for the same reasons exposed here.

153.8.4 Neurodegenerative Disorders and Cell Death

Inherited low vitamin B2 status and related disruption of Rbf homeostasis in the CNS feasibly favor cell death in neurodegenerative disorders by a number of mechanisms leading to a decline in GSH/GSSG ratio (Bains and Shaw 1997). One is increased conversion of GSH to GSSG by oxidative stress (overproduction of reactive species of both oxygen and nitrogen) secondary to impairment of mitochondrial function related to low availability of FMN and FAD. Another mechanism is decreased GSH synthesis: the availability of cysteine to γ-GCS activity is the rate-limiting factor in GSH formation, and cysteine synthesis from *S*-adenosylhomocysteine is impaired in low Rbf status due to decreased PLP supply. A third mechanism is decreased reduction of GSSG to GSH by FAD-dependent GR. GSH depletion and post-translational modifications of proteins through glutathionylation

mediate apoptotic cell death triggered by a wide variety of stimuli including activation of death receptors, oxidative stress, environmental agents, and cytotoxic drugs (Franco and Cidlowski 2009). Accordingly, disturbed NO (peroxynitrite formation from superoxide and NO) and GSH metabolism may be involved in both necrotic and apoptotic phenomena related to Parkinson's disease, Alzheimer's disease, Huntington's disease, amyotrophic lateral sclerosis, multiple sclerosis, and brain ischemia (Guix et al. 2005).

Within the CNS, both microglia and neurons express 1alpha-hydroxylase and VDR, while VDR is also expressed by astrocytes and oligodendrocytes. Besides tolerance to neural auto-antigens, the local bioactivation of calcidiol into calcitriol provides a myriad of critical autocrine and paracrine benefits in the developing as well adult CNS. These include neuroprotective (through antioxidative mechanisms, neuronal calcium regulation, neuro-immunomodulation, enhanced nerve conduction and detoxification mechanisms), and neuroregenerative effects (neurogenesis stimulation, neurotrophin biosynthesis, myelination) (Garcion et al. 2002; Buell and Dawson-Hughes 2008).

Current knowledge indicates that progesterone synthesis occurs in the brain, for the brain, by neurons and glial cells in the central and peripheral nervous system of both male and female individuals. Progesterone has anticonvulsant actions, enhances mitochondrial function, neurogenesis and regeneration, promotes myelin repair, protects or reconstructs the BBB, downregulates inflammatory cascades, and limits cellular necrosis and apoptosis (reviewed by Brinton et al. 2008). According to the mechanisms explained elsewhere, a low vitamin B2 status associated with genetically determined disruption of Rbf homeostasis in the CNS may significantly impair the synthesis of calcitriol, progesterone, and other steroids in the nervous tissue.

153.8.5   Brain Ischemia and Traumatic Brain Injury

Enhanced lipolytic activity secondary to intracellular calcium overload during brain ischemia removes considerable amounts of arachidonic acid from membrane phospholipids. Reperfusion of the ischemic tissue restores oxygen supply required for the activity by the arachidonate oxygenase (prostaglandin synthetase) system, generating a sudden burst of free radical formation followed by postischemic inflammation-induced iNOS expression, with continuous production of reactive species of oxygen and nitrogen. The results include peroxidation of cellular membranes, oxidative damage to proteins and nucleic acids. The so-called "reperfusion injury" affects mitochondrial respiratory enzyme complexes and mitochondrial DNA with subsequent defects in oxidative phosphorylation, impaired ATP production, and sustained mitochondrial generation of reactive species at a rate sufficient to escape endogenous antioxidant defenses. Subsequently, peroxynitrite and hydroxyl radical production resulting from the combined effects of disturbed electron transport in the mitochondrial respiratory chain, active inflammatory processes, and failure of antioxidant defenses create a vicious cycle by further damaging lipids, nucleic acids, and proteins. This scenario of pathophysiologic events ultimately results in both necrotic and apoptotic cell death.

Conceivably, ischemia/reperfusion creates a potentially unmatched demand for numerous FNM- and/or FAD-dependent metabolic processes, including DNA resynthesis and replication (mitochondrial DNA repair), GST-mediated detoxification of oxidized DNA and lipid molecules, maintenance of the GSSG-GSH antioxidant cycle, reactions requiring NADPH-dependent cytochrome P450 reductase activity (catabolism of arachidonic acid and eicosanoids, heme degradation by HO, synthesis of steroid molecules endowed with neuroprotective and neurodegenerative actions like calcitriol and progesterone), eNOS and nNOS activities. A higher supply of vitamin B2 active forms (FMN and FAD, respectively required by complexes I and II) may plausibly improve the activity of

the electron transport chain, reducing the electron leakage and the formation of superoxide ions. Preservation of GSH levels may prevent apoptotic cell death (Franco and Cidlowski 2009).

The metabolic dependency of PLP, folate, and methylcobalamin on FMN and/or FAD availability unveils other neuroprotective and neurodegenerative enzyme activities indirectly dependent on vitamin B2 status. Rbf administration may optimize PLP synthesis and the activity of several PLP-dependent enzymes is of potential benefit in ischemia/reperfusion. The synthesis of l-cysteine by γ-GCS increases the availability of l-cysteine for GSH synthesis (Griffith 1999), thereby enhancing antioxidant defenses and antagonizing apoptosis. Rbf administration may facilitate amino acid, protein, and nucleic acid synthesis by increasing PLP availability. The PLP-dependent activity of δ-aminolevulinate synthase allows the biosynthesis of prosthetic heme required for de novo synthesis of HO, cytochrome P-450 superfamily, electron transfer proteins (cytochromes *b* and c), peroxidases, catalases, iNOS and nNOS isoforms, and guanylate cyclases, thus further enhancing antioxidant defenses, decreasing free radical production, and opposing necrotic and apoptotic pathophysiologic events. Enhancement folic acid cycle (Fig. 153.5) by Rbf administration may optimize the methylation of phospholipids, proteins, DNA, RNA, and other small molecules and critically improve cell survival in ischemia/reperfusion.

Accordingly, Rbf protects the brain tissue against brain ischemia (Betz et al. 1994) and traumatic brain injury (Hoane et al. 2005). The proposed mechanism of action is the intracellular formation of dihydroriboflavin from administered Rbf by a NADPH-dependent flavin reductase, first detected in erythrocytes 75 years ago. Dihydroriboflavin quickly reduces Fe(IV)O and Fe(V)O oxidation states of hemeproteins (implicated in tissue damage associated with ischemia and reperfusion) to Fe(III)O thus protecting cells from oxidative injury (Hultquist et al. 1993). Due to the wide range of FMN- and or FAD-dependent metabolic processes required for cell survival after ischemia/reperfusion, the protective effect of Rbf administration is not likely to be exclusively determined by increased dihydroriboflavin synthesis. Conceivably, individuals with inherited low vitamin B2 status associated with disruption of brain Rbf homeostasis may be particularly vulnerable to reperfusion injury of the nervous tissue.

153.8.6 Epilepsy and Antiepileptic Therapy

Some epileptic disorders are responsive to specific vitamins like pyridoxine and folic acid derivatives (Wolf et al. 2005). The administration PLP may result in better seizure control than pyridoxine in vitamin B6-responsive epilepsy (Hoffmann et al. 2007). PLP plays a key role in the synthesis of many neurotransmitters, particularly biogenic amines like dopamine and serotonin, and in the decarboxylation of the dominant excitatory neurotransmitter glutamate to the major inhibitory transmitter GABA in the mammalian CNS (Jansonius 1998) by serving as a coenzyme for the rate-limiting enzyme GAD (Fricke et al. 2007). Patients with an autosomal recessive defect of GAD have an imbalance of the neurotransmitters glutamate and GABA (Gospe 1998). Accordingly, GAD-knockout mice show decreased GABA transmission and increased seizure susceptibility (Asada et al. 1997); low vitamin B6 status in genetically normal humans is associated with a lowered seizure threshold (Apeland et al. 2003). Conceivably, a decreased activity of PPO (the FMN-dependent, PLP synthesizing enzyme) or abnormalities of folate metabolism may facilitate seizures. Thus, a low vitamin B2 status reduces FMN availability, which may destabilize neuronal excitability by impairing GABA synthesis.

The active form of vitamin D (calcitriol) also plays an anticonvulsant role in the brain (Siegel et al. 1984; Kalueff et al. 2005). A reduced FMN and FAD availability and incorporation to NADPH-dependent cytochrome P450 reductase may impair the hydroxylations of vitamin D to calcitriol in the brain tissue, thereby lowering the threshold for epileptic seizures.

Similarly, a number of folate-dependent metabolic roles may influence neuronal excitability, and a specific epileptic disorder responds to folic acid derivatives (Wolf et al. 2005). Folate-dependent mechanisms possibly involved in stabilization of neuronal activity include biosynthesis of the neurotransmitters serotonin, catecholamines, and melatonin (Djukic 2007), and the regulation of homocysteine concentrations (Fig. 153.5). The main route of catabolism of homocysteine is through conversion to cystathionine, catalyzed by a PLP-dependent enzyme (CBS). Cystathionine is converted to cysteine and cysteine is oxidized to cysteine sulfinic acid and subsequently, to cysteic acid. Cysteine sulfinic acid and cysteic acid are decarboxylated to hypotaurine and taurine, respectively, by another PLP-dependent enzyme (CADCase/CSADCase). The oxidation products of homocysteine (homocysteine sulfinic acid and homocysteic acid) and cysteine (cysteine sulfinic acid and cysteic acid) are excitatory sulfur amino acids and may act as excitatory neurotransmitters, whereas taurine and hypotaurine (decarboxylation products of cysteic acid and cysteine sulfinic acid) may act as inhibitory transmitters (Santhosh-Kumar et al. 1994). As discussed elsewhere, vitamin B2 deficiency impairs folate (and methylcobalamin) cycle and PLP synthesis. Vitamin B2 deficiency is expected to increase homocysteine-derived excitatory sulfur amino acids while decreasing the levels of inhibitory transmitters, hypotaurine and taurine. The result is a shift in excitatory–inhibitory balance toward a lower threshold for epileptic seizures (Fig. 153.9).

The dependency of vitamins D3 (Fig. 153.7) B6, B12, and folate on FAD and/or FMN availability (Fig. 153.5) therefore, indicates that vitamin B2 deficiency may be epileptogenic. Accordingly, high doses of Rbf abolish epileptic activities in MADD (Kmoch et al. 1995) and high prevalence of low vitamin B2 status is found in association with preeclampsia (Wacker et al. 2000) which may evolve to eclamptic convulsive seizures. The large prevalences of epilepsy (Sander 2003) and Rbf malabsorption (Anderson et al. 1994) suggest that uptake, trafficking, and cellular homeostasis of Rbf in the brain tissue may be disturbed in a significant number of epileptic individuals, and may contribute for a lower threshold for epileptic seizures (Fig. 153.9).

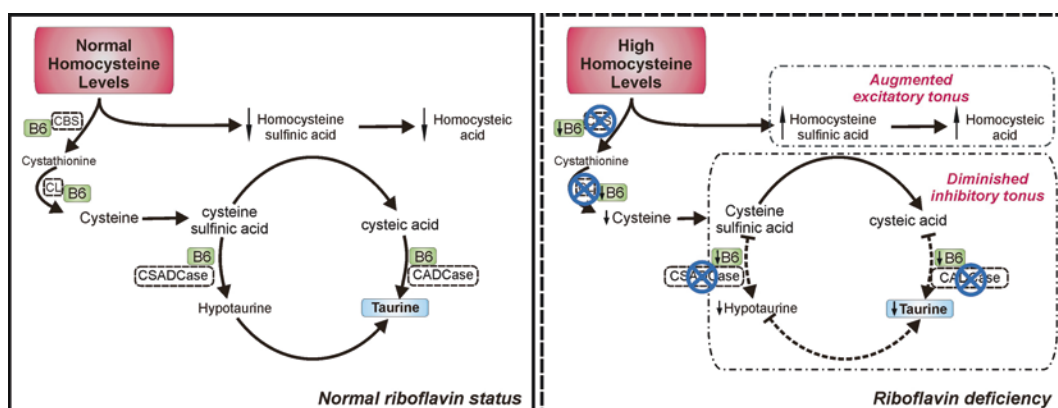
Taken together these data support the need for adequate diagnosis and treatment of all these vitamin deficiencies in epileptic patients to optimize seizure control. In contrast, antiepileptic drug therapy is associated with hyperhomocysteinemia (Schwaninger et al. 1999; Apeland et al. 2003) and


Fig. 153.9 The role of vitamin B2 status on seizure control in epileptic patients. *Left panel*: normal neuronal excitability is observed when enough flavin monophosphate is available for pyridoxal 5′-phosphate (PLP, the active form of vitamin B6) synthesis by pyridox(am)ine 5′-phosphate oxidase. *Right panel*: reduced epileptic threshold for epileptic seizures in low vitamin B2 status due to both increased levels of excitatory compounds and decreased levels of inhibitory neurotransmitters (hypotaurine and taurine). "X inside the circle" indicate enzyme activities secondarily inhibited under low vitamin B2 status (primarily due to low PLP availability). *CL* cystathionine-γ-lyase, *CBS* cystathionine β-synthase, *CADCase/CSADCase* cysteine and sulfinic acid decarboxylase
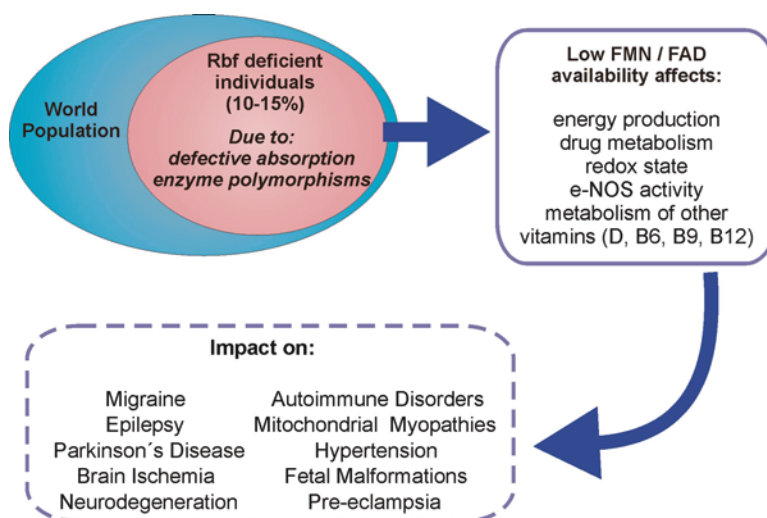

Fig. 153.10 Key facts of riboflavin. Key facts about the impact of riboflavin deficiency on human health. Riboflavin is an essential micronutrient playing a critical role in myriad of biological phenomena, including energy production, DNA replication and repair, nitric oxide synthesis, necrosis and apoptosis, drug metabolism, and antioxidant defense systems. The potential relevance of Rbf status for the pathophysiology, prevention, and treatment of a wide range of human diseases has been largely underestimated

multiple vitamin deficiencies, including those of vitamins B1, B2, B6, B12, C, D, E, beta-carotene, biotin, and folate (Krause et al. 1988; Apeland et al. 2003; Aslan et al. 2008; Nettekoven et al. 2008). Whether these metabolic changes are related to the epileptic condition or represent a pharmacologic side effect is unknown. Discussions on the relevance of vitamin supplementation to patients on anti-epileptic therapy have been usually limited to the preventive context of decreasing the risks of cardiovascular disease and birth defects (Apeland et al. 2002). Only pyridoxine supplementation for enhancing seizure control has been (barely) considered in patients on antiepileptic therapy. However, the metabolic interdependency among these vitamins, as well as their key neurophysiologic roles strongly indicate that untreated multiple vitamin deficiencies may significantly hamper the very antiepileptic effect of these drugs, leading to poor seizure control (apparent drug-resistant epilepsy) and avoidable polytherapy (Fig. 153.10).

Summary Points

- Vitamin B2 directly or indirectly participates in a much wider range of metabolic pathways than usually considered in human physiology; often the same biologic function involves FMN and/or FAD in more than one of its regulatory and integrative steps.
- The high prevalence of genetic polymorphisms related to absorption and cellular trafficking of Rbf, particularly considering the primary and secondary participation of FMN and FAD in a large number of regulatory and metabolic networks highly emphasizes the pathophysiological significance and potential therapeutic/preventive implications of unrecognized deficiency of this micronutrient.
- The interactions between the genetically determined low Rbf status and another highly prevalent inherited metabolic change – the MTHFR mutation restrictive of FAD binding (C677T) – may be of clinical relevance, since high-dose Rbf therapy may plausibly minimize the metabolic effects of that particular MTHFR polymorphism.

- The concrete possibility of a highly prevalent genetically determined disruption of Rbf homeostasis in the CNS makes the nervous tissue particularly prone to Rbf deficiency and raises higher potentially significant implications for prevention and therapy of neurologic disorders in comparison to systemic diseases.
- According to experimental evidence of benefits of Rbf treatment in models of tissue injury, the pathophysiology of cellular damage seem to set up localized higher demands for FMN and FAD required for upregulation of antioxidant, antiapoptotic and proregenerative processes dependent on Rbf metabolism.
- Future research should address the potential association between genetically determined Rbf malabsorption and disorders like migraine, neurodegenerative and autoimmune diseases, as well as in several other neurologic and systemic conditions pathophysiologically related to disturbed metabolism of lipids, amino acids, DNA, cytochrome P-450, NO, vitamin D3, HO and homocysteine metabolism;
- Whenever such association is demonstrated, further studies should investigate the dynamics (including CSF distribution) and therapeutic potential of high-dose Rbf administration in affected individuals, as well as the expression of polymorphic genes related to cellular uptake and trafficking of Rbf at the terminal ileum, proximal renal tubules, and CNS.
- Following the demonstration of low vitamin B2 status (altered EGRAC) associated with a normal dietary Rbf content, a paradigm of 30 mg three to four times a day required for maintenance of normal EGRAC throughout the 24-h period should be considered in future clinical trials aimed at investigating the therapeutic value of Rbf status normalization.

Definition Terms

Enzymes are proteins that catalyze chemical reactions in virtually all biochemical processes, requiring a substrate molecule for conversion into a product.

Cofactor is a nonproteic component that is necessary for the enzyme activity. It can be categorized into a coenzyme or prosthetic group.

Coenzyme is a cofactor of organic nature not covalently bound to the enzyme. Many coenzymes are vitamin derivatives, such as FMN and FAD.

Heme is a prosthetic group, usually an iron-containing heteroclyclic ring, the porphyrin.

Heme oxigenase is an enzyme that catalyzes the degradation of heme group, producing biliverdin, iron, and carbon monoxide.

Prosthetic group is a cofactor covalently bounded to the enzyme. It may be of organic nature, such as vitamins, or inorganic nature, like metal ions.

Synthetases are enzymes that catalyze the linkage of two molecules by using the energy derived from the ATP hydrolysis. The International Union of Biochemistry now classifies them as type 6 enzymes (ligases).

Synthases are enzymes that do not use energy from nucleoside triphosphates, differently from synthetases (see above). The Joint Commission on Biochemical Nomenclature (JCBN) dictates that the term 'synthase' may be applied to any enzyme that catalyzes synthesis (whether or not it uses nucleoside triphosphates), whereas 'synthetase' is to be used synonymously with ligase.

Microsomes are vesicles only formed from the endoplasmic reticulum in laboratory preparations for studying the metabolism of some compounds and drug interactions.

Chapter 154
Brain Mechanisms Involved in the Detection and Adaptation to Lysine Deficiency

Takashi Kondoh and Kunio Torii

Abbreviations

LHA   Lateral hypothalamic area
MSG   Monosodium L-glutamate
PEP   Purified egg protein
TVX   Subdiaphragmatic total vagotomy
VMH   Ventromedial nucleus of the hypothalamus

154.1 Introduction

Essential amino acids, such as L-lysine, cannot be produced by the body, and must therefore be obtained from diet in order to support growth, reproduction, and, ultimately, survival. Deficiency of a specific essential amino acid represents a relevant model to describe the overall adaptive changes in ingestive behaviors resulting from nutrient deficiency. Lysine deficiency is, arguably, one of the best models to study the adaptive changes in behavior that take place during specific nutrient deficiencies (Table 154.1). For example, while lysine is the limiting amino acid in proteins found in feed grains (Torii et al. 1987), it is not a direct precursor of any neurotransmitter in the brain. Lysine levels both in the blood and cerebrospinal fluid are high among 20 amino acids (Nishimura et al. 1995). The risk of lysine deficiency is high in low socioeconomic human populations who depend predominantly on wheat for their protein supply (Young and Pellett 1990). Rats fed a bread-based, lysine-impoverished diet based on wheat gluten, show low weight gain, reduced appetite, nervousness, and ingestion of their own body hair (Culik and Rosenberg 1958). However, rats fed lysine-supplemented bread do not show any of the above signs, and grow normally. In humans, negative nitrogen balance by consumption of wheat gluten is also observed (Bricker et al. 1945).

Deficiency of an essential amino acid affects both appetite and taste preferences for other amino acids and NaCl. Rats in nutritionally well-balanced conditions normally display strong preferences for monosodium L-glutamate (MSG; an umami substance) and L-arginine solutions (Torii et al. 1987). However, inducing states of lysine deficiency will result in concomitant abnormal patterns in both body physiology and taste preferences. In fact, when rats are restricted to a lysine-deficient diet, lysine levels in both plasma and brain decline (Mori et al. 1991a), since lysine concentrations in

Table 154.1 Key features of L-lysine

1. Lysine is a basic and essential amino acid with bitter taste quality.
2. Among 20 amino acids, lysine levels in the blood and cerebrospinal fluid are high.
3. Lysine is not a direct precursor of any neurotransmitter in the brain.
4. Lysine is the first limiting amino acid in proteins of some feed grains (wheat and corn).
5. Substantial risk of lysine deficiency exists in low socioeconomic human populations who consume wheat or corn as a major protein supply.
6. Characteristic symptoms of lysine (or an essential amino acid) deficiency are reduced appetite, low weight gain, and nervousness.
7. Replete of missing nutrient will cause rapid recovery from these symptoms.

This table lists the key facts of lysine in our body or in food

plasma directly reflect the lysine content in the diet (Mori et al. 1991a). Under lysine deficiency, food intake and growth are depressed, a physiological pattern that is accompanied by increased preferences for NaCl in detriment of MSG or arginine (Torii et al. 1987). However, when offered a lysine solution, which is bitter and hence normally aversive to animals, lysine-deficient rats will robustly drink the solution, resulting in normalization of food intake levels and growth (Tabuchi et al. 1991; Torii et al. 1987, 1996). In this repleting process, their initial preference for NaCl changes towards MSG as in nondeficient rats. As the immediate licking responses to lysine solution in brief (10 s)-access tests do not increase during lysine deficiency (Markison et al. 1999), the preference for the missing amino acid appears to be learned rather than innate. In other words, learning a positive association between the taste of lysine (conditioned stimulus) and its repleting, postingestional consequences (unconditioned stimulus) is required before a lysine-deficient animal will engage in adaptive increases in lysine intake. However, the sensing mechanisms involved in detecting the deficient nutrient and the brain mechanisms regulating adaptive preferences remain poorly understood.

This review describes our current knowledge on the peripheral sensing sites, signaling pathways, and primary brain areas regulating adaptation to nutrient deficiency. We focus on lysine deficiency since this constitutes a functional working model of essential amino acid deficiency.

154.2 Changes in Food Intake, Weight Gain, and Taste Preference During Protein Deficiency

Before discussing overall changes occur during lysine deficiency, we would like to describe what happens during protein deficiency. Protein is a macronutrient essential for growth, reproduction and survival. Protein is involved not only for muscle contraction but also for numerous physiological functions since they form the constitutive material of receptors, ion channels, transporters, enzymes, immunoproteins, and transcription factors.

During low protein intake starvation, body nitrogen concentration declines to negative levels (Harper 1974). During fasting, body protein breaks down into amino acids that are used to produce energy as a replacement for glucose (Harper 1974). A characteristic symptom of Kwashiokor disease is hypoproteinemia, due to fasting-induced malnutrition; recovery takes place immediately upon treatment with a high-protein diet (Rosenberg and Rohdenburg 1952). Rats offered a low or no-protein diet show reduced food intake and reduced body weight (Mori et al. 1991a) (Fig. 154.1). Considering data from body weight measurements, the minimum percentage of protein content in diet required for normal growth in young growing rats is estimated to be 12.5% (Mori et al. 1991a) in the case of purified egg protein (PEP), an ideal protein source associated with highly efficient nitrogen storage (Forbes et al. 1958). In fact, in the choice experiments involving low (5% PEP) and
Fig. 154.1 Mean daily food intake and body weight (BW) changes in rats fed diets with various protein levels for 1 week. Rats at 4 weeks of age were fed a diet containing purified egg protein (PEP) at levels between 0% and 30%, or given a choice between 5% PEP and 45% PEP diets. Results are expressed as mean ± SD, $n = 8$. $^*P < 0.05$ and $^{**}P < 0.01$, significance compared to rats fed 20% PEP diet (control) by ANOVA followed by Dunnet's test (Reprinted from Mori et al. 1991a. With permission)

high (45% PEP) protein diets, rats tend to ingest an average of 13.2% protein content, very close to the 12.5% minimal estimate, a pattern associated with normal growth (Mori et al. 1991a).

Preferences for amino acid and NaCl solutions are also related to protein nutrition (Fig. 154.2). When dietary protein levels are normal, preference for umami taste substances such as MSG is high, suggesting that umami taste is a marker of protein ingestion (Torii et al. 1987). In contrast, preference for NaCl and glycine increases under severe protein deficiency, possibly reflecting negative nitrogen balance in the body. Glycine is effective in ameliorating low nitrogen levels under protein deficiency, suggesting a sparing effect on endogenous protein degradation (Torii et al. 1987). Therefore, preferences for certain amino acids (e.g., MSG and glycine) and NaCl depend on protein nutrition.

154.3 Lysine Deficiency and Lysine Levels in the Plasma and Brain

Some protein-rich foods contain low levels of certain amino acids. For example, wheat gluten contains low levels of lysine and methionine (20% and 17%, respectively), and corn zein is low in lysine and tryptophan (0.7% and 15%, respectively) compared to PEP (Table 154.2). Wheat flour is a major supply of plant protein for humans, and gluten is the major protein in the wheat. These proteins have been used to investigate animal ingestive behaviors associated with protein or amino acid deficiency.

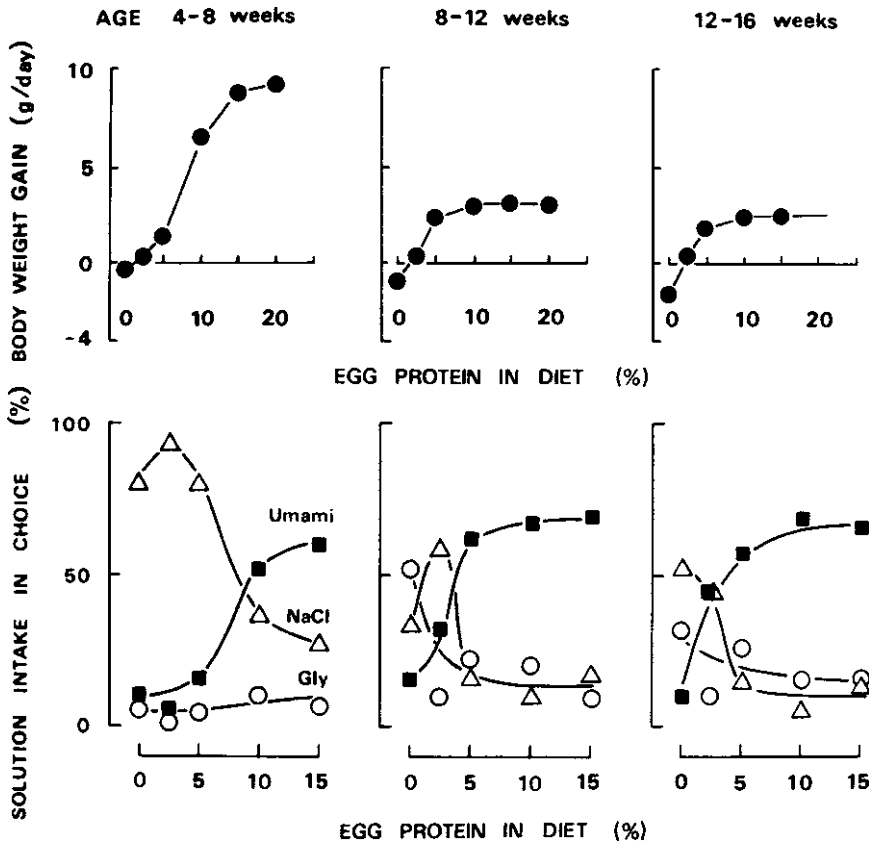
Since feeding of crystalline amino acid mixture-based diets readily suppress further food intake, the protein component of a lysine-deficient diet is obtained from wheat gluten fortified with crystalline essential amino acids excluding lysine (Table 154.3). Control diets ("lysine-sufficient" diets) are fortified with crystalline lysine (L-lysine HCl). Different amounts of glutamine are added to the diets to make them isonitrogenous to a 20% PEP diet (Mori et al. 1991a). Since wheat gluten contains 20% of the total lysine levels found in PEP, a lysine-deficient diet should have 20% of the lysine levels of a control diet, rather than 0% (unless stated otherwise). This level of lysine (20% of control) is required to maintain homeostasis and avoid negative nitrogen balance in experimental animals (Torii et al. 1987).


Fig. 154.2 Body weight gain (*upper*) and taste preference (*lower*) in rats fed diets with various protein levels and at various ages. Rats at 4, 8, and 12 weeks of age were fed diets containing purified egg protein at levels between 0% and 15% for 4 weeks. Averaged values of daily weight gain and percentage intake of each solution [NaCl, glycine (Gly), and umami] are shown, $n = 8$ (Reprinted from Torii et al. 1987. With permission)

The diurnal patterns of lysine concentrations in the plasma and brain are quite comparable to each other. In lysine-repleted (control) rats, lysine levels in plasma and brain are stable throughout the day (Mori et al. 1991a). In lysine-deficient rats, however, both plasma and brain lysine levels decline dramatically following onset of feeding (mainly during the dark phase since rats are nocturnal animals), but return to control levels by the end of the light phase (Fig. 154.3). During the dark phase, plasma lysine declines to near zero, but brain lysine declines to approximately one-third of control levels. Recovery of lysine levels during the light phase may reflect degradation of body proteins in order to supply amino acids to the body, especially to the brain. In fact, lysine concentrations in plasma reflect dietary lysine levels (Mori et al. 1991a) (Fig. 154.4).

154.4 Changes in Taste Preferences During Lysine Deficiency

When rats are offered diets deficient in or containing imbalanced levels of amino acids, food intake is remarkably depressed (Harper et al. 1970), followed by an attempt by animals to change their dietary source (Inoue et al. 1995). Under states of amino acid deficiency, the dietary restricted amino acid, rather than protein content, can act as the dietary stimulus to control food selection.

Table 154.2 L-Amino acid composition of whole egg protein (PEP), wheat gluten, and corn zein (Reprinted with modification from Torii et al. 1987. With permission)

L-amino acid	Concentration (% of 16 g nitrogen)		
	PEP	Wheat gluten	Corn zein
Essential amino acids			
Lysine	7.39	1.48	0.05
Methionine	3.30	0.56	1.62
Tryptophan	1.44	0.77	0.21
Phyenlyalanine	5.66	4.87	7.47
Isoleucine	5.72	3.23	3.91
Leucine	9.71	6.71	21.85
Valine	6.61	3.53	3.69
Threonine	4.83	2.46	2.81
Histidine	2.41	1.90	1.23
Nonessential amino acids			
Glutamic acid	12.84	33.58	23.81
Aspartic acid	10.08	3.13	5.70
Arginine	7.04	3.27	1.31
Serine	7.76	4.87	5.48
Alanine	6.05	2.50	10.98
Glycine	3.53	3.31	1.18
Proline	4.28	13.95	1.15
Tyrosine	4.05	3.09	5.17
Cysteine	2.30	2.82	0.34

Each protein sample was hydrolyzed and assayed for amino acid content by an automatic amino acid analyzer (micro-Kjeldahl method)

Table 154.3 Composition of lysine-sufficient (control) and lysine-deficient diets (Reprinted from Torii et al. 1987. With permission)

Composition	Experimental diets	
	Control	Lysine-deficient
Wheat gluten	24.35	24.35
L-Lysine HCl	1.35	–
L-Glutamine	0.68	1.76
L-Amino acid mixture	3.72	3.72
Corn starch	55.69	55.96
Mineral mixture	4.00	4.00
Vitamin mixture	1.00	1.00
Choline chloride	0.20	0.20
Vitamin E	0.01	0.01
Cellulose powder	4.00	4.00
Corn oil	5.00	5.00
Total	100	100
L-Lysine content in diet (%, w/w)	1.35	0.27

Each protein sample was hydrolyzed and assayed for amino acid content by an automatic amino acid analyzer (micro-Kjeldahl method). Values are shown as % of weight in each diet

Lysine deficiency drastically changes the behavioral response of rats to lysine solutions from aversion to attraction. When rats are given a lysine-deficient diet, they will select the lysine solution out of various other sapid solutions (Mori et al. 1991a; Tabuchi et al. 1991; Torii et al. 1987).

DIURNAL VARIATION OF LYSINE
Fig. 154.3 Diurnal variation of lysine concentration in the plasma (*upper*) and brain (*lower*) under lysine-sufficient (control) and lysine-deficient conditions in rats. (**a**), in control, lysine levels in blood and brain are stable within a day. During lysine deficiency, however, lysine levels in both plasma and brain are reduced during dark period (feeding period). Lysine solution was not supplied in this experiment. Lysine concentration was assayed using an automated amino acid analyzer after deproteinization by sulfosalicylic acid. Results are expressed as mean ± SD, $n = 5$. $^*P < 0.05$ and $^{**}P < 0.01$, significance compared to control by Student's t-test (Reprinted from Mori et al. 1991a. With permission)
Fig. 154.4 Lysine levels in the plasma (**a**) and brain (**b**) in rats fed diets with various lysine levels. Rats at 4 weeks of age were given free access to a diet with various levels of lysine from deficiency to excess, equivalent to a lysine composition in 4–30% purified egg protein (PEP), for 8 weeks. The diet containing 1.35% lysine (equivalent to the lysine content in 20% PEP) was employed as control. Lysine solution was not supplied in this experiment. Results are expressed as mean ± SD, $n = 6$. $^*P < 0.05$ and $^{**}P < 0.01$, significance compared to control by ANOVA followed by Dunnet's test (Reprinted from Mori et al. 1991a. With permission)
Fig. 154.5 Preference for lysine solution appears during lysine deficiency. *Upper*, intake (mL/10 min) of 0.4 M lysine solution; *Lower*, intake (mL/10 min) of monosodium L-glutamate (MSG) solution. Rats were offered lysine-deficient (– Lysine) or lysine-sufficient (+ Lysine) diets. Preference for lysine solution increased gradually during lysine deficiency and reduced rapidly after recovery from deficiency. Preference for MSG solution also appeared only when nutritive conditions are well-balanced (Reprinted from Mori et al. 1991a. With permission)

Preference for lysine solutions increase gradually during lysine deficiency and is rapidly reduced after repletion (Fig. 154.5). Preferences for MSG solution also appear only when nutritive conditions are well-balanced. Rats fed a tryptophan-deficient diet also prefer a tryptophan solution (bitter) over a saccharin solution (sweet), a choice that ameliorates their state (Mori et al. 1991b). The increased preference for a deficient nutrient is commonly observed when rats are given a diet deficient in one of the other essential amino acids (Mori et al. 1991a). These adaptive behavioral changes are considered to be learned preferences (Gietzen et al. 1992; Markison et al. 1999; Naito-Hoopes et al. 1993). In fact, lysine deficiency in rats does not seem to enhance the "palatability" of lysine as assessed by licking responses including lick rate, bout size and bout number (Markison et al. 2000). In contrast, increases in acceptance (i.e., reduction in aversion) to lysine solution are reported in lysine-deficient mice (Ninomiya et al. 1994b).

154.5 Peripheral Mechanisms

The detection of deficiency in amino acid levels will take place only after digestion of protein. Absorption of amino acids also plays an important role in sensing the levels of a deficient nutrient. Nutritional stimuli in the gut elicit hormonal release into the circulation as well as vagal activation, which are key components of the gut-brain communication. For detection of chemical compounds, specific receptors and neural coding mechanisms may exist in the gastrointestinal tract and hepatoportal region. Integration of postingestive consequences with oronasal sensory stimuli (e.g., taste, odor, and texture) occurs in the brain. Both peripheral and central mechanisms are involved in the responses observed during amino acid deficiency (Hawkins et al. 1994; Tabuchi et al. 1991).

In what follows, we describe the elevated serum levels of inhibin, a heterodimeric protein composed of α and β-subunits and a member of the transforming growth factor-β (TGF-β) superfamily, and increases in the sensitivity of hepatic vagal efferent fibers 100-fold during lysine deficiency. Behavioral aversion threshold to lysine solutions also increases 100-fold. Sensitivity of taste nerves, however, does not change under the same condition. Furthermore, in the transection of peripheral nerves, we describe the contributions of the taste and vagus nerves to the adaptive behavioral changes induced by lysine deficiency.

154.5.1 Humoral Factors

It is possible that different neurotrophic or neuromodulatory factors are released in the systemic circulation during lysine deficiency resulting in changes in sensitivity to the deficient nutrient and/or in adaptive responses. There are a number of bioactive candidates that may act at concentrations too low to be detected by most available methods. One very sensitive assay, able to detect a number of humoral factors at the femtomolar concentration range, makes use of Hydra Japonica (hydra) (Hanai 1981). Tentacle ball formation is a sign of feeding behavior in the hydra under various levels of S-methylglutathione, and inhibition of this behavior can be differentially and quantitatively observed when certain humoral factors are present along with the feeding stimulus (Hanai 1981).

Rats fed a protein-restricted diet overnight show elevated serum levels of activin A (Torii et al. 1993), a homodimeric protein composed of two inhibin β_A-subunits and a member of the TGF-β superfamily. In contrast, inhibin is increased during lysine deficiency while activin A-like activity in the serum is severely suppressed. Inhibin has opposing biological effects to activin by competing with activin for binding with its receptors and/or binding to inhibin-specific receptors (Robertson et al. 2004). Results from additional assays, i.e., radioimmunoassays for inhibin and an erythroid differentiation assay for activin A, also confirmed the release of inhibin during lysine deficiency (Torii et al. 1996). These results suggest that activin A levels in the blood plays a role in alerting the brain of amino acid imbalance, and might subsequently induce an adaptive response aimed at reversing amino acid imbalances.

154.5.2 Taste Nerve

Neurophysiological studies have shown that the chorda tympani and glossopharyngeal nerves considerably differ in their responses to various taste stimuli. For example, bitter-tasting substances, such as quinine, sucrose octaacetate, and some essential amino acids (tryptophan, phenylalanine, and histidine), elicit greater responses in the glossopharyngeal nerve compared to the chorda tympani (Ninomiya et al. 1993; Shingai and Beidler 1985). The glossopharyngeal nerve also shows greater responses to MSG, an umami substance (Ninomiya et al. 1993), suggesting that the glossopharyngeal nerve carries the main taste inputs regarding both behaviorally aversive and nutritionally important substances present in food (Ninomiya et al. 1994b).

In mice, behavioral aversion thresholds to lysine solution, which is bitter and normally aversive for animals, increase approximately 100-fold during lysine deficiency compared to the control in brief (10 s) acceptance tests (Ninomiya et al. 1994b). Licking responses to other essential amino acids (phenylalanine, leucine), quinine, and various other taste substances do not change during lysine deficiency. The increase in acceptability to lysine induced by deficiency is also observed after
Fig. 154.6 Concentration-response relationships for lysine in the chorda tympani (CT) and glossopharyngeal (GL) nerves, and their double reciprocal plots in mice. The vertical axis represents relative responses to 0.1 M NH_4Cl as the standard stimulus. C, concentration of lysine (in mM for CT and in μM for GL). R, relative response. Results are expressed as mean ± SD, n = 8-10 (Reprinted from Ninomiya et al. 1994a. With permission)

transection of the chorda tympani while it disappears after bilateral transections of the glossopharyngeal nerve. These results suggest that taste information conveyed via the glossopharyngeal nerve plays a major role on an increase in hedonic value of lysine solution.

Neural responses to lysine are relatively larger in the glossopharyngeal nerve compared to the chorda tympani in control mice (Ninomiya et al. 1994a) (Fig. 154.6). The neural threshold for detection of a lysine solution is 2.5 log units lower in the glossopharyngeal nerve (~1.0 μM) than in the chorda tympani (~300 μM). An analysis of concentration-response relationships suggest a possibility that there are two different receptors (high- and low-affinity types) for lysine, each showing a different dissociation constant. The posterior region of the tongue would express both types, while the anterior region would express only the low-affinity type (Ninomiya et al. 1994a). Interestingly, lysine deficiency hardly affects the neural thresholds of both chorda tympani and glossopharyngeal nerves to lysine (see discussion in Ninomiya et al. 1994b), suggesting that the increased acceptance to lysine during lysine deficiency is primary mediated by the brain not by alteration of peripheral taste information.

In contrast to mice data mentioned above, rats show behavioral changes for lysine ingestion only over mM concentration range (Pritchard et al. 1982) and data from transection of taste nerves in rats point to a relatively more important role for the chorda tympani than the glossopharyngeal nerve in selecting lysine solutions during lysine deficiency (Tabuchi et al. 1996). Further studies are required to clarify the roles of these primary taste nerves in increasing preferences for deficient amino acids.

154.5.3 Vagus Nerve

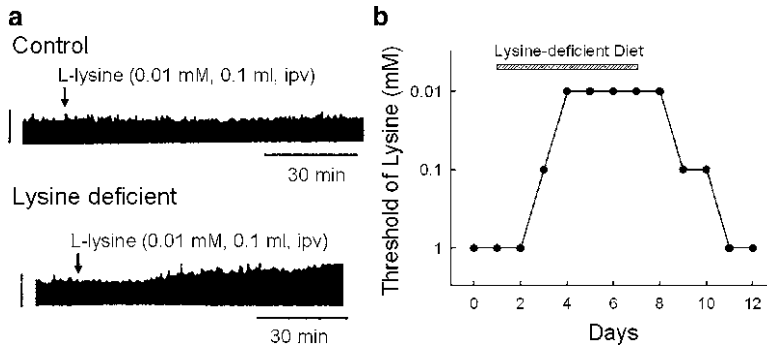
The vagus nerve innervates major portions of the gastrointestinal system and is important in the control of feeding. As lysine in food normally exists in a protein-bound form, it is reasonable to assume that a peripheral lysine sensor that monitors free lysine levels following protein digestion exist in the


Fig. 154.7 Responses of hepatic vagal afferent fibers to lysine (**a**) and the chronological changes in lysine sensitivity (**b**) in control and during lysine deficiency. (**a**) Administration of L-lysine solution (0.01 mM, 0.1 mL) in the portal vein (ipv) increases the firing rate of the hepatic vagal afferents during lysine deficiency but not in control. Vertical bar, 60 spikes/5 s. (**b**) The threshold (the least effective concentration) of lysine changes 100-fold within 4 days both during lysine deficiency and recovery, each period from deficiency. Each data correspond to observation from one rat (Reprinted from Torii and Niijima 2001. With permission)

luminal side of gastrointestinal tract, the hepatoportal region, or in the systemic circulation. The hepatoportal region is an appropriate area for detecting amino acid levels, and abdominal vagal afferents may provide the brain with information about the current levels of dietary amino acids. Accordingly, sensitivity of hepatic vagal afferents to intraportal administrations of lysine increases 100-fold during lysine deficiency compared to control states: the lowest effective concentration of lysine to evoke hepatic vagal activity is 1 mM during lysine repletion and 0.01 mM during lysine deficiency in rats (Torii and Niijima 2001) (Fig. 154.7). Sensitivity to other L-amino acids (L-alanine and L-leucine) and D-lysine remains unchanged. To reach maximum sensitivity to lysine, 4 days of lysine restriction are required (Torii and Niijima 2001). These results indicate the existence of putative lysine sensors in the hepatoportal region that contribute to maintain amino acid homeostasis.

Recently, a receptor for basic amino acids, namely "GPRC6A" (G-protein-coupled receptor, family C, group 6, subtype A), was found in the brain and peripheral organs such as kidney, skeletal muscle, testis, and white cells (Wellendorph et al. 2004). The receptor is also evident in the mesenteric arteries (Harno et al. 2008). The receptor may contribute monitoring of lysine levels in the blood and brain. However, GPRC6A responds not only to lysine, but is a broadly-tuned sensor of other basic amino acids such as arginine, citrulline, and ornithine with EC_{50} values in the range 20–100 μM (Wellendorph et al. 2005). If there are other types of basic amino acid receptors with different ligand specificity, combination of these putative receptors may enable to monitor the lysine levels in our body.

The enhanced sensitivity of hepatic vagal afferents contributes in the identification of the deficient nutrient, and to alter preferences towards enhancing selective intake of foods containing the deficient nutrients, which prevents malnutrition and anorexia.

154.5.4 Effects of Vagotomy on Food Intake and Food Selection

The abdominal vagotomy, especially the transection of the hepatic branch, attenuates anorexia induced by an amino acid (threonine) imbalanced diet (Dixon et al. 2000), suggesting an involvement of the vagus nerve in detecting peripheral nutritional signals. To investigate the primary sensing site for lysine, Inoue et al. (1995) studied the effects of continuous lysine infusions via the intragastric, intraperitoneal, and intracerebroventricular routes on dietary choice. Rats were given a food choice between a lysine-deficient

and a protein-free diet. Previous to lysine infusions, they consumed consistently more of the protein-free compared to the lysine-deficient diet (approximately 70% versus 30% in preference, respectively). After lysine infusions via either intragastric or intraperitoneal routes, ingestion of the lysine-deficient diet increased while the intracerebroventricular infusions, within the physiological range, failed to affect food choice. Hepatic vagotomy delayed the increased preference for the lysine-deficient diet in rats injected with lysine intraperitoneally. These results implicate postabsorptive mechanisms (but not the cerebrospinal fluid) in sensing a deficient amino acid, and suggest the involvement of the hepatic vagal afferents in this sensing pathway.

154.6 Brain Mechanisms

154.6.1 Neuronal Activity in the Lateral Hypothalamic Area

The lateral hypothalamic area (LHA) is one of the most important central structures involved in feeding and drinking behaviors (Oomura 1980). LHA neurons receive information from various exogenous (visual, auditory, olfactory, and gustatory) and endogenous inputs (Ono et al. 1985; Nakamura et al. 1989; Nishino et al. 1988; Oomura et al. 1980), which are important factors regulating the ingestion and rejection of foods and fluids. Some LHA neurons respond during feeding and gustatory stimulation, and the ingestion responses are modulated by food palatability, deprivation, and satiation (Fukuda et al. 1986; Aou et al. 1991). Accordingly, it is reasonable to hypothesize that the LHA may control the selection of amino acids and NaCl under different nutritive conditions.

To evaluate the role of the LHA in the regulation of preference for amino acids and NaCl, single neuronal activity from the LHA was recorded during cue tone presentation and subsequent ingestion of various amino acids and NaCl solutions in both control and lysine-deficient rats (Tabuchi et al. 1991). Generally, LHA neurons do not discriminate between sapid solutions during ingestion. However, "MSG (umami)-specific" neurons that respond only during licking of a MSG solution are found only in control rats, whereas "lysine-specific" neurons that respond only during licking of a lysine solution were found only in lysine-deficient animals (Tabuchi et al. 1991) (Fig. 154.8). Although it is difficult to determine whether MSG-specific neurons are the same as lysine-specific neurons, these neural responses appear to be related to behavioral preferences; MSG is the most preferred solution in control and lysine is the most preferred one in lysine-deficient rats (Torii et al. 1987). Moreover, both MSG and lysine-specific neurons are localized mainly in the dorsal and lateral part of the LHA (Tabuchi et al. 1991), where gustatory pathways are traced via the pontine taste area in rats (Norgren et al. 1976). It is plausible that some LHA neurons might be related to positive reinforcement such as "satisfaction", when rats ingest a solution that is metabolically necessary for the body. These data suggest that plastic changes in neuronal responses do occur, at least in the LHA, to promote ingestion of required nutrients. The LHA may be the primary site regulating the increased preferences for deficient amino acids.

154.6.2 Microinjection in the Lateral Hypothalamic Area

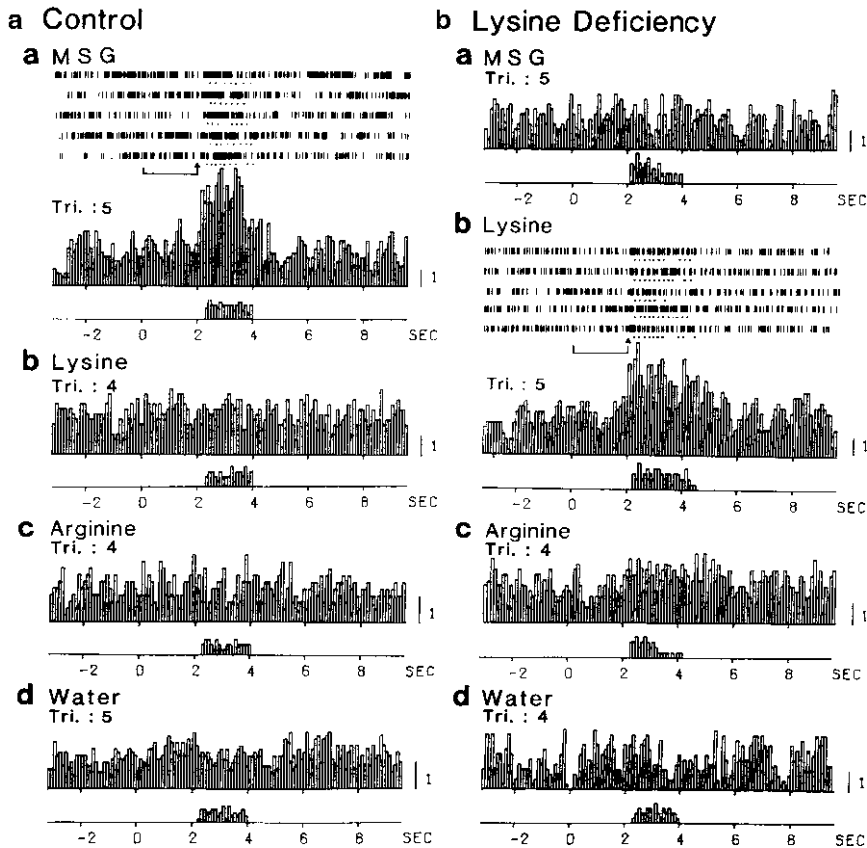
Lysine levels in the brain, as well as in the blood, decreases a few hours after ingestion of a lysine-deficient diet (Mori et al. 1991a). Neurons in the LHA are more responsive to iontophoretically applied amino acids (i.e., extracellular environment) than those in thalamus or zona incerta (Wayner


Fig. 154.8 Two examples of taste specific neurons in the lateral hypothalamic area, responding only to monosodium L-glutamate (MSG) in control (**a**) and to lysine during lysine deficiency (**b**). Rats were trained to lick solutions for 2 s licking period (2.0–4.0 s) after the end of each 2 s cue tone period (0.0–2.0 s). The neuron in (**a**) is excited during licking of MSG solution but not for any other solutions. In (**b**), the neuron is excited during licking of lysine solution but not for any other solutions. Neuronal responses to MSG in control (Aa) and to lysine during lysine deficiency (Bb) are shown by raster display (*bars*). Small dots, lick signals. Horizontal brackets, cue tone period. Arrow heads, presentation of drinking tube for licking. In each pair of averaged histograms: upper, neuronal responses; lower, lick signals; Tri, trial number. Calibration of 1 impulse per bin (100 ms) are shown at right of each upper histogram (Reprinted from Tabuchi et al. 1991. With permission)

et al. 1975). Microinjection of balanced solutions of amino acid mixture directly into the dorsolateral perifornical hypothalamus inhibited feeding in rats (Panksepp and Booth 1971). These data suggest that the LHA may be involved in the detection and recognition of deficient nutrients.

Intakes of lysine-deficient and nonprotein diets induce the release of the growth factors inhibin and activin, respectively, in the systemic circulation (Torii et al. 1993). These indicate that ingestion of lysine-deficient or nonprotein diets cause changes in blood (and possibly brain) levels of physiological factors, including inhibin and activin. These factors may be involved in the plasticity of LHA neurons regarding their responses to deficient amino acids. In addition to these peripheral changes, the β_A subunit of activin and inhibin (Torii et al. 1993) and activin receptors (Funaba et al. 1997) has been immunolocalized in a variety of brain regions including the LHA.

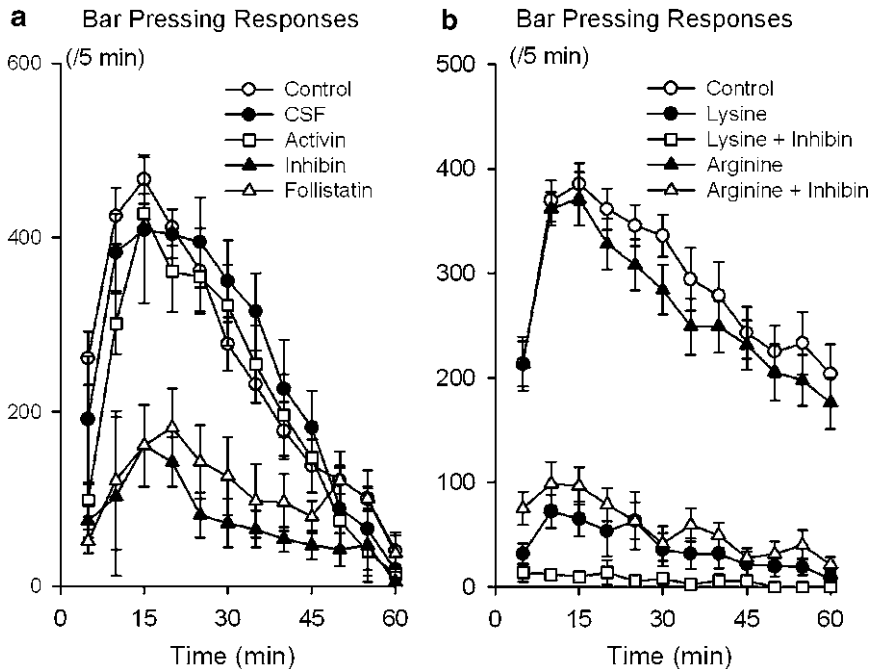
To investigate the roles of LHA on ingestive behavior of a deficient nutrient, rats were trained to press a bar to obtain small (50 mg) pellets of a complete diet (Hawkins et al. 1994, 1995, 1998). Rats given a lysine-deficient diet maintained a high rate of bar pressing. This behavior is reduced by (1) ad


Fig. 154.9 Bar pressing behavior of lysine-deficient rats to receive complete diet (lysine-containing diet). Continuous infusions of inhibin ($P < 0.001$), follistatin ($P < 0.01$) or lysine ($P < 0.01$) into the lateral hypothalamic area reduces bar pressing behavior, while infusions of artificial cerebrospinal fluid (CSF), activin A or arginine have no effects. Results are expressed as mean ± SEM, $n = 9$ (Reprinted from Hawkins et al. 1995. With permission)

libitum access to a lysine solution, (2) intraperitoneal injections of lysine 2 h before the test session, (3) continuous infusion of a lysine solution into the LHA, (4) continuous infusion of inhibin or follistatin (activin inhibitors) into the LHA (Fig. 154.9), or (5) continuous infusion of activin antiserum into the LHA. Interestingly, infusions of lysine, inhibin, follistatin, or activin antiserum into the LHA do not ameliorate the reduced consumption of a lysine-deficient diet, suggesting the presence of different mechanisms involved in anorexia and in the preference for the missing amino acid. Neither the voluntary consumption of other solutions nor the continuous infusion of other amino acids or activin into the LHA suppressed bar-pressing behaviors. Although LHA lysine infusion decreases consumption of a concurrently available lysine solution, inhibin infusion does not change ad libitum lysine consumption. These results indicate that inhibin may work in the LHA to inhibit bar pressing to obtain a complete diet via mechanisms other than sensing lysine deficiency.

154.6.3 Norepinephrine Release in the Hypothalamus

Hypothalamic norepinephrine is involved in regulation of food intake (Bray 1993). Lysine is not a precursor of norepinephrine and does not affect norepinephrine synthesis. In control rats, norepinephrine release in the ventromedial nucleus of the hypothalamus (VMH) shows a diurnal pattern, with the lowest levels measured at the onset of the dark phase (Smriga et al. 2000a). This circadian release of norepinephrine is depressed during early lysine deficiency and ingestion of lysine solution restores the circadian pattern of norepinephrine release.

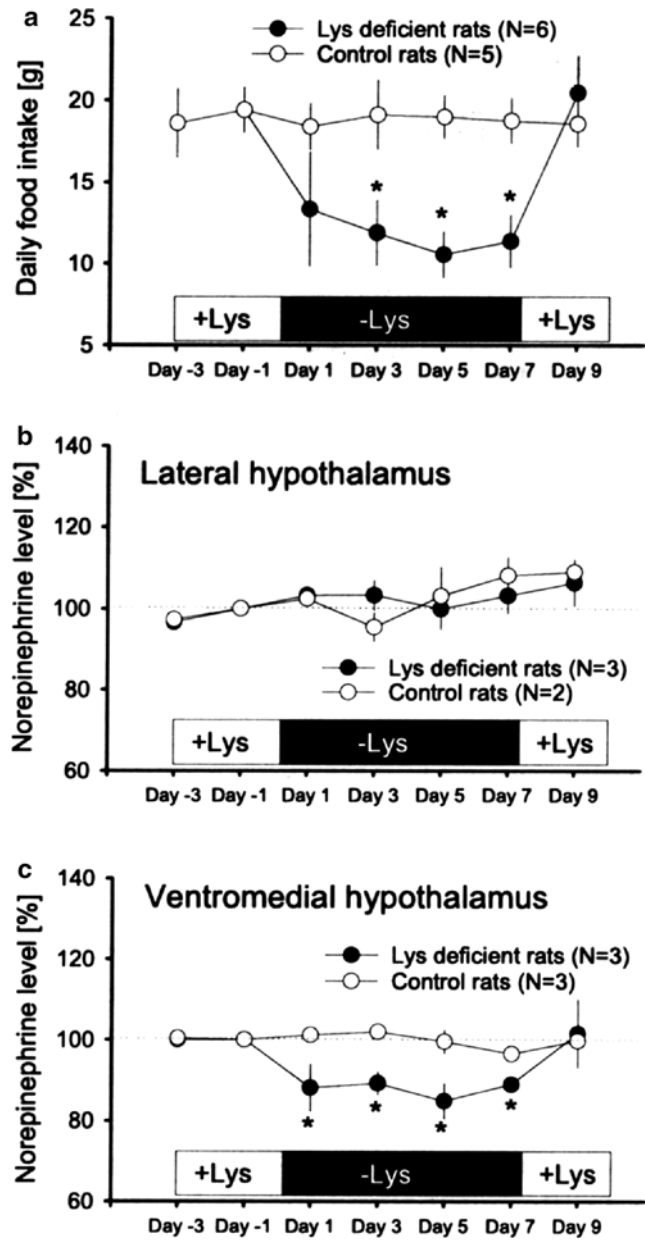
In longitudinal measurements, norepinephrine release in the VMH significantly declines within the first 24 h after the introduction of a lysine deficient diet, and the reduction of norepinephrine release persists throughout the lysine deficiency period i.e., 1 week (Smriga et al. 2000b) (Fig. 154.10). When the lysine-sufficient diet is offered, the reduced norepinephrine levels recover rapidly. The pattern of norepinephrine release is parallel to the suppression of food intake. In threonine deficient rats, increases in norepinephrine levels in homogenized VMH tissue have been reported (Gietzen et al. 1998). This increase can be attributed to reduced release of norepinephrine. Since no changes in norepinephrine release were observed in the LHA (Smriga et al. 2000b), reduced norepinephrine release in the VMH appears to be involved in both the initiation and the regulation of anorexia during lysine deficiency.


Fig. 154.10 Daily food intake (**a**), and norepinephrine release in the lateral hypothalamus (**b**) and medial hypothalamus (**c**) in rats fed lysine-deficient diet for 1 week (Day 0–7). Dietary lysine status is illustrated in each lower part of panel. +Lys, lysine-sufficient (control) diet; –Lys, lysine-deficient diet. Results are shown as percent differences from basal levels that were measured just before the introduction of lysine-deficient diet (Day -1). *$P < 0.05$, significance compared to control rats by Student's *t*-test (Reprinted from Smriga et al. 2000b. With permission)

154.6.4 Lysine Preference and Reward Circuits

The dopaminergic neurons in the ventral tegmental area have a crucial role in regulating behavioral responses to natural rewards such as sweet solutions, as well as artificial rewards such as drugs of abuse. However, lesions of the ventral tegmental area dopaminergic neurons by microinjection of 6-hydroxydopamine (a selective neurotoxin for dopaminergic neurons) do not interfere with enhanced preference for lysine during lysine deficiency, whereas the preference for sucrose is largely reduced (Shibata et al. 2009). Preferences for umami (MSG and 5'-ribonucleotides) and NaCl solutions are also unaffected by ventral tegmental area lesions. These results suggest that preferences for essential amino acids, umami, and NaCl, but not sweet, solutions operate through reward circuits that are independent of ventral tegmental area dopaminergic neurons. Contribution of dopaminergic neurons from other brain areas and the identification of the reward circuits regulating preferences for deficient nutrient must be clarified in future experiments.

154.7 Applications to Other Areas of Health and Disease

Essential amino acids are absolutely necessary for growth, reproduction, and survival. Since lysine is the limiting amino acid in proteins of some feed grains (wheat and corn), lysine deficiency is commonly found in human populations living in developing areas, where staple diet is based on such grains. Characteristic symptoms of essential amino acid deficiency include reduced appetite, low weight gain, and nervousness. Repletion of the missing nutrients will result in rapid attenuation of these symptoms. Supplementation of deficient nutrients in food is one reasonable treatment or preventive measure against nutrient deficiency. The further clarification of the mechanisms involved in the adaptation to and recovery from nutrient deficiency may provide us with significant information on how to improve the quality of our dietary choices.

Summary Points

- Lysine is a basic and essential amino acid with a bitter taste quality.
- Lysine is present at low levels in proteins found in some feed grains (wheat and corn), and hence a substantial risk of lysine deficiency exists in low socioeconomic human populations who depend predominantly on such grains for their protein supply.
- Lysine is not linked directly to the synthesis of any neurotransmitter in the brain.
- Lysine deficiency can be induced in animals upon presentation of a lysine-deficient diet.
- During lysine deficiency, lysine levels in the blood and brain decline.
- During lysine deficiency, food intake and weight gain are suppressed.
- Lysine-deficient animals display increased preferences for lysine solutions, and the consumption of which results in normalization of food intake and growth.
- During lysine deficiency, blood levels of inhibin are increased and activin A-like activity are severely suppressed.
- During lysine deficiency, aversion thresholds for lysine, but not for other bitter solutions, increase 100-fold.
- During lysine deficiency, sensitivity of primary taste nerves to lysine does not change, while the sensitivity of the hepatic vagal afferents to intraportal lysine increases 100-fold within just 4 days.
- During lysine deficiency, some LHA neurons specifically respond to the ingestion of lysine.

- Microinjection of lysine, or an activin inhibitor (inhibin, follistatin, or activin antiserum), into the LHA suppresses bar pressing behaviors to obtain lysine-containing food.
- During lysine deficiency, norepinephrine release is decreased in the VMH but does not change in the LHA.
- Lesions of the ventral tegmental area dopaminergic neurons (a reward circuit) do not interfere with enhanced preference for lysine during lysine deficiency.
- These findings indicate that signals conveyed by vagal hepatic afferent fibers play an important role in the detection of a deficient nutrient. Taste information is important in the expression of taste-guided behaviors upon association of taste information with the metabolic effects of lysine.
- Brain circuits including the lateral and medial nuclei of the hypothalamus integrate neural and humoral inputs, and regulate taste preferences for deficient nutrients. The reward circuit of the ventral tegmental area is not involved in the development of lysine preferences during lysine deficiency.

Definitions and Explanations of Key Terms

Activin: A gonadal hormone composed of two inhibin beta subunits ($\beta_A\beta_A$, $\beta_A\beta_B$, or $\beta_B\beta_B$) and belongs to the transforming growth factor-β (TGF-β) superfamily. Activin is produced in the gonads, pituitary gland, placenta, and other organs and has multiple functions including secretion of follicle-stimulating hormone and regulation of erythrocyte differentiation.

Follistatin: A monomeric autocrine glycoprotein that binds directly to both activin and inhibin through the common β subunit. Follistatin is produced by folliculostellate cells of the anterior pituitary and inhibits follicle-stimulating hormone secretion. Its primary function is binding and bioneutralization of members of the TGF-β superfamily, with primary focus on activin.

Homeostasis: Conditions under which the internal environment in the body is maintained within a stable level. Homeostasis is very important for animals to live well in a healthy condition and its disturbance may cause illness.

Inhibin: A gonadal glycoprotein closely related activin, composed of α and β subunits. Inhibin has opposing biological effects to activin such as inhibition of follicle-stimulating hormone synthesis and inhibition of gonadotropin-releasing hormone release in the pituitary gland. Inhibin is considered to compete with activin for activin receptors and/or binding to inhibin specific receptors.

Lateral hypothalamic area (LHA): One of the most important central structures involved in feeding and drinking behavior (also known as the feeding center). LHA neurons receive information from various exogenous (visual, auditory, olfactory, and gustatory) and endogenous inputs, which are important determinant for ingestion or rejection of foods and fluids, and appropriate autonomic responses.

L-Lysine: A basic and essential amino acid with bitter taste quality. Since lysine content in the wheat and corn is very low, people who eat wheat or corn as a staple food are susceptible to lysine deficiency. Lysine is not linked to levels of any neurotransmitter in the brain and hence lysine deficiency is considered as one of the best models for investigating mechanisms of nutrient deficiency.

Monosodium L-glutamate (MSG): A sodium salt of L-glutamic acid. Glutamate has multi-function involvement in perception of umami taste, intermediary metabolism, and excitatory neurotransmission. In addition, it plays important roles in activation of gut–brain axis and regulation of energy homeostasis. Several types of glutamate receptors (ionotropic and metabotropic receptors) are expressed in the body.

> **Vagus nerve:** The Xth cranial nerve that innervates the larynx, heart, lungs, and visceral organs. It consists of both afferent and efferent fibers at the abdominal levels. Several stimuli such as mechanical pressure, temperature, osmotic pressure, and chemicals alter afferent activity of the vagus nerve.
>
> **Ventral tegmental area:** An area in the midbrain implicated in drug and natural reward circuitry, motivation, cognition, drug addiction, and several psychiatric disorders. Dopaminergic cell bodies originate and their two primary efferent projections are the mesocortical (innervates the prefrontal and insular cortices) and mesolimbic (innervates septum, hippocampus, amygdala, and nucleus accumbens) pathways.
>
> **Ventromedial nucleus of the hypothalamus (VMH):** A nucleus in the hypothalamus most commonly associated with satiety (also known as the satiety center). Early studies showed that VMH lesions caused overeating and obesity in animals.

Part XXV
Anorexia Nervosa

Chapter 155
Genotypes and Phenotypes of Anorexia Nervosa

Janet Treasure, Natalie Kanakam, and Christine-Johanna Macare

Abbreviations

5HT	5-hydroxytryptamine
ACC:	Anterior cingulate cortex
AN	Anorexia nervosa
AN-R	Anorexia nervosa restricting subtype
AN-BP	Anorexia nervosa binge-purge subtype
ASD	Autistic spectrum disorders
DSM IV	Diagnostic and Statistical Manual of Mental Disorders, 4th edition
BDNF	Brain-derived neurotrophic factor
BMI	Body mass index
BN	Bulimia nervosa
COMT	Catechol-O-methyltransferase
CSF	Cerebrospinal fluid
CT studies	Computed tomography studies
CT	Constitutionally thin
DA	Dopamine
ED	Eating disorders
EDNOS	Eating disorder not otherwise specified
fMRI	Functional magnetic resonance imaging
HTR1D	Serotonin 1D receptor.
ICD-10	International Statistical Classification of Diseases and Related Health Problems 10th Revision
NICE	National Institute for Clinical Excellence

e-mail: Janet.Treasure@iop.kcl.ac.uk

OA   Object Assembly subtest
OCD   Obsessive compulsive disorder
OCPD   Obsessive compulsive personality disorders
QTL   Quantitative trait linkage
PYY   PeptideYY
SNP   Single nucleoid polymorphisms
WAIS   Wechsler Adult Intelligence Scale
WCC   Weak Central Coherence

155.1 Introduction

This chapter aims to discuss individual characteristics such as genotypes and intermediate phenotypes that increase the susceptibility to developing Anorexia Nervosa (AN). First, clinically specified phenotypes of anorexia nervosa will be outlined and the difficulties in diagnosis will be discussed. A summary of the literature relating to possible intermediate phenotypes, biomarkers, and endophenotypes relevant to AN follows. Subsequently, the methodological issues in the search for AN genotypes will be presented. Finally, the implication of these findings for health and treatments will be suggested.

155.1.1 Diagnostic Criteria

Anorexia Nervosa was first described by Gull (1873). The current DSM classification includes the following symptoms (Table 155.1):

There are two subtypes of AN: restricting (AN-R) and binge-purge type (AN-BP). The restricting subtype is characterized by behaviors of extreme and prolonged fasting and restraint. The binge-purge subtype is also defined by prolonged fasting although it is punctuated by episodes of overeating followed by behaviors to compensate for weight gain such as self-induced vomiting; the misuse of laxatives, diuretics, or enemas; and exercise.

155.1.2 Epidemiology

The onset of AN is usually reported in puberty and females are more likely to be affected than males (APA 2000). The likelihood of being diagnosed with AN at least once during lifetime is estimated at

Table 155.1 DSM IV diagnostic criteria for AN (APA 2000)

DSM IV criteria for anorexia nervosa
• Severe weight loss and maintenance of that under 85% of the expected
• Intense fear of weight gain
• Distortion of body image and overemphasis on weight as an index for self-evaluation
• Amenorrhea

These diagnostic criteria must be satisfied for AN diagnosis. At present, diagnosis is based on its visible phenotypes.

approximately 1% (Hudson et al. 2007). The annual incidence of new AN cases presenting to primary care is given in 8 out of 100,000 individuals (Hoek and van Hoeken 2003).

155.1.3 Prognosis

Mortality in AN is increased (standard mortality ratio of 6.2–10.5 (Birmingham et al. 2005; Papadopoulos et al. 2009; Lowe et al. 2001); and life expectancy reduced by 25 years for females who have suffered from AN since the age of 15 (Harbottle et al. 2008). The outcome for AN patients is poor, with only half recovering, approximately 6–10% developing a chronic condition (Berkman et al. 2007; Lowe et al. 2001), and up to 25% having poor psychosocial functioning (Wentz et al. 2009).

155.1.4 Chronic Disability

People with AN have a diminished quality of life (Mond et al. 2005). Eating disorders were placed fourth in terms of burden of disease (years of life lost through death or disability) in women aged 15–24 years (Mathers et al. 1999) with both physical and psychological comorbidity. Education in terms of attendance at school is disrupted (Byford et al. 2007). Moreover vocational functioning is impaired: 21% of cases still rely on state benefits 10–15 years after the onset of the illness (Hjern et al. 2006). Social isolation is common; social communication skills are poor (Takahashi et al. 2006) and social networks are small (Tiller et al. 1997). The costs of these disabilities are high (Su and Birmingham 2003).

155.1.5 Diagnostic Difficulties

The nosological status of the current DSM IV diagnostic criteria has been questioned (Hebebrand et al. 2004). A substantial number of patients change diagnosis over time. As many as 55% of patients who initially suffer with restrictive AN (AN-R) subsequently develop AN-BP, bulimia nervosa or eating disorder not otherwise specified (Eddy et al. 2008).

Some patients do not present with all the symptoms necessary for a diagnosis of AN according to DSM IV criteria or ICD criteria. The ICD operationalized the weight threshold as a Body Mass Index (BMI, weight in kg/height in m) below 17.5. Regular menses may occur below this threshold and medication or the contraceptive pill may make amenorrhea an unreliable diagnostic marker. Furthermore, a subgroup of patients do not fulfill the criterion of having a fear of weight gain or a distorted body image (Strober et al. 1999). Comorbidity with other psychiatric disorders can make diagnosis on the basis of phenotypes challenging. As weight loss increases, patients often present with a variety of mood and anxiety disorders. For instance, 30% of AN patients meet the criteria for Obsessive Compulsive Disorder (OCD). Also a subgroup has characteristics associated with the Autistic Spectrum Disorders (ASD). Gillberg and colleagues described 20% with an empathy disorder and social disturbances (1994). These features were predictive of poor psychosocial outcome over time (Rastam et al. 2003). Intermediate phenotypes or biomarkers may be more stable over time than illness phenotypes.

155.2 Biomarkers and Endophenotypes

Increasingly, there is an interest in intermediate phenotypes such as biomarkers (biological marker) and endophenotypes as a means to describe and identify an illness. Biomarkers are underlying cognitive or behavioral traits that are associated with a disorder, but not part of their visible presentation. They can be state or trait related. Biomarkers have a number of different applications such as being antecedent, screening, diagnostic, prognostic, or stratification markers (Ritsner and Gottesman 2009). One valuable kind of biomarker is that of an endophenotype: a heritable trait biomarker that falls on the pathway between behavior and biology (phenotype and genotype). Gottesman and Gould (2003) have defined specific criteria to be fulfilled for an endophenotype status (Table 155.2):

Although the endophenotype and biomarker concepts have been used interchangeably in the literature, Gottesman and Gould (2003) use the former when there are some signs of heritability, and biomarkers when the trait does not fulfill the criteria of genetic underpinnings. It is hoped that endophenotypes will provide a more direct association with the genotype than the phenotypes of AN (see Fig. 155.1). Recent reviews have included the concept of endophenotypes in discussions of ED etiology (Treasure et al. 2007).

Table 155.2 Endophenotype criteria (Gottesman and Gould 2003)

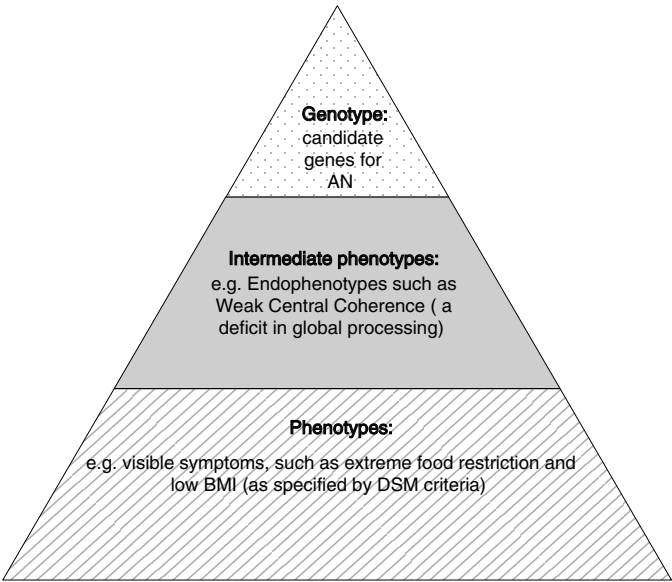
Endophenotype criteria
• Association with the illness in the population
• Heritability
• State-independence
• Cosegregation with the illness in families
• Presence in unaffected relatives at a higher level than in the general population

Endophenotypes are heritable trait biomarkers. The above criteria must be satisfied for the trait to be classified as an endophenotype.

Fig. 155.1 Pathway between genotype and phenotype. Intermediate phenotypes lie on the pathway between candidate genes that make an individual susceptible to anorexia nervosa (*AN*) and its visible symptoms. Potential biomarkers and endophenotypes are more directly associated with AN etiology. For example, endophenotypes such as "weak central coherence" (which refers to deficits in global processing) may be involved in causing and maintaining visible symptoms such as the inability to see the adverse consequences of extreme food restriction on physical health

Genotype: candidate genes for AN

Intermediate phenotypes: e.g. Endophenotypes such as Weak Central Coherence (a deficit in global processing)

Phenotypes: e.g. visible symptoms, such as extreme food restriction and low BMI (as specified by DSM criteria)


It is hoped that research to establish characteristics as intermediate phenotypes of AN will lead to a more biologically based system of classification and a more accurate understanding of causation, pathophysiology, prognosis, and treatment.

155.2.1 Distinguishing Biomarkers Associated with the Illness from Secondary Consequences of Starvation

The search for suitable biological markers in AN is complex since starvation and impaired nutrition, core elements of the disorder, have a profoundly disrupting effect on both the psychology and physiology of the individual. This causes a proliferation of biological abnormalities in the acute state. One way of trying to distinguish between the consequences of starvation and features that suggest an underlying biological vulnerability is to examine people after weight recovery. This in itself is not without problems; for example, how does one define recovery? Is it important to have a minimal duration of recovery? Is the abnormality a risk factor or a scar from the illness? Some risk factors may only occur in the context of environmental or developmental risk factors and may remain hidden. Despite these difficulties several groups have undertaken studies of biomarkers in patients after recovery. Fewer studies have taken the next step which is to examine whether the biomarkers represent a familial and genetic vulnerability.

155.3 Introduction to the Concept of Biomarkers

At present, evidence-based relevant biomarkers include (a) altered serotonin function (Kaye 2008); (b) opioid alterations (Kaye et al. 1982); (c) dopamine disturbances (Frank et al. 2005); (d) variant hormonal profiles (Germain et al. 2007); (e) alterations in brain structure (Gagel 1953; van den Eynde and Treasure 2008; Martin 1958; Roser et al. 1999); and neuropsychological endophenotypes such as (f) difficulties in set-shifting (Roberts et al. 2007; Tchanturia et al. 2004); (g) weak central coherence (Lopez et al. 2008b); and (h) social cognitive deficits (Gillberg et al. 1994).

155.3.1 Serotonin

There is growing evidence that a disturbance in serotonin function may be a biomarker involved in the etiology and pathogenesis of AN (Kaye 2008). 5HT1A receptors are increased especially in the acute state but also after recovery (Bailer et al. 2005a, b, 2007; Galusca et al. 2008), particularly in the prefrontal areas (associated with regulatory control) and the mesial temporal/subgenual areas (associated with reward). 5HT receptors in the striatum are increased in the restricting form of anorexia nervosa after recovery whereas they appear to be decreased in the binge-purge form (Bailer et al. 2004). In summary, people with eating disorders have key abnormalities in 5HT function in both the hedonic and the regulatory regions of the brain.

Dysregulation of these emotional and reward pathways not only impacts upon feeding but also contributes to a dysphoric temperament with symptoms of anxiety, obsessionality, and inhibition.

Indeed Walter Kaye has developed a hypothesis which states that, restricting food can become powerfully reinforcing since it reduces the availability of plasma tryptophan, which is a rate-limiting step in the production of 5HT. The reduced functional activity of 5HT is thought to reduce anxiety, which is in itself reinforcing (2008).

In support of this theory, positive correlations between anxiety measures used to assess harm avoidance and 5-HT2a binding have been shown in the temporal cortex (Bailer et al. 2004) and the supragenual cingulate, frontal, and parietal brain regions of recovered AN patients. This is regardless of any abnormality in overall 5-HT2a receptor activity (Bailer et al. 2007).

155.3.2 BDNF

Brain derived neurotrophic factor (BDNF), a protein, has been shown to regulate the serotonergic neurotransmitter system. BDNF is also present in the hypothalamic nuclei that are associated with weight regulation (Pelleymounter et al. 1995). Research has shown that BDNF levels are significantly decreased in people with anorexia nervosa in comparison to healthy controls (Monteleone et al. 2004) and persists into recovery (Nakazato et al. 2006).

155.3.3 Opioid

The opioidergic neurotransmitter system is also associated with regulating feeding behavior. It is thought to be implicated in the "liking" aspects of food intake and may mediate the rewarding aspects of food. Blockade of opioid receptors in rats using the opioid antagonist, naloxone, decreases consumption of more preferred and palatable foods (Glass et al. 1996). In AN higher levels of cerebrospinal fluid activity was found in those who were severely underweight in comparison to those with AN who were weight recovered, suggesting that it may be related to BMI (Kaye et al. 1982).

155.3.4 Dopamine

Dopamine-related disturbances has been related to a number of symptoms encountered in AN, such as amenorrhea, obsessive compulsive traits, hyperactivity, and weight loss (Kaye et al. 2004). This potential biomarker may also contribute to feeding behavior and to the generally anhedonic temperament in AN. Dopamine DA is a key neurochemical in the hedonic system For example, the presentation of palatable foods to fasting humans is associated with an increase in DA in the dorsal striatum (Volkow et al. 2002). Furthermore the amount of dopamine released is correlated with the amount of pleasure experienced when eating (Small et al. 2003).

Frank and colleagues (2005) demonstrated higher dopamine D2/D3 receptor binding in recovered AN subjects in the anteroventral striatum, suggesting either decreased intrasynaptic dopamine concentration or increased D2/D3 receptor density or affinity to be present in AN. This abnormality of dopamine in the hedonic system might be associated with the altered response to reward seen in AN (difficulties in differentiating between positive and negative feedback) (Wagner et al. 2007).

Moreover, in the AN group, dopamine binding potential in the dorsal caudate and dorsal putamen correlated positively with harm avoidance. This observation supports the view that the dopamine abnormalities in AN might contribute to the characteristic harm avoidance or increased physical activity (Frank et al. 2005).

155.3.5 Hormones

AN is associated with many abnormalities in the hormonal profile. Adiponectin and leptin are produced by adipose tissue and are involved in energy metabolism. Serum leptin levels were found to be severely decreased in restricting anorexics and only moderately decreased in purging anorexics. Furthermore, compared to controls, circulating levels of adiponectin were increased by 53% in purging anorexics and by 96% in restricting anorexics (Liu et al. 2008).

Other orexogenic and anorexogenic hormones which regulate appetite have been found to be important biomarkers that distinguish between AN and people who are constitutionally thin (CT). Orexogenic hormones such as ghrelin which is known to initiate appetite was found to be significantly higher in those that were CT than in people with AN. Anorexogenic hormones including PeptideYY and leptin were significantly lower in people with anorexia nervosa than in CT subjects. Interestingly, GLP-1 concentrations were significantly higher in AN than in CT subjects (Germain et al. 2007).

155.3.6 Brain Structure

Structural and metabolic changes occur in the brain during the acute phase of AN. The most consistent alteration is the reduction in brain mass. This was first suggested by postmortem findings of reduced cerebral mass with prominent sulci and small gyri (Gagel 1953; van den Eynde and Treasure 2008; Martin 1958) and later confirmed in vivo in several CT studies that additionally demonstrated enlarged ventricles (Dolan et al. 1988; Krieg et al. 1989; Palazidou et al.1990). For the most part, brain mass is restored with weight gain (Castro-Fornieles et al. 2009; McCormick et al. 2008).

155.4 Neuropsychological Endophenotypes

155.4.1 Cognitive Biomarkers

A number of cognitive deficits have been observed in AN. In particular, executive function is disrupted in the acute phase of ED. For example, Jones and collegues (1991) reported mild cognitive impairments in the domains of focusing/execution, memory, and verbal and visuospatial processing. However, most of these deficits were not present in weight recovered AN participants. Set-shifting deficits and weak central coherence are of interest in that they are associated with obsessive compulsive traits which are present before and after the acute illness phase.

155.4.2 Set Shifting

Set-shifting is one of the main aspects of executive functioning and refers to the ability to be flexible with one's mindset in adapting to new task demands or changes in situations (Miyake et al. 2000). A series of studies using a variety of neuropsychological tasks to measure this concept found that people with AN have difficulties in set-shifting in the acute state (Anderluh et al. 2003; Tchanturia et al. 2001, 2002). A meta-analytic systematic review of the literature confirmed this impairment in cognitive flexibility which was present in the various eating disorder subgroups (Roberts et al. 2007).

Women recovered from AN also demonstrate impairment in set-shifting ability but with reduced effect sizes (Tchanturia et al. 2004; Roberts et al. 2007). Examples of effect sizes across a range of set shifting tasks are shown in Table 155.3. Problems with set-shifting were also seen in the sisters of individuals with ED (Holliday et al. 2005).

Results from these studies suggest that executive function as marked by poor cognitive flexibility may be a state independent trait in some cases but that this difficulty is exaggerated during the illness phase. It does not appear to be simply a consequence of malnutrition alone since other aspects of eating disorder psychopathology such as depression and anxiety also have an impact. The limitation of a cross-sectional design to address state-independence is noted. As the recovered group had managed to overcome their AN, it is possible that they represent a different cohort than those with chronic, persistent AN.

Poor set-shifting may represent a prognostic biomarker of AN and be involved in the maintenance of the illness. Cognitive remediation therapy which addressed this deficit has been tested and proved effective (Tchanturia et al. 2006). Replication of these studies with larger samples is required as well as genetic examination to complete the exploration as to whether poor set shifting might meet the criteria for an endophenotype of some forms of ED.

155.4.3 Weak Central Coherence

Weak central coherence is another neuropsychological trait of interest because of its association with OCPD and the autistic spectrum of disorders. Central coherence is the natural cognitive

Table 155.3 Effect sizes (Cohen's *d*)* for neuropsychological tasks relating to set-shifting in AN

Task	Current AN	Recovered AN	Time	Repeat
Set-shifting				
TMT-B	0.8	0.5	5	Yes-2
WCST	0.6	0.4	10	No
Brixton	0.2	0.3	5	Yes-2
CatBat	0.6	0.4	3	No
Haptic	1.2	0.9	5	No

TMT-B (Trail Making Task, Trial B); WCST (Wisconsin Card Sorting Test); Time (Time taken in minutes to administer each task); Repeat (Can the task be repeated?); Yes, Yes-2 (have 2 versions of the task), No, ? (unsure if task can be repeated); The effect size in the table represent the mean of the published studies.
*Cohen's *d* effect sizes are understood as follows: 0 to <0.15 – negligible; >0.15–0.40 – small; >0.40–0.75 – medium; >0.75–1.10 – large; >1.10 – huge.

style of most people in adult life, and is defined as the skill of integrating large amounts of incoming information into context, gestalt, and meaning (Frith 1989). The opposite tendency, weak central coherence, is characterized by a tendency to process information in parts (detail) rather than as a whole, with relative difficulty in global or integrative processing (Happe and Booth 2008).Weak central coherence is a key component of the cognitive style in autistic spectrum disorders (ASD) (Happe and Booth 2008; Happe and Frith 2006) and has also been found in their first-degree relatives (Smalley and Asarnov 1990; Happe et al. 2001; Baron-Cohen and Hammer 1997).

Initial findings which suggested that this trait was associated with ED were found in Gillberg and collaborators' longitudinal study (1996). This cohort of early onset cases of AN were found to be persistently impaired over time on the Object Assembly subtest (OA) from WAIS. This test requires the ability to integrate pieces of information into a whole, to construct a familiar object (Gillberg et al. 1996, 2007). They also found that a subgroup of people with AN who met the criteria for ASD also had a cognitive profile resembling that found in ASD. Although the authors initially hypothesized that the poor performance in the OA was due to poor abstract thinking (Gillberg et al. 1996), they later associated their findings with weak central coherence (Gillberg et al. 2007). Our group has furthered the investigation of the weak central coherence hypothesis in people with ED with a systematic, hypothesis driven approach using a battery of tests used to measure central coherence. It was found that weak central coherence may be a feature of AN since there is superiority in tasks that require detail processing (e.g., Group/Embedded Figures and Matching Familiar Figures) and a weakness in tests that require a global strategy such as the Sentence Completion and Homograph Reading Tasks, the Rey-Osterrieth Complex Figure, and OA (Lopez et al. 2008a, b, c; Southgate et al. 2008) (see Table 155.4). A recent systematic review of the literature found some evidence supporting this account particularly for decreased global processing (Lopez et al. 2008a).

This trait has been reported also to be present in women in recovered state, with medium effect sizes for global integration and large for detail focused processing. A recent study of our group has

Table 155.4 Effect sizes (Cohen's *d*)* for neuropsychological tasks relating to weak central coherence in AN

Task	Current AN	Recovered AN	Time	Repeat
Central coherence				
D-EFT	0.5	1.0	10	Yes-2
D-GEFT	0.8		15	?
D-BD	0.0	0.2	10	?
D-MFFT	0.9		10	No
G-Rey CC	0.9	0.6	5	Yes-2
G-OA	0.6	0.6	15	No
G-Frag. Pic	1.7		10	Yes-2
G-SCT	0.7	1.2	10	No
H-HRT	0.0	0.4	10	No

EFT (Embedded Figures Task); BD (Block Design); MFFT (Efficiency Matching Familiar Figures Test); Rey CC (Rey Central Coherence Index); OA (Object Assembly); Frag. Pic. (Fragmented Pictures Task); SCT (Total Score in Sentence Completion Task); HRT (Total Score in Homograph Reading Task); Time (Time taken in minutes to administer each task); Repeat (Can the task be repeated?); Yes, Yes-2 (have 2 versions of the task), No, ? (unsure if task can be repeated). The effect size in the table represent the mean of the published studies.

*Cohen's *d* effect sizes are understood as follows: 0 to <0.15 – negligible; >0.15–0.40 – small; >0.40–0.75 – medium; >0.75–1.10 – large; >1.10 – huge.

found that weak central coherence is also present in the healthy sisters of those with AN. Using the Group Embedded Figure Test and the Rey-Osterreith Complex figure copy (central coherence index), it was found that like their AN sisters, 30 healthy sisters displayed a more detail focused processing style on both.

Thus weak central coherence appears to be a trait associated with AN. Enhanced detail function is present even in the acute phase of the illness and superiority in this skill is similar in size to that seen in cases of Asperger's Syndrome. Global integration appears to be weakened in the acute phase of the illness and deficits in this are less apparent after recovery. Thus the imbalance between local and global functioning and weak central coherence is most marked during the acute phase. This biomarker may be involved in maintaining maladaptive behaviors so that they are unable to see the "bigger picture" and ignore the severe consequences of applying a detailed thinking style to the laws of thermodynamics has on their health in terms of weight loss.

155.4.4 Social Cognition

Social cognition refers to those complex cognitive processes involved in attuning behavior to that of other people (Adolphs 1999). The study by Gillberg and colleagues suggested that a subgroup of early onset cases of AN have empathy deficits similar to those found in ASD and this was associated with poor outcome in AN (Gillberg et al. 1994). A recent review has summarized the evidence for problems in this area (Zucker et al. 2007). Traits of emotional dysregulation, social inhibition, and compulsivity are found in acute AN and persist with recovery, although to a milder degree (Holliday et al. 2006).

Women with acute AN appear to be impaired in visual and verbal recognition of emotions (Zonnevijlle-Bendek et al. 2002, 2004; Kucharska-Pietura et al. 2004). This contrasts with normal self-reported levels of empathic response (Hambrook et al. 2008). A study in our unit that administered tasks developed in the field of ASD to women with acute AN (e.g., Reading the Mind in the Voice, Films, Eyes) found large effects in all of the task domains suggesting greater difficulties in the acute state relative to a healthy comparison group (see Table 155.5). However, the deficits in the tasks particularly related to theory of mind (voice and film) were not present in people who had recovered from the illness. Our group has found that in the acute illness state, women with AN have an attentional bias to threatening social stimuli using the E-Stroop paradigm. This appears to be present albeit in an attenuated form in people recovered from the illness.

These findings suggest that emotional recognition problems which may be associated with a tendency to avoid threatening stimuli may be trait abnormality in AN whereas poor Theory of Mind is

Table 155.5 Effect sizes (Cohen's *d*) for neuropsychological tasks relating social cognition in AN

Social cognition	Current AN	Time
RMI eyes	1.1	10
RMI voice	0.8	10
RMI film	0.8	10
E-Stroop	1.6	10

RMI (Reading the Mind in the Eyes; Voice and Films); E-Stroop (Emotional Stroop Task); Time (Time taken in minutes to administer each task)

more of a state effect. Poor regulation of emotional and social stimuli possibly contributes to both causal and perpetuating factors. This has implications for the development of novel approaches to treatment.

155.4.5 Genotypes

Cultural, social, and interpersonal elements have been well recognized as having etiological significance in AN. However, increasingly, the pathogenesis of AN is investigated by looking at familial and genetic patterns. Twin studies have estimated the heritability of AN around 56% (Bulik et al. 2006). In general, relatives of those with AN have a tenfold increased risk to develop AN (Strober et al. 2000; Lilenfeld et al. 1998). These results indicate that AN has a genetic component, which makes it reasonable to go one step further and identify genes that might be involved in AN (Table 155.6).

One approach to discover genetic loci are genome-wide studies wherein large regions are mapped which then can be scrutinized further using candidate gene approaches. No previous knowledge on the genes involved in the disorder are required (Winchester and Collier 2003). Linkage studies aim to identify the genomic regions that might harbor predisposing factors for the disorder. For complex disorders such as AN, nonparametric (i.e., model-free) methods are used so that no knowledge on the mode of inheritance is needed. It is assumed that risk alleles and marker alleles will be inherited more frequently in affected relatives than expected by chance alone. The pattern of inheritance is usually compared within families with affected family members (Winchester and Collier 2003). Having identified a region, it is possible to narrow down the search space for potential candidate genes (Bulik et al. 2007). The advantage of genome-wide linkage studies is that genes with a small effect on a trait can be identified and therefore this approach offers a potential tool in investigating genes involved in complex disorders (Winchester and Collier 2003). Grice and colleagues (2002) examined the linkage of the gene coding for serotonin in families wherein two siblings were affected by an eating disorder. They found modest evidence for a linkage at marker D4S2367 and D1S3721 at chromosome 1 in a "pure" AN restricting subsample. Linkage analysis on a sample of binge-purge and restricting AN patients provided evidence for a smaller linkage peak at marker D1S3721 at chromosome 1. However, as acknowledged by the authors, these linkage peaks might also represent false positives, as the genetic makeup of AN might be composed of a large number of interacting

Table 155.6 Methodology to identify genotypes

Methodology for investigating disorder relevant genes	
Approach	Candidate gene studies
	Genome wide studies
Methodology	Linkage mapping
	Association
Types of samples	Family trios
	Case control

Relevant genes can be studied using two main approaches: candidate gene studies and genome wide studies. Within these approaches linkage or association can be studied. Types of sample include family trios, wherein families with one affected member are studied, and case-control studies wherein affected cases and matched controls are used.

loci, with each locus contributing a small effect to susceptibility, which are difficult to localize with linkage analysis (Grice et al. 2002).

In contrast to linkage studies, association studies focus on population frequency of susceptibility genes rather than heritance pattern of markers. Two types of samples are used: case control and family trios. In case control studies, affected individuals are matched and compared to healthy controls. Here, the aim is to examine patterns of differences in allelic frequency with differences in disease frequency. In family trio samples, these measures are compared within one family (i.e., mother, father, and affected child). Genes associated with key putative neuronal pathways have been examined (Bulik et al. 2007). In the following section: serotonin, dopamine, opioid systems, and the brain-derived neurotrophic factor will be discussed.

155.4.6 Serotonin

Chromosome 1 was examined closely by Bergen and colleagues(2003) who focused on region 1p36.3–34.4 and examined genes that were suggested to code for the serotonin 1D receptor. Additional evidence for the implication of a gene coding for serotonin at rs674386 SNP in AN was found (Bergen et al. 2003). Brown and colleagues (2007) reported an association between a gene encoding for HTR1D at marker rs674386 and AN. Moreover, evidence was given for an association between the restricting subtype with marker rs856510 (Brown et al. 2007). The latter results however have to be replicated in an independent sample.

Focusing on the 2A receptor, Gorwood and colleagues (2002) reviewed the evidence for an association between the rs6311 polymorphism of the HTR2A gene. Ricca and colleagues (Ricca et al. 2002) examined the −1438 G/A polymorphism, which has been located in the regions of the 5-HT2A receptor gene and has been linked to AN. In particular, an over-representation of the A allele and the AA genotypes have been documented in ANR (and BN) patients as compared to healthy controls. Interestingly, this pattern of results did not emerge in AN-BP patients who showed a similar allelic frequency as the control group (Ricca et al. 2002). Devlin and colleagues (2002) also focused on the HTR2A gene in AN patients and compared linkage of this gene in 196 families with an individual suffering from AN. This group has identified 3 regions on chromosomes 1, 2, and 12, suggestive of a linkage (markers D1S1660, DS1790 and D13S894).

The general picture with genes involved in serotonin functioning linked to AN is unclear. Overall, studies investigating genes involved in the serotonin system have been hampered by low power and a lack of replication in independent samples. Therefore, results should be interpreted with caution and replication in larger, independent samples is awaited.

155.4.7 Dopamine

The genetic basis underlying dopamine dysfunction has been examined. Gabrovsek and colleagues (2004), for instance, looked at a gene that encodes catechol-*O*-methlytransferase (COMT), which metabolizes more than 60% of dopamine especially in frontal areas. Results yielded no evidence for an association between the Val158 allele of the COMT gene and AN. The D2 receptor has been implicated in altered reward, affect, decision-making, executive control, stereotypic motor activity and decreased food ingestion in AN patients (Kaye 2008). An association was found for the rs1800497

and the rs6278 polymorphism, both polymorphisms in the gene encoding for D2 receptor, and the binge-purge subtype of AN (Bergen et al. 2005). Overall, evidence for genes involved in encoding the dopamine system involved in AN is sparse and further methodologically sound evidence is needed to draw conclusions.

155.4.8 Opioids

Bergen and colleagues (2003) examined delta opioid receptor loci in the 1p33–36 region and reported evidence for an association at 3 SNPs (8214T4C, 23340A4G, 47821A4G) for AN patients. However, as acknowledged by the authors, replications in a larger sample are needed as the current sample ($N = 191$) was underpowered. Further examination of the implication of the gene encoding for OPRD1 was added by Brown and colleagues (2007) who examined the impact of the two candidate genes previously identified by Bergen and colleagues (2003) in a case control study of AN patients. Using different SNPs than Bergen and colleagues (2003) this group found evidence for marker rs56356 with AN. Further analyses revealed a higher frequency of the C,T genotype in AN-R as compared to AN-BP patients. Patients suffering from the binge-eating/purging subtype presented with this genotype at a lower rate than controls. It was therefore tentatively suggested that this locus not only compromises susceptibility towards AN but might differentiate even between subtypes (Brown et al. 2007). Yet, it has to be kept in mind that power in this study varied between 0.63 and 0.99.

155.4.9 Brain-derived Neurotrophic Factor

Evidence for a susceptibility gene for brain-derived neurotrophic factor (BDNF) related to AN has been found. It has been suggested that this gene predisposes to AN through its impact on affective symptoms (Ribases et al. 2005). Associations have been found between the Met 66 allele, AN-R, and minimum BMI and replicated in 359 family trios.

155.5 Conclusion

Progress towards revealing potential biomarkers in AN has considerably advanced in the last decade. The search for potential genotypes, biomarkers, and endophenotypes in AN has revealed a number of features that are present in the acute state, some of which persist into recovery. The main findings in this direction highlight the involvement of altered neurotransmitters systems particularly those relating to serotonin, dopamine, BDNF, and the opiates. In addition, cognitive information processing anomalies such as weak set-shifting and central coherence may be biomarkers. The talent for perceiving detail forms part of the endophenotype in some cases of AN. Problems with executive function may arise as a secondary consequence of the illness. Difficulties in emotional recognition and avoidance of threat may be part of the trait biomarkers associated with anxiety in some cases of anorexia nervosa. Problems with social cognition with impairments in the theory of mind tasks may arise as a consequence of the illness. The trait biomarkers may be

part of the causal process that leads to the development of an eating disorder. Also in conjunction with state related markers these can form part of the maintaining processes that cause eating disorders to be stuck and less easy to recover from the longer they persist. Thus, biomarkers have implications for the prognosis of the illness. Furthermore biomarkers can inform treatment strategies (emotional, social, and cognitive remediation skills) that may reduce the duration of the illness and improve outcome. It is hoped that a deeper understanding of AN based on biomarkers and the search for endophenotypes will improve awareness, early intervention, and make for better prognosis in the long term.

155.6 Applications to Other Areas of Health and Disease

Food is one of the several natural rewards amongst others, such as sex, fluid, and social affiliation. There is evidence that the brain systems which modulate these natural rewards are also used in the processing of other rewards, such as money and material assets. Interactions between these different forms of reward can occur. Therefore, investigation into the addictive nature of extreme food restriction may inform research into other addictive behaviors.

The reward system is comprised of dopamine, opioid, and cannabinoid signaling (Cota et al. 2006). Extreme food restriction or dieting can disrupt the systems that underlie appetite motivation, increasing the reinforcing aspects of food (Epstein et al. 2003). Furthermore overactivation of the homeostatic system by extreme hunger may result in problems with regulating eating such as binge eating, emotional eating, and reduction in metabolic rate, making weight gain more likely (Lowe and Levine 2005). It may be argued that a greater understanding of AN etiology in terms of a disrupted reward system may facilitate research into the binge eating seen in bulimia nervosa and obesity.

Substance abuse disorders may also be informed by research into the reward system since this may rely on the same neuronal pathways as eating (Cota et al. 2006). Chronic food deprivation increases reward to all addictive drugs (Carr 2002). Furthermore, both eating and drugs such as cocaine and amphetamines have the same effect of increasing dopamine in the reward system (Hernandez and Hoebel 1988).

Current research findings on genotypes and phenotypes of AN can be applied to other areas of health and disease. The aforementioned serotonin and dopamine systems are known to be involved in other mental disorders such as depression and schizophrenia. Furthermore, genomic variation studies which reveal risk alleles for AN might inform other pathologies that are comorbid with AN, such as depression, anxiety disorders, and in particular obsessive compulsive disorder.

As yet clear recommendations for the effective treatment of AN have not been established. The National Institute for Clinical Excellence (NICE) guidelines state that AN patients should be treated on an outpatients basis and emphasize the combination of re-feeding with psychosocial interventions in AN, but do not specify a treatment for AN. Gaining more knowledge of the neurobiological mechanisms and genotypes is essential when designing new therapies for AN and all types of eating disorders. Treatment which addresses the stable traits of AN such as weak set-shifting and central coherence have been pioneered by our group. Cognitive remediation therapy has been developed as a pre-therapy intervention for in-patients to moderate information processing biases by strengthening flexibility in daily activities and eating rituals. This has been shown to improve the outcome of subsequent therapy interventions (Tchanturia et al. 2006; Davies and Tchanturia 2005).

Summary Points

- Diagnostic difficulties: Given the difficulties with diagnostic categories (Anderluh et al. 2009) attention should be directed toward identifying core stable traits. This will facilitate diagnosis, the creation of more accurate models of AN etiology, and enhance the search for more effective treatments.
- Biomarkers and endophenotypes: Biomarkers are traits associated with the disorder, but not part of their visible presentation. They can be state- or trait-related and may be used for screening, diagnostic, prognostic, or stratification markers. One valuable type is that of an endophenotype; a heritable trait biomarker.
- Serotonin, dopamine, and neuropsychological traits such as weak central coherence and set-shifting have been researched as potential biomarkers and endophenotypes of AN.
- Genotypes are defined as the genetic makeup of an individual. It can be described in terms of the combination of alleles at a particular locus. The locus is determined using association or linkage studies.
- Several loci have been identified and relate to serotonergic, dopaminergic, opioid, and BDNF systems. However, further research is awaited since current studies are subject to methodological limitations.

Definitions and Explanations

Anorexia nervosa: The term derives from the Greek word an-orexis which can be translated as "without appetite." The term "nervosa" is of Latin origin and indicates that the lack of food intake is due to a nervous constitution. Anorexia nervosa is one type of eating disorder that is a psychiatric illness. Individuals with this diagnosis control their body weight and often present with severe weight loss, an intense fear of weight gain, distortion of body image, and amenorrhea.

Genotypes: They contain an individual's genetic information in the form of a pair of genes.

Endophenotype: A valuable kind of biomarker is that of an endophenotype; a heritable trait biomarker that falls on the pathway between behavior and biology (phenotype and genotype). Gottesman and Gould (2003) have defined specific endophenotype criteria which include: (1) association with the illness in the population, (2) heritability, (3) state-independence, (4) cosegregation with the illness in families and (5) presence in unaffected relatives at a higher level than in the general population.

Biomarkers: They are underlying cognitive or behavioral traits associated with a disorder, but not part of their visible presentation. They can be state- or trait-related, and have a number of different applications such as being antecedent, screening, diagnostic, prognostic, or stratification markers (Ritsner and Gottesman 2009). The term biomarker is used when the trait does not fulfill the criteria of genetic underpinnings.

Phenotypes: They are the observable symptoms of a psychiatric illness, such as behavior. The AN phenotype involves a range of symptoms characterized by a disturbance of body (or self) image associated with extreme behaviors to control weight (e.g., fasting) and underweight BMI.

Key Facts of Diagnostic Difficulties in Anorexia Nervosa

1. The nosological status of the current DSM IV diagnostic criteria is suggested to lack an empirical basis. Some patients do not present with all the symptoms required for a clinical AN diagnosis. Furthermore, a substantive number of AN patients switch between diagnostic categories over the course of the illness.
2. Intermediate phenotypes such as biomarkers and endophenotypes may represent more stable characteristics of AN than illness phenotypes.
3. The search for intermediate phenotypes may lead to a more biologically based system of classification and a more accurate understanding of causation, pathophysiology, prognosis, and treatment.

Key Features of Endophenotypes and Biomarkers

1. Biomarkers are underlying cognitive or behavioral traits that are associated with a disorder, but not part of their visible presentation.
2. One valuable kind of biomarker is that of an endophenotype.
3. Gottesman and Gould (2003) use the term "endophenotype" when there are some signs of heritability, and biomarkers when the trait does not fulfill the criteria of genetic underpinnings.

Key Facts of Genotypes

1. To identify genetic loci involved in a disorder, linkage and association approaches can be used.
2. A large number of genetic loci are supposed to be involved in AN, each of which is suggested to express a small effect in the occurrence of the disorder.
3. Genetic loci relating to serotonergic, dopaminergic, and opioid systems and BDNF have been investigated in AN.
4. Research into AN genotypes should address the methodological limitations, such as population stratification and low sample sizes, which may distort results.

Chapter 156
Metabolic Consequences in Anorexia Nervosa

Daniel Rigaud and Marie-Claude Brindisi

Abbreviations

ACTH	Adrenocorticotropic hormone
AN	Anorexia nervosa
BMI	Body mass index
CETP	Cholesterol ester transfer protein
DIT	Diet-induced thermogenesis
ED	Eating disorder
EE	Energy expenditure
EEPA	Energy expenditure linked to physical activity
EETR	Energy expended for thermoregulation
FFM	Fat free mass
HDL-C	High density lipoprotein cholesterol
IGF1	Insulin like growth factor 1
LDL-C	Low density lipoprotein cholesterol
REE	Resting energy expenditure
TSH	Thyroid stimulating hormone
VLDL-C	Very low density lipoprotein cholesterol

156.1 Introduction

Anorexia nervosa (AN) is a chronic disease which affects eating behavior and has severe health consequences (Rigaud 2003). It is the psychiatric disease with the highest mortality rate in such young women (15–35 years old). It is the rarest, but the most severe eating disorder (ED). AN is a complex disease that includes mental, genetic, behavioral, and somatic factors. Metabolic and energetic adjustments take place in the wake of the restrictive diet and malnutrition, and the mechanisms involved in these adjustments are beginning to be understood. In this chapter, impact on energy of AN will be developed. All the components of the energy expenditure (EE) will be detailed: resting energy

expenditure (REE); diet-induced thermogenesis (DIT); EE linked to physical activity; thermoregulation. Then, we will pay attention to the metabolism of the different energetic substrates (protein, carbohydrates, lipids) in AN. The evolution of the body mass will be detailed, as will the physical activity and other abnormal behaviors (smoking, obsessive compulsive disorder, compulsive food intake, and bulimic crises) observed in AN. Then, we will detail the hormonal changes due to ED.

Anorexia nervosa is associated with a weight loss of more than 15% of previous weight, low weight (body mass index or BMI < 18.5 kg/m^2), impaired body image, amenorrhea, and, above all, an intense fear of gaining weight (Rigaud 2003). More than 90% of the patients see themselves as fat, even though they know they are thin. In AN, there is a voluntary restriction in fat and protein intake (Rigaud 2003). In most of the chronic cases, it is not true anorexia, i.e. a decrease in hunger feeling. On the contrary, there is a strong will to decrease food consumption because of an overpowering need to slim. In AN, the fear of gaining weight, the fear of not being able to stop the increase in body weight, and the fear of eating too much are foremost in the minds of patients.

Two clinical types of AN are described (Rigaud 2003):one is called the restrictive type and the other the binge eating type with vomiting. In the restrictive type, patients lose weight by reducing food intake and, in 50–60% of the cases, by developing hyperactivity. In the second form, patients can't bear losing control, and because they are afraid of gaining weight, they cause themselves to vomit. If they cannot vomit or lose enough weight (5–10% of cases), they use laxatives and diuretic drugs. The binge-eating/purging type represents 30–40% of AN.

Females account for 95% of cases of AN patients, of whom 75–80% are under 25 years old and 20–25% are 20–30 years old (Rigaud 2003).

Anxiety is frequent in AN. In more than 60–70% of the cases, anxiety contributes to the evolution of the disease. In around one patient in five, anxiety is a pre-existing trait of the ED. Finally, a depressive state is often seen: in one case in seven, a depressive state precedes AN; and in one case in four, a depressive state is the price to pay for going to recovery.

156.1.1 Impact on Energy: Energy Expenditure (EE) *(Table 156.1)*

Two periods are seen in AN: A restrictive period (fasting state) when high energy foods are low or absent from the patient's diet; a refeeding and/or binge-eating period, where an excessive increase in food consumption is noted, either related to binge eating episodes and/or to hypercaloric diet medically prescribed. In terms of energy metabolism, these two periods are associated with very different profiles in the four components of EE (Rigaud and Melchior 1992): REE, DIT, EE related to physical activity, and thermoregulation.

1. REE is low during the fasting state (Melchior et al. 1989; Vaisman et al. 1991; Obarzanek et al. 1994; Platte et al. 1994; Scalfi et al. 2001; Forman-Hoffman et al. 2006; Konrad et al. 2007). It is around 80–88% of normal levels when the BMI is between 16 and 18 kg/m^2, and it can be around 60–65% of normal levels if the BMI is under 12 kg/m^2. In AN, the ratio of REE to lean mass is approximately 7–14% lower (extreme values, in 87 patients) than in same-age, same-sex controls with the same lean body mass (Van Wymelbeke et al. 2004). During this chronic fasting state, the calculation of REE is as follows: weight (kg) × 0.90 (lean mass) × 28 kcal/day. When the BMI is under 10 kg/m^2 (ultimate phase of the disease), the REE can increase, almost exclusively by the oxidation of the proteins, because of a lack of usable fatty substances (Rigaud et al. 2000). An increase in REE follows the start of refeeding: An increase in REE from 12% to 20% (Rigaud et al. 2000; Van Wymelbeke et al. 2004) within the first days of starting renutrition is seen, long

Table 156.1   Key facts of energy expenditure

Energy expenditure	Is the amount of energy, measured in calories, that a person uses (e.g. during a particular activity). The energy expenditure (EE) of a man or woman over a whole day is often divided into different components, which can be individually determined. These are: resting energy expenditure (REE), diet-induced thermogenesis (DIT), physical activity (PA), and thermoregulation
Resting energy expenditure	Is the minimum amount of energy that a body requires when lying in physiological and mental rest
Diet-induced thermogenesis (DIT):	Also called postprandial thermogenesis or the thermic effect of food. This is the amount of energy utilised in the digestion, absorption, and transportation of nutrients.
Energy expenditure linked to physical activity (PA):	Is the most variable component of EE in humans. It includes the additional EE above resting metabolic rate and DIT due to muscular activity and comprises minor physical movement (such as shivering and fidgeting) as well as purposeful gross muscular work or physical exercise.
Thermoregulation	Is the ability of an organism to keep its body temperature within certain boundaries.

Key facts of EE with its different components and their definitions: Resting energy expenditure, diet-induced thermogenesis (DIT), EE linked to physical activity (PA), and thermoregulation
Fig. 156.1   Resting energy expenditure (REE) and level of energy intake, physical activity, and smoking. This figure shows the increase in REE according to the levels of energy intake (food intake), physical activity, and smoking behavior. When there is an increase in these factors, the REE increases too. *FFM* fat-free mass
■ *For energy intake*: "0" = before renutrition (energy intake = 830 kcal/day), "1" to "3" = during refeeding; "1" = for patients having energy intake between 1.1 and 1.3 × REE; "2" = for patients having energy intake between 1.3 and 1.8 × REE; "3" = for patients having energy intake higher than 1.8 × REE
□ *For physical activity*: "0" = none; "1" = 1 to 2 h/day; "2" = 2 to 3 h/day; "3" = >3 h/day
▨ *For smoking*: "0" = none; "1" = 1 to 5 cig/day; "2" = 6 to 10 cig/day; "3" = >10 cig/day

time before any significant increase in fat-free mass (Obarzanek et al. 1994; Platte et al. 1994; Van Wymelbeke et al. 2004; Winter et al. 2005; Konrad et al. 2007). Four factors were described to be associated with this increase in REE: smoking, having a high level of physical hyperactivity,

Fig. 156.2 Resting energy expenditure (REE) and levels of anxiety and depressed state. Level of anxiety and depressive state: 0 = none; 1 = a little; 2 = much; 3 = very much. *FFM* fat-free mass. This figure shows that when anxiety increases, there is an increase in REE, unlike depression. Indeed, when depressive state increases, we can observe a decrease in REE
anxiety, and food intake. Conversely, depression and low food intake in the previous days decrease it (Figs. 156.1 and 156.2).

2. Diet-induced thermogenesis: A high level of DIT is observed before renutrition, compared to normal subjects (Moukaddem et al. 1997). This DIT still increases at the eighth day of renutrition, before any increase in lean body mass. In a double-blind experimental study, a 300- or 700-kcal load was given through a gastric tube. Before renutrition, DIT accounted for 36% of the 300 kcal and 26% of the 700 kcal. At the eighth day of renutrition, DIT accounted for 52% and 39% of the 300 and 700 kcal, respectively (for normal females: it was 14% and 16% for 300- and 700-kcal-loads, respectively). This increase correlates with different factors: the energy content of the meal, the fear of gaining weight, anxiety, and digestion disorders (Rigaud et al. 2007). This profile persists during renutrition; it disappears once normal weight has been reached and anxiety has disappeared. The increase in DIT during renutrition is due to the increase in food intake, and, first of all, protein intake (Fig. 156.3).

3. The EE linked to physical activity is low before renutrition (fasting period). It increases rapidly during renutrition, but it is no higher than in normal subjects with the same fat-free mass and the same level of physical activity (Rigaud et al. 1997). In fact, the increase is due to the increase in physical activity during renutrition (Kaye et al. 1988; Casper et al. 1991; Birmingham et al. 2005).Two causes explain this, a good and a bad one. The good one is that, when a severely malnourished patient is on refeeding program, his activity increases, although it was very low before refeeding. Such a behavior is seen, for example, in patients suffering from cystic fibrosis. The bad reason in AN patients is excessive exercising. Indeed, because of the fear of gaining weight, some patients engage in physical hyperactivity, and thus, largely increase their EE. This explains, in part, the slow rate of weight gain in AN (Walker et al. 1979; Dempsey et al. 1984; Leonard et al. 1996; Bossu et al. 2007). Moreover, obsessive compulsive disorders may increase EE significantly.
Fig. 156.3 Diet-induced thermogenesis (DIT) and energy load before and during renutrition. This study shows the increase in diet-induced thermogenesis according to the energy load before and during renutrition in 15 AN patients vs. 15 age-matched healthy women (controls). The period of renutrition corresponds to the eighth day of a renutrition program with input > 2,200 kcal/day. Loads are given in double blind manner by a nasogastric tube (0, 300 and 700 kcal in random order). This figure shows that diet-induced thermogenesis increases with the level of intragastric load

4. Energy expended for thermoregulation (EETR): it is at a low level before renutrition (fasting phase), but it increases rapidly with renutrition. Two causes explain this: the increase in thyroid hormone secretion (free T3 and T4) as soon as food intake is higher than energy needs. The increase in plasma T3 and T4 levels are noted only after the third week of renutrition. But the increase in secretion probably starts earlier, and could be responsible for the increase in REE (Onur et al. 2005). The second reason is that the body cannot store the energy (because of a lack of adipose tissue) when the fat mass is too low. This problem disappears during renutrition, well before a normal weight is reached.

156.2 Metabolism of Energetic Substrates

1. Protein metabolism: during the fasting period, a deep decrease in protein catabolism is observed, with very low nitrogen and urea 24-h urinary outputs: in 118 AN patients with a BMI of 13.4 ± 1.5 kg/m^2, the urinary nitrogen loss was 4.9 ± 0.6 g/24 h and the fecal nitrogen loss was 0.29 ± 0.6 g/24 h. This decrease in catabolism is an adaptive response to malnutrition and is due to the decrease in food intake and in hepatic and muscle protein synthesis. It does not exist during renutrition and recovery (Gniuli et al. 2001). This very low catabolism explains why markers of nutritional protein synthesized in the liver remain at a normal level for a long time (until a BMI of 12 kg/m^2 has been reached). In our study (Rigaud et al. 1989), patients with decreased plasma concentrations

of albumin, pre-albumin (transthyretin) and transferrin were AN patients with a BMI below 12 kg/m², or with an associated infectious or inflammatory disease. Moreover, the amino-acids from muscle catabolism might be used for the hepatic synthesis. Indeed, in AN, muscle mass decreases as quickly as body weight (see below).

2. Metabolism of carbohydrates: during the fasting period, low serum glucose, insulin, and C peptide levels are observed. Hypoglycemia (< 3.6 mmol/L) is found in 28% of AN patients (cohort of 487 patients hospitalized in our nutrition department, unpublished data). At the beginning of renutrition, insulin sensitivity, measured by the glycemia/insulinemia ratio is nearly always high. A decrease in fasting and postprandial serum glucose level can be observed during the first 2 weeks of renutrition. However, insulin resistance has been found during renutrition, when intakes are higher than energy needs. After a glucose load, the area under the insulin curve was reduced (3.2 ± 0.6 nmol/L/5 h in 14 AN patients and 49.6 ± 2.7 nmol/l/5 h in 12 normal patients), glucose oxidation was increased (646 ± 84 μmol/L/min vs. 368 ± 62 μmol/L/min in normal subjects), and lipid oxidation was decreased (16 ± 34 μmol/L/min, vs. 351 ± 57 μmol/L/min) (as measured by calorimetry and urinary nitrogen). Gniuli et al. found similar results (2001). This abnormal profile disappears with renutrition, well before the recovery of a normal weight.

3. Plasma lipids and lipoprotein metabolism: lipid oxidation is reduced during the fasting period. However, REE mostly depends on lipid metabolism. Lipids contribute to 22% of the REE, proteins to 16% and carbohydrates to 62% in AN (14 patients), versus 54% (lipids), 16% (proteins) and 30% (carbohydrates) in 12 normal subjects. On average, the fasting respiratory quotient is higher during fasting phase of the disease, in severely malnourished patients than in normal subjects (in 118 patients with BMI = 13.4 ± 1.5 kg/m², the respiratory quotient was 0.78 in AN patients vs. 0.71 in normal patients) (Russell et al. 2001). The reason is the increase in protein and carbohydrate oxidation, above all during renutrition. Concerning plasma lipoproteins, a decrease in cholesterol and total triglycerides is often observed (Jaguenaud et al. 1989). But, hypercholesterolemia is observed in one case in six (Rigaud et al. 2009): in 120 AN patients, a total cholesterolemia > 270 mg/100 mL was observed in 18% of cases. Low density lipoprotein-cholesterol (LDL-C), apo B, high density lipoprotein-cholesterol (HDL-C) and apo A1 levels were higher in the AN patients. Cholesterol ester transfer protein (CETP) activity is high during fasting periods in AN, partly explaining the increase in LDL-C (Ohwada et al. 2006); only denutrition and a decrease in apolipoprotein synthesis can counteract this (Jaguenaud et al. 1989). Triglycerides, which are normally low in malnutrition cases, are high in 15% of AN cases, because of a lack of lipoprotein lipase.

156.2.1 Evolution of Body Mass

AN patients want to lose fat mass, but the loss of fat-free mass and muscle mass is high (Dempsey et al. 1984; Obarzanek et al. 1994; Forman-Hoffman et al. 2006), which disturbs muscle functions (Rigaud et al. 1988; Murciano et al. 1994; Polito et al. 2000; Cuerda et al. 2007). The AN patients loss similar percentage of body weight and fat-free mass (a 15% body weight loss corresponds to a 15% fat-free mass loss). In AN patients, the fat mass represents 20–25% of body weight at the beginning of the disease and only 7–8% when their BMI is 12–14 kg/m². A decrease in cerebral grey mass and white mass are observed in AN, probably because of malnutrition. Under a BMI of 15 kg/m², hydro-sodium retention appears, with edema of the lower limbs during renutrition. This leads to

excessive weight gain, which is independent of the food intake, if a salted diet is prescribed. So, a low-salt diet is necessary as soon as BMI is under 15 kg/m^2.

156.2.2 Physical Activity

Physical hyperactivity is frequent in EDs, and particularly in AN patients (Rigaud 2003). It is observed in 35–85% of the patients. In our cohort of 487 patients followed for 10 years, physical hyperactivity was quoted in 68% of the patients with the restrictive type, and in 52% of the bulimic ones (unpublished data).

The restrictive diet and the physical hyperactivity increase each other. The activity-based anorexic rat is a very interesting model (Hillebrand et al. 2005). This model has been developed by several teams, with similar results. In this model, four groups of rats are compared: the first control group includes rats that eat normally and are put in individual cages where they can engage in limited activity. The second group has the same diet (20–21g/day) but they can go on a wheel as often as they wish. The third control group is on a low-calorie diet (–25% of the previous intake), and their cages are standard. In the experimental group, the rats receive a low-calorie diet (15–16 g of food) and can use the wheel as much as they want to. Rats eating normal diet and allowing going to the wheel increase their physical activity during few days, then less and less. Rats on a restrictive diet in standard cage do not develop physical hyperactivity. Rats on sliming diet allowed to go on the wheel, use it more often each day, and curiously decrease their restricted food intake. They lose more weight than any other rat. A recent study using a quite different model found similar results (Martin et al. 2007): when male and female rats are put on a low-calorie diet; the females lose their menstruation, take on a male hormonal profile and lose weight faster, have more stress, and engage in more physical activity than do males. So, in rats, the female predisposition to AN is seen, without the need for psychological mechanisms (which, however, does not exclude them).

156.2.3 Other Behavioral Consequences

Smoking: there is a relationship between smoking and EDs. Generally speaking, binge eating and bulimic patients smoke more and are more often dependent on tobacco (addiction), than normal subjects and restrictive AN patients. This is also true in the bulimic form of AN (binge-eating, vomiting, and low BMI). Conversely, restrictive AN patients smoke less and are less dependent on tobacco than normal subjects of the same age and sex.

Obsessive compulsive disorder: Obsessive compulsive disorder may have an effect on daily EE for two reasons: by the physical activity that they often impose (obsessive compulsive disorder for housework, cleaning, washing hands, etc.) and by the anxiety, which is often associated (obsessive-compulsive disorder patients are very frequently anxious). It must be remembered that physical hyperactivity can be considered as an obsessive compulsive disorder at least in some eating-disorder patients.

Compulsive food intake and bulimic crises: In AN patients, true bulimia is 80–100 times more frequent than compulsion without vomiting (Rigaud 2003). Bulimia means there at least two episodes a week of compulsive food intakes, without pleasure or hunger, ending with vomiting. Bulimia is six times more frequent in AN patients than in nonanorexic women. It's hard to assess the precise

risk of developing bulimic crises (binge-eating/purging episodes) in AN. Such crises occurred in 25–45% of AN patients. In our statistics (unpublished data), 31% of our 487 patients followed-up for more than 10 years developed binge-eating/purging episodes within the first 2 years. If no such crisis or vomiting is noted during the two first years, the risk of developing chronic bulimia is ten times less (4% of cases) than it is if patients exhibit such crises (36%). Almost 20–30% of the AN patients of the bulimic type do develop normal-weight chronic bulimia nervosa. On the contrary, evolution from bulimia nervosa towards the pure restrictive form of AN is very rare (6% of cases).

There are three explanations for going from the pure restrictive form to binge-eating/purging episodes: (1) frustration due to chronic food deprivation, in patients who keep the sensation of hunger and desire to eat; (2) Chronic energy deficit and various nutritional deficiencies, which lead patients to "need to eat" to avoid death; (3) An on-off response in such patients who deny the hedonic value of any sweet and savory foods. So in AN patients, cognitive restriction could be responsible for similar consequences that what is seen in obese patients on very restrictive low-calorie diet for a long time.

156.2.4 Hormonal Component

1. **Thyroid hormones**: Plasma concentrations are low during fasting; this is called the "low T3 syndrome". Thyroid hormones increase during renutrition and return to the normal level in 3–4 weeks. Normal levels of thyroid stimulating hormone (TSH) are restored at about the same time (Onur et al. 2005).
2. **Cortisol and adrenomedulla hormones**: During fasting, plasma cortisol and free urinary cortisol are often increased. Adrenocorticotropic hormone (ACTH) is high too. Physiological stress linked to the fatal risk of denutrition can explain this increase in cortisol. But physical hyperactivity increases both cortisol and ACTH. When the BMI is below 15 kg/m^2, hyperaldosteronism due to denutrition is observed.
3. **Leptin:** Leptin is reduced in AN (Polito et al. 2000; Satoh et al. 2003; Haas et al. 2005). This decrease correlates with the BMI, and may be responsible for reduced REE. But this leptin related decrease can be avoided by renutrition, because REE increases before any increase in fat mass, while leptin does not increase. When the BMI is above 18 kg/m^2, leptin increases and menstruation starts again.
4. **Adiponectin**: This is often high in AN (Pannacciulli et al. 2003). It could contribute to the increase in energy metabolism during renutrition.
5. **Ghrelin and PYY**: Their roles in EE regulation have been mentioned, but are still unclear (Misra et al. 2006).
6. **Catecholamines:** A high level of catecholamines has been found, but the results are inconsistent. They could be responsible for the increase in REE, postprandial EE, and EE linked to physical activity (Rigaud et al. 2007).

156.3 Conclusion

Understanding of the energy and metabolism components of AN and their evolution during refeeding are increasing. AN seems to be a metabolic and psycho-behavioral syndrome in which the different elements work together to perpetuate the disease. The body has a remarkable capacity to adapt to chronic fasting, but also wastes energy as soon as the patient starts eating again to build up body weight. These mechanisms of adaptation to fasting are partly known: decrease in leptin and thyroid hormone secretion, increase in cortisol secretion, reduction of the cardiac rhythm, reduction

Table 156.2 Evolution of energy needs, before and during renutrition according to the physical activity of the patient

EE weight gain	0	0	0	0	700	700
Total	**1305**	**1483**	**1756**	**1945**	**2929**	**3178**

This table describes the necessary Kcalories for a 36-kg AN patient of 1.70 m (BMI = 12.4 kg/m^2), 92% of fat-free mass (33 kg), who wants to reach a weight of 48 kg, with 86% (41 kg) of lean mass, on the measured basis of a supplement of 700 kcal/day to have a weight gain of 100 g/day. The AN patient is able to not lose weight, eating 1,300 kcal/day (for 36 kg), and she is able to not gain weight eating 1,950 kcal/day if she engages in moderate activity. In order to gain 100 g/day at 48 kg, she will need 3,200 kcal/day

AN anorexia nervosa, *REE* resting energy expenditure, *DIT* diet-induced thermogenesis, *EEPA* energy expenditure linked to physical activity, *EETR* energy expended for thermoregulation

in the body temperature, in association with a state of depression. Mechanisms involved in the increase in EE are better known too: increase in lean mass, increase in metabolic activities linked to the high energy content of meals and increased physical activity. Nearly all of the abnormalities described above are the consequences of the disease and do not seem to play a direct role in the physiopathology.

156.4 Applications to Other Areas of Health and Disease

Knowledge of the evolution of EE and its different components in AN patients will help to understand the mechanisms involved in weight gain in this disease (Table 156.2). REE should be used to know the level of food intake required to obtain the desired weight gain. For example, one can analyze the body weight gain on the basis of the need of 700 kcal/day above the daily total EE to obtain a weight gain of 100 g/day.

The measure of the EE at rest and after physical activity will be useful for a cognitive behavioral therapy. Indeed, one of the bases of the cognitive therapy is the understanding of the body's needs. The aim of this approach is to reassure AN patients and help physicians to prescribe more scientifically based therapy.

Summary Points

- In anorexia nervosa (AN), weight loss and malnutrition trigger a cascade of metabolic, hormonal, and behavioral consequences.
- A considerable decrease in energy expenditure (EE) is observed during fasting states of the disease, but refeeding and weight gain induce a marked increase in EE, including an increase in resting EE, in DIT, and in EE related to physical activity.

Definitions of Key Terms

Anorexia nervosa: Anorexia nervosa (AN) is a psychiatric diagnosis that describes an ED characterized by low body weight and body image distortion with an obsessive fear of gaining weight.

Fat-free mass: Fat-free mass is comprised of the nonfat components of the human body. Skeletal muscle, bone, and water are all examples of fat-free mass.

Body mass index (BMI): Body Mass Index is a standardized ratio of weight to height, and is often used as a general indicator of health. BMI can be calculated by dividing weight (in kilograms) by the square of height (in meters). A BMI between 18.5 and 24.9 is considered normal for most adults.

Obsessive compulsive disorder: Is a mental disorder characterized by intrusive thoughts that produce anxiety, by repetitive behaviors aimed at reducing anxiety, or by combinations of such thoughts (obsessions) and behaviors (compulsions).

Binge eating: Is a pattern of disordered eating which consists of episodes of uncontrollable overeating. It is sometimes as a symptom of binge ED. During such binges, a person rapidly consumes an excessive amount of food.

- There is a dramatic fall in protein catabolism and in glucose disposal during the fasting stages of the disease. Lipid oxidation is reduced too. During renutrition, these profiles become normal a long time before normalization of body weight.
- The loss of fat-free mass and muscle mass is high, which disturbs muscle functions.
- Physical hyperactivity is frequent in EDs, and particularly in AN patients.
- Hormonal disturbances are observed: Low T3 syndrome, increased plasma cortisol, reduced leptin level, high adiponectin level, high level of catecholamines.

Chapter 157
Application of Personal Construct Theory to Understanding and Treating Anorexia Nervosa

PCP	Personal construct psychotheraphy

157.1 Introduction

Anorexia nervosa is a serious, chronic illness with significant morbidity and mortality for most patients (Kaplan 2002). This condition continues to be poorly understood and is rather mysterious (Schmidt and Treasure 2006). To be diagnosed as having anorexia nervosa according to the DSM-IV-TR (2000), a person must display: (1) Refusal to maintain body weight at or above a minimally normal weight for age and height (e.g., weight loss leading to maintenance of body weight less than 85% of that expected; or failure to make expected weight gain during the period of growth, leading to body weight less than 85% of that expected); (2) Intense fear of gaining weight or becoming fat; (3) Disturbance in the way in which one's body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or denial of the seriousness of the current low body weight; (4) In postmenarcheal, premenopausal females (women who have had their first menstrual period but have not yet gone through menopause), amenorrhea (the absence of at least three consecutive menstrual cycles). Anorexia nervosa is seen by clinicians as one of the most frustrating and undisciplinable forms of psychopathology (Blank and Latzer 2004) because of the anorectic's apparent stubbornness in the face of impending death which blocks all attempts to help her (Lemma-Wright 1994). It is no wonder that anorectic patients have retained the reputation of being difficult to help or treat. This is the most difficult problem for clinicians who try to help anorectics. Their resistance to treatment and denial of illness seem to result from the fact that anorexia nervosa provides the afflicted person with a sense of identity. Many scientists assume that anorexia nervosa is caused by impairment of healthful identity develop-

ment and failure to establish a self-definition (Stein and Corte 2007). It is highly probable that controlling and perfectionistic parents can be held responsible for impairment in the development of an independent sense of one's self as well as hindrance of autonomy (Stein and Corte 2007). Such adolescents often seek self-definition in the ability to control their body weight (Stein and Corte 2007) because this way they try to counterbalance the lack of clear identity and the accompanying feeling of impotence (Stein and Corte 2007). Thus anorexia nervosa seems to be the result of maladaptive coping with the absence of an authentic self (Stein and Corte 2007) and the search for a new, ideal identity. As a consequence, such persons begin to define their self through self-starvation (Lemma-Wright 1994) and success can be easily quantified in lost pounds, which offers immediate gratification and may explain why anorectics find it difficult to abandon weight loss (Lemma-Wright 1994). This problem is easy to notice in the following statement of a former anorectic: 'When I looked at myself in the mirror I saw someone beautiful; I saw myself … the clearer the outline of my skeleton became, the more I felt my true self to be emerging (…). Without anorexia I should have been a nothing' (Lemma-Wright 1994, p. 40). Clearly, such identity, which is also called thin (Fransella and Button 1983) or anorectic (Wojciechowska 2000), is maladaptative (Wojciechowska 2000) but for the anorectic it is highly desirable because her beliefs about weight and shape are viewed as being specifically relevant for her (Vandereycken 2006). This phenomenon, which is typical only of anorexia nervosa and refers to the sense experienced by many patients that anorexia nervosa is their identity (Tan et al. 2003a), is called egosyntonicity and it is deemed to be the condition's core feature (Crisp 2006). This specific state is very difficult to change because self-starvation can be very empowering – it offers a sense of accomplishment and self-control as well as fulfilment of the need to make autonomous decisions (Lemma-Wright 1994). Thus, anorexia nervosa is highly valued by people who suffer from it. Notably, afflicted patients sometimes call the disorder their friend (Serpell et al. 1999). It is highly probable that anorectic symptoms are maintained by beliefs about the positive function of the illness for the person (Schmidt and Treasure 2006) and that the egosyntonic nature of anorexia nervosa may be responsible for the chronicity of this condition.

157.2 Egosyntonicity Within a Cognitive Model of Anorexia Nervosa

The egosyntonicity of anorexia nervosa can be well explained and understood within a cognitive model of anorexia nervosa. Central to all cognitive theories of eating disorders is the hypothesis that beliefs and expectancies pertaining to body size and eating are biased in favor of selectively processing information related to fatness/thinness, dieting, and control of food intake or body weight. According to this hypothesis, the anorectic's beliefs and values should be treated as implicit rules which affect the way she assesses her experience of herself and her world as well as the meaning she associates with it (Lemma-Wright 1994). Thus, the primary disorder in anorexia is distortion of the individual's perception of shape and weight (Lemma-Wright 1994), and self-starvation seems to be secondary to the individual's overvalued ideas. Recently, controlled investigations of the predictions of cognitive theories of eating disorders have yielded empirical support for these theories. Vitusek and Hollon (1990) argue that the core psychopathology of anorexia nervosa results from highly organized cognitive structures that unite views of the self with beliefs about weight. These weight-related self-schemas may exert automatic effects on the processing of information and may also help to account for the clinical observation that patients frequently regard their symptoms as egosyntonic. Stein and Corte (2007) found that anorectic patients had fewer positive and more negative and highly interrelated self-schemas compared to controls and that their self-concept was associated with pathological eating- and weight-related attitudes and behaviors. The anorectic person is continuously under the influence of her malad-

aptative self-constructs that are very difficult to change. She believes that without these schemas she would lose herself because they seemingly create her sense of identity. Studies conducted by cognitive researchers have clearly revealed that egosyntonicity of anorexia can be understood in terms of cognitive self-structures which are predominantly negative and very persistent.

157.3 Egosyntonicity Within an Existential Model of Anorexia Nervosa

Some researchers underline that the most important task in the psychotherapy of anorexia nervosa is to understand the anorectic's worldview. This term was proposed by Binswanger who described various aspects of so-called being-in-the-world. This theory has its roots in the existential psychotherapeutic literature which was preoccupied with emphasizing the importance of understanding the client's experience and herself in the world (Lemma-Wright 1994).

   According to existential psychologists, although the anorectic's choice not to eat sometimes leads to death, it is the search for another life, a pursuit of attaining internally what cannot be accomplished or managed in the outer world (Lemma-Wright 1994). The anorectic's worldview seems to be dominated by control. Without control, she would be without a self, thus her unfailing perseverance essentially turns her life into a self-starvation project (Lemma-Wright 1994). Thus, according to the existentialists, anorexia nervosa is a specific solution to psychic pain. It is very important to note that existential clinicians are quite sceptical of diagnoses, for example DSM diagnoses, in general, and the diagnosis of anorexia nervosa in particular. Their primary concern is not whether the diagnosis exists but how it is used. For them, the question of so-called cure in anorexia is a controversial issue when the most important criterion appears to be weight gain. According to the existentialists, the individual who cannot find any other way of being-in-the-world than living a life of self-starvation is not necessarily cured when she starts to eat again. In our attempts to help the anorectic achieve this, we may well benefit from reminding ourselves that, as Joseph Conrad claimed, the question is not how to get cured but how to live (Lemma-Wright 1994).

   Undoubtedly, the existentialists' most important contribution to the understanding of anorexia is their critical analysis of refeeding (treated as an element of behavioral therapy) in the case of this condition.

157.4 Similarities Between Cognitive and Existential Approaches to Anorexia Nervosa

Both cognitive and existential models seem to explain the meaning of self and especially its disturbances in the etiology and maintenance of anorexia nervosa. While cognitive researchers focus on the specific maladaptive self-schemas of anorectics, existentialists focus on their worldview but both groups despair that biological therapies of anorexia are insufficient and may even have paradoxical effects because they ignore the most important feature of the disorder, namely self-disturbances. Both cognitive and existential theories strive to understand the meaning of personal identity in anorectic patients. Vitousek and colleagues (1991), cognitive researchers, explain the reasons for therapeutic difficulties during anorexia nervosa treatment partly from an existential perspective: eating disorder patients, notably anorectics, are notorious for their secrecy, making it difficult to establish communication based on mutual trust and openness. They do so by concealing their behavior, feelings, and experiences, and especially by denying that they are ill (Vitousek et al. 1991). The authors review traditional methods of entering or reconstructing the private experience and overcoming or correcting

Table 157.1 Similarities between cognitive and existential approaches to anorexia nervosa

Understanding anorexia nervosa	
In cognitive approaches	In existential approaches
Both underline that anorectics in particular are notoriously protective of their private experience.	
Both seem to explain the meaning of self and especially its disturbances in the etiology and maintenance of anorexia nervosa	
Both despair that biological therapies of anorexia are insufficient, and even have paradoxical effects, because they ignore the most important feature of the disorder, namely self-disturbances.	
Both cognitive and existential approaches adopt a similar stance with respect to anorexia nervosa in that they emphasize the importance of private experience and self-disturbance in the etiology, maintenance, and treatment of this condition	

the denial of the anorectic individual but they suggest that these methods which rely on clinical intuition, patients' testimony, and direct confrontation are likely to result in a combined perspective of clinician-researchers and their subjects (1991) so they propose a variety of alternative methods of reducing denial and distortion in patients' self-report that may prove to be more useful. Surprisingly, their terminology (internal world, private experience, etc.) is partly existential (Table 157.1).

157.5 George Kelly – Cognitivist or Existentialist?

Interestingly enough, one of the most well-known cognitive researchers, George Kelly, whose Personal Construct Theory has been successfully applied to anorexia nervosa, has been deemed an existentialist by some. Although Kelly was sceptical of phenomenology per se because of its introspective idealism and lack of clear theory and rigorous methodology and experimentation, he was convinced, just like the phenomenologists, that to understand behavior one needs to understand how a person construes reality: how he or she understands it, perceives it, and that this is more important than knowing what that reality truly is. In fact, he pointed out that everyone's view – even the hard-core scientist's – is just that: a view. This is exactly the meaning of the phenomenologist's basic principle, known as intentionality. Although Kelly's theory may sound very cognitive, with its emphasis on constructs and constructions, Kelly himself disliked being called a cognitive theorist. He maintained that his theory included the more traditional ideas of perception, behavior, and emotion. According to Boeree (2006) it is yet to be seen whether Kelly will be remembered as a phenomenologist or a cognitivist. Nevertheless it must be underlined that there are aspects of Kelly's theory that are in contradiction to phenomenology. First, Kelly was a true theory-builder whereas existential researchers tend to avoid theory. Second, he had high hopes for a rigorous methodology for psychology (Boeree 2006). Most existential researchers are much more sceptical about experimentation.

157.6 A Personal Construct Theory Framework

Personal Construct Psychology is a theory of personality developed by George Kelly in the 1950s. Kelly called his theory and philosophy constructive alternativism. His idea was that although there is only one true reality, reality is always experienced from one or another perspective, namely each person perceives the world from his/her own, completely unique vantage

point. According to Kelly, people develop internal models of reality, which he called constructs, in order to understand and explain the world around them in the same way as scientists develop theories (Kelly 1955; Hall Lindzey and Campbell 2004). Therefore, all people can be called scientists because they have constructions of their reality. Like scientists, they have theories and they improve their understanding of reality on the basis of their experiences and, like scientists, they adjust their theories to fit the facts. Constructs are usually defined by words but they can sometimes be nonverbal and very difficult to explain (http://changingminds.org/explanations/theories/personal_construct.htm).

According to Kelly, we store experience in the form of personal, usually bipolar constructs. Where there is thin, there must be fat, where there is good, there must be bad, etc. If everyone were fat, then fat would become meaningless or identical in meaning to everyone. Some people must be skinny in order for fat to have any meaning, and vice versa.

157.7 Roots and Core of Psychopathology and Psychotherapy in Personal Construct Theory

Kelly believed that a psychological disorder was any personal construction which was used repeatedly in spite of consistent invalidation. The behaviors and thoughts which occur in depression, paranoia, schizophrenia, addictions, eating disorders, and so on are examples. Such people cannot learn new ways of relating to the world. They are full of anxiety and/or hostility and other negative feelings (Kelly 1955; Hall et al. 2004).

The main method that Kellian psychotherapists use to diagnose and treat patients with various disorders or psychological problems is the repertory grid interview. Kelly derived this technique from his theory to help patients uncover their own constructs with minimal intervention or interpretation by the therapist and to reconstruct them (Kelly 1955; Hall et al. 2004; http://en.wikipedia.org/wiki/Personal_construct_psychology). In other words, Kellian psychotherapy gets the client to see things in a different way, from a new perspective. It has the following goals: to open people up to alternatives, help them to discover their freedom, and allow them to live up to their potentials (Boeree 2006). This is a noninvasive approach to psychotherapy (Kelly 1955; Hall et al. 2004). The UK Council for Psychotherapy, a regulatory body, classifies PCP therapy under Experiential Constructivism.

157.8 Repertory Grid Presentation

To create their own repertory grid (Table 157.2), patients must first name a set of ten to twenty people, called elements, likely to be of some importance in their lives. In therapy, these people are named in response to certain suggestive categories, such as "my mother," "my father," etc. Second, the therapist (or researcher) must pick out three of these at a time, and ask the patient to tell her/him which of two are similar and which one is different. Then the therapist must ask the patient to give her/him something to call the similarity and the difference. The similarity label is called the similarity pole, and the difference is called the contrast pole. Together they make up one of the constructs applied in social relations. If, for example, a girl says that both she and her mother are nervous people but her father is very calm, then nervous is the similarity pole and calm the contrast pole

Table 157.2 Elements used by 20 anorectics in Button's study

Elements 1–10	Subject's personal elements
Element 11	Me now
Element 12	Me if I was overweight
Element 13	Me as I was one year ago
Element 14	Me as I will be one year ahead
Element 15	Patient's consultant psychiatrist
Element 16	Me at the weight I would prefer to be
Element 17	Me at the sort of weight I imagine the treatment team wants me to be
Element 18	Me at what most people would call a normal weight for me
Element 19	Me as I would ideally like to be
Element 20	Me at the thinnest I've been
Element 21	Me at the heaviest I've been
Element 22	Father – if not included in the subject's personal elements
Element 23	Mother – if not included in the subject's personal elements
Fig. 157.1 A blank rep grid. The blank rep grid has two components, namely: elements (which correspond to important persons in one's life) and constructs (which correspond to both similarity and contrast between the elements) (Reprinted from Boeree 2006 [Online]. Available at: http://webspace.ship.edu/cgboer/kelly.html [accessed 1 June 2009]. With permission)

of the construct nervous–calm. The patient and therapist continue in this fashion, with different combinations of three, until about 20 (but sometimes fewer) contrasts are listed. The therapist, but especially the researcher, may perform certain statistical operations on the completed chart (Kelly 1955; Hall et al. 2004). The rep grid itself is a matrix where the rows represent the discovered constructs, the columns represent the elements, and cells indicate (numerically) the position of each element within each construct (Fig. 157.1). Software is available to produce several reports and graphs from these grids. In diagnostic and self-discovery applications, the therapist may encourage the patient to use constructs that refer to people's behaviors and personalities and, if necessary, to the self (Kelly 1955; Hall et al. 2004).

In therapy, the rep grid gives the therapist and client a picture of the client's view of reality that can be discussed and worked with. The rep grid is a unique test in that the client is invited to change his or her mind about it at any time. Neither is it assumed to be a complete picture of the person's mental state. It is what it is: a diagnostic tool.

Noteworthy, in research, therapists and researchers use a number of computer programs that enable measurement of the distances between constructs or elements. Thus it is possible to get a picture, created by the subjects themselves, of their world-views. It is also possible to compare the views of several people, for example a person's world-view, before and after training or therapy. Such comparisons were made in the studies described in this article (Boeree 2006).

The rep grid is an exciting tool, a creative combination of the subjective and objective side of personality research. It could be said that this technique is very attractive not only for cognitive researchers but also, due to its sensitivity to subjectivity, for methodologically oriented existentialists (Boeree 2006).

157.9 Application of Kellian Theory to Egosyntonic Aspects of Anorexia Nervosa

In 1980 Button (cited in Fransella and Button 1983) conducted a study in which he used the rep grid method. He asked 20 anorectic patients to rate 23 elements in terms of 21 constructs on a 7-point scale. It must be underlined that the constructs and elements were both specific to the individual (named: personal) and supplied by the experimenter (Tables 157.3 and 157.4).

Table 157.3 Constructs used by 20 anorectics in Button's study (Reprinted from Fransella and Button 1983. With permission)

Constructs 1–12	Subject's personal constructs
Construct 13	Very thin–very fat
Construct 14	Attractive–unattractive
Construct 15	Sexually attractive–sexually unattractive
Construct 16	Anorectic–nonanorectic
Construct 17	Eats normally–doesn't eat normally
Construct 18	Needs medical help–doesn't need medical help
Construct 19	Doesn't need psychiatric help–needs psychiatric help
Construct 20	Not physically ill–physically ill
Construct 21	Mentally ill–not mentally ill

Button construed his rep grid on the basis of the answers of 20 anorectic patients whom he asked to rate 23 elements in terms of 21 constructs on a 7-point scale. Both constructs and elements were specific to the individual (he called them personal) and supplied by the experimenter

Table 157.4 Effects of the anorectic's (thin) self construal on treatment results in Button's study

The more extremely the self (especially ideal, anorectic, thin self) was construed, the poorer the treatment outcome. The more fixed patients' views of themselves, the more resistant they were to permanent weight change.

At first follow-up a more extreme view of the self at treatment team weight and at normal weight was associated with good outcome. It therefore appears that weight maintenance after discharge is associated with the patient having a reasonably clear idea of what it means to be normal in terms of weight.

Between first and second follow-up the most significant finding was that a decrease in meaningfulness of the construct fat–thin was associated with good weight maintenance. This suggests that an important goal of therapy is to help anorectics find ways of construing themselves other than in terms of weight or fatness.

Button demonstrated that treatment outcome depends on the importance of the fat–thin construct for the anorexic patient

Results, as in the former study conducted by Fransella and Crisp in 1979, showed no evidence of denial of illness among these patients: intercorrelations between the construct anorectic–nonanorectic (its "anorectic" end) and remaining constructs supplied by the experimenter that could be named "illness" constructs (the following ends: very thin, needs medical help, mentally ill) were positive and very high, ranging between 0.95 and 0.63. Intercorrelations between the "not anorectic" end of the construct anorectic–nonanorectic and such ends of "illness" constructs as: attractive, sexually attractive, eats normally, doesn't need psychiatric help, not physically ill were negative and very high, ranging between 0.98 and 0.74. Analysis of the results showed that the present "thin self" (me now) is seen as undesirable and the "normal weight self" as desirable.

Interestingly, Button decided to take the analysis one step further by scrutinizing the relationships between the "self" elements only in terms of the personal (specific to the individual) constructs because he wanted to establish whether the dispersion of elements was simply a function of the particular constructs supplied by the experimenter (constructs 13–21, Table 157.4). Analysis of data using the same elements (Table 157.3) but different constructs (constructs 1–12, Table 157.4) revealed very similar relationships between the aforementioned elements when all constructs were used, namely self now (element 11) was not ideal (element 19) and thin (element 20), but it also revealed a new, astonishing result (compared with the analysis using all constructs), namely there was an interesting relationship between ideal self (element 19), self at treatment team, weight and self at normal weight (personal elements); ideal self was not self at treatment team and self at normal weight (Figs. 157.2 and 157.3). This
Fig. 157.2 Plot of "Self" Elements in terms of their loadings on components 1 and 2 for a group of 20 anorectic patients
Fig. 157.3 Plot of "Self" Elements in terms of their loadings on components 1 and 3 for a group of 20 anorectc patients. Interestingly, Button decided to scrutinize the relationships between the "self" elements only in terms of the personal (specific to the individual) constructs because he wanted to establish whether the dispersion of elements was simply a function of the particular constructs supplied by the experimenter (constructs 13–21, Table 157.4). This analysis of group data using identical elements but different constructs can be performed using Slater's PREFAN program. Analysis of data using the same elements (Table 157.3) but different constructs (constructs 1–12, Table 157.4) revealed very similar relationships between the aforementioned elements when all constructs were used, namely self now (element 11) was not ideal (element 19) and thin (element 20) (Fig. 157.2), but it also revealed a new, astonishing result (compared with the analysis using all constructs), namely there was an interesting relationship between ideal self (element 19), self at treatment team, and self at normal weight (personal elements); ideal self was not self at treatment (Fig. 157.3) (Reprinted from Fransella and Button 1983. With permission)

implies that ideal self is probably closer to thin self than to medically treated self at normal weight. According to Button, this result may be a possible source of insight into the anorectic's dilemma – wanting to gain weight and be normal while at the same time sensing that this is not viable for her.

157.10 Egosyntonicity of Anorexia in the Light of Results of the Study

Disclosure of this specific ambivalence (ideal self is in contradiction to self at treatment team and self at normal weight) provides us with a real and reliable picture of anorexia: this is a condition which is inextricably linked with sense of identity, namely an anorectic person must be anorectic (i.e., thin) in

order to preserve a sense of identity (Lemma-Wright 1994) and to preserve its egosyntonic symptomatology (Vandereycken 2006). Clearly, in addition to having an anorectic (thin) self, the afflicted person also has other selves (for example, self at normal weight) but the anorectic (thin) self seems to dominate. This is why anorectics are so reluctant to accept treatment, even when they are very low in weight and at significant risk to themselves (Tan et al. 2003b). Using Kellian terms it could be said that an anorectic person is caught with her constructs down and her anxiety involves anticipations of great changes in her core (Kelly's term) constructs (interestingly, Crisp described egosyntonicity as a core feature) (1990). It is therefore understandable that she does not want to get rid of her anorexia because it constitutes her most important construct: anorectic, i.e., thin–nonanorectic, i.e., fat. Button's findings confirm that egosyntonicity (craving for an anorectic, thin identity) is the most important feature of anorexia and it is impossible to understand this condition without this phenomenon which scientists, clinicians, and lawyers dealing with capacity problems must take into account.

157.11 Effects of the Anorectic's (Thin) Self-Construal on Treatment Results

Button (1980, cited in Fransella and Button 1983) also intended to explore the effects of self-construal, in the sense of relationships between elements within specific constructs, on treatment results measured by weight maintenance. His analyses revealed that:

- The more extremely the self (especially ideal, anorectic, thin self) was construed, the poorer the outcome of treatment. The more fixed patients' views of themselves, the more resistant they were to permanent weight change.
- At first follow-up a more extreme view of the self at treatment team weight and at normal weight was associated with good outcome. It therefore appears that weight maintenance after discharge is associated with the patient having a reasonably clear idea of what it means to be normal in terms of weight.
- Between first and second follow-up the most significant finding was that a decrease in meaningfulness of the construct fat–thin was associated with good weight maintenance. This suggests that an important goal of therapy is to help anorectics find ways of construing themselves other than in terms of weight or fatness.

One statistically significant relationship of some interest was found between change in construal from time of admission to time of discharge and poor clinical outcome; this was an increase in meaningfulness of being anorectic compared with being normal weight. It was as if the girls who failed to maintain their weight came to see themselves more clearly as anorectic while in hospital. Therefore, how patients see themselves in relation to their disorder at the onset of treatment has prognostic significance. For anorectics, the more meaningful the self in relation to weight, the poorer the clinical outcome (Fransella and Button 1983). These results show that our self-image affects our behavior and may influence our proneness to change (Fransella and Button 1983) (Table 157.5).

157.12 Applications to Other Areas of Health and Disease

Results of studies on self-construal in anorexia nervosa within Personal Construct Theory may be applied to other mental disorders, or simply to problems which seem to be connected with the sense of identity. It is worth mentioning patients with anxiety disorders whose anxiety concerns a specific

Table 157.5 Key points concerning application of Personal Construct Theory to understanding and treating anorexia nervosa

Resistance to treatment and denial of illness in anorexia nervosa seem to result from the fact that anorexia nervosa provides the afflicted person with a sense of identity which is named egosyntonicity.

Personal Construct Psychology provides us with a very useful tool with which to study the egosyntonicity of anorexia nervosa, the rep grid. Studies which have used this technique show that the way patients see themselves in relation to their disorder at the onset of treatment has prognostic significance. For anorectics, the more meaningful the self in relation to weight, the poorer the clinical outcome.

Analyzing personal constructs of anorectic patients and attempts to find ways of construing themselves other than in terms of objects of fear or problems can literally change their life into easier to bear and even very successful.

Resistance to treatment and denial of illness in anorexia nervosa seem to result from the egosyntonicity of this condition, and Personal Construct Psychology provides us with a very useful tool with which to study the egosyntonicity of anorexia nervosa, the rep grid. Studies using this method have shown that the main aim in treating anorexics should be to help them find ways of construing themselves other than in terms of fatness

area of life or persons but who are not mentally disordered, only distressed about, for example, stuttering. When analyzing their personal constructs and attempts to find ways of construing themselves other than in terms of objects of fear or problems, they can literally change their life, making it easier to bear or even very successful.

157.13 Conclusion

Thanks to Button who explored various self elements, especially in anorectics, i.e., thin constructs, it is possible to understand what the term egosyntonic really means. Anorexia with its main symptom, thinness, is inseparably linked with sense of identity. As a consequence, an anorectic person is scared of life without her disorder and this phenomenon seems to be responsible for her denial of illness and resistance to treatment. It is noteworthy that both cognitive and existential models seem to explain the importance of the self and especially its disturbances in the etiology and maintenance of anorexia nervosa and both models try to explain the sense of personal identity in anorectic patients. Although some researchers stress the importance of the sense of identity in the course of anorexia nervosa, biological (mainly refeeding) and behavioral therapeutic programs are still in common use. The results of the studies presented show that the most important aim in the therapy of anorectics should be to help them find a way of self-realization that does not involve self-starvation (and sometimes death). Existential and cognitive researchers and therapists manifest considerable consensus in their analyses of this phenomenon. This aim is very ambitious and very difficult to achieve but undoubtedly worth the effort.

Summary Points

1. Anorexia nervosa is a serious, chronic illness with significant morbidity and mortality. This condition continues to be poorly understood and rather mysterious and is also seen by clinicians to be one of the most frustrating forms of psychopathology because of the anorectic's apparent stubbornness in the face of impending death which blocks all attempts to help her.
2. Resistance to treatment and denial of illness seem to result from the fact that anorexia nervosa provides the afflicted person with a sense of identity called egosyntonicity.
3. Paradoxically, both cognitive and existential models seem to explain the meaning of self and especially its disturbances in the etiology and maintenance of anorexia nervosa and both attempt to understand anorectic patients' sense of personal identity.

4. Personal Construct Psychology provides us with a very useful tool with which to study the ego-syntonicity of anorexia nervosa, the rep grid.

5. Studies which have used this technique show that the way patients see themselves in relation to their disorder at the onset of treatment has prognostic significance. In anorectics, the more meaningful the self is in relation to weight, the poorer the clinical outcome.

Definitions and Explanations of Key Terms

Anorexia nervosa: A serious psychiatric disorder characterized by distorted body image which triggers intensive self-starvation and – as a consequence – significantly diminished body weight. The very essence of this eating disorder is categorical refusal to change in conjunction with profound denial of illness.

Cognitive theories of eating disorders: Theories according to which beliefs and expectancies pertaining to body size and eating are biased in favor of selective processing of information related to fatness/thinness, dieting, and control of food intake or body weight.

Egosyntonicity: A phenomenon present in very few disorders, whose main feature is that the afflicted person derives a sense of identity from the disorder.

Personal construct theory: A theory of personality developed by George Kelly in the 1950s, based on constructive alternativism, that is, on the idea that although there is only one true reality, reality is always experienced from one perspective or another.

The repertory grid interview: The main method used by Kelly and designed on the basis of Personal Construct Theory.

158.1 Introduction

It is well established that individuals with eating disorders (ED) have a high rate of Axis I psychiatric comorbidity, particularly depressive and anxiety disorders broadly termed as internalizing conditions. The association between Axis II personality disorders (PD) and ED is also frequent with a prevalence of cluster C and B. Accompanying Axis I and Axis II diagnoses play an important role in the outcome of ED and in the planning of therapeutic interventions.

Although psychiatric disorders are common in ED, current literature shows an overlapping of data. In fact, many studies do not consistently consider the distinction between different types of ED; considering ED as a whole, additional axis I disorders were found in 86% by Lewinsohn et al. (2000) and Cotrufo et al. (1998), in 73% by Salbach-Andrae et al. (2008), in 74% by Milos et al. (2004), in 58% by Zaider et al. (2000), in 43% by Kennedy et al. (1994), in 66% by Geist et al. (1998). All these studies found a higher comorbidity in the binge-purging subtype than in the restricting subtype. As regards Axis II disorders, incidence varies from 90% in the study by Piran et al. (1988), to 84% by Grilo et al. (1996), and to 68% in the sample studied by Milos et al. (2004), where a prevalence of cluster C was found.

Secondly, many of these studies have examined comorbidity without considering limited ranges of age. Encompassing adolescent, young adult, and adult patients creates a loophole in the research on the specific psychiatric comorbidity of ED during adolescence when the disorder does not last for many years.

158.2 Depressive Comorbidity in Adolescent Eating Disorders

A wide range of depressive symptoms such as depressed mood, low self-esteem, and social withdrawal are very frequent in anorexic adolescents. Literature data report up to 80% of anorexic samples with a depressive disorder, especially during the acute phase of illness: depressive symptoms were found in 86% by Rastam (1992), in 62% by Smith and Steiner (1992), in 60% by Salbach-Andrae et al. (2008), in 56% by Fosson et al. (1987), and in 46% by North and Gowers (1999) and Saccomani et al. (1998). Lilenfeld et al. (1998) found high multiple lifetime comorbidity with significant differences with a control group. Herzog et al. (1992b) investigated current and lifetime comorbidity and found current comorbidity on axis I in 73% of the restricting subtype. In the study by Heebink et al. (1995), a lower level of depression and anxiety was found in younger restricting patients than in older patients.

Data on the incidence of suicide and suicidal attempts in adolescent samples are lacking (Herpertz-Dahlmann 2008); however, this varies from 10% to 20% in anorexic patients, especially combined with major depression (Bulik et al. 2008; Franko et al. 2006). In particular, in the sample studied by Bulik, around 17% of AN patients (mean age: 30 years) attempted suicide, this being significantly more evident in the purging or binging subtype.

To explain this high comorbidity between AN and depressive symptoms, some authors consider AN as a particular form of mood disorder (Alessi et al. 1989; Cooper et al. 2002; Levy and Dixon 1985). Similarly, Mouren-Simeoni MC et al. (1993), in describing a prepubertal anorexic sample, reported an association with depressive symptoms in 85% of subjects and considered prepubertal AN as a depressive equivalent. In a more recent study, Chen et al. (2009) found that dietary restraint and depressive symptoms combined at age 10 and became a risk factor for binge-eating at ages 12–14. Moreover, "dietary-depressive" subtypes (with a greater negative effect) compared to "dietary"

subtypes (with dietary restraint only) had considerably greater eating disorder behaviors. Presnell et al. (2009) revealed that depressive and bulimic symptoms contributed reciprocally to each other. In particular, they examined the reciprocal relations between the two disorders over an 8-year period, and concluded that depressive symptoms predicted increase in bulimic symptoms while bulimic symptoms predicted increase in depressive symptoms.

Other authors consider depressive symptoms as a result of a prolonged state of starvation with neuroendocrine and serotoninergic alterations (Couturier 2004).

158.3 Anxiety Comorbidity in Adolescent Eating Disorders

Anxiety disorders such as social phobia, obsessive-compulsive disorder (OCD), panic disorder, general anxiety disorder are common both in adult and juvenile anorexic samples with percentages ranging from 7% to 65% (Herzog et al. 1992b; Kaye et al. 2004). In the adolescent sample studied by Salbach-Andrae et al. (2008), anxiety disorders without OCD followed by OCD occurred in 26% and 17% respectively. Moreover, the category containing anxiety disorders without OCD was three times likely to co-occur with the AN binge eating and purging type than with the AN restrictive type. In the study by Godart et al. (2000), the most frequent lifetime anxiety disorder in its adolescent sample was social phobia (55%) followed by simple phobia (45%). In anorexic patients, food-related obsessive-compulsive symptoms arise, especially during the acute phase, such as cutting food into a certain number of pieces, counting calories, preparing meals, and setting the table in the same way. However, real OCD comorbidity with additional thought and behavior is often signaled in anorexic samples with a range from 17% to 40% (Kaye et al. 2004; Salbach-Andrae et al. 2008) and with frequent childhood onset preceding the onset of AN. Furthermore, anorexic patients show rigidity and perfectionism which are considered risk factors for obsessive disorders.

Finally, the majority of studies report the onset of anxiety disorders before the onset of an ED, supporting the possibility that anxious symptoms are a vulnerability factor for developing AN. This temporal correlation between anxiety disorders and AN has significant implications for course and treatment. In particular, since social preoccupations are very frequent in anorexic patients, many authors propose social competence training during treatment (Herpertz-Dahlmann 2008).

158.4 Personality Disorders in Adolescent Eating Disorders

The frequent association between personality traits and disorders (both in acute phase and during recovery) and ED is well described in literature. Above all, perfectionism, rigidity, and obsessiveness (cluster C) seem to be prevalent personality traits in restrictive AN patients. In the study by Thornton (Thornton and Russell 1997), 34% of an AN sample met criteria for obsessive-compulsive personality disorder (OCPD; Cluster C); Wonderlich et al. (1990) also found 60% prevalence of OCPD in 46 women with restricting subtype. Impulsivity, emotional liability, and self-aggressiveness (cluster B, Borderline Personality Disorder) are more evident in the binge eating/purging subtype of AN.

The incidence seems to decrease with the state of ED severity; for example in the study conducted by Herzog et al. (1992a), the incidence of PD in a sample of 210 nonsevere outpatients with ED was only 27%. Recent research (Thompson-Brenner et al. 2008) on ED during adolescence confirmed the results of several studies carried out on ED in adults (Claes et al. 2006; Holliday et al. 2006). Three personality subtypes were found: a high-functioning, an undercontrolled, and an avoidant/depressed

group. In particular, the high-functioning/perfectionist group showed negative associations with comorbidity and positive associations with treatment response. The Emotionally Dysregulated group was associated with externalizing Axis I and Cluster B Axis II disorders, poor school functioning, and adverse events in childhood. The Avoidant/Depressed group showed specific associations with internalizing Axis I disorders and Cluster A Axis II disorders, and poor peer relationships.

158.5 Assessment of Comorbidity in Adolescent Eating Disorders

The accurate assessment of internalizing and externalizing symptoms is a key aspect in adolescent eating disorders, where there is a tendency to deny not only anorexic behavior, but also anxiety and depression, which is very common in AN psychopathology (Viglione et al. 2006).

It is exactly for this reason that assessment with anorexic adolescent patients should be performed by a child psychiatrist having extensive experience with adolescents and sufficiently trained in psychological assessment, use of standardized measures, developmental psychology, and adolescent eating disorders. The assessment should be conducted in an office or other site where confidentiality can be ensured and where the adolescent can feel comfortable and safe. The validity of the information provided by the youth may depend on the setting and on the level of trust between the adolescent and the assessor. During the first interviews, both with the adolescent and with the parents, information should be collected on the history of eating disorders and mental health, with a focus on depression, suicidal ideation or attempts, anxiety disorders, and behavioral disorders (aggressiveness toward self and others, impulsivity, etc.); family history and school history, including academic, behavioral performance, and peer relationships.

The use of instruments is evidently required to perform standardized assessment, that is to say, to systematically, and as coherently as possible, explore the psychopathology so as to receive answers from the patients and their parents and to compare them. Psychiatric assessment instruments enable exploration of the psychopathological entity and provide a quantitative assessment in terms of severity or frequency.

The presence of comorbidity in ED is usually assessed with structured or semistructured clinical interviews, self-report questionnaires, and checklists. Nevertheless, in a recent critical review (Godart et al. 2007) it is observed that diagnostic instruments were not used in earlier studies and that, in later studies, those used varied with differences in diagnostic procedures.

The instruments more frequently used in literature to explore comorbidity in ED are: the Structured Clinical Interview for Axis I (SCID-I, Williams et al. 1992) and the Structured Clinical Interview for Axis II (SCID-II, Skodol et al. 1988) for Axis I and II diagnosis; the Hamilton Depression Rating Scale (HDRS, Williams 1988) and the Beck Depression Inventory (BDI Beck et al. 1996) for depression symptomatology; the Yale-Brown Obsessive Compulsive Scale (Y-BOCS Goodman et al. 1989), the Beck Anxiety Inventory (BAI Beck et al. 1988) and the State-Trait Anxiety Inventory (STAI Spielberger et al. 1970) for anxiety symptoms.

Studies dealing with adolescent samples make use of several specific instruments such as the Child Behavior Checklist (CBCL, Achenbach 1991) for the general psychopathology; the Schedule for Affective Disorders and Schizophrenia for School Aged Children (K-SADS, Chambers et al. 1985) or the Diagnostic interview for children and adolescents (DICA Reich 2000) for Axis I diagnosis; the Multidimensional Anxiety Scale for Children (MASC, March et al. 1999) or the Pediatric Anxiety Rating Scale (PARS, The Research Units on Pediatric Psychopharmacology anxiety study group 2002) for anxiety; the Children's Depression Inventory (CDI, Kovacs 1985) or the Children's Depression Rating Scale – Revised (CDRS – R, Overholser et al. 1995) for depression.

BS		
SIAB-EX		

The diagnostic instruments that we selected consider the specificity of the disorder in the young age of our patients

Kiddie-SADS Schedule for Affective Disorders and Schizophrenia for School Aged Children, *EAT-26* Eating Attitude Test (*ChEAT* Children version), *EDI-3* Eating Disorder Inventory, *BS* Binge Scale, *SIAB-EX* Structured Interview for Anorexic and Bulimic Disorders-Expert Form, *SCID-II* Structured Clinical Interview for Axis II, *CBCL* Child Behavior CheckList; *YSR* Youth Self Report, *PBI* Parental Bonding Instrument

The assessment protocol used in the Eating Disorder Program at the Stella Maris Scientific Institute was elaborated by considering the type of patients and, above all, the clinical features of the eating disorders, and the patients' young age. It is composed of: the Schedule for Affective Disorders and Schizophrenia for School Aged Children (K-SADS) for ED diagnosis and Axis I comorbidity; the Structured Clinical Interview for DSM-IV Axis II Disorders (SCID-II) for Axis II comorbidity; the Achenbach System of Empirically Based Assessment (ASEBA), in particular, the Child Behavior CheckList (CBCL) and Youth Self Report (YSR, Achenbach 1990) for general psychopathology. Naturally, instruments for assessing eating disorders are also used (EDI-3; EAT-26; SIAB-EX; Table 158.1).

158.5.1 Psychopathological Assessment Using the ASEBA System

To verify if psychopathology in adolescent anorexia is as frequent as in older samples, we assessed a sample of 43 anorexic adolescents referred to the Eating Disorder Program at the Stella Maris Scientific Institute with a mean age at admission of 14.9 (range from 10.7 to 17.8 years) and with a mean duration of illness prior to admission of 13 months (Muratori et al. 2004).

ED diagnosis and psychiatric assessment were carried out by an independent trained child psychiatrist who interviewed the child and the parents separately, using the Schedule for Affective Disorders and Schizophrenia for School Aged Children (K-SADS). The K-SADS belongs to the category of clinical diagnostic interviews which – although long – are very useful instruments (Table 158.2).

They may only be used by trained child psychiatrists and explore Axis I diagnosis (some of them also Axis II), allowing the psychiatrist to formulate diagnosis. They envisage a first nonstructured part (10–20 min) and a second semistructured part (40–60 min) during which the child psychiatrist conducts the interview according to a predefined layout. In particular, the K-SADS is a semistructured psychiatric interview based upon the diagnostic criteria of DSM-IV (Chambers et al. 1985; APA 1994) which is used to asses current and past episodes of psychopathology in children and adolescents. The K-SADS is administered by interviewing the parent(s), the child, and finally achieving summary ratings which include all sources of information (parent, child, school, etc.). At the start of the interview (first part), it is important to establish an empathic relationship, to explain the purpose of the interview, and inform the patient on the obligation of professional secrecy. Generally, if the patient is a preadolescent we interview the parents first and then the patient; instead, if the patient is an adolescent, it is important to start with the patient. In the case of discrepancies between

Table 158.2 Criteria for diagnosing adolescents anorexic syndrome (DSMIV)

Anorexia nervosa (full syndrome)

1. Refusal to maintain body weight above minimal normal weight for age and height (body weight less than 85% of the expected) or failure to achieve expected weight gain during period of growth
2. Intense fear of gaining weight or becoming fat, even though underweight
3. Disturbance in the way in which one's body weight or shape is experienced or denial of the seriousness of the current low body weight
4. In postmenarcheal females, amenorrhea of at least three consecutive menstrual cycles

Specify if Restricting subtype or Binge Eating/purging subtype

Eating disorders not otherwise specified (partial syndrome)

Eating disorders that do not meet the criteria for a AN full syndrome, for example:

1. AN criteria are met but the individual has regular menses
2. AN criteria are met except that, despite significant weight loss, the individual's current weight is in the normal range
3. Regular use of inappropriate compensatory behavior by an individual of normal body weight after eating small amounts of food

EDNOS diagnosis (partial syndromes) is very frequent in adolescent samples; furthermore, in these syndromes psychopathological and physical conditions are very serious and require a multidimensional treatment

AN anorexia nervosa

Table 158.3 Key features of Achenbach System of Emirically Based Assessment (ASEBA)

1. ASEBA gives a dimensional description of psychiatric symptomatology by elaborating an individualized profile in the various areas taken into consideration.
2. ASEBA allows psychopathological assessment by using several information sources. In fact, it may be filled in by the parents (CBCL), the youth (YSR) or the teachers (TRF: Teaching Report Form)
3. The checklist forms that are more extensively used to obtain standardized reports of child and adolescent behavior are Child Behaviour CheckList (CBCL) and Youth Self Report (YSR).
4. They contain 118 item behavioral scales which allow evaluation of a total problem score (TP), eight syndromes (withdrawn, anxious/depressed, somatic complaints, social problems, thought problems, attention problems, delinquent behavior, aggressive behavior) and two broadband groups of syndromes designated as internalizing (INT) and externalizing (EXT).
5. The last version also includes DSM-oriented scales.
6. In clinical activities, ASEBA is useful for diagnosis and for the treatment follow-up. A cut-off distinguishing clinical from non-clinical cases is defined.

In the ASEBA checklists filled in by anorexic patients and by their parents the anxious-depressed symptomatology is very evident and may cause great disturbances

parents' and child's reports, the most frequent disagreements occur in the items dealing with subjective phenomena where the parent does not know, but the child is very definite about the presence or absence of certain symptoms. This is particularly true for internalizing items such as hopelessness and suicidal ideation. Reliability, validity, administrative characteristics, and use of the K-SADS were recently reviewed (Ambrosini 2000).

Psychopathology was also studied using the Achenbach System of Empirically Based Assessment (ASEBA), in particular the Child Behavior CheckList (CBCL) and Youth Self Report (YSR). ASEBA gathers assessment data through several sources of information (it may be filled in by the parents, youth, or teachers); it provides a dimensional description of symptomatology and elaborates an individualized profile in the various areas taken into consideration. The aim is to reach a diagnostic formulation which is not focused on one or on a few symptoms, but which bears in mind the countless features of the child's/adolescent's life and of his/her complexity (Table 158.3).

The CBCL and YSR are two of the most frequently used empirically-based assessment instruments for obtaining standardized reports of children and adolescent behavior as observed by the

parents (CBCL) or self-evaluated (YSR). They contain 118 item behavioral scales which allow the evaluation of a total problem score (TP), eight syndromes (Withdrawn, Anxious/Depressed, Somatic Complaints, Social Problems, Thought Problems, Attention Problems, Delinquent Behavior, Aggressive Behavior) and two broad-band groups of syndromes designated as Internalizing (INT) and Externalizing (EXT). Internalizing score encompasses emotional disorders characterized by inhibition and overcontrol, while Externalizing score indicates the presence of attention, oppositional, antisocial, and aggressive problems. A cut-off to distinguish clinical from nonclinical cases is defined. Good reliability and validity have been reported in literature for both scales (Krol 1990). Only two symptoms of anorexia nervosa are comprised in the CBCL and YSR (no. 24: "Doesn't eat well" and no. 53: "Overeating") but they are not included in any patterns of internalizing or externalizing scales, which is of importance for our study.

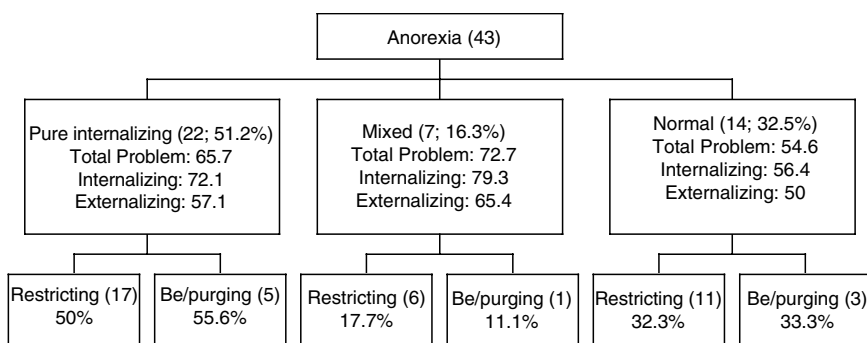
Briefly, the results of our study, thanks to the use of the ASEBA, revealed that the pathological mean score on the internalizing CBCL summary scale (parents' evaluation), with 67.4% of subjects within pathological range, is highly consistent with the findings of a prevalence of affective and anxiety disorders in ED, and the percentage of subjects with psychopathological problems associated with ED are parallel to those reported in literature (Braun et al. 1994; Fosson et al. 1987; Halmi et al. 1991; Herzog et al. 1992b; Lilenfeld et al. 1998; Smith et al. 1993; Smith and Steiner 1992). Above all, on the basis of these internalizing and externalizing profiles and on the number of subjects in the clinical range, three types of adolescent anorexia emerged from our study (Fig. 158.1): (1) "normal" anorexia (32.5% of cases) with a nonclinical CBCL profile; (2) pure internalizing anorexia (51.2% of cases) with TP and INT pathological values; and mixed anorexia (16.3%) with TP, INT, and EXT pathological values. Even if both restricting and binge eating/purging subgroups are allocated in each group, the majority of both of them are represented in the pure internalizing group. The small mixed group, featuring a more severe psychopathology, highlights a type of adolescent anorexia characterized by opposition and difficulties in concentration where Internalizing symptoms are also more severe. This latter type is totally different from the pure internalizing type characterized by a lower rate of psychopathological problems and which we could call unipolar. On the basis of these psychopathological findings we could hypothesize a less severe type of ED in binge eating/purging anorexia and a more severe type in restricting anorexia; the identification of these different anorexic disorders could be of particular interest for subtyping eating disorders, for therapeutic decisions and for defining prognostic trajectory.


Fig. 158.1 Clinical and psychopathological characteristics at CBCL for the three types of adolescents with anorexia nervosa. The three types of anorexic groups differ on the basis of CBCL score. In fact, in the pure internalizing group, the pathological score is reached on total and internalizing global scales; in the mixed the pathological score is reached on INT and EXT scales, while in the normal group the pathological score is not reached
Fig. 158.2 Comparison of pscychopathological asset between full (all criteria of DSM-IV) and partial anorexic adolescent subgroups using CBCL. *Black lines* represent the clinical cutoff for global and syndrome scales. The scores of global and syndrome scales are expressed as mean values. *TP* total problems, *Int* internalizing, *Ext* externalizing, *With* withdrawn, *SomComp* somatic complaints, *AnxDep* anxious/depressed, *SocProb* social problems, *ThougProb* thought problems, *AttProb* attention problems, *Delprob* delinquent problems, *Aggprob* aggressive behavior

By comparing Full versus Partial at CBCL and YSR it is possible to assume a psychopathological continuum between full and partial syndromes, although in full syndromes anxious-depressed and concentration problems combine to represent a more disturbed anorexic adolescent (Fig. 158.2).

When comparing the Restrictive versus the Binge-eating subgroup, higher internalizing psychopathology was found in binge eating/purging subtype only at YSR (no differences at the CBCL), especially for the anxious/depressed subscale. These data seem to describe the binge eating/purging group as a group where self-reported psychopathology is specifically higher compared to that reported by parents. This is probably due to a greater difficulty by the parents in recognizing these disorders in their offspring or due to a particular way of underlining self-symptomatology by the adolescent girls.

To conclude, the use of ASEBA revealed that the amount of psychopathology in anorexia increases over time (higher mean values were found at CBCL and YSR for almost all summary and syndrome scales in the group arrived 12 months after disease onset) and suggests that it could represent a secondary complication of the illness. This finding seems a powerful argument for early intervention in adolescent ED; in fact an ongoing devious pathway can produce negative effects on many domains of functioning.

158.5.2 Psychopathological Assessment Through Semistructured Interviews

Subsequently, we investigated the incidence of personality disorders in a sample of 100 anorexic girls (mean age at admission: 14.4 years). The Kiddie-SADS was used to assess axis I comorbidity, and the SCID-II was used to asses personality disorders (PD). The Structured Clinical Interview for DSM-IV Axis II Disorders (SCID-II) is a semistructured interview for assessing DSM-IV Axis II PD through integration of the personality diagnosis in appendix B of the manual. It consists of a self-report Questionnaire and a semistructured Interview. The Questionnaire comprises 119 items for

Fig. 158.3 Axis I comorbidity in an adolescent anorexic sample using Kiddie-SADS. The anorexic adolescent sample shows a high internalizing symptomatology (depressive and anxiety disorders together: 80%). *MaD* major depression, *MiD* minor depression, *GAD* generalized anxiety disorder, SAD separation anxiety disorder

screening the ten DSM-IV PDs, in addition to the Passive-Aggressive and Depressive PDs in Appendix B of the DSM-IV. Since the Questionnaire was created for adults, we adjusted it for use with adolescents: we changed certain items, making them more suitable for the age range (for example, the term "school" was used instead of "job") but without altering their original meaning. The "yes" response to the items of the Questionnaire is reassessed in the Interview through specific questions. The answers to these questions are rated on a four-level scale. PD diagnosis is made when the number of items assessed as present (that is, presenting pathological, persistent, and diffused features) is above the cut-off determined for making diagnosis.

We confirm high axis I comorbidity also in adolescent girls with anorexia, with a prevalence of depressive and anxiety disorders. In particular, acute depressive symptoms are very frequent (Major depression: 30%; Minor Depression: 48%), as also Generalized Anxiety Disorder (43%) and Separation Anxiety Disorder (16%). Furthermore, our study highlights how 34% of the sample had a pure depressive disorder. This percentage rises to 80% if the association between depressive and anxiety disorders (46%) is considered, while only 3% of the sample had at least 1 pure anxiety disorder (Fig. 158.3).

The Kiddie-SADS is a semistructured psychiatric interview in which the items score used for the categorical diagnosis is obtained by posing the same questions separately to both parents and to the children/adolescents. In our case, therefore, the high percentage of internalizing symptoms (and in particular depressive symptoms) is the expression of both parents' and children's combined opinions. The Kiddie-SADS results are in accordance with the previous study based on CBCL and YSR data, and they seem to support the hypothesis that in anorexic girls, depressive disorder and AN are strictly connected, mutually influencing each other. Nevertheless, the high depressive values in our sample may also be considered as an expression of serious clinical and physical conditions since the mean BMI value of the sample was only 15.6.

The association with axis II comorbidity PD is also high, with values similar to those of recent studies (Milos et al. 2004). In fact, 59% of the sample had at least one PD with a prevalence of OCDP (25%) and Borderline PD (22%). It is very interesting to notice that our binge-eating subgroup also presented higher psychopathology values both in axis I and II. In particular, 88% of this subgroup had at least one PD against 53% of the restrictive subgroup, with a significantly higher value for various PDs, especially for Borderline PD (65% vs. 13%), Avoidant PD (35% vs. 11%) and Depressive PD (47% vs. 13%). We also observed that OCPD reached similar values both in the restricting and in the Binge-Eating subgroup, while there are clear differences between the full and the partial subgroup, with higher values in the first case (28% vs. 18%). Accordingly, we may assume that certain personality traits may highly favor the early onset of AN. Specifically, traits such as perfectionism, rigidity, and overcontrol may favor, together with other factors, the complete onset of the anorexic disorder, while traits such as impulsivity and emotional liability may contribute to be a defining AN quality.

158.6 Clinical Implications

It is possible to confirm the importance of psychopathological evaluation in adolescent eating disorders. The prevalence of internalizing conditions, the worst psychopathology in full syndromes and in the binge-eating/purging subtypes deserves attention when establishing treatments. Finally, the increasing psychopathology later on after the onset of the disease is of particular importance for the development of specialized services for adolescents with anorexia nervosa where early interventions, designed to change both medical and psychological issues, could prevent secondary psychopathology.

158.7 Applications to Other Areas of Health and Disease

Psychiatric assessment of adolescent pathologies is an extremely important step in clinical practice. It provides an accurate and prompt diagnosis in an age when comorbidity is extremely frequent. For this reason, a large amount of standardized interviews and self-administered scales have been identified for adolescents, in order to acquire a complete and objective description of clinical picture. Incidentally, the use of such tools is equally diffused in nonpsychiatric populations for the purpose of identifying risk factors. This aspect is particularly evident as far as Eating Disorders are regarded. Some of the tests mentioned, such as the EAT-26 or the CBCL and YSR, are often used for the screening phase in the general population.

Summary Points

- Adolescent anorexia nervosa presents high psychiatric comorbidity, as in adults.
- Depressive disorders (above all, major depression), especially during the acute phase of illness, are the most common axis I comorbidity in adolescent anorexia nervosa.
- Social difficulties as well as generalized and separation anxiety disorders are also frequent in AN.
- Obsessive–compulsive symptoms, not only food related, are often signaled in anorexic samples, with frequent onset during childhood preceding the onset of AN.
- Axis II comorbidity is frequent in adolescent anorexic samples, with a prevalence of Cluster B (especially in the binge-eating subtype) and Cluster C (especially in the restrictive subtype).

Definitions and Explanations of Key Terms

Adolescent Eating Disorders: Anorexia nervosa (AN), bulimia nervosa (BN) and EDNOS (eating disorder not otherwise specified) are all characterized by an excessive concern with weight and shape, accompanied by inadequate and irregular food intake. Many adolescents do not fulfill criteria for AN and BN but for subthreshold eating disorders (EDNOS), which are often as severe as the classical syndromes

Comorbidity: Presence of more than one diagnosis occurring in an individual at the same time. In the ED is a frequent condition that plays an important role as for diagnosis as for outcome and for planning of specific treatments.

Assessment: Evaluation of the patient for the purposes of forming a diagnosis and a treatment plan. It is very important, in clinical work with eating disorder (ED), to have a comprehensive assessment of DSM-IV comorbid disorders.

Internalizing condition: Depressive and anxiety disorders; this is the most frequent comorbidity in adolescent ED.

Personality disorders: An enduring pattern of inner experience and behavior that deviates markedly from the expectations of the culture of the individual who exhibits it. This pattern is manifested in two (or more) of the following areas: cognition, affect, interpersonal functioning, and impulse control. This diagnosis is a very frequent comorbidity in adolescent ED.

Key Points on Comorbidity in Adolescent Anorexic Disorders

High comorbidity of adolescent anorexia nervosa contributes to define specific and well-defined clinical disorders and to make therapeutic decisions more effective.

The Restrictive AN subtype is associated to higher levels of internalizing symptomatology, perfectionism, rigidity and obsessiveness (they frequently describe a Cluster C personality disorder). Impulsivity, emotional liability and self-aggressiveness (which frequently describe a Borderline Personality Disorder) are more evident in the binge eating/purging subtype of AN.

A psychopathological continuum may be assumed between full and partial syndromes.

The anxious-depressed symptomatology may cause greater disturbances in adolescents with anorexia.

The prevalence of internalizing conditions and the worst psychopathology in full syndromes and in the binge-eating/purging subtypes, deserves attention when establishing treatments. The identification of girls with anorexic partial syndrome is an opportunity to intervene at an early stage of the disorder and to improve outcome.

Chapter 159
ACTH, Cortisol, Beta Endorphin, Catecholamines, and Serotonin in Anorexia Nervosa: Implications for Behavior

Marie-Claude Brindisi and Daniel Rigaud

Abbreviations

AN	Anorexia nervosa
ACTH	Adrenocorticotropic hormone
CBG	Cortisol binding globulin
5-HIAA	5-hydroxyindolacetic acid
5-HT	5-hydroxytryptamine or Serotonin
CNS	Central nervous system
CRH	Corticotropin-releasing hormone
CSF	Cerebrospinal fluid
DHEA-S	Dehydroepiandrosterone-sulfate
ED	Eating disorder
FFA	Free fatty acid
NE	Norepinephrine
PET	Positron emission tomography
POMC	Proopiomelanocortin
SNS	Sympathetic nervous system
SPECT	Single photon emission computed tomography
SSRIs	Selective serotonin reuptake inhibitors

159.1 Introduction

Anorexia nervosa (AN) is a psychiatric disorder with a current prevalence of 1.5% and a mortality rate of 5–10%. AN is characterized by a dramatic decrease in energy and fat intake and by excessive physical exercise, which together result in physiological, biochemical, and behavioral disturbances. Excessive exercise is present in 40–80% of AN patients. In one-third to one-half of cases, AN patients control their body weight by purging, vomiting, or even laxative abuse, or by using diuretics. Two subtypes of AN have been identified: Restricting-type AN patients lose weight by pure dieting;

e-mail: marie-claude.brindisi@chu-dijon.fr

bulimic anorexics also restrict food, but engage in inappropriate episodic compensatory behaviors (binge-purge behavior).

Understanding of how genetic and neurobiologically mediated mechanisms contribute to the likelihood of developing eating disorders (ED) is growing. In this review, we will focus on the role of hormones, above all adrenocorticotropic hormone (ACTH) and cortisol, and neurotransmitter pathways.

159.2 Corticotrope Axis

The adrenal glands of AN patients produce more cortisol in response to ACTH than do those of normal women (Gold et al. 1986). Thus, an increase in 24h-urinary free cortisol (Bliss and Migeon 1957), and a 30% increase in plasma cortisol, with a normal nycthemeral cycle, are observed with normal levels of cortisol-binding globulin (CBG). Most studies have reported maintenance of a plasma cortisol rhythm in AN patients (Boyar et al. 1977). The rhythm of both the free salivary cortisol secretion and the plasma cortisol has been investigated by Putignano et al. (2001). The authors pointed out that the circadian rhythm was maintained in blood and saliva levels, although they reported a "flattening" of the 24-h cortisol concentration curve in AN patients as compared to controls (Putignano et al. 2001). Dos Santos et al hypothesized that this flattened daily curve of cortisol may reflect altered circadian rhythm in some, but not all of the patients included in the analysis (dos Santos et al. 2007). Sensitivity of the corticotrope axis to the inhibitory effect of a free fatty acid load (FFA) is preserved, like in healthy adult subjects (Lanfranco et al. 2006).

Most investigators have attributed the elevated level of plasma cortisol to dysfunctions in hypothalamic mechanisms that control ACTH secretion in AN patients, but the mechanisms involved have not been fully clarified. The elevated serum concentration of cortisol results partly from increased secretion, and partly from increased half-life due to malnutrition and hypometabolism; changes such as a decrease in the metabolic rate of cortisol clearance have been reported too, suggesting a dysfunction in peripheral glucocorticoid metabolism (Vierhapper et al. 1990). A nearly constant finding in AN patients is the response to ACTH, which contrasts with the weakened response to stimulation with corticotropin- releasing hormone (CRH). Moreover, CRH hypersecretion has been observed frequently in AN: patients have a high level of CRH in their cerebrospinal fluid (CSF). Studies on cortisol and ACTH responses to the dexamethasone-suppression test or the response to a competitive glucocorticoid antagonist showed abnormal cortisol suppression and high CRH secretion. Finally, CRH activates the same cerebral area as the one associated with stress and causes anorexia, an increase in motor activity, and a decrease in sexual activity. It appears that these high levels of cortisol and ACTH are secondary to weight loss, since they are normalized by weight gain. Nevertheless, they could also have a pathophysiological role, since in AN patients, low weight is associated with anxiety in 40% of the patients, true anorexia in some patients, and sexual dysfunction in most of them, which may decrease after weight gain. The hypersecretion of CRH, ACTH, and cortisol could be part of a vicious circle in AN patients, by counteracting the need to eat and increasing the risk of binge-eating in malnutrition.

The mechanisms of the flattened cortisol rhythm still need to be elucidated. Besides the effects of the central nervous system (CNS) on the hypothalamic–pituitary–adrenal axis, other factors could be involved, such as reduction in CBG levels due to the low estrogen levels and/or by the malnourished status of these patients (dos Santos et al. 2007).

A high level of cortisol is not associated with an increase in other ACTH-dependent adrenal hormones, such as dehydroepiandrosterone sulfate (DHEA-S). Sirinathsinghji and Mills (1985) demonstrated that in AN patients, hypercortisolism is observed together with a loss of DHEA-S rhythm,

and a low DHEA-S level. This situation cannot be explained by the mechanisms involved in the increase in cortisol.

This excess of cortisol could be responsible for lanugo and for the decrease in bone formation, and could also be implicated in the feeling of well-being observed in denutrition. Moreover, the size of the increase in fasting serum cortisol levels is dependent on the severity of the fasting hypoglycemia observed in these patients (Casper 1996).

159.3 Beta-endorphin

The opioid system has a direct influence on eating behavior and motor activity. It certainly plays a role in the ability of predators to catch their prey in the wild: endorphin, secreted with cannabinoids, decreases pursuit-related pain and fatigue. One may suppose that in AN patients the oversecretion of beta-endorphin enables them to deny the seriousness of their malnutrition and to endure the pain and distress related to their disease. Despite some discrepancies among studies, an increase in beta-endorphin activity has been observed in AN patients (Ericsson et al. 1996). Whereas moderately high levels of beta-endorphin stimulate feeding, higher levels allow tolerance to starvation (Hubner 1993).

Feeding blindly by a nasogastric tube induced a dose-dependent decrease in beta-endorphin and a dose-dependent increase in levels of ACTH, cortisol, norepinephrine, and dopamine in hospitalized malnourished AN patients. There was no significant change in these variables in healthy women (Rigaud et al. 2007). The decrease in the level of beta-endorphin could partly explain the abdominal discomfort, the anxiety, and the depressive state after a meal. This could also explain why some AN patients feel the need to engage in physical activity after a meal, because exercise stimulates the release of beta-endorphin. With this drop after a meal, there is a loss of the sensory benefit related to the elevated fasting level of beta-endorphin (Russell et al. 2001).

159.4 Catecholamines

159.4.1 1-Dopamine

Several symptoms of AN, such as excessive exercise, reduction in food intake, and amenorrhea have been attributed to dopamine dysfunction (Barry and Klawans 1976). Most studies have found abnormalities in peripheral and central noradrenergic activity in ill AN patients (Pirke 1996). But the results are inconsistent. For example, homovanillic acid, the major metabolite of dopamine in humans, is decreased in the CSF of AN subjects (Kaye et al. 1984). But Jimerson (1993) found normal CSF levels of dopamine in their AN patients.

By contrast, Barbato et al. (2006) showed significant increase in the eye-blink rate in their AN patients. Such an increase suggests excessive central dopaminergic activity, since the eye-blink rate is a peripheral measure of central dopaminergic activity. Moreover, a trait-related disturbance of dopamine metabolism has been shown to contribute to vulnerability to restricting-type AN (Kaye et al. 1999)

In activity-based anorexia in rats, an animal model mimicking AN, treatment with a dopaminergic antagonist inhibits anorexic behavior (Verhagen et al. 2009). This result suggests that hyperactive behavior and reduced food intake observed in anorexic patients may be treated by dopamine receptor antagonists. Antipsychotics may therefore be considered in the treatment of AN patients, when reducing an important hyperactive behavior is likely to accelerate body weight gain.

159.4.2 2-Norepinephrine

Catecholamines, especially norepinephrine (NE), are the main lipolytic hormones in human. In some studies, based on the levels of NE in plasma, urine or CSF, lower basal sympathetic nervous system (SNS) activity was found in AN patients compared with healthy controls (Pirke 1996). This contrasts with basal NE levels in subcutaneous abdominal adipose tissue which were markedly higher in AN patients than in healthy women, suggesting an increase in SNS activity in this area (Nedvidkova et al. 2004).

159.4.3 Serotonin

Serotonin (5-hydroxytryptamine, 5-HT) is a brain neurotransmitter that plays a key role in satiety (Leibowitz 1990). A lot of data are available concerning serotonin and AN. High serotonin activity could be responsible for anxiety, sleep deprivation, excessive physical exercise, true anorexia (loss of appetite), a feeling of high power, and denial of nervous and physical exhaustion (Capasso et al. 2009). In contrast, depressed serotonin activity could be responsible for a depressive mood and binge eating (symptoms frequently observed after months or years of AN). It is well known that estrogens modulate serotonergic function as well as levels of CRH; this could be why AN often begins after puberty, during late adolescence. A recent review suggested that anorexia is linked to a disturbed serotonin system (Kaye et al. 2005). Low cerebral-spinal fluid levels of the serotonergic metabolite 5-hydroxyindolacetic acid (5-HIAA) have been found in AN patients as compared to healthy women. This low level normalizes after weight gain (Kaye et al. 1988). Whether this is caused by reduction in dietary supplies of the 5-HT synthesizing amino-acid tryptophan, or by other effects of malnutrition on hormonal or neurotransmitter systems remains uncertain.

Altered brain serotonin function thus contributes to the dysregulation of appetite, mood, and impulse control in AN. A trait-related disturbance of 5-HT neuronal modulation precedes the onset of AN and contributes to premorbid symptoms of anxiety, obsessionality, and inhibition (Steiger et al. 2004). Such a dysphoric temperament may involve the inherent dysregulation of emotional and reward pathways which also mediate the hedonic aspects of feeding, thus making these individuals vulnerable to disturbed appetitive behaviors. Restricting food intake may become powerfully reinforced because it provides a temporary respite from a dysphoric mood. Puberty-related female gonadal steroids or age-related changes may exacerbate 5-HT dysregulation. Stress and/or cultural and social pressures may contribute by aggravating an anxious and obsessional temperament. AN patients may discover that reduced dietary intake, by reducing plasma tryptophan availability, is a means by which they can modulate brain 5-HT functional activity and anxiety (Kaye 2008).

Platelet monoamine oxidase activity has been proposed as an index of cerebral serotonin activity. Studies in AN patients have shown contradictory results: in 59 malnourished AN patients, platelet monoamine oxidase activity was similar to that observed in normal women. In contrast, in 35 AN patients who had recovered their normal BMI, it was 20% lower than in normal controls (Ehrlich et al. 2008). Diaz-Marsa et al. (2000) found lower than normal platelet monoamine oxidase activity in their malnourished AN patients. Biederman et al. (1984) hypothesized that this low platelet monoamine oxidase activity could be related to a depressive mood, since they found low levels in their 13 depressive AN patients, and normal levels in their 18 nondepressive AN patients, as compared with 28 matched normal control subjects. Carrasco et al. (2000) reported

that this low level was found both in bulimia nervosa patients and in patients with the binge/purging form of AN.

The efficacy of antidepressant medications in the treatment of eating disorders has been tested. Cyroheptatide, a drug with 5-HT properties has been tried to accelerate weight gain in AN. The effect of the drug was quite small (Halmi et al. 1986). Whereas antidepressants have been shown to be effective in patients with bulimia nervosa, initial studies with traditional antidepressant agents in AN patients only showed a limited benefit. Several studies have failed to demonstrate any beneficial effect of including selective serotonin reuptake inhibitors (SSRIs) in the treatment of hospitalized AN patients (Ferguson et al. 1999).

Moreover, AN patients who have recovered their normal weight often have persisting psychological symptoms that are accompanied by a significant risk of recurrent low-weight episodes. This has led to interest in studies on relapse prevention. A clinically-based, prospective, longitudinal, follow-up study failed to show any significant benefit of treatment with fluoxetine (SSRI) (Strober et al. 1997). However, recent data from a double-blind, placebo-controlled trial in weight-restored patients demonstrated that treatment with fluoxetine was associated with a reduced relapse rate and reductions in depression, anxiety, obsessions, and compulsions. This study showed that after 1 year, 10 of 16 subjects treated with fluoxetine remained well while only 3 of 19 subjects who received placebo remained well (Kaye et al. 2001).

Today, new technology using brain imaging with radioligands may lead to a better understanding of brain 5-HT neurotransmitter function and its dynamic relationship with human behavior. Up to now, single photon emission computed tomography (SPECT) and positron emission tomography (PET) studies have been used. The 5-HT2A receptor is of interest because it is thought to be involved in the regulation of feeding, mood, and anxiety, and in the action of antidepressants. Other studies of ill, underweight AN patients, which used SPECT with a 5-HT2A receptor antagonist (Audenaert et al. 2003), found a significant reduction in 5-HT2A receptor activity in the left frontal cortex, the left and right parietal cortex, and the left and right occipital cortex. These studies are consistent in that they report reduced 5-HT2A activity in cortical regions in AN, and the findings are independent of the severity of the illness. These studies raise the possibility that anorexic subtypes may share a disturbance of 5-HT2A receptor activity in the subgenual cingulate, whereas regional differences in 5-HT2A receptor activity may distinguish between ED subgroups after recovery. The subgenual cingulate is thought to play a role in emotional and autonomic responses (Freedman et al. 2000), and a disturbance in this region has been implicated in mood disorders. Mood disturbances are common in individuals with EDs, although there is some controversy as to whether EDs and mood disorders are transmitted from generation to generation independently or together (Lilenfeld et al. 1998). These data raise the possibility that some factor related to subgenual cingulated function, perhaps related to mood and autonomic modulation, creates a predisposition for anorexia.

A chapter of this book is devoted to HT1A receptor images.

159.5 Applications to Other Areas of Health and Disease

AN is a complex disease involving psychological, sociological, and neurobiological components. By understanding these mechanisms, physicians will be able to treat this eating disorder using not only dietetic and psychiatric approaches, but also chemical approaches. Nevertheless, because of the contradictions between studies and the current lack of knowledge, AN is still difficult to treat. Hopefully, as new technologies like imaging (developed in another chapter) become increasingly available, they may open doors to new therapeutic approaches (Table 159.1).

Table 159.1 Key features of biology in anorexia nervosa

1. An excess of cortisol is observed in AN with a normal nycthemeral cycle. A nearly constant finding in AN patients is the normal response to ACTH, which contrasts with the weakened response to stimulation with corticotropin- releasing hormone (CRH).
2. An increase in beta-endorphin activity has been observed in AN patients. During refeeding, there is a decrease in the level of beta-endorphin.
3. Results about catecholamines are inconsistent.
4. Low cerebral-spinal fluid levels of the serotonergic metabolite 5-hydroxyindolacetic acid (5-HIAA) have been found in AN patients as compared to healthy women. This low level normalizes after weight gain.

This table lists the different biological abnormalities observed in anorexia nervosa

Summary Points

- Anorexia nervosa (AN) is a psychiatric diagnosis that describes an eating disorder characterized by low body weight and body image distortion with an obsessive fear of gaining weight.
- AN is a complex disease including social, psychological, and biological factors.
- An excess of cortisol is observed in AN, and could be responsible for lanugo, decrease in bone formation, and in the feeling of well-being observed in denutrition.
- Oversecretion of beta-endorphin enables AN patients to deny the seriousness of their malnutrition and to endure the pain and distress related to their disease.
- Serotonin plays a key role in satiety; however, several studies have failed to demonstrate any beneficial effect of selective serotonin reuptake inhibitors (SSRIs) in the treatment of hospitalized AN patients.
- New technology using brain imaging with radioligands may lead to a better understanding of brain serotonin neurotransmitter function and its dynamic relationship with human behavior.

Definitions of Key Terms

Anorexia nervosa: Anorexia nervosa (AN) is a psychiatric diagnosis that describes an eating disorder characterized by low body weight and body image distortion with an obsessive fear of gaining weight.

Corticotrop axis: Corticotrop axis is the hypothalamic–pituitary–adrenal axis. CRH (Corticotropin-releasing hormone) from the hypothalamus stimulates ACTH (in the pituitary gland) in a pulsatile manner, and ACTH stimulates the secretion of glucocorticoids (cortisol) from the adrenal cortex.

Beta-endorphin: Beta-endorphin is an endogenous opioid peptide neurotransmitter found in the neurons of both the central and peripheral nervous system. It is a peptide 31 amino acids long, resulting from processing of the precursor proopiomelanocortin (POMC).

Catecholamines: Catecholamines are molecules that have a catechol nucleus. They include dopamine, norepinephrine and epinephrine. Epinephrine is synthesized mainly in the adrenal medulla, whereas norepinephrine is found not only in the adrenal medulla but also in the central nervous system and in the peripheral sympathetic nerves. Dopamine, the precursor of norepinephrine, is found in the adrenal medulla and in noradrenergic neurons.

Serotonin: Serotonin is a monoamine neurotransmitter. It is found extensively in the gastrointestinal tract of animals, and about 80–90% of the human body's total serotonin is located in the enterochromaffin cells in the gut, where it is used to regulate intestinal movements. The remainder is synthesized in serotonergic neurons in the central nervous system where it has various functions, including control of appetite, mood, and anger.

Part XXVI
Bulimia Nervosa and Night Eating Syndrome

Chapter 160
Ethnicity in Bulimia Nervosa and Other Eating Disorders

Athena Robinson and W. Stewart Agras

Keywords Anorexia nervosa • Bulimia nervosa • Binge eating disorder • Obesity • Minorities • Treatment

Abbreviations

BMI   Body mass index
WHO   World Health Organization

160.1 Introduction

Historically, epidemiological studies of eating disorders have focused on white women and girls and relatively little research has been conducted utilizing participants from racial and ethnic minority groups (National Eating Disorder Association (NEDA) 2005). Consequently, eating disorders are often described as affecting primarily white women of high socio-economic classes (American Psychiatric Association 1993; Fairburn and Beglin 1990; Striegel-Moore and Smolak 1996). Thus, research prior to the mid-1990s typically reported that eating disorders were less common among specific minority groups in the United States including blacks, Hispanics, Native Americans, and Asian Americans (Dolan 1991; Hsu 1987; Jones et al. 1980). However, more recent empirical studies suggest that minority populations are substantially affected by disordered eating behaviors (Yanovski 2000, Streigel-Moore et al. 2003; Taylor et al. 2007).

This chapter provides a review of the occurrence of disordered eating among ethnic minority groups for anorexia nervosa, bulimia nervosa, binge eating disorder, overweight and obesity, and dieting and other forms of body disturbance. Discussion of issues related to assessment and access to treatment, and areas for future research are provided.

Table 160.1 Prevalence rates of anorexia nervosa, bulimia nervosa, binge eating disorder, and any binge eating

		Lifetime prevalence n (%)			
Reference	Sample	Anorexia nervosa	Bulimia nervosa	Binge eating disorder	Any binge eating
Streigel-Moore et al. (2003)	985 white women	15 (1.5)	23 (2.3)	27 (2.7)	–
	1061 black women	0	4 (.4)	15 (1.4)	–
Taylor et al. (2007)	5191 African American and Caribbean Black adults	7 (.17)	79 (1.49)	88 (1.66)	245 (5.08)
	Adolescents[a]	2 (.07)	5 (.40)	4 (.28)	18 (1.56)
Alegria et al. (2007)	2554 Latino adults	2 (.08)	41 (1.61)	49 (1.92)	143 (5.61)
Nicado et al. (2007)	2095 Asian American adults	2 (.08)	23 (1.09)	43 (2.04)	91 (4.35)

This table lists the prevalence rates of anorexia nervosa, bulimia nervosa (BN), binge eating disorder, and binge eating as reported by four recent studies

Rates for Alegria et al. 2007 and Nicado et al. 2007 were calculated by A. Robinson using percentage data provided in manuscripts

–Data not provided by study

[a] Only 12-month prevalence rates for adolescents provided by original paper

160.2 Prevalence Rates

Table 160.1 outlines data from four recent studies that provide prevalence estimates of anorexia nervosa, bulimia nervosa, binge eating disorder, and the presence of any binge eating among whites, blacks, Latinos, and Asian Americans. Taken together these studies suggest, with the exception of anorexia nervosa among blacks, that the rates of disordered eating behaviors among ethnic minorities are substantial.

160.2.1 Anorexia Nervosa

General anorexia nervosa prevalence estimates are approximately 0.3 among young females (Hoek 2006; Hoek and van Hoeken 2003) with crude mortality rates ranging from 5.1% to 7.4% (Herzog et al. 2000; Sullivan 1995; Crow et al. 1999) and relatively poor prognosis (Steinhausen 2002). Key features of anorexia nervosa are outlined in Table 160.2.

Prevalence rates of lifetime criteria for anorexia nervosa among 2,046 young black and white women assessed via telephone and confirmatory in-person diagnostic interviews were reported as 15 (1.5%) and 0 (0%) for white and black women respectively (Striegel-Moore et al. 2003). Another recent study interviewed a nationally representative sample of 5,191 African American and Caribbean black adults and adolescents and found that anorexia nervosa was the rarest eating disorder among African American adults and adolescents and that no single case of anorexia nervosa of at least 12-months in duration was found among Caribbean black adults (Taylor et al. 2007). Other authors echo the rarity of anorexia nervosa among black women (Hoek 2006; Mullholland and Mintz 2001). Results from the National Latino and Asian American Study (NLAAS) indicate that 2 women out of 2,554 Latinos (1,127 male, 1,427 female) met lifetime criteria for anorexia nervosa and none met current criteria for anorexia nervosa or subthreshold anorexia nervosa (Alegria et al. 2007). Lifetime and 12-month prevalence rates of anorexia nervosa among a nationally representative sample of 2,095 Asian Americans (998 male, 1,097 female) were reported as 0.08% and 0.02% for men and women respectively (Nicado et al. 2007).

Table 160.2   Key features of anorexia nervosa

Disorder	Features
Anorexia Nervosa	• Refusal to maintain body weight at or above minimum normal weight for age and height
	• Intense fear of weight gain
	• Disturbance in perception and experience of body weight and/or shape, or denial of the seriousness of low body weight
	• Amenorrhea (the absence of menstruation)

This table lists the key features of anorexia nervosa, including behavioral and cognitive symptoms and physical manifestations. Diagnostic criteria are described fully in the Diagnostic and Statistical Manual of Mental Disorders, 4th ed (DSM IV) (APA 1994)

Table 160.3   Key features of bulimia nervosa

Disorder	Features
Bulimia nervosa	• Recurrent episodes of binge eating
	• Purging behaviors (such as vomiting, laxative abuse, or compulsive exercise) used to control weight and shape
	• Self-evaluation largely based on perceptions of body shape and weight

This table lists the key features of bulimia nervosa including behavioral and cognitive symptoms. Diagnostic criteria are described fully in the Diagnostic and Statistical Manual of Mental Disorders, 4th ed (DSM IV) (APA 1994)

While firm conclusions cannot be drawn regarding the prevalence of anorexia nervosa among ethnic minority groups, data to date suggest that rates of anorexia nervosa are lower among ethnic minority groups than among their white counterparts, and are particularly low among blacks.

160.2.2 Bulimia Nervosa

General prevalence rates of bulimia nervosa have been estimated at 1% among young females (Hoek 2006). Key features of bulimia nervosa are outlined in Table 160.3.

Striegel-Moore and colleagues (2003) reported lifetime prevalence rates for bulimia nervosa among 2,046 young white and black women to be 23 (2.3%) and 4 (0.4%), respectively, and concluded that bulimia nervosa is less common among blacks than white women. Among 4997 African American and Caribbean black adults, 79 (1.49%) and 38 (0.69%) met lifetime and 12-month criteria for bulimia nervosa respectively (Taylor et al. 2007). Rates of bulimia nervosa were significantly lower among black than white college women (Gray et al. 2006) and no cases of bulimia nervosa were found among 421 black college women enrolled at a predominately white public university (Mulholland & Mintz, 2001). Alegria et al. (2007) reported a lifetime and 12-month bulimia nervosa prevalence rate of 0.08% and 0.03% respectively among a sample of 2,554 Latinos. Lifetime and 12-month prevalence rates of bulimia nervosa among 2,095 Asian American adults were 1.09% and 0.36% respectively (Nicado et al. 2007). Women from four ethnic groups (Hispanic, Asian–American, black, white) were equally likely to present behavioral symptoms of bulimia nervosa (Regan and Cachelin 2006). Similarly, a review noted bulimia nervosa rates among white women were not significantly greater than nonwhite women (Wildes et al. 2001).

160.2.3 Binge Eating Disorder

Binge eating disorder impacts approximately 2–5% of the general population (Bruce and Agras 1992) and up to 30% of weight control program participants (Spitzer et al. 1992, 1993). Key features

Table 160.4 Key features of binge eating disorder

Disorder	Features
Binge eating disorder	• Recurrent episodes of binge eating • Binge episodes are associated with some of the following: eating much more rapidly than normal, eating until uncomfortably full, eating large amounts of food when not physically hungry, eating alone due to embarrassment over food quantity consumed, and feeling depressed, guilty, or disgusted after eating • No purging behavior present

This table lists the key features of binge eating disorder including behavioral and cognitive symptoms. Diagnostic criteria are described fully in the Diagnostic and Statistical Manual of Mental Disorders, eth ed (DSM IV) (APA 1994)

of binge eating disorder are outlined in Table 160.4. The literature is in agreement that binge eating is the most prevalent disordered eating behavior among minority groups. Data from field studies reported comparable rates of binge eating disorder in white and black women (Spitzer et al. 1992, 1993) and some studies suggest that binge eating rates among black women are equal or even more common than among white women (Striegel-Moore and Smolak 2000). Similar lifetime prevalence rates of binge eating were found among adults of three minority groups: African American and Caribbean blacks at 5.08% (Taylor et al. 2007), Latinos at 5.61% (Alegria et al. 2007), and Asian Americans at 4.35% (Nicado et al. 2007).

160.2.4 Applications: Overweight and Obesity

Overweight and obesity are one of the leading causes of morbidity and mortality in the USA (US Department of Health and Human Services 2001) and obesity may be a risk factor for binge eating disorder. These conditions are particularly prevalent among some ethnic minority and immigrant groups in the USA including African–Americans and Hispanics (Centers for Disease Control (CDC) 2003). For example, Mexican American adults have reported higher rates of overweight (11% higher for males; 26% higher for females) and obesity (7% higher for males; 32% higher for females) than non-Hispanic whites. Similarly, Mexican–American adolescents aged 12–19 years reported higher rates of overweight (112% higher for males and 59% higher for females) than non-Hispanic white adolescents. Acculturation to the USA has been identified as a risk factor for obesity-related behaviors, specifically the high frequency of eating fast food and low rates of physical activity among Asian–Americans and Hispanic adolescents (Lauderdale and Rathouz 2000; Unger et al. 2004).

Overweight rates among Asian–Americans are relatively low compared to other ethnic minority groups (Lauderdale and Rathouz 2000). Whereas Asian-Americans have been found to have lower Body Mass Index (BMI), they have a higher percent body fat than whites (Wang et al. 1994). A World Health Organization (WHO) expert consultation recently reviewed evidence suggesting that Asian populations have different associations between BMI, percent body fat, and health risks than European populations and concluded that while the international BMI specifications (<18.50 = underweight, 18.50–24.99 = normal weight, 25.00–29.99 = overweight, and >30.00 = obese; WHO 2000) should be retained, the proportion of Asians with a high risk of type 2 diabetes and cardiovascular disease is substantial at BMIs lower than the existing WHO cut-off point for overweight (WHO Expert Consultation 2004).

Findings from clinic, community, and population-based studies note that binge eating disorder is associated with overweight and obesity (Bruce and Agras 1992; Fairburn et al. 2000; Smith et al. 1998, Spitzer et al. 1992; Striegel-Moore et al. 2000) and the prevalence of binge eating increases with BMI (Telch et al. 1988). Given the high rates of obesity among ethnic minority populations, experts have hypothesized that binge eating or binge eating disorder is a significant concern among

these groups (Striegel-Moore and Smolak 2000). Interestingly, a recent study found that despite white women having statistically significant higher rates of binge eating disorder than black women (2.7% vs 1.4%), black women remained significantly more likely than white women to have ever been obese and be currently obese (Striegel-Moore et al. 2003). More data on the association between overweight/obesity and binge eating disorder in minority populations is needed.

160.3 Rates of General Disordered Eating Behaviors

Key features of disordered eating behaviors are outlined in Table 160.5.

160.3.1 Among Minorities

Various studies note the presence of general disordered eating behaviors among minority populations. For example, Hispanics were found to have equal rates of eating disturbances compared to whites, while blacks, Native Americans, and Asian Americans had lower rates than whites (Crago et al. 1996). However, black females in South Africa had higher rates of eating disorder symptoms than white females (Le Grange et al. 1998; Szabo and Hollands 1997). Black college women reported less fear and discouragement concerning food and weight control than white women (Gray et al. 2006). A meta-analytic review, based on data from over 17,000 participants, indicated that as a whole, white women living in Western countries experience greater eating disturbance and body dissatisfaction than nonwhite women (Wildes et al. 2001). However, results suggested that Asian American women report similar and in some cases higher levels of disordered eating than their white counterparts. For example, Asian women, who report weighing significantly less than white women, differ from white women in having higher body dissatisfaction in the magnitude of one-third of a standard deviation.

160.3.2 Among Adolescent Minorities

Research on disordered eating behaviors and dieting among adolescents from minority groups has also challenged preexisting assumptions about the prevalence of such behaviors. Data from the 1998 Minnesota Student Survey indicated that among 9th graders, 56% of girls and 28% of boys report disordered eating behavior (i.e., one or more of the following to lose weight: fasting or skipping meals, diet pills, vomiting, laxatives, and binge eating) and that among both genders, Hispanic and Native American youth reported the highest prevalence of disordered eating (Croll et al. 2002).

Table 160.5 Key features of disordered eating

Disordered eating	• Severe restriction of food intake (may include limiting type, quantity, or frequency of consumption)
	• Compensatory behaviors used to prevent weight gain such as laxative abuse, self-induced vomiting, fasting, diuretics, diet pills, and excessive exercise
	• Intense scrutiny of body (may include repetitively analyzing self in mirrors or pinching of body parts) or purposeful avoidance of seeing body (in mirrors or when changing clothes)
	• Negative feelings about body weight and shape
	• Self-esteem and self-evaluation largely influenced by perception of body weight and shape
	• Exaggerated sense of the importance of weight and shape

This table lists examples of various behavioral and cognitive symptoms of disordered eating

Another study found few differences between ethnic groups among adolescent girls on eating disorder symptoms whereas among boys, black, Native American, Asian/Pacific Islander, and Hispanic boys reported significantly more eating disorder symptoms than white boys (Austin et al. 2008).

Dieting was found to be associated with weight dissatisfaction, perceived overweight status, and low body pride among adolescents of all ethnic groups assessed (Story et al. 1995). Perceived overweight and body dissatisfaction were found to be consistent correlates of dieting and binge eating among white, black, Hispanic, Native American, and Asian American adolescent females (French et al. 1997). Among the leanest 25% of sixth and seventh grade girls, Hispanics and Asians reported significantly more body dissatisfaction than did white girls (Robinson et al. 1996). A survey of 6,504 adolescents indicated that Asians, blacks, Hispanics, and white adolescents all reported attempting to lose weight at similar rates (32.7%, 31.9%, 36.1%, 34.9%, respectively) while 48.1% of Native American adolescents were attempting to lose weight (Kilpatrick et al. 1999).

A recent study examining family adaptability, cohesion, and satisfaction among white and ethnic minority families of adolescents seeking treatment for BN found that there were no significant differences between whites and ethnic minority patients' perceived and ideal levels of family cohesion and adaptability, or level of family functioning (Hoste et al. 2007). Likewise, there were no significant differences between white and ethnic minority parents on these same measures. In fact, both white and ethnic minority patients perceived their families to be less cohesive than did their mothers and fathers and reported lower ideal levels of cohesion than their mothers and fathers.

160.4 Treatment

Primary care physicians play a critical role as a liaison between patients and potential eating disorder treatment. Such practitioners may benefit from being more aware of recent data on the prevalence of disordered eating behaviors among ethnic minority groups and attempt to provide thorough assessments to all suspect eating disorder presentations regardless of ethnic and/or racial backgrounds. In addition, increased knowledge regarding ethnic minorities' differing worldviews, values and beliefs, patterns of acculturation, assimilation, and immigration, effects of oppression, and ethnic identity, as well as naturally occurring individual differences within eating disorder diagnostic classification could serve to augment the physician's cultural sensitivity in assessment of eating disorder symptoms and provision of appropriate treatment referrals (NEDA 2005). A recent study found that ethnic minority patients were less likely to be referred for eating disorder treatment services than white patients although once treatment was offered, treatment type did not differ (Waller et al. 2009). Race-based stereotypes about the frequency of eating disorder among minorities have been found to prevent physician detection of eating disorder symptoms in black girls (Gordon et al. 2006). Data to date suggest the necessity of a re-evaluation of assumptions regarding who is susceptible to disordered eating in order to better ensure that our efforts to combat these issues are inclusive of all (NEDA 2005). In terms of response to treatment, a recent study found that black women, compared to other ethnic groups, demonstrated greater reductions in binge eating when treated with Interpersonal Psychotherapy rather than Cognitive Behavioral Therapy (Chui et al. 2007).

Erroneous assumptions about eating disorder prevalence, cultural influence, course of illness, and access to treatment among minority persons can create referral biases and differences in service availability and access and, consequently, make it more difficult to estimate the true prevalence of eating disorders in these groups (Dolan 1991; Crago et al. 1996). Data are needed to further our understanding about disordered eating behaviors among all ethnic and racial groups in order to prevent bias in assessment, prevention, and intervention endeavors.

160.5 Areas for Further Research

There remain a variety of areas in need of further research regarding disordered eating behaviors among ethnic minorities. First, further research is needed to better understand potential variation of psychosocial risk factors for eating disorders within a minority group. For example, a recent study of Hispanic women including Dominicans, Venezuelans, Columbians, Brazilians, Puerto Ricans, Central Americans, and Mexicans found that Dominicans, Venezuelans, and Columbians had significantly higher total scores on the Psychosocial Risk Factor Questionnaire and Concern subscale than White Non-Hispanics, Central Americans, and Mexicans (George et al. 2007) and that Puerto Ricans had significant higher BMIs and ideal body image scores than Brazilians. Second, additional longitudinal studies among minority groups, perhaps assessing eating disorder symptoms and risk factors within the same cohort over time, may serve to illuminate patterns that may change across the age span. The potential influence of level of acculturation on eating disorder development and maintenance, and the relationship between overweight/obesity and binge eating disorder among various minority groups should be explored further. It is also critical to ascertain variation in minority groups' access and response to eating disorder treatment. Last, consistent use of standardized eating disorder assessment instruments can facilitate cross-study comparisons. Such research will encourage the reexamination of assumptions regarding who is susceptible to disordered eating behaviors in order to better ensure that our prevention and intervention efforts are inclusive of all, regardless of ethnic and/or racial background.

Summary Points

- Data indicate that disordered eating behaviors are notably prevalent among ethnic minorities.
- It can be tentatively concluded that anorexia nervosa is rare among blacks.
- Data are mixed on whether the rates of bulimia nervosa among ethnic minority and white females differ.
- Rates of binge eating among ethnic minorities are higher than other forms of disordered eating.
- There remain a variety of areas in need of further research regarding disordered eating behaviors among ethnic minorities.
- Further studies of eating disturbances among minority groups are needed before firm conclusions can be made about disordered eating prevalence and risk factors in such groups.

Key Terms

Anorexia nervosa: Characterized by severely limiting food intake, refusal to maintain body weight at or above minimum normal weight for age and height, and intense fear of weight gain
Bulimia nervosa: Characterized by binge eating episodes that are followed by compensatory behaviors to prevent weight gain and reduce feelings of distention resulting from the binge episode
Binge eating disorder: Characterized by binge eating episodes without associated compensatory behaviors
Binge eating: Eating episodes defined as

(a) The consumption of an unusually large amount of food within a discrete time period (e.g., eating, within a 2-h time period, an amount of food that is unambiguously large) and

(b) Accompanied by a sense of loss of control over eating (e.g., feeling loss of control over type or quantity of food consumed, or unable to stop the episode from continuing once it has begun).

Purging: Compensatory behavior used to control weight and shape. Examples include laxative abuse, self-induced vomiting, fasting, diuretics, diet pills, and excessive exercise.

Disordered eating behaviors: Weight and shape controlling/influencing behaviors including but not limited to restrictive eating, fasting, excessive dieting and exercise, binge eating, vomiting, and abuse of laxatives, diet pills, diuretics.

Body Mass Index (BMI): A ratio that relates a person's body weight to their height. The ratio is weight (in kilograms) divided by height (in meters squared). Normal weight is defined as having a BMI of 18.5 through 24.9.

Overweight/obesity: Categorization based upon BMI. Overweight and obese are defined as having a BMI of 25.00–29.99 and greater than 30.00, respectively.

Ethnic minority: For the purposes of this chapter, ethnic minority refers to a subgroup of a population defined by ethnicity and/or race such as Asian Americans and Latinos.

Prevalence: A statistical concept which refers to the proportion of individuals in a population having a particular disease at a given time.

GNG	Go/No-Go task
HRV	Heart rate variability
IAPS	International Affective Picture System
IGT	Iowa Gambling Task
SAM	Self-Assessment Manikin
SMR	Startle motor reflex

161.1 Introduction

The cardinal feature of bulimia nervosa (BN) is bouts of uncontrolled food intake (binges). During bingeing, individuals ingest large amounts of food while experiencing an uncontrollable desire to eat. Individuals with BN tend to be highly concerned or dissatisfied with their body shape and, as a consequence, repeatedly display compensatory behaviors aimed at preventing weight gain. Compensatory behaviors include purging, excessive exercise, dietary restraint, or fasting between periods of binge eating (APA 2000).

S. Rodríguez-Ruiz (✉)

Departamento de Personalidad, Evaluación y Tratamiento Psicológico, Facultad de Psicología, Universidad de Granada, Campus de la Cartuja s/n, 18071, Granada, Spain
e-mail: srruiz@ugr.es

Individuals with BN are characterized by obsessiveness and perfectionism and by their greater impulsivity in comparison to anorexia nervosa (AN) patients (Fairburn 1995). BN patients also tend to be emotionally unstable, experience strong food cravings (Cepeda-Benito and Gleaves 2001), and be prone to substance abuse, sensation seeking, and antisocial behaviors (Rosval et al. 2006; Ortega-Roldán et al. 2009).

161.2 Loss of Control Over Eating and Sexual Behaviors in Women with Bulimia Nervosa

There are reasons to suspect that BN also has an impact on women's sexuality. First, the biological effects of severe dietary restrictions lead directly to dysfunctions of the reproductive system, affecting secondary sexual characteristics (Pirke 1995). Moreover, it seems plausible that individuals who are not comfortable with their bodies, such as individuals with eating disorders, will have difficulties in deriving pleasure from sexual activity (Wiederman and Pryor 1997). Finally, eating and sexual activity are highly self-reinforcing behaviors controlled by the primary appetitive motivational circuit in the brain: the mesolimbic dopaminergic system (Koch and Schnitzler 1997). This neurophysiological circuit may explain why women with AN seem to be able to go on without food and sex so consistently (Zuckerman 1994), whereas women with BN go through cycles of restriction and loss of control over both appetitive behaviors.

Published empirical research confirms that women with eating disorders (ED) tend to face disorder-specific sexual difficulties throughout their lives (Wiederman and Pryor 1997). Inadequate body weight in women with AN compromises the presence of secondary postpubertal characteristics and leads to a childlike appearance. Women with BN are more dissatisfied with their body image than women with AN, but BN individuals are able to maintain normal body weight and also engage more frequently in sexual activity than women with AN (Cash and Deagle 1996). Compared to controls, women with BN report more sexual activity and more pressure to "perform" sexually (Katzma and Wolchick 1984), as well as greater sexual dissatisfaction. This association between increased sexual activity and sexual dissatisfaction in women with BN seems to parallel their pattern of binge eating and subsequent dysphoria.

Based on clinical observations, several authors have suggested that impulsivity and loss of control seem to be the central clinical features that discriminate between BN and AN (Matsunaga et al. 2000). Zerbe (1993) has speculated that loss of control over eating prompts individuals with BN to attempt, in vain, to gain external approval through promiscuous behavior with new partners (see also Troop 1998). Interested in this hypothesis, we recently tested the extent to which women with BN and healthy controls differed in their reactivity to food images and erotic pictures (Rodríguez et al. 2007a). Women with (n = 24) and without (n = 24) BN observed a set of food and erotic pictures, together with neutral and unpleasant ones, all selected from the *International Affective Picture System* [IAPS]. Participants rated their feelings while viewing the pictures using the *Self-Assessment Manikin* [SAM] scales: valence (pleasant–unpleasant), arousal (activated–relaxed), and control (dominant–dominated). In comparison to women without BN, women with BN responded to the erotic and food pictures with lower scores in valence and control (see Fig. 161.1). These results suggest that women with BN experience less pleasure and control over both food and sexual impulses than healthy individuals.

The finding by Rodríguez et al. (2007a) of similar reactivity to erotic and food pictures is not surprising given that both eating and sexual behaviors are controlled by the same brain circuit (Bradley and Lang 2007). According to these authors, there are two primary motivational circuits

Fig. 161.1 Food and sexual-related stimuli used to test the emotional reactivity of women with bulimia nervosa (*BN*). Food images and erotic stimuli retrieved from the Internet with similar content to the International Affective Picture System (*IAPS*) pictures used in the study of Rodríguez et al. (2007a). Food and erotic pictures were rated by women with bulimia nervosa as less pleasant and controllable than women without bulimia nervosa

in the brain: the appetitive and the defensive. The appetitive circuit is mediated by the mesolimbic dopaminergic system (nucleus accumbens) and its activation is signaled by approach/consumption behaviors. The defensive circuit is mediated by the amygdala and other subcortical areas (e.g., stria terminalis, ventral tegmental area, and paraventricular hypothalamus, among others) and its activation results in avoidance/defense behaviors. For the majority of people, eating and sexuality are two basic gratifying activities that reflect the exclusive activation of appetitive mechanisms. However, sexual and food-related stimuli seem to evoke dyscontrol and negative mood in women with BN, an effect congruent with the simultaneous co-activation of aversive and appetitive motivations (Bradley 2000). Co-activation of both circuits would lead to a typical approach–avoidance conflict, explaining the observed reduction in pleasure and control in both eating and sex observed in individuals with BN.

The dyscontrol hypothesis also predicts that increased sexual activity leads to increased sexual dissatisfaction in women with BN. It has been suggested that individuals with BN use sexual activity instrumentally as a means of obtaining approval (Zerbe 1993) or of assuring continuity in their relationships (Katzma and Wolchick 1984). Some authors consider eating disorders the result of a faulty coping mechanism aimed at resolving unpleasant emotional states (Troop 1998). That is, women with BN may attempt to gain emotional relief and control by bingeing, or becoming sexually promiscuous. However, bingeing, like promiscuity, increases rather than decreases the feelings of dyscontrol and dissatisfaction.

161.3 Impulsivity and Impairment of Decision-making in Women with Bulimia Nervosa

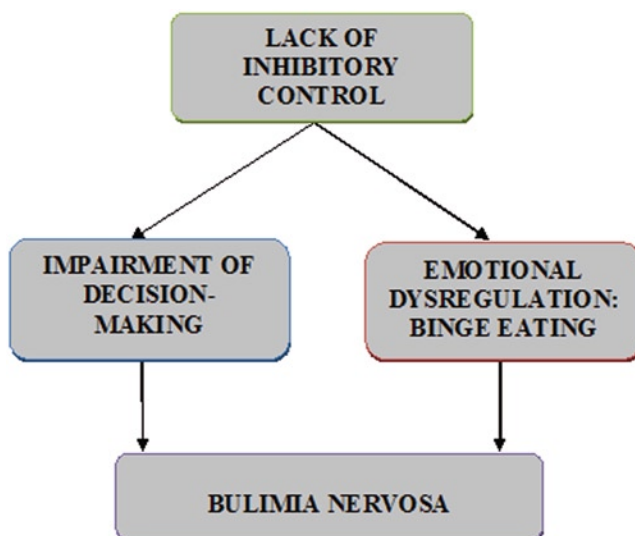
Whereas the cognitive and behavioral symptoms that characterize eating disorders have been researched since the beginning of the nineteenth century, our understanding of the neuropsychological characteristics of individuals with eating disorders is restricted to research conducted mostly over the past two decades. Neuropsychological research in this area aims to explore the possible implication of neural dysfunctions in the etiology of ED (Duchesne et al. 2004). The general symptoms that characterize ED have been associated with damage in the right frontal and parietal lobes. This finding was supported by reports of cerebral hypoperfusion in parietal, temporal, and right frontal lobes of patients with BN purging-type (BNP) and AN restrictive-type (ANR). Images of high-calorie food were associated with anomalous activity in the ventromedial prefrontal cortex and anterior cingulate cortex of patients with BN and AN (Uher et al. 2004). Thus, the presence of functionally altered cortical (cognitive) and subcortical (emotional) areas in the brain are congruent with some of the most frequent problems reported by BN patients: deficits in selective attention and in executive function related to poor inhibitory control (Figs. 161.2 and 161.3).


Fig. 161.2 Relationship between impulsivity, decision-making, and emotional dysregulation in bulimia nervosa. The poor inhibitory control shown by bulimia nervosa patients suggests that impulsivity may be a central and distinctive component of the disorder, mediating emotionally guided decision-making and binge eating behavior as demonstrated by Ortega-Roldán et al. (2009)
Fig. 161.3 Decision-making impairment in bulimia nervosa. The overall IGT performance of Bulimia Nervosa-Purging patients (*BNP*) was significantly worse than the one of the Anorexia Nervosa-Restrictive patients (*ANR*) or controls, which may be a consequence of their poor learning from rewards and punishments received during the course of the task (Reprinted from Ortega-Roldán et al. 2009. With permission)

The cognitive behavioral model of ED hypothesizes that ED symptoms are precipitated and maintained by maladaptive thoughts and dysfunctional assumptions about food. Research using the emotional *Stroop task* (Black et al. 1997) found higher interference and lower inhibitory control in bulimia and anorexia nervosa participants than in controls when presented words related to food, body shape, and weight (Fassino et al. 2002). Studies using the *Go/No-Go task* (Newman et al, 1985) to examine inhibitory control in ED patients have found greater impulsivity (see Table 161.1) in patients with BN and AN bingeing/purging type (ANBP), compared to patients with AN restrictive-type (ANR), and individuals without ED (Rosval et al. 2006). Finally, studies using the *Iowa Gambling Task* (IGT) (Cavedini et al. 2004; Davis et al. 2004) have found impairment of decision-making function (see Table 161.2) in individuals with AN, BN, and obesity, reflected by their inability to successfully perform the task.

The above findings on impulsivity, a key factor in emotionally triggered binge eating (Nederkoorn et al. 2004), prompted our team to examine the relationships between impulsivity, emotion, and decision-making in women with BN ($n = 14$), ANR ($n = 22$), and controls ($n = 29$) (Ortega-Roldán et al. 2009). Participants carried out two tasks: the IGT and an affective version of the Go/No-Go task. The IGT imitates real-life decision-making by means of a card game that evaluates the capacity to balance immediate rewards with long-term negative consequences. The affective version of the Go/No-Go task is a measure of motor impulsivity, since the participant must inhibit a behavioral response (pressing a key) to affect-related stimuli. Participants also completed a set of questionnaires on cognitive impulsivity, mood state, anxiety, and food craving. The results showed that patients with BN performed considerably worse in the IGT and Go/No-Go task than both AN and control participants. In addition, the results indicated that BN and AN patients performed differently in the Go/No-Go task, with BN participants showing greater cognitive impulsivity, more negative mood, and greater anxiety and food craving than AN participants. The poor inhibitory control shown by BN patients suggests that impulsivity may be a central and distinctive component of the disorder, mediating emotionally guided decision-making and binge eating behavior.

The lower performance in the IGT of BN than AN may be related to the different nature of both disorders. AN individuals may derive strong short-term reinforcement from successfully avoiding food intake, such as a reduction in their fear of becoming fat, at the expense of the long-term negative

Table 161.1 Key features of impulsivity

1. Impulsivity has been defined as the inability to think over when confronting a conflictive situation, resulting in failure to anticipate the consequences of one's actions, a rushed style when making decisions, difficulties in planning one's future behavior, and/or inability to exert self-control
2. Motor (or behavioral) impulsivity has been distinguished from cognitive (or choice) impulsivity
3. Motor impulsivity is equivalent to lack of response inhibition
4. Cognitive impulsivity is considered the inability to weigh the consequences of immediate and future events and, consequently, delay gratification
5. Motor impulsivity has been measured with a variety of instruments such as the Go/No-Go, reversal learning tasks, continuous performance tests, or stop tasks
6. Cognitive impulsivity has been measured using decision-making tasks such as the Iowa Gambling Task
7. Motor impulsivity is associated with impairments to the dorsolateral prefrontal cortex
8. Cognitive impulsivity is associated with impairments to the ventromedial prefrontal cortex

This table lists the key features of impulsivity, including the definition of impulsivity, the differentiation between motor and cognitive impulsivity, the measurement and the location of brain impairments for each type of impulsivity

Table 161.2 Key facts of decision-making

1. The generic structure of decision-making involves three independent processes:
(a) Appraisal of the stimuli or options
(b) Selection or execution of an action
(c) Evaluation of the experience or outcome of the choices that were made
2. Each of these stages may be differentially affected by various psychological and neural factors
3. When pleasurable or aversive events are confronted in one's immediate circumstances, appropriate somatic states are generated via activation of subcortical circuitry, and these emotions are subconsciously remembered for future occurrences of the same stimuli
4. The orbitofrontal cortex, in particular, is critical for activating feelings or emotional states from "thoughts" about rewarding or punishing events that are not currently present in one's environment
5. The behavioral deficits of the impaired decision-making are typically caused by an inability to advantageously assess future consequences
6. Poor decision-making is a core symptom of certain mental health problems such as drug dependence, mania, and some forms of eating disorder

This table lists the key facts of decision-making including the processes involved, the psychological and neural factors that influence these processes, the behavioral deficits of the impaired decision-making, and the affected populations

consequences of their behavior, i.e., severe physical and psychosocial impairments. Similarly, BN individuals appear to succumb to binge and purging impulses, arguably to escape negative emotional states, causing an unhealthy, long-term cycle of extreme dieting, bingeing, and purging.

On the other hand, the results obtained with the *Go/No-Go* task support the hypothesis that patients with BN have greater motor and cognitive impulsivity than patients with AN. Thus, our findings support the notion that lack of impulsivity diagnostically differentiates AN from BN.

161.4 Loss of Control Evoked by Dietary Restraint, Food Craving, and Binge Eating in Women with Bulimia Nervosa

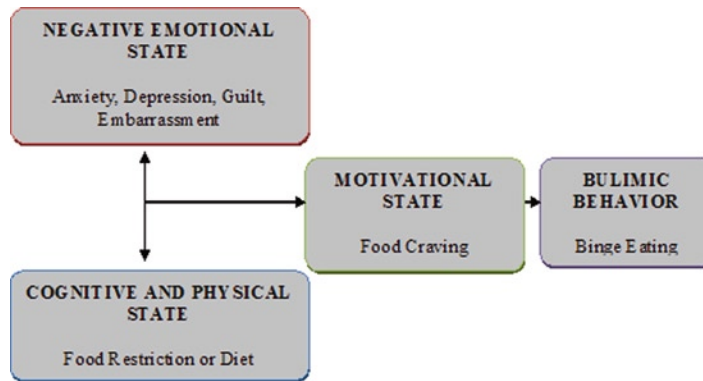
Women with BN not only show risk-behaviors (e.g., multiple sexual relationships) and impulsivity, they also experience very intense food cravings (Fig. 161.4). Craving has been defined as a state of strong desire to consume a given substance. Food craving has been linked to binge eating in women with BN, increased food consumption in restrained eaters, early dropout from weight-loss treatments, overeating in obese individuals, and lifetime prevalence rates of BN (Cepeda-Benito and


Fig. 161.4 Relationship between emotional states, dietary restraint, and food craving in bulimia nervosa. This model (Moreno et al. 2009a) proposes that a negative emotional state (such as anxiety, depression, guilt, embarrassment…) and a cognitive and physical state (associated with food restriction) are required to provoke a motivational state of food craving. The food craving might be a trigger of the binge eating as a typical behavior of bulimia nervosa patients

Gleaves 2001). The experience of craving has often been conceptualized as an "irresistible demand" for a substance and having a craving equates with losing control over the craved substance (e.g., Gendall et al. 1997).

Researchers have postulated that food craving plays an instrumental role in the development and maintenance of binge-eating behavior (e.g., Heatherton and Polivy 1992). For example, the starvation/dietary restraint model explains that dietary restraint practices produce a state of strong food craving that provokes a loss of control over eating (i.e., binge eating; Cepeda-Benito and Gleaves 2001).

However, it has also been reported that energy deprivation does not always precede food cravings and binge eating (Hill et al. 1991). Specifically, negative emotions such as anger, fear, or sadness have been found to increase binge eating among BN individuals, as well as in people diagnosed with Binge Eating Disorder (Agras and Telch 1998).

BN patients use binge eating to seek relief from their negative moods (anxiety, sadness, boredom…), but overeating also produces negative emotions as a consequence of the recognition of their inability to maintain control over their intake (Cavallo and Pinto 2001). Thus, food deprivation allows BN individuals to escape the negative affect produced by excessive consumption of food, and it may also be a maladaptive response to cope with other negative aspects of their daily lives. From this perspective, dieting may be considered a self-regulatory mechanism to reduce both the negative affect elicited by food intake and the fear of gaining weight (Mann and Ward 2004).

The effects of emotions on eating have been studied extensively, but less research has been conducted on how negative emotions modulate food craving responses as potential mediators of overeating (Waters et al. 2001). In order to better understand the relationship between negative mood and food craving, we asked women with BN ($n = 21$) and healthy controls ($n = 21$) to refrain from eating and drinking (except water) for 20 h (see Moreno et al. 2009a). Participants were asked to complete several self-report measures at different time intervals to assess mood, anxiety, and food craving. After the 20-h fasting period, all participants were allowed to eat as much as they wanted from a breakfast buffet. The number or calories and the portion of carbohydrates, proteins, and fats consumed were estimated for each participant by weighing the food and counting the servings remaining in the buffet.

The results showed that food deprivation increased food cravings in both BN and healthy controls, but that the effect was considerably greater in the BN participants. The results also demonstrated that emotional state and craving fluctuated together throughout the period of deprivation in both groups. Initially, food deprivation increased craving and negative mood in both BN and control

participants. However, as the fasting period increased, food craving was associated with higher negative mood and anxiety in healthy individuals, but with improved mood and reduced anxiety in participants with BN. Finally, although BN and healthy participants did not differ in the amount of food consumed, food cravings and caloric intake were positively correlated just in BN participants.

Together, our findings support several hypotheses put forth by numerous authors. The observed increase in craving as a direct result of fasting is congruent with the hypothesis that food deprivation increases the desire to eat and may lead to binge eating (Hill et al. 1991). This conclusion is further strengthened by the finding that craving and food intake were correlated in BN but not in healthy participants. That is, BN patients appeared to be particularly vulnerable to the effects of food cravings on food intake. The observation that prolonged fasting reduced negative emotions in women with bulimia nervosa support our earlier conclusion that women with BN escape negative emotional states through fasting (Mann and Ward 2004).

We also studied the nature of the relationship between dietary restraint and loss of control over eating in AN and BN participants (Moreno et al. 2009b). It was hypothesized that food craving would be highly prevalent in individuals known to have marked tendencies to temporarily restrain their diets but lose control over eating (BN participants), but would be rare in individuals with marked tendencies to restrain food intake but not break their diets (AN participants). Using the Discriminatory Factor Analysis (DFA) on the *Food Craving Questionnaire-Trait* (Cepeda-Benito et al. 2000) to differentiate between women diagnosed with ANR, ANBP, BNP, and BNNP, we found that patients with ED who reported very low levels of food craving were accurately classified as individuals with AN, whereas patients with ED that reported high levels of food craving were accurately classified as individuals with BN (Fig. 161.5).
Fig. 161.5 Food Craving Questionnaire-Trait (*FCQ-T*) scales for the different types of Eating Disorders. Mean scores of the nine scales of the Food Craving Questionnaire-Trait (*FCQ-T*) for Anorexia Nervosa-Restrictive (*ANR*), Anorexia Nervosa-Binge/Purging (*ANBP*), Bulimia Nervosa-Non-Purging (*BNNP*), and Bulimia Nervosa-Purging (*BNP*) participants. The order of scale presentation is Lack of Control over Eating (*LC*), Negative Affect (*NA*), Intentions to Eat (*IE*), Cue-Dependent Eating (*CD*), Preoccupation with Food (*PF*), Hunger (*H*), Guilty Feelings (*GF*), Negative Reinforcement (*NR*), and Positive Reinforcement (*PR*). Clearly, ANR patients reported the lowest levels of food cravings across the board, followed in ascending order by ANBP, BNNP, and BNP participants (Reprinted from Moreno et al. 2009b. With permission)

Overall, the above findings suggest that dietary restraint does not lead to food craving in individuals with AN. Food craving is associated with binge eating only in women diagnosed with BN. This result is congruent with the observation by Cepeda-Benito and Gleaves (2001) that a positive association between dietary restraint and food craving is confined to unsuccessful dieters.

161.5 Lack of Inhibitory Control on Physiological and Emotional Processes in Women with Bulimia Nervosa

Heart Rate Variability (HRV) has recently attracted the interest of scientists as an index of autonomic and emotional regulation. Thayer and Lane (2000) proposed a model of neurovisceral integration in which a network of neural structures associated with emotional and autonomic regulation is related to HRV via connections from the prefrontal cortex to the amygdala, and from the amygdala to the sympathetic and parasympathetic innervations of the heart. Numerous authors have found a negative association between vagally-mediated HRV and poor psychological and physiological functioning, including conditions characterized by a lack of impulse control, i.e., cravings (Ingjaldsson et al. 2003; Rodríguez-Ruiz et al. 2009). Experimental data also support a relationship between HRV and emotional regulation. High vagally-mediated HRV has been associated with larger orienting responses but faster habituation to nonthreat stimuli, whereas low HRV has been related to a failure to habituate (hypervigilance) and to greater defensive reactions (Thayer and Lane 2000).

The modulation of defensive reflexes also offers an interesting paradigm to examine autonomic and emotional regulation in BN. The magnitude of defense reflexes, such as the *startle motor reflex* and the *cardiac defense response* elicited by a brief acoustic probe stimulus, is augmented during viewing of unpleasant and threatening pictures and is reduced while viewing pleasant images (see Bradley 2000 and Vila et al. 2007, for review). The phenomenon has been explained, according to the *motivational priming hypothesis* (Lang 1995), as due to the congruence or incongruence between the emotional state induced by the pictures (positive versus negative) and the type of reflex being elicited (appetitive versus defensive): defensive reflexes are augmented if the organism is in a negative emotional state and reduced if the organism is in a positive emotional state.

Several studies have examined the modulation of defensive reflexes in people with eating disorders. Drobes et al. (2001) used this methodology to evaluate the affective state evoked by food stimuli in women who suffer from binge eating. The results showed that women who suffer from binge eating displayed an increased startle reflex when presented with food pictures. Nevertheless, some verbal, behavioral, and psychophysiological responses were consistent with an appetitive motivational reaction to food pictures, while other responses were consistent with a defensive one. Rodríguez et al. (2005) also found that the experience of chocolate craving included both appetitive (inhibition of the cardiac defense) and aversive (potentiation of the startle reflex) components. These findings suggested that the motivational circuits (appetitive and defensive) in women with bulimic symptomatology would be co-activated by food stimuli (Konorski 1967; Lang 1995).

Similarly, Mauler et al. (2006) studied the modulation of the eye-blink startle reflex while viewing food pictures in women without ED and those with BN (both groups under food deprivation and nondeprivation, respectively). Their findings showed a greater magnitude of the startle reflex to food pictures in women suffering from BN. However, food pictures did not elicit greater skin conductance responses in women with BN. These findings suggest that food pictures instead of provoking a typical fear response mediated by the sympathetic nervous system (*flight*) seem to provoke a disgust or anxiety response mediated by the parasympathetic nervous system. In addition, the startle reflex potentiation upon presentation of food pictures in patients with BN was attenuated by food deprivation, a

finding also reported by Rodríguez et al. (2007b). Thus, a period of successful food restriction might create a sense of control over food and this may render it less threatening.

Overall, the above findings are congruent with the observation that food deprivation increases craving but reduces negative mood in BN participants (Moreno et al. 2009a). This observation suggests that negative affect primed by food cues might motivate dietary restraint to ameliorate the negative affect associated with food intake in women with BN. It could be argued that individuals with BN make food less threatening by demonstrating control over their consumption through restrained eating.

Nevertheless, it has been reported that the above findings are also modulated by individual differences in emotional regulation indexed by HRV. Rodríguez-Ruiz et al. (under review) found that food cues evoked negative emotional responses, comparable to those elicited by unpleasant stimuli, in deprived individuals with BN and low HRV. Participants with BN and low HRV exhibited a substantial potentiation of their blink response magnitudes to all stimulus categories (see Fig. 161.6),

Fig. 161.6 Food, pleasant, neutral, and unpleasant stimuli used to examine the physiological reactivity of women with bulimia nervosa (*BN*). Food, pleasant, neutral, and unpleasant stimuli retrieved from Internet with similar content to the International Affective Picture System (*IAPS*) pictures used in the study of Rodríguez-Ruiz et al. (under review).
Fig. 161.6 (continued) All pictures provoked in women with bulimia nervosa and low HRV a greater eye-blink startle compared to those with bulimia nervosa and high heart rate variability (*HRV*), although food pictures evoked a blink response almost comparable to the augmentation that could be observed during the viewing of unpleasant emotional stimuli

although food pictures evoked a blink response almost comparable to the augmentation that could be observed during the viewing of unpleasant emotional stimuli. Deprived participants with BN and low HRV also labeled their feelings associated with food cues as more disgusting and uncontrollable than deprived participants with BN and high HRV and control participants.

Thus, our results confirm the inverse association between vagally-mediated HRV and psychological functioning (Thayer and Lane 2000). To sum up, HRV appears to modulate defensive reactions to food in BN individuals, supporting the hypothesis that poor emotional and autonomic regulation plays a role in the observed lack of inhibitory control in BN.

161.6 Applications to Other Areas of Health and Disease

The research reviewed in this chapter has potential applications. For example, IGT could become a useful tool for the assessment and treatment of ED patients. IGT provides an individual profile on the decision-making process of the individual and could be used to enhance the patient's awareness of the nature of his/her disease and improve patients' motivation for treatment compliance. IGT can also serve as a pre- and post-treatment measure to evaluate treatment outcome. IGT may be also useful in the detection of individuals at risk for ED. Finally, the data indirectly support the presence of neurological deficits in ED, with probable involvement of the frontal lobe, indicating that neuropsychological rehabilitation might be an appropriate treatment for these patients.

The clinical implications of the research on dietary restraint, food craving, and emotion in BN are twofold. First, it would be advisable, in the context of cue-exposure therapy, to elicit craving by means of manipulation other than mere food exposure and include strategies to modulate affective states, feelings of control over eating, and motivation to consume or avoid foods. The goal would be to elicit and extinguish the underlying craving factors that are most relevant to bingeing (e.g., negative affect and lack of control). Second, the effectiveness of cue exposure therapy might be increased if exposure is combined with physiological techniques aimed at improving emotional and autonomic regulation in patients with BN, as well as in patients with disorders characterized by lack of control (e.g., drug addiction). A number of nonpharmacological techniques have been used to increase HRV, including breathing training and HRV biofeedback (Lehrer et al. 1999). HRV biofeedback has been proposed as a powerful tool to help individuals learn emotional and autonomic self-regulation skills (Nolan et al. 2005).

Summary Points

- Impulsivity and loss of control seem to be the central clinical features that discriminate between bulimia and anorexia nervosas
- In our studies the women with bulimia nervosa experience lack of pleasure and control over both food-related and sexual impulses
- They showed significant motor impulsivity and an impairment of decision-making abilities based on short-term consequences, more negative mood, anxiety, and food craving than women with anorexia nervosa
- Prolonged fasting increased food craving and reduced negative emotions in women with bulimia nervosa since they escape from negative emotional states by fasting
- The positive association between dietary restraint and food craving is confined to unsuccessful dieters who lose control over eating as do women with bulimia nervosa
- In our studies the women with bulimia nervosa and low heart rate variability labeled their feelings associated with food cues as more disgusting and uncontrollable than women with bulimia nervosa and high heart rate variability
- To be effective, treatment interventions for bulimia nervosa must combine not only behavioral and neuropsychological approaches, but also physiological techniques aimed at improving emotional and autonomic regulation.

Definitions

International Affective Picture System [IAPS]: (Lang et al. 1999). The IAPS is an instrument for the study of emotion in laboratory settings. The IAPS is an instrument under continuous development created by the Center for the Study of Emotion and Attention, under the direction of Professor Peter J. Lang, at the University of Florida. It includes over 800 color photographs, in slide and digitalized format, belonging to different semantic categories: animals, nature scenes, house objects, naked people, erotic couples, human faces, mutilated bodies, weapons, food, sports, etc.

Self-Assessment Manikin [SAM]: (Lang 1980). The SAM is a universally applied instrument consisting of three pictographic nonverbal scales (valence, arousal, and control or dominance). It does not require language and is therefore easy to administer. The instrument provides information for each picture on three general emotional dimensions: valence (pleasant–unpleasant), arousal (activated–relaxed) and control (dominant–dominated).

Stroop task: (Stroop 1935). The Stroop task is a classic experimental paradigm to examine the Stroop interference effect, a measure of word reading's influence upon color naming. The procedure involves naming the color of a color word presented visually using the same or different color. The interference is quantified in terms of increase in reaction time to color naming when noun and presentation color are incongruent compared to the condition, in which they are congruent. The task demands resolution of a conflict between two competing tendencies, that of reading versus naming.

Go/No-Go task [GNG]: (Newman et al. 1985). The GNG is a computerized measure of motor impulsivity in which participants must try to inhibit their responses to certain stimuli, with the number of errors and false alarms indicating motor impulsivity.

Iowa Gambling Task [IGT]: (Bechara et al. 1994). The IGT is a computerized task that imitates a card game and is made up of 100 trials. Participants choose a card from one of four virtual decks (A, B, C, and D). Depending on the deck selected in each trial, the person gains (reward) or loses (punishment) symbolic money. Two of the decks, A and B, generate losses in the long term because, although profits are higher, so too are the losses. The other two decks, C and D, generate a profit in the long-term because the losses are smaller. The IGT score is calculated by subtracting the number of cards selected from decks A and B from the number of cards selected from decks C and D in each of the 5 blocks of 20 trials that comprise the task.

Food Craving Questionnaire-Trait [FCQ-T]: (Cepeda-Benito et al. 2000). The FCQ was created consistent with the theory that food cravings can arise from and be expressed as both physiologically and psychologically mediated processes. Using confirmatory Factor Analyses (CFA), the FCQ-T has yielded excellent fit indices for a nine-factor solution (e.g., Moreno et al. 2009b). The nine factor derived scales of the FCQ-T measure cravings experienced as or associated with: (1) *Positive Reinforcement*; (2) *Negative Reinforcement*; (3) *Cue-dependent Eating*; (4) *Feelings of Hunger*; (5) *Preoccupation with Food*; (6) *Intentions to Eat*; (7) *Lack of Control*; (8) *Negative Affect*; and (9) *Guilty Feelings*. The FCQ-T instructs participants to indicate how frequently each statement "would be true for you in general" using a six point scale that ranges from 1 (*Never* or *Not Applicable*) to 6 (*Always*). Full-scale and factor-scale totals can be calculated by simply adding the corresponding item scores.

Startle motor reflex [SMR]: (Lang 1995). The SMR is a pattern of motor activation elicited by sudden intense stimulation. The SMR in humans is based on the psychophysiological recording via the electromyography (EMG) of the orbicularis oculi muscle. The pattern and magnitude of the response can be obtained through both raw EMG and filtered EMG.

Cardiac defense response [CDR]: (Vila et al. 2007). The CDR is a complex pattern of heart rate changes to an intense acoustic stimulus with accelerative and decelerative components that appear in an alternate sequential order (acceleration–deceleration–acceleration–deceleration) during the 80 s following the presentation of the stimulus.

162.1 Introduction

The following chapter reflects qualitative data collected as part of a broader study that sought to understand how college-age women with bulimia nervosa experienced participating in a Mindfulness-Based Eating Disorder Treatment Group (Proulx 2008). In that phenomenological study, six college-age women who met the DSM-IV-TR criteria for bulimia nervosa (APA 2000) were interviewed prior to the group by the researcher. Initial data was collected and self-portraits were completed. Then the participants attended an 8-week mindfulness group designed and facilitated by the researcher. Journal data was collected during the group and the researcher kept notes for each group. When the group was completed, the researcher again interviewed each participant to explore their experience of the group. Final self-portraits were completed at that time. In addition to having bulimia nervosa for several years, participants also had comorbid mood or anxiety disorders and some were taking psychotropic medications. None of the participants met DSM-IV-TR criteria for substance abuse or Dissociative Identity Disorder (Table 162.1).

162.2 Bulimia Nervosa

In response to the cultural idealization of thinness, over 50% of adolescent girls think they are overweight and consequently diet (Fisher et al. 1995). Moreover, 5–10 million adolescent girls and women in the USA are estimated to struggle with eating disorders (National Eating Disorders Association 2006). Bulimia nervosa occurs in 1–4% of American college-age women (APA 2000).

Table 162.1 Key features of bulimia nervosa

- Recurrent episodes of binge eating characterized by both:
    1. Eating, in a discrete period of time (e.g., within any 2-h period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances
    2. A sense of lack of control over eating during the episode, defined by a feeling that one cannot stop eating or control what or how much one is eating
- Recurrent inappropriate compensatory behavior to prevent weight gain
    1. Self-induced vomiting
    2. Misuse of laxatives, diuretics, enemas, or other medications
    3. Fasting
    4. Excessive exercise
- The binge eating and inappropriate compensatory behavior both occur, on average, at least twice a week for 3 months.
- Self evaluation is unduly influenced by body shape and weight.
- Gradually binge eating becomes a response to emotional upset. It functions to reduce stress and is triggered by such emotions as anxiety, anger, and depression.

This table lists key criteria of bulimia nervosa as identified by the Diagnostic and Statistical Manual of Mental Disorders

Bulimia nervosa typically begins with a fear of weight gain and the need for dieting (Fairburn and Cooper 1982; Pipher 1994). Self-imposed starvation eventually leads to binge eating in 30–50% of patients with anorexia nervosa referred for treatment (Garfinkel et al. 1980; Hsu et al. 1979). The gradual breakdown of self-control and the emergence of binge eating typically occur about 9 months after the initiation of dieting (Garfinkel et al. 1980).

An episode of binge eating is characterized by eating, within a 2-h period of time, an amount of food that is definitely larger than most people would eat during a similar period of time in similar circumstances (APA 2000). Individuals with bulimia nervosa experience a sense of lack of control over their eating during the episode including the feeling either that one cannot stop eating, control how much one is eating, or control the type of foods eaten. Recurrent inappropriate compensatory behaviors include self-induced vomiting, the misuse of laxatives, diuretics, diet pills, medications, fasting, and excessive exercise. Individuals with bulimia nervosa are often normal weight or overweight, making it a hidden disorder.

Gradually, the eating binges get separated from mealtime or desire for food and become more and more a response to emotional upset. Once bulimia is entrenched, it functions to reduce stress and is triggered by such emotions as anxiety, anger, and depression. Over time, the behavior takes on a life of its own where eventually pleasure and normal interpersonal relationships are replaced by compulsion, secrecy, and guilt. According to Bruch (1988), the drive for excessive thinness experienced by young women with bulimia nervosa acts as a "cage" that constricts their psychological growth and the development of a genuine self.

Many women with bulimia nervosa are disconnected from their bodies and feelings, rendering them easily influenced by cultural pressures and peer expectations (Brown and Gilligan 1992; Pipher 1994). These women experience low self-esteem, anxiety, depression, and interpersonal difficulties (Bruch 1988).

162.3 Methodological Considerations

This chapter will focus on the phenomenology of living with bulimia nervosa as it emerged thematically from the qualitative data. Data analysis was completed from a phenomenological, interpretive Hermeneutic perspective (Husserl 1913/1983; Van Manen 1990), which included my own process of

self-reflection throughout every aspect of the study (Drew 1999, 2001, 2004). Once the data from the initial assessments, interview transcripts, self portraits, and journals were closely examined and highlighted, common themes were identified and then synthesized into an integrated whole.

162.4   Thematic Analysis of Living with Bulimia Nervosa

This section will present themes that emerged from the data analysis related to the participants' sense of self, coping skills, and interpersonal relationships. The first theme, "Waging War on a Fragile Self," is divided into two major subsections. The first subsection entitled the "Fragile Self" describes how the participants see themselves and reveals the highly judgmental quality of their attitudes towards themselves. The second subsection in this theme entitled "Waging War as a Means of Gaining Control" addresses how the participants try to cope with the day-to-day stress experienced in their lives. Family and cultural influences on identity and women's roles are imbedded within these themes. The names of the six participants: Ana, Kelley, Rena, Sophia, Eva, and Ruth as they appear below are fictitious to preserve their confidentiality.

162.5   Waging War on a Fragile Self

162.5.1   The Fragile Self

Each of the participants identified that their experience of themselves felt fragmented and incongruent. Their sense of self changed in different environments and seemed to vacillate between extremes. They internalized the media images of beauty and strove to achieve this standard of thinness as the most important measure of self worth and success.

Because of their high degree of disconnection from themselves, they were unable to receive accurate feedback from their bodies. They unanimously experienced self-loathing and distorted body perceptions. The commonalities of their experiences related to self are organized as follows: Hiding the truth, Hating myself, Distorting my body, and Keeping me from where I want to be.

162.5.1.1   Hiding the Truth: I Am Not Who I Seem On the Outside

Kelley is a graduate student who has experienced symptoms of bulimia nervosa for approximately 14 years (Fig. 162.1). Her problems with eating and body image began following a motor vehicle accident that immobilized her for several months. She abruptly went from having been very physically active to total inertia and began to gain weight. As she reflects on her first self-portrait in which she drew two separate images of herself, she comments that the two images are "polar opposites of me." "There is the completely horrible, ugly, fat way I feel inside which is also the way I think that other people see me now, and a 19 year old version of me that is thin, pretty, perfect, very put together, and confident."

In her initial self-portrait Kelley draws two completely separate versions of herself reflecting her sense of "being split within myself, like there are multiple versions of me in here."

Rena, a college junior with a performance major, describes herself as being made up of "sunshine and happiness which is the ultimate of what I want from life, as well as fatigue and depression, which

Fig. 162.1 Kelley's self portrait. This figure represents Kelley's first self-portrait. The left image represents the idealized, thin confident self and the right image is the horrible, ugly, fat, totally devalued self

is a plague on my life and not so good." She points out that in her first self-portrait, love was surrounding her but was outside of her. Her focus was on being thin, pretty, and perfect in order to attract the prince who would provide her with love so she could feel sunny and happy evermore.

She was hoping for a man to feed her the love she craved so she could feel good about herself (Fig. 162.2). She believed that in order for any man to love her, she had to be thin and beautiful. When a man would hurt or reject her she would blame herself and think, "What did I do wrong? What's wrong with me? Look at my stomach, that's why it all went wrong."

Before the start of one group, Rena verbally told me she was having a very stressful day and was feeling quite depressed, all the while smiling, laughing, and impeccably dressed and groomed. Her affect and appearance were incongruent with her verbal description of how she was feeling and how she had experienced her day.

Sophia, a graduating senior, has had problems with bulimia nervosa since middle school. She is interested in Buddhism and feminism and so remarks about her "inability to find a middle ground", a topic she has been writing about all semester. She sees herself as "vacillating between extremes and torn between all the dichotomies of life." Sophia approaches every interpersonal situation with pre-planned ideas of "who I think I am and how I think I ought to act or how I've got to be." She adds, "When I am in a room with a bunch of people I would become those people. They envelop me instead of me being able to stay grounded in myself. I don't feel a core self."

Ruth is a junior student experiencing some academic problems this semester due to her mood instability and problems with focus and concentration. Out of all the women, Ruth was the most apprehensive about participating in a group. She had never joined a group before and indicated that her greatest fear was "hearing about my problem coming out of someone else's mouth." Secrets are really important to Ruth, which is why she was so apprehensive about coming to the group. She had

Fig. 162.2 Rena's self portrait. This figure represents Rena's first self-portrait. It depicts her belief that she must be thin, pretty, and perfect in order to attract the prince whose love would bring her happiness. She is dependent on external sources for validation and love

never told anyone about her eating disorder. She was ambivalent about keeping her secrets in that, although her secrets made her feel special, they also kept her separate from others. She worked hard at presenting herself as happy, funny, outgoing, and competent but expressed the following in her journal: "Fucking body. Fucking secrets. DO YOU UNDERSTAND THAT I AM NOT ON THE OUTSIDE THIS PERSON ON PAPER – DO YOU UNDERSTAND? I like who I am on the outside; I love myself. I am a very good person. Nobody knows. My mom knows about my anxiety and depression, but I still have my fucking secrets (bulimia, cutting), even from her."

Ana, a graduate student, who continues to live with her abusive parents admits, "I have to be two different people, like I am one person inside the house with my family but as soon as I step outside the house, I become somebody else, like I have to smile." Ana recognizes that she so urgently wants "approval from authority figures and peers that I won't rock the boat or stir up trouble for fear that people won't respect or like me." The outcome is that she sacrifices getting her needs met or creating authentic connections in her life, especially with herself. She is frustrated with herself, "I need to find myself in me but I don't know how to do that. I don't know how to be happy in myself." With respect to connections with others she describes, "I always tried to hide myself behind my hair…so people wouldn't see my face (Fig. 162.3)."

Eva was an undergraduate freshman and the youngest member of the group with a history of trauma, depression, and bulimia nervosa. She was experiencing significant emotional distress over the first 3 weeks of the group, frequently tearful and, on one occasion, needing to be seen at urgent care at the health service for symptoms of anxiety. Of all the participants, Eva was perhaps the least

Fig. 162.3 Ana's self portrait. This figure represents Ana's first self-portrait. It demonstrates her preoccupation with weight and how her sense of self is totally connected to her external appearance

verbal about her experience in the group but as you will see below her initial self-portrait is quite remarkable with respect to the experience of self-fragmentation (Fig. 162.4).

It is evident from Eva's self-portrait that she experienced herself as fragmented, disconnected, and barely held together.

162.5.1.2 Hating Myself

All the participants believed their sense of self worth was entirely contingent on perfectionistic standards of accomplishment and external validation and approval from others. The women were consistently self-critical and judgmental and felt the need to constantly compare themselves to others.

Ruth describes her tendency towards self-criticism, "I'm sooo hard on myself… I bash, I bash, I bash…I'll say, Damn, I should have done that. And then all the would've, could've, should've cross my mind. I am judging myself without even thinking about it."

Eva explains that she is "overly self-critical" and describes "a constant barrage of negative self-talk such as 'You know you're not doing this right'." Or "Why can't I do it correctly?" She adds that if she falls short of her goals or self-expectations, she is "devastated." Her self worth is reliant on her accomplishments, primarily in the academic realm. She is generally unaccepting of her body shape and size and feels self-conscious about her appearance.

Rena was a performer who had several shows at the end of the semester. These were very stressful experiences for her. She shared that she is very critical of her performances so that, even if people she admires complement her, she continues to doubt and degrade her abilities. "I can never say I'm

Fig. 162.4 Eva's self portrait. This figure represents Eva's first self-portrait. It clearly depicts the fragility of Eva's sense of self

proud of my performance because there's always something wrong with it." She uses words such as "heferly" and "walrus" to describe her body size, even if others reassure her she is attractive.

Both Ruth and Ana had actresses on their original self-portraits reflecting the cultural image of what is valued as real beauty. Actresses in our culture set the standards for beauty and the ideal towards which women should strive. The actresses on their posters (Elizabeth Taylor, Katherine Hepburn, Renee Zellweiger) were thin, beautiful, glamorous women whom Ruth and Ana actually resembled (Fig. 162.5).

162.5.1.3   Distorting the Body

The women objectified their bodies as a "thing" to be "controlled and manipulated". They regarded their bodies as nonself, thereby justifying their regular abuse of their bodies. By placing their highly judgmental focus on their objectified bodies, they were distracted from the painful underlying emotional turmoil they felt powerless to change. As the women strove to meet self-imposed, perfectionistic standards, their level of stress rose, which they then took out on their objectified body, creating a never-ending cycle of self-dissatisfaction, failure, and guilt.

In reflecting on her first self-portrait in which she depicts two distinctly separate selves (Fig. 162.1), Kelley notes that in the right hand self representation,

> I didn't even have a neck because I just did not feel at all connected to my body. I could not feel anything; I was just numb. I perceived it more like the Michelin Tire man, the one that's like a stack of tires, like a snowman. That's kind of how I felt, like a series of ripples of fat stacked together or something. But I was missing any connection between my body and mind.

Kelley remembers that while some people may not like what they see when they look in a mirror, she took it one step further, "When I looked in the mirror I would simply say that isn't me." She totally

Fig. 162.5 Part of Ruth's self portrait (**a**). Part of Ana's self portrait (**b**). These figures display components of Ruth and Ana's Self-portraits related to their idealization and identification with glamorous movie stars who are held as the standard of beauty in our culture

refused to have a conscious connection with her body. She further illustrates her disconnection from her body by recounting this story, "A couple of years ago I wanted to know what I looked like to other people so I actually took pictures of myself without my head because I didn't want to know that it was me." She adds that she has no pictures of herself after the age of 23.

Following a body scan, Ruth commented that if her stomach could talk with her it would say, "You hurt me with all you put me through." Her response was "You know, I'd think about my stomach as another unit, a thing, not a part of me."

In looking at her first self-portrait (Fig. 162.2), Rena remembers that she deliberately left off her body because "There is so much more I can think and laugh about without having to worry about the thing that's attached to my head." She confesses she had thoughts of "just wanting to get a knife and cutting off her abdomen" she hated it so much.

In exploring with Ana ways that she could begin to nurture herself more she observed,

> I guess I don't recognize my body as being important or valid. I know that my body needs to be taken care of and that it doesn't deserve all the treatment from my parents and myself, its just so much easier for me to be caring to somebody else.

162.5.1.4 Keeping Me from Where I Want To Be

As the participants reflected on their earlier self-portraits, significant insights emerged regarding the depths of their inner emptiness and emotional fragility, inability to tolerate the intensity of their emotions, and unending fears of not being good enough or lovable. Although each of these women was

Fig. 162.6 Part of Ruth's self portrait (**a**). This figure was included in Ruth's initial self-portrait. Ruth felt that her bipolar disorder and intense moods interfered with her ability to reach her full potential and created problems in her relationships
obsessively focusing on body shape and size, controlling all aspects of eating and exercise, they clearly felt out of control and overwhelmed on an emotional level.

The women identified experiencing very intense emotions that were difficult to regulate and that interfered with their functioning at times. Anxiety was a common emotion that frequently escalated to the level of panic. Most of the women had been treated for symptoms of depression. One woman had bipolar disorder. Several women had experienced significant traumatic events in their lives. The angry feelings experienced by the women were primarily viewed as negative and frightening. Participants also identified guilty feelings, for not being good daughters, for displeasing others, or in response to their own anger.

In her initial self-portrait (Fig. 162.6), Ruth poses the question: "Are depression symptoms keeping you from where you want to be?" She worries,

> that question will go with me for the rest of my life. Right now it's keeping me from where I want to go. It kept my grandmother from going where she wanted to go. Sometimes I just break down uncontrollably and I can't…I lose all control, and that's really scary. In the past I would take out my anger and frustration on the people closest to me, like my family. I would beat them with words and I felt so bad afterwards.

Eva shared with the group that she has problems managing her anger. When faced with conflict within her family she would become very angry and retreat to her room, slamming the door and turning off communication. During family therapy she learned how to be assertive and has found that helpful. She has had problems with depression since age 16 and there is a maternal family history of depression as well. During the time of the mindfulness group, Eva was having symptoms of panic, which was making it difficult for her to sit through class, thereby interfering with her schoolwork.

Sophia recalls being an angry, difficult child and that she frequently expressed her anger through head-banging behaviors. She first experienced depression as a high school sophomore, which

included irritability and self-harming behaviors. She describes being abusive to her boyfriend at the time. In addition, Sophia experiences problems with social anxiety that can culminate in panic attacks. Her mother also has a history of depression and eating disorder. As a result of her experiences within her family and her own depression, anxiety, and bulimia, Sophia had difficulty feeling positive about herself and establishing healthy relationships. She often felt that she lost herself in relationships with others.

> If you threw me in a room with a bunch of people and they were the only people I had to interact with, I am afraid that I would become those people, and that's really scary. Especially when lets say, it's a room full of misogynists, which leaves me hating myself. That's why I fear looking at magazines and stuff like that, because I feel like it will envelop me, instead of me being able to take a position against it.

Rena has experienced symptoms of depression since seventh grade marked by extreme self-criticism and thoughts of hopelessness such as "life is not worth living." She also can become highly anxious and experience panic attacks. Rena's mother and maternal extended family have been treated for depression. Rena recognizes that the level of self-hatred and self-criticism she experiences can have a detrimental effect on her performance and will hinder her career aspirations.

Kelley tracks the onset of her depression to her father's unexpected death by motor vehicle accident. Her father's death was very difficult for Kelley and she continues to harbor guilt feelings. Her anxiety and depression have kept her feeling dependent and inadequate. She admits there is a part of her that is terrified of finishing her degree and beginning a professional career beyond the university. Because of this, she delayed her comprehensive exams and remained in an abusive relationship for quite some time.

Ana experiences intense feelings of grief and sadness for the childhood she did not have within her abusive family. She often blames herself for the abuse and explains,

> I feel like the abuse is my fault, like I haven't been that good to my parents; or like I'm betraying them if I get angry about the way they treat me. The anger goes inside and that's what like goes to the eating and stuff because there's no other place for it. Usually my parents focus their abuse on me and I take some pride in the fact that this protects my two younger brothers; but if my brothers do something really crazy and my parents focus on them, I feel guilty since I'm the oldest and should protect them.

Ana also experiences symptoms of panic when her mother is berating her for long periods of time. She typically turns her emotions against herself rather than externalizing them. She is desperate for approval from others so avoids conflict as much as possible. She has learned to experience pleasure somewhat vicariously by observing others having fun, with little expectation of experiencing happiness for herself.

162.5.2 Waging War as a Means of Gaining Control

This second subsection of the theme describes the strategies used by the participants to cope with stress in their daily lives. Their choice of coping methods is connected to their experience of themselves as described above. Although in the short term the strategies they used helped to lower the intensity of their emotional turmoil, over time these choices perpetuated their sense of fragmentation, ineffectiveness, and lack of control within themselves and within the world. Their experiences are synthesized as follows: Numbing out; Going into Trance; Binging; Purging; Weighing, Measuring and Constantly Comparing; Cutting; and Abusing Alcohol and Pot.

162.5.2.1 Numbing Out

Many of the participants unconsciously used denial rather than face the emotional pain of their situations, particularly in relation to family dysfunction and past trauma. Being aware of and facing

emotional pain is very difficult for all of us, but for the women in this study who experienced a fragmented, inadequate sense of self, it was especially overwhelming.

Sophia experienced a great deal of emotional numbness to create an illusion of calm. She became aware of this emotional numbness while completing self-awareness assignments in the group. In attempting to notice pleasant and unpleasant events she recognized that she does not allow herself to experience any emotions at all. She explained,

> Numbness is not in and of itself a bad thing. It's sort of like a placid thing. It becomes problematic when something is being covered up or isn't being handled. Its harder to notice problems when things are placid, so then a variety of symptoms may emerge such as anxiety, depression, and bulimia nervosa.

Sophia used a great deal of numbing out to avoid her angry, sad feelings about her family situation. She did not feel comfortable with those feelings and preferred to feel nothing.

162.5.2.2 Going into Trance

Going into trance is another way that participants unconsciously tried to manage powerful, unpleasant feelings. When the stress of a situation was sufficiently high, an alternate mode of consciousness took over to protect them from the painful feelings of their current experience.

In describing her choice of spiral as a representation of herself, Sophia explained, "the spiral characterizes the experience of a drowning kind of hypnotic thing, like falling into a tunnel, and where your mind goes away (Fig. 162.7)."

Fig. 162.7 Sophia's self portrait. This figure represents Sophia's self-portrait. She describes that the spirals represent her tendency to use dissociation to cope with stress. Several of the women describe dissociation as part of the binge–purge cycle

In situations where she experiences extreme emotional distress such as when her mother is verbally abusing her or she experiences personal rejection, Ana described the following,

> When I get very wound up there's something inside me that I feel like is not even me, that automatically sets in and I can't stop it. Its like I go into a trance and binging is all I can think about. Nothing's satisfied until the binge is over. The trance takes over and everything else stops.

Ana has not found a way to stop the trance from occurring. Nor has she found anything that soothes her as completely as a binge when she is feeling her worst emotionally.

162.5.2.3 Binging

Several of the participants identified that when they felt stressed, they frequently binged. Binging with food was self-soothing. Binges were frequently anticipated in advance and a great deal of time and energy went into the planning. Social opportunities were passed up if they would interfere with the binge. Guilt and shame commonly followed the binge, triggering the urge to purge or to socially isolate.

Ana has occasional success with delaying the urge to binge but she notes that there are times when she wants to binge and will consciously choose to binge because she has been unable to find anything else that is as self-soothing. She is aware that the urge to binge is associated with stress and remembers that she started eating instead of crying during high school. "My mother was always big on appearances so when I began to wear mascara in high school I stopped crying because I had to look good and crying would cause my mascara to run." Moreover,

> I didn't want my parents to have the satisfaction of seeing me cry. I knew they had control over everything I did and I didn't want them to have control over me too. I guess I always thought of crying as weakness and once my parents knew how to get to me they would use it against me over and over. I didn't want to give them something else to hurt me with. With eating, once I cleaned up all the food, they never noticed.

Ana knows the locations of many grocery stores between school and home. She will buy food in the store and eat it secretly in her car. She worries what her roommate thinks when large quantities of food come into the dorm room and quickly disappear.

Ruth describes the previous week as follows,

> I didn't stop eating and throwing up one after the other. I couldn't sit still, I didn't sit while I ate, I jumped around fidgeting, scrounging around in my cabinets looking for more to eat. Right now, I don't have enough money to eat normally, never mind to binge with. I sneak into the dining halls and go crazy.

When Kelley feels anxious and depressed she goes to fast food restaurants, buys large quantities of fast food, isolates in her apartment, and eats and sleeps for an entire weekend. She will cancel social obligations, not do any work, and stay in bed around the clock. If friends come to her door she won't let them in because all the food wrappers are visible. Other times she will purchase large quantities of food at the grocery store, spread it out on her bed, and eat is as fast as she can. Kelley bakes desserts in large quantities, which she rarely eats but just keeps in her apartment or sends to relatives.

When Sophia feels stressed she isolates in her room and eats large quantities of whatever food is available, although she prefers sugary foods and carbohydrates such as ice cream, cake, or cereal. She eats until she literally feels ill and then stays alone until the gastric symptoms subside. She alternates between the extremes of binging and restricting and struggles to achieve moderation. Sophia shared her story of buying an entire cake for herself in preparation for a binge. She had the bakery write "happy birthday Joe" on the top of the cake so that if she ran into a classmate, she then had a story to hide her true purpose. She remembers occasions even in middle school where she would binge on food on returning home from having been out socially with friends.

162.5.2.4 Purging

Purging refers to the compensatory behaviors participants used to rid their body of the food or calories resulting from a binge. The two main purging behaviors that the women reported using were inducing vomiting or compulsive, rigorous exercise. Each of these will be described below.

162.5.2.5 Vomiting

Each of the participants acknowledged that stress and anxiety led to purging behaviors. Purging generally followed eating, and was not always in response to a binge. Just the sensation of food in the stomach could result in purging. For most participants, vomiting was cyclical in relation to stress levels and could occur following every meal. Following the initial lowering of anxiety that resulted from vomiting, guilt and shame frequently ensued. The women felt isolated by their secret behaviors. For some vomiting could occur spontaneously with minimal or no inducement.

On spring break Ruth went home to visit her family. She and her mother went to a tearoom for lunch and Ruth ate tiny tea sandwiches, scones, and drank tea. She wrote in her journal,

> Such a nice place and what do I do? I got up to the bathroom and threw it up! Then what? The toilet didn't flush the vomit away (which Ruth has perfected over the years). Then I noticed a sign *Antique Plumbing*. Blah, Blah, Shit! What do I do?!!! Panic. People are outside waiting! Waiting! I wait until the water stops hissing and flush a second time but still lettuce is floating on top. I try to sift it out with my fingers, but still a few left. Why didn't I throw up in the garbage? Sometimes I do that. Throw up in paper towel and stick it under wads of used towels. I flush a third time and walk out. Panicky that people next in line will know. Will they say something? My hands are shaking; itty-bitty shakes that rattle my teacup. My chest is aching, pressure.

Ruth has been purging since high school. Her eating symptoms began as restricting (anorexia) but then she switched to binging and purging since the effects of bulimia could be hidden from her mother. Her binging and purging episodes may be correlated with her mood swings. There are stretches of time when she purges multiple times a day at least following every meal alternating with a period of time when she is not binging or purging at all or only a few times per week. Generally if she is eating more than she would like, she will purge. If her eating is restricted, there is less need to purge.

As a performer, there are times when Rena cannot purge since this adversely affects her performance. At times, she has performances daily over the course of a week. She relates that, "As soon as my performances are over, the first thing I do after I eat is just purge." She notes that when she feels very stressed she finds it difficult to tolerate the feeling of food in her stomach. Usually purging will alleviate the feeling and lower her stress. At those times when it is not possible for her to purge, she may then engage in self-mutilation as an alternative means of lowering her stress.

Kelley has purged for so long, it happens reflexively with minimal stimulation. Just brushing her teeth results in vomiting. She has to warn her dentist to use a light touch or she vomits in the chair. Kelley tends to vomit every morning on awakening without any noticeable precipitant. On one occasion she began to wretch in my office while exploring deeply emotional issues related to her fears of taking care of herself as an adult.

162.5.2.6 Exercising

An alternative way to purge is through excessive exercise. The goal is enhanced body shape and lowered weight, rather than health. The workouts have a compulsive, frantic quality to them, so if they are missed or shortened, the women experience feelings of guilt and failure.

Ana exercises excessively and compulsively. Prior to the mindfulness group she was jogging on a treadmill at home for 10 miles or 3 h daily. Occasionally she jogged twice a day. Missing a workout created tremendous guilt and anxiety.

Kelley described herself as "rigid" in regards to her exercise routine. She would not allow herself a day off and would only work out on a certain piece of equipment. If someone else were using the equipment, she would either pressure that individual to give up "my machine" or leave the gym angry and resentful. She could never override her need to go the gym for any reason.

Rena was forcing herself to go to the gym in order to work out at the end of a full day of classes during which time she had only eaten "lightly." She confides, "The exercising I do now is like punishing myself, really it is. I've never really liked going to the gym. I watch the clock and it's just a pain. Even while doing Palates I have to be distracted by music or some kind of dance moves."

Eva historically was a gymnast and was a member of the crew team at school. Practice for crew was daily and entailed hours of grueling exercise and rowing beginning in the early morning hours before dawn. She was used to being very physically active which had reduced her need to restrict or purge. Eva decided to drop crew because playing a sport and academic pressures had overwhelmed her. With less physical activity, her eating and purging markedly increased.

162.5.2.7 Weighing, Measuring, and Constantly Comparing

Each of the participants was obsessively preoccupied with their body shape and size. They compulsively weighed themselves, scrutinized themselves, compared themselves to others, and counted calories and fat content in their diet.

As Rena puts it,

> Beauty, I'm obsessed with beauty and any achievement thereof. That, together with the perfectionist in me, grows eating disorders. I want to be like a Barbie doll but I can't because, even at my thinnest, I have a certain size bone. I wake up in the morning and I'm just like 'Oh gosh you look awful' because I'm expecting to see a size 4 in the mirror, but I'm a size 10 or 12."

She historically has counted carbohydrates, fat, and calories, and measured and weighed herself after grueling exercise workouts.

Kelley is preoccupied with her appearance and weight. She was so unhappy with her body that she would only use the exercise machine at the gym that was located in the corner next to the wall away from the mirrors. That way neither she nor anyone else could see her while she exercised. She tended to weigh herself frequently at home and at the gym and would set specific weight loss goals for herself. Her standard of comparison was her own body image at age 16. She has cycles where she restricts her food intake and exercises regularly alternating with loss of control of her eating resulting in binging and purging.

Sophia reveals that she is really neurotic about her diet.

> If I eat pizza it has to be completely blotted and then I pick half the cheese off. I have so many habits in terms of food. It has to do with the fact that I am not accepting of a certain weight. I chronically buy clothing that is too small for me and then I have nothing nice to wear.

162.5.2.8 Cutting

Sometimes, as an alternative to purging, women in the M-BED Group turned to self-mutilation to reduce intolerable levels of stress and anxiety. While some of the women were continuing to use cutting to lower emotional distress, others had used it in the past, but had stopped.

 In her journal, Rena wrote about what these episodes were like for her,

I was feeling tired and weak from a long day of classes, followed by an hour of exercise with nothing to eat. While I was undressing to take a shower, I happened to glance in the mirror and had never looked so disgustingly fat. I freaked out and began to hyperventilate. All I could focus on was my walrus-sized gut. I didn't know what to do. There was nothing in my stomach to throw up, so I cut my wrist. What I really wanted to do was to cut my stomach open and drain out whatever was in there making me fat!!! I HAVE to be thin.

Only a few days later Rena again viewed herself in the mirror and judged herself to be "incredibly, disgustingly fat." She again "freaked out" and began to have a panic attack. She was feeling all alone and unable to accept her body size. She could not throw up because of a performance the following day. All she could think of was to hurt herself. She cut herself with a pair of scissors and with a piece of glass hoping that "draining my blood might make me thinner." She wrote in her journal, "My mind is out of control and I want to destroy all my mirrors and murder any humans who decided thin was desirable."

Sophia had a history of cutting herself in high school but has not had recent self-harming behaviors. Like wise, Ruth had cut her arms between the ages of 12–14 but not recently. In fact, Ruth had an angry reaction to the group's discussion of Rena's cutting behavior. Ruth wrote in her journal "When I hear the mention of cutting I cringe, I feel ill to my stomach." She obsesses about a visible scar on her arm from a time she cut herself at age 14. This scar is very upsetting to her because she feels people who see it know her secret (similar to the lettuce floating in the toilet).

162.5.2.9 Abusing Alcohol and Pot

In another attempt at lowering stress and anxiety, two of the women used marijuana and alcohol to relax and numb intense emotion. Ruth relates that she was a "little pothead" during high school and that now she drinks, "to have fun and to make myself happy." While drinking last year, Ruth had an unwanted sexual experience about which she continues to feel angry and taken advantage of (Fig. 162.8).

Fig. 162.8 Part of Ruth's self portrait (C). This figure represents a part of Ruth's initial self-portrait. It reveals her tendency to rely on alcohol and drugs to cope with stress. At the bottom, she refers to her unwanted sexual experience and her residual guilt, shame, and anger

Sophia was not very academically motivated when she started college. She was still struggling with depression and ended up partying with drugs and alcohol through freshman year. After counseling and a medical withdrawal in her sophomore year, Sophia stopped using drugs and alcohol, realized she had nothing in common with her old friends, and transferred to a college that could better meet her academic and social needs.

162.6 Implications for Recovery from Bulimia Nervosa

Human vulnerability and suffering is an existential given (Chodron 1997; Clemence 1966; Peck 1978). This human "wound" (Todres 2004), common to us all, can serve as a vehicle for hardening (becoming psychologically defended) and closing off to relational life or softening (remaining vulnerable and open) and extending empathy as the great connector to relational life on behalf of humanity's shared "wound" (Salzberg 1997; Todres 2004; Welwood 2000). It is clear that in response to their human vulnerability, these six women were experiencing extremes in their thoughts, feelings, and behavior. They felt worthless, unlovable, inadequate, powerless, victimized, angry, sad, and numb. They were out of touch with their authentic selves, their bodies, and their personal needs. The women could not trust themselves or others to meet their needs because their needs were perceived as being either too great or altogether unimportant. Because they were so disconnected from their inner selves and because of their underlying, negative beliefs about themselves, the women experienced great difficulty regulating their extreme feelings, causing their behaviors to become out of control. Based on their temperaments, family experiences, and cultural expectations, they developed a belief system that if they achieved the perfect body size and shape, they would be seen as successful and loveable. In response to this belief system, they adopted the coping behaviors of restricting eating, which then progressed to binging and purging. When controlling food and purging activities were insufficient or unavailable, many of the women resorted to cutting themselves to obtain relief from their excruciating feelings and self-loathing. The women's thoughts, feelings, and behaviors were aimed at control, self-sufficiency, and completeness in response to their internal sense of lack of control, dependency, and incompleteness. They had grown to hate their personal experience of vulnerability and human need, closing off to authentic relational life with self and other.

Binging and purging, as private and secret activities, isolated them from others, creating a deep sense of loneliness. The women experienced shame regarding their behaviors, further lowering their self worth. In the mean time, they engaged in a driven and endless pursuit of external achievements, abusive or sexualized relationships, and culturally defined beauty in a futile effort to feel lovable.

162.7 Application for Other Areas of Health and Disease

Bulimia nervosa reflects an underlying disorder of self and, as such, effective treatment requires a trauma-informed, interdisciplinary, integrated approach that restores both physiological and psychological health. Because of the serious medical risks associated with bulimia nervosa, consistent medical and nutritional monitoring and education are central to recovery. Concurrent with these interventions, a phase model of psychotherapeutic treatment is essential that includes cultivating a therapeutic relationship, providing ongoing psychoeducation, building a positive support system, and developing nonharming coping skills. Depending on the severity of the symptoms and the presence of comorbid disorders, additional therapies that may be helpful to the recovery process include mindfulness-based approaches (Proulx 2008), sensorimotor approaches (Ogden et al. 2006), ego

state work (Seubert 2008), Eye Movement Desensitization and Reprocessing (EMDR) (Forgash and Copeley 2008; Shapiro 2009), dialectical behavioral treatment (Linehan 1993), and cognitive behavioral treatment (Fairburn et al. 1993). Up to 40% of women with bulimia nervosa do not respond to traditional treatments and symptoms can become chronic with deleterious medical, psychological, and social outcomes (Fairburn et al. 1992; Stice 1999). Bulimia nervosa is a mind-body disorder that responds best to the active collaboration of many healthcare disciplines.

Summary Points

- The women in this study with bulimia nervosa lacked connection with their inner selves as well as their bodies.
- They experienced deep self-loathing and were highly self-critical.
- They sense of lovability became related to the achievement of external, cultural ideals of beauty, thinness, and perfection.
- The symptoms of bulimia, which originated as a way to control body size and shape, became a coping strategy for lowering stress and regulating emotion.
- The addictive coping cycle compounded feelings of shame and guilt and was cloaked in secrecy and isolation.
- In up to 40% of women with bulimia nervosa, the condition can become chronic, with significant medical sequelae.
- To be effective, treatment interventions for bulimia nervosa must not only address health and nutritional concerns, but also the lack of self-connection, self-compassion, and effective coping strategies that are not self-harming.

Definitions

Cognitive behavioral therapy: A therapy developed by Beck that is aimed at changing maladaptive, distorted thoughts and behaviors to lower depression and anxiety. Relaxation and deep breathing exercises are emphasized behaviorally.

Dialectical behavioral treatment: An empirically tested, cognitive-behavioral treatment approach developed by Marsh Linehan to assist individuals with symptoms of borderline personality disorder to improve the quality of their lives by learning how to regulate emotions, tolerate emotional distress, and improve their interpersonal effectiveness.

Ego state therapy: A therapeutic approach developed by Watkins & Watkins that identifies and connects with all parts of the personality for the purpose of relieving symptoms and healing conflicts. Ego states formed in childhood trauma may function maladaptively in present life situations. Ego state therapy helps the healthier, core parts of the self to collaborate with and reparent the immature, wounded parts of the self.

EMDR: Eye Movement Desensitization and Reprocessing is a therapeutic intervention developed by Francine Shapiro that utilizes dual stimulation to activate the information processing system allowing individuals to transform dysfunctionally stored traumatic events into a normal narrative memory that is no longer disturbing.

Hermeneutic phenomenology: a philosophy and qualitative research methodology that attempts to understand the internal world or lived experience of human beings by "going to the things themselves." The researcher approaches the phenomenon with rigorous self- awareness and an

open mind in order to more deeply understand and accurately interpret the specific phenomenon. It is based on the beliefs of Husserl, Heidegger, Gadamer, and Merleau-Ponty.

Mindfulness: Paying attention to one's moment-to-moment experience with an attitude of non-judgment. Derived from Buddhist mediation practices and adapted to Western culture as a life style that has been shown to lower stress and depression.

Sensorimotor approaches: Based on the belief that traumatic experience disrupts the body's physiological and emotional regulation, these approaches advocate for working with the body's own defensive systems, autoregulatory patterns, and adaptive responses to promote reconnection with the body.

SCID	Structured Clinical Interview for the DSM
SRED	Sleep-related Eating Disorder
SSRI	Selective Serotonin Reuptake Inhibitor

163.1 Introduction

Night Eating Syndrome (NES) is a delay in the circadian pattern of food intake, manifested by evening hyperphagia (consuming ≥ 25% of the total daily food intake after the evening meal) and/or nocturnal awakenings accompanied by ingestions of food (O'Reardon et al. 2004). First recognized by Stunkard and colleagues (1955), research on the nosology, etiology, pathophysiology, and treatment of NES has advanced over the past decade. This chapter will provide an overview of NES, including a brief history of its conceptualization over the past 50 years, its prevalence and comorbidity, hypothesized etiology and pathophysiology, its consequences and treatment, and will end with a review of future directions needed to further characterize the nutritional, behavioral, and neurobiological aspects of NES (Table 163.1). Other chapters in this section will review in detail the current status of the neurobiological and neuroendocrine aspects of NES.

Table 163.1 Key facts of NES

Diagnosis	NES research diagnostic criteria have been developed and should be used in future studies to diagnose NES
Prevalence and comorbidity	The prevalence of NES in the general population is low (around 1.5%) and increases with adiposity and psychiatric symptoms
Etiology	The etiology of NES is unknown, but likely involves behavioral/functional (i.e., night eating serves to help someone sleep), nutritional, neuroendocrine, and pathophysiological mechanisms
Health implications	Studies of the relationship between NES and obesity are equivocal, although certain populations may be at higher risk for weight gain due to night eating (e.g., those who are already obese or taking weight promoting medications). More research is needed on the health implications of NES
Assessment and treatment	Validated assessment measures and efficacious treatments exist for NES. Individuals with NES should be referred for treatment to a qualified healthcare provider

NES night eating syndrome

Table 163.2 Comparison of 1955 and 1999 NES diagnostic criteria

Symptom domain	1955 NES criteria[a]	1999 NES criteria[b]
Evening hyperphagia	Consumption of large amounts of food in the evening and night; at least 25% of total calories for the day during the period following the evening meal	Evening hyperphagia ≥ 50% of total daily energy after the evening meal
Sleep disturbance	Sleeplessness, at least until midnight, more than half of the time	Awakening at least once a night
Nocturnal ingestions	–	Consumption of snacks during the awakenings
Morning hunger	Morning anorexia with negligible food intake at breakfast	Morning anorexia, even if the person eats breakfast
Duration	–	At least 3 months
Other diagnoses	–	Person cannot receive a diagnosis of NES if they meet criteria for BN or BED

This table compares the 1955 and 1999 proposed diagnostic criteria for NES

NES night eating syndrome, *BED* binge eating disorder, *BN* bulimia nervosa

[a]Criteria cited in Stunkard et al. (1955)

[b]Criteria cited in Birketvedt et al. (1999)

163.2 History of Night Eating Syndrome

NES was first described in 1955 as a disorder of morning anorexia, evening hyperphagia, and insomnia, usually accompanied by depressed mood and stressful life circumstances (Stunkard et al. 1955). Table 163.2 shows the original diagnostic criteria outlined by Stunkard and colleagues (1955).

NES did not receive much research or clinical attention until the 1990s, coinciding with increasing rates of obesity and the search for factors related to excessive weight gain. In 1999, Birketvedt and colleagues added awakenings with ingestions of food (*nocturnal ingestions*), increased the percent of food consumed after the evening meal from 25% to 50% (*evening hyperphagia*), and added duration and rule out criteria to those originally described in 1955 (see Table 163.2 for a comparison of the diagnostic criteria). Additionally, they noted that NES affects both obese and nonobese persons, which is an observation that has become more important as discussions of the clinical significance of NES have ensued.

163.3 Current Conceptualization of NES

As research has advanced our understanding of NES, the diagnostic criteria for NES have continued to evolve, making comparisons across studies difficult. In an effort to move NES research forward based on current research evidence, the First International Night Eating Symposium (April 26, 2008, Minneapolis, MN) was held to reach a consensus on a set of provisional research diagnostic criteria for NES and to discuss a roadmap for future NES research. Approximately 20 researchers in the areas of eating disorders, obesity, and sleep attended the meeting and contributed to the development of the proposed research diagnostic criteria presented in Table 163.3.

These criteria offer the most comprehensive conceptualization of NES to date. The first criterion reflects the notion that NES is at its core a disorder of eating and circadian rhythm. This is manifested by either the consumption of an unusually large percent of the total daily food intake in the evening hours after the evening meal (*evening hyperphagia*) and/or the consumption of food upon awakening in the middle of the night (*nocturnal ingestions*). Figures 163.1 and 163.2 demonstrate the differences in eating patterns of individuals diagnosed with NES compared to weight matched controls.

O'Reardon and colleagues (2004) found that obese persons with NES did not consume significantly more total daily calories than weight matched controls, but they did have a strikingly different circadian pattern of food intake (Fig. 163.1). Weight matched controls showed typical increases in food consumption during the lunch and supper hours, whereas night eaters had a steady food intake that continued until 6:00 a.m. the following morning. There were no significant differences in sleep onset or offset times, indicating that the circadian sleep pattern is not delayed in parallel with the food intake delay, but the night eaters did report significantly more awakenings per night (1.5 vs. 0.5 awakenings).

Table 163.3 2009 Proposed research diagnostic criteria

Symptom domain	Diagnostic criterion
Eating pattern	I. The daily pattern of eating demonstrates a significantly increased intake in the evening and/or night-time, as manifested by one or both of the following:
	(A) At least 25% of food intake is consumed after the evening meal
	(B) At least two episodes of nocturnal eating per week
Awareness of eating behavior	II. Awareness and recall of evening and nocturnal eating episodes are present
Associated mood, hunger, and sleep features	III. The clinical picture is characterized by at least three of the following features:
	(A) Lack of desire to eat in the morning and/or breakfast is omitted on four or more mornings per week
	(B) Presence of a strong urge to eat between dinner and sleep onset and/or during the night
	(C) Sleep onset and/or sleep maintenance insomnia are present four or more nights per week
	(D) Presence of a belief that one must eat in order to initiate or return to sleep
	(E) Mood is frequently depressed and/or mood worsens in the evening
Distress/impairment in functioning	IV. The disorder is associated with significant distress and/or impairment in functioning
Duration	V. The disordered pattern of eating has been maintained for at least 3 months
Other diagnoses or Medical conditions	VI. The disorder is not secondary to substance abuse or dependence, medical disorder, medication, or another psychiatric disorder

This table shows the 2009 proposed research diagnostic criteria for NES. These criteria are comprehensive and based on more recent research than those presented in 1955 and 1999 (see Table 163.2)

Cumulative Caloric Curves For Controls vs. NES Participants
Fig. 163.1 Comparison of 24-h food patterns of obese persons with NES and weight-matched controls. This figure illustrates the significantly different circadian patterns of food intake between obese persons with night eating syndrome and weight matched controls, although the total caloric intake is not significantly different over 24 h (Reprinted with permission)
Fig. 163.2 Comparison of 24-h food patterns of non-obese persons with NES and weight-matched controls. This figure illustrates the significantly different circadian pattern of food intake between nonobese persons with night eating syndrome and weight matched controls. Total daily caloric intake is significantly greater for the group with night eating syndrome (Reprinted with permission)

Lundgren and colleagues (2008a) found nearly identical patterns of delayed circadian food intake in nonobese night eaters compared to weight matched controls (Fig. 163.2). Nonobese night eaters, compared to weight matched controls, however did consume significantly more total calories per day (night eater = 2284.5 kcal; control = 1856.2 kcal). Nonobese night eaters had significantly more nocturnal awakenings and ingestions of food than did controls.

Currently, only evening hyperphagia *or* nocturnal ingestions are necessary to meet the first proposed NES diagnostic criterion. This criterion was left intentionally broad because further research is needed clarify the relationship between these two manifestations of the circadian delay of food intake, and because individuals often report both behaviors. For example, Lundgren and colleagues (2008a) found that 84% of nonobese individuals with NES met criteria for both evening hyperphagia *and* nocturnal ingestions of food. In another study of night eating in women diagnosed with bulimia nervosa (BN), however, Lundgren and colleagues (2008b) found that only 14% of BN patients with night eating features reported both behaviors. More research is needed to clarify this core criterion.

The second criterion (Table 163.3), that awareness and recall of evening and nocturnal eating episodes are present, was proposed to differentiate NES from parasomnias such as sleep-related eating disorder (SRED) (Howell et al. 2009). Persons with SRED can consume food in the middle of the night, do so while in a sleep-walking state, and often consume nonfood items. Although persons with NES occasionally report a lack of full awareness with nocturnal ingestions of food, they must report awarness and recall of the nocturnal eating episodes in general.

At least three of five additional features must be present in order for one to receive a diagnosis of NES (Table 163.3). These include a lack of morning hunger or omission of food in the morning, a strong urge to eat either after dinner or upon awakening in the middle of the night, difficulty falling or staying asleep at night, presence of a belief that one must eat in order to return to sleep, and mood that is frequently depressed and that may worsens in the evening hours.

Evidence of problems with morning hunger, morning food omission, and sleep disturbance in individuals with NES is presented in Figs. 163.1 and 163.2. Anecdotal evidence and that collected with self-report instruments, such as the night eating questionnaire (NEQ; Allison et al. 2008) suggest that many persons with NES experience a strong urge to eat after dinner or upon awakening in the middle of the night. Allison and colleagues (2004) noted several different themes associated with these urges, including cravings for specific foods, anxiety and agitation, distress about sleep disruption, and feeling compelled to eat/needing to feel full to sleep.

Similarly, some persons with NES feel that they must eat in order to fall asleep initially or to fall back asleep after a nocturnal awakening. Again, this is assessed with the NEQ (Allison et al. 2008) and is often described as a function of night eating for some who suffer from NES (Allison et al. 2004).

Night eating syndrome is associated with mood disturbance in some individuals. Stunkard and colleagues (1955) noted this disturbance in their original description of NES and several studies have confirmed that night eaters have high rates of comorbid mood disorders and increased scores on depression measures (Gluck et al. 2001; de Zwaan et al. 2006; Lundgren et al. 2008a). Interestingly, persons with mood disorders are not necessarily at increased risk for NES (Lundgren et al. 2006). A recent SPECT study has provided preliminary evidence that the pathophysiology of NES and MDD is distinct (Lundgren et al. 2009), and will be reviewed in a later chapter.

Finally, the night eating and associated features must cause distress and impairment, be present for at least 3 months, and not be better explained by another psychiatric diagnosis, medical condition, or medication/substance. The conditions which are frequently comorbid with NES, in addition to mood disorders, will be reviewed below.

163.4 Prevalence of NES

The prevalence of NES varies substantially depending on the criteria used to diagnose it and the population under study. To date, no studies have examined the prevalence of NES using the recently proposed research diagnostic criteria (Table 163.3). Studies using previous criteria have provided a general sense of the magnitude of NES in the general population, among obese individuals, and

Table 163.4 Prevalence of NES

Population	Prevalence (%)	Citation
General population	1.5	Rand et al. (1997)
	1.6	Striegel-Moore et al. (2006)

Psychiatric	27	Rand et al. (1997)
	3.8	Allison et al. (2007)
	9.7	Morse et al. (2006)
	12.3	Lundgren et al. (2006)
	25	Lundgren et al. (in press b)

This table shows the prevalence of night eating syndrome in several populations

among other psychiatric populations, such as those with eating disorders and severe mental illness (Table 163.4).

Variability in prevalence is due to differences in assessment measures, diagnostic criteria, and populations.

Prevalence of night eating in the general population has been reported at 1.5% (Rand et al. 1997) to 7.1% (Lundgren et al. 2010a). Prevalence rates in special populations suggest ranges of 6% (Stunkard et al. 1996) to 16% (Adami et al. 2002) in weight loss samples of class I and II obesity. Among bariatric surgery candidates, the range in prospective interview studies is 9% (Allison et al. 2006) to 27% (Rand et al. 1997); Allison and colleagues (2007) found a prevalence of 3.8% among older adults in a large multicenter study of type 2 diabetes (Allison et al. 2007).

Three studies have examined the prevalence of night eating in other psychiatric populations. Lundgren and colleagues (2006) found a prevalence of 12.3% in two university outpatient psychiatric clinics which included patients with a variety of Axis I and Axis II psychiatric disorders. In a sample of weight loss seeking individuals with serious mental illness (schizophrenia, bipolar disorder, and severe major depressive disorders), the prevalence of NES was striking at 25% (Lundgren et al. 2010b). It is unlikely that participants grossly over-reported night eating behavior in this sample, as only 5.9% of participants met the criteria for binge eating disorder (BED) (Lundgren et al. 2010b). Finally, Lundgren, Shapiro, and Bulik (2008b) reported that nearly half of women seeking outpatient treatment for BN reported evening hyperphagia, nocturnal ingestions of food, or both core symptoms of NES. These later prevalence studies suggest that much research on the comorbidity of NES, especially the temporal relationship of night eating to other psychiatric symptoms is needed.

163.5 Comorbidity of NES

163.5.1 Medical Comorbidity

The most commonly studied medical comorbidity of NES is obesity (Stunkard et al. 1955, 1996; Colles et al. 2007; Lundgren et al. 2010a) and early descriptions of NES suggested that it was a pathway to obesity. Andersen and colleagues (2004) found that endorsement of the question "Do

you get up at night to eat?" prospectively predicted weight gain among obese women in the Danish MONICA study. Recently, Lundgren and colleagues (2010a) found that nocturnal eating, but not evening hyperphagia, was associated with obesity in a sample of community adults.

Not all studies have supported a relationship between NES and obesity. Using large national databases Striegel-Moore and colleagues (2005, 2006) did not find an increased risk of obesity with night eating; these studies, however, were not designed to assess NES specifically, but were based on 24-h food record data. More recent research, however, has suggested that obesity may only be associated with NES in certain populations. For example, psychiatric outpatients with NES were nearly five times more likely to be obese than the non-night eating outpatients (Lundgren et al. 2006). Discrepancies in studies examining the comorbidity of NES and obesity suggest that more work, using similar diagnostic criteria, is needed to understand the relationship between NES and obesity.

163.5.2 Psychiatric Comorbidity

High rates of psychiatric comorbidity have been noted among persons diagnosed with NES. Lifetime prevalence of Axis I disorders assessed by the Structured Clinical Interview for the DSM (SCID) is high among those with NES. Lundgren and colleagues found that 74% of night eaters, compared with 18% of controls had at least one comorbid Axis I diagnosis (Lundgren et al. 2008a). Mood disorders are common and NES has been related to high rates of lifetime diagnosis for major depressive disorder at 52.6% (Lundgren et al. 2008a), 55.7% (de Zwaan et al. 2006), and 57.1% (Boseck et al. 2007). Lundgren and colleagues (2008a) also found high rates of anxiety disorders among NES patients (47.4%).

Fewer studies have examined the comorbidity of NES among psychiatric samples. Lundgren and colleagues (2006) examined the prevalence of NES in psychiatric outpatients with a variety of diagnoses. In this sample, the only diagnoses to co-occur with NES were current and lifetime histories of substance use disorders. Participants prescribed atypical antipsychotics were more likely to be diagnosed with NES compared to those not prescribed this class of medication, but in this study serious mental illness was not associated with NES. In a follow-up to this study, Lundgren and colleagues (2010b) found that obese adults with serious mental illness who were prescribed psychotropic medications were at risk of NES, with nearly 25% of the sample meeting criteria. Combined, these studies suggest that there is perhaps a synergistic effect of obesity, medication use, and psychiatric symptoms that increase risk of night eating behavior.

The relationship of NES to other eating disorders has also been investigated. The comorbidity of BED and NES ranges from 5% to 20% (Stunkard et al. 1996; Geliebter 2002, Allison et al. 2005b, 2007; Striegel-Moore et al. 2005). Few studies have examined the relationship between NES and anorexia nervosa (AN) or BN. Lundgren and colleagues (2008b) found that 35.5% of women seeking outpatient treatment for BN reported evening hyperphagia of at least 25% of their caloric intake after dinner, and 19.3% reported eating at least half of their intake after dinner. It is unclear, however, whether their reported evening hyperphagia is distinct from evening binge eating episodes. More striking, however, is that 38.7% of the patients with BN reported at least occasional nocturnal ingestions, while 12.9% reported eating during awakenings at least half of the time. More research is needed to clarify the relationship of NES to these other eating disorders.

163.6 Hypothesized Causes of NES and Potential Pathophysiology

The causes of NES are unknown and hypothesized explanations include behavioral/functional (i.e., night eating serves to help someone sleep), nutritional, neuroendocrine, and pathophysiological. From a behavioral level of explanation, the onset of NES is often associated with a life stressor (Allison et al. 2004; Stunkard et al. 2006) and the function of night eating behavior could be to calm someone who experiences difficulty with sleep onset and/or maintenance and help him or her return to sleep. In a review of common thoughts experienced by persons with NES, Allison and colleagues (2004) point out that many people with NES have a core belief that they must eat in order to return to sleep. This explanation is informative for behavioral and cognitive-behavioral treatments for NES, but alone do not explain the development of NES.

Early hypotheses involving nutritional deficits or carbohydrate craving were suggested by Birketvedt and colleagues (1999). They found that the proportion of carbohydrates consumed during night eating episodes was greater than during the day and that the carbohydrate to protein ratio was 7:1 during nocturnal ingestions. More recent data have not supported such differences in the proportion of macronutrient content of foods consumed during the night versus the day (Allison et al. 2005a).

Neuroendocrine and pathophysiological abnormalities have been noted among persons with NES. These will be reviewed in detail in later chapters.

163.7 Consequences and Clinical Significance of NES

Although NES research has progressed significantly in the past decade, there are lingering questions about the consequences of evening and nocturnal eating. Specifically, questions have been raised about its *clinical significance*, given that late evening dinners and midnight snacking are normative in different cultures. The clinical significance of NES has been challenged even more as studies on NES and obesity have been equivocal (see above) and because earlier versions of NES diagnostic criteria did not specify that distress or impairment in functioning due to night eating be present for a diagnosis. The most recently proposed criteria (Table 163.4) have included such specifiers. Other than obesity, the two primary health consequences of NES that have been reported in the literature are diabetic complications and poor oral health.

Morse and colleagues (2006) examined night eating in individuals with Type I and II diabetes. They found that patients with NES were less adherent with their nutrition and exercise plans, as well as glucose monitoring. Night eaters' had higher A1C values and were more likely to have diabetes complications than non-night eaters. No studies have reported the prevalence of metabolic syndrome among persons with NES, and more research is needed to replicate Morse and colleagues' findings.

In a recent study, nocturnal ingestions of food, but not evening hyperphagia, predicted poor oral health on a variety of oral heath indices (Lundgren et al. 2010a). Specifically, nocturnal eating was a significant predictor of the number of missing teeth, periodontal disease, and active tooth decay.

163.8 Assessment and Treatment of NES

Assessment of NES can be aided with the help of self-report inventories, interviews, and food records. A description of common NES assessment measures is presented in Table 163.5. The NEQ (Allison et al. 2008) is a brief self report inventory which assesses the pattern and timing of food

Table 163.5 Commonly used NES assessment measures

Measure	Description
Night Eating Questionnaire (NEQ)	14-item self report inventory which assesses the pattern and timing of food intake, hunger and cravings for food, and mood and sleep difficulties. Administration time is approximately 5 min. Published in Allison et al. (2008)
Night Eating Syndrome History and Inventory (NESHI)	Semi-structured, unpublished interview available from Drs. Albert Stunkard and Kelly Allison at the University of Pennsylvania. This interview assesses current eating behavior, cravings, sleep patterns, and mood, as well as the history and precipitating NES factors. Administration time is approximately 30 min
Night Eating Diagnostic Questionnaire (NEDQ)	Similar to the NEQ, this brief measure provides information on one's eating patterns, sleep, and mood, as well as diet and weight history. It has recently been revised to reflect proposed research diagnostic criteria, and can be obtained from its authors (Gluck et al. 2001). Administration time is approximately 5 min
Food Record	Prospective food records which assess the timing of food intake, type of food consumed, and amount of food consumed and which can be helpful in identifying night eating patterns and in confirming night eating behavior. Week-long food records are preferred as they provide more stable estimates of night eating behavior than 1–2 day records or recalls
Dietary Recall	Dietary recalls assess the timing, type, and amount of food consumed retrospectively and typically focus on the previous 24-h. Recalls can be helpful in assessing very recent night eating behavior, but are less useful than prospective food records at assessing night eating behavior for longer periods of time
Actigraphy	Actigraphy can be used to assess patterns of activity and sleep. Actigraphs can be purchased through commercial suppliers and are useful in research studies to verify nocturnal awakenings

This table shows assessment measures that are available for screening and diagnosing NES
NES night eating syndrome

intake, hunger and cravings for food, and mood and sleep difficulties. The NEQ can be used as a symptom or screening measure, and a score of 30 or greater is suggestive of NES (Allison et al. 2008). The Night Eating Diagnostic Questionnaire (NEDQ) (Gluck et al. 2001) is useful in establishing a diagnosis of NES. It has recently been revised to reflect the proposed NES diagnostic criteria (Table 163.3) and can be obtained from its authors.

For a more thorough assessment of one's current and past night eating patterns, the Night Eating Syndrome History and Inventory (NESHI) can be used. It is an unpublished, semi-structured interview that assesses the current and past symptoms of NES, precipitating factors, familial night eating patterns, and treatment attempts. It can be obtained from its authors, Drs. Kelly Allison and Albert Stunkard at the University of Pennsylvania.

Finally, food and sleep records, dietary recalls, and actigraphy are essential in documenting eating and sleeping patterns in both research and clinical contexts. Food records and sleep records can be used to establish antecedents of night eating and treatment targets. Actigraphy is helpful in verifying nocturnal ingestions of food and in studying sleep/activity patterns.

With the increased research interest in NES over the past decade, several promising therapies have been developed and tested. Three studies have found that the selective serotonin reuptake inhibitor (SSRI), sertraline, significantly reduces evening hyperphagia, night-time awakenings, and nocturnal ingestions of food, as well as body weight (O'Reardon et al. 2004, 2006; Stunkard et al. 2006). These studies were the impetus for examining the role of serotonin transporter in the development and maintenance of NES, which is reviewed in a later chapter.

Cognitive behavioral therapy has also shown promise for treating NES. In a pilot study patients have shown a benefit, including a weight loss of 3 kg for completers, which is comparable to that seen with sertraline (Allison et al. 2010a). The combination of pharmacotherapy and psychotherapy has not been tested; this may prove to be a useful approach in the future.

Investigators have also reported some success with progressive muscle relaxation (Pawlow et al. 2003), paroxetine (Miyaoka et al. 2003), and light therapy (Friedman et al. 2002). Further research is necessary to confirm these findings and to determine whether behavioral weight loss treatment would be effective for reducing weight and NES symptoms.

163.9 Future Directions

As can be concluded from the review of NES above, the research community is just starting to develop a knowledge base of the causes and correlates of NES. Several research initiatives are underway to further characterize NES, including the standardization and testing of the newly proposed NES Research Diagnostic Criteria (Allison et al. 2010b; Table 163.4). As these new criteria are being tested, several aspects of NES are in need of more research, including its health implications, its relationship to other eating disorders, obesity, and sleep disorders, its pathophysiology, and its treatment. Later chapters in this section will review state-of-the-art findings on the neuroendocrine aspects of NES as well as recent research on the potential role of serotonin transporter in its pathophysiology. Significantly more research is needed in these areas as well to further understand and treat NES.

163.10 Applications to Other Areas of Health and Disease

Research on NES has significant implications for other areas of health, including obesity and eating disorders, sleep disorders, metabolic syndrome, and oral heath. As reviewed above, the impact of night eating on obesity has potentially serious consequences for certain populations, especially those with serious mental illness. Given the potential for weight gain that so many antipsychotic medications have, it is crucial to understand why night eating is so prevalent in this population. Similarly, the field is only now beginning to study night eating in the context of other eating disorders. The data reviewed above regarding night eating in women with BN suggests that there is potentially much more overlap between NES and other eating disorders than previously suspected. This has implications for the diagnosis and treatment of not only NES, but of BN and, potentially, AN as well.

Although not reviewed in detail in this chapter, the relationship between NES and sleep disorders is understudied. Both sleep and eating disorder researchers would benefit from improved communication and collaboration when studying night eating. There is likely much that both fields can share with one another to further understand the neurobiology of NES and other eating-related sleep disorders, such as SRED.

Finally, as this chapter points out, much work is needed on further understanding the health implications of NES. Preliminary studies have suggested that NES puts one at increased risk for metabolic disturbance and poor oral health. Future studies are needed to replicate and extend these findings so that they can better inform weight management, endocrine, and dental professionals.

Summary Points

- Night Eating Syndrome (NES) is a disorder of circadian rhythm manifested by the core criteria of evening hyperphagia and/or nocturnal ingestions of food.
- Research diagnostic criteria for NES have recently been proposed and should be tested in future NES research.
- NES is rare among the general population, but its prevalence increases with obesity and among persons with psychiatric symptoms.
- The etiology of NES is unknown, but research on behavioral and neuroendocrine causes, as well as the role of the serotonin system, is underway.
- Assessments and treatments for NES are available and should be disseminated more broadly, despite limitations in known pathophysiology.

Definition of Key Terms

Night eating syndrome: A disorder of the circadian pattern of food intake, manifested by evening hyperphagia and/or nocturnal awakenings accompanied by ingestions of food.
Evening hyperphagia: The consumption of an unusually large amount of food after the evening meal. Current NES diagnostic criteria suggest that the consumption of 25% or more of one's total daily calories after supper constitutes evening hyperphagia.
Nocturnal awakenings: Awakening in the middle of the night after sleep onset.
Nocturnal ingestions of food: Consuming food upon awakening in the middle of the night after sleep onset.

Metabolic Syndrome
and Non-obese Overweight

Chapter 164
Metabolic Syndrome as a Disorder of the Brain with Its Origins in the Perinatal Period

Undurti N. Das

Abbreviations

PUFAs	Polyunsaturated fatty acids
EFAs	Essential fatty acids
IL	Interleukin
TNF	Tumor necrosis factor
ROS	Reactive oxygen species
NO	Nitric oxide
CRP	C-reactive protein
CHD	Coronary heart disease
NF-κB	Nuclear factor kappaB
IkBα	Inhibitor kappaB alpha
NADPH	Nicotinamide adenine dinucleotide phosphate
G6P	Glucose-6-phosphate
TBSA	Total body surface area
NPY	Neuropeptide Y
AgRP	Agouti-related peptide
POMC	Pro-opiomelanocortin
MSH	Melanocyte stimulating hormone
CART	Cocaine and amphetamine-regulated transcript

164.1 Introduction

The various components of the metabolic syndrome include: dyslipidemia, hypertension, hyperglycemia, insulin resistance, polycystic ovary syndrome, fatty liver, cholesterol gallstones, asthma, sleep disturbances, and some forms of cancer.

The incidence of metabolic syndrome is increasing and by the year 2010, in the United States alone there may be about 50–75 million people with the disease. An early stage of the metabolic

Table 164.1 Key features of metabolic syndrome

 I. Key clinical features are:
    1. Abdominal obesity
    2. Insulin resistance
    3. Hyperlipidemia
    4. Hypertension
    5. Type 2 diabetes mellitus
    6. Atheroslcerosis
    7. Decreased heart rate variability

II. Key biochemical features are:
    1. Hyperinsulinemia and hyperglycemia
    2. Low plasma endothelial nitric oxide levels
    3. Low plasma adiponectin levels
    4. Hyperleptin emia
    5. Low plasma levels of antioxidants
    6. High plasma levels of lipid peroxides and resistin
    7. Elevated plasma ADMA (asymmetrical dimethyl arginine)
    8. Elevated plasma IL-6, TNF-α, MIF (macrophage migration inhibitory factor), HMGB-1
      (high mobility group box-1), hs-CRP (high sensitive –reactive protein), and adhesion molecules
    9. Low plasma BDNF and visfatin
  10. Low plasma GLP-1 (glucagon-like peptide-1) and gastric inhibitory polypeptide (GIP)

syndrome is characterized by insulin resistance restricted to muscle tissue whereas adipose tissue is not resistant to insulin (Grundy et al. 2004). This explains why exercise is beneficial in the prevention and treatment of insulin resistance since it decreases insulin resistance and enhances glucose utilization in the muscles. In addition, exercise is anti-inflammatory in nature (Table 164.1) (Das 2004, 2006a).

164.2 Low-grade Systemic Inflammation Occurs in Metabolic Syndrome

Obesity, insulin resistance, hypertension, hyperlipidemia, and coronary heart disease (CHD) are all associated with low-grade systemic inflammation since plasma levels of C-reactive protein (CRP), tumor necrosis factor-α (TNF-α), and interleukin-6 (IL-6), markers of inflammation, are elevated (reviewed in Das 2008), whereas anti-inflammatory molecules adiponectin, IL-4, IL-10, and eNO (endothelial nitric oxide) are decreased in these conditions (Das 2002a). The exact reason why low-grade systemic inflammation occurs in metabolic syndrome is not clear. But it is interesting to note that glucose is pro-inflammatory whereas insulin is anti-inflammatory in nature.

164.3 Glucose Can Initiate and Perpetuate Inflammation

Hyperglycemia is one of the major components of the metabolic syndrome, and metabolic syndrome is a low-grade systemic inflammatory condition; it is therefore likely that hyperglycemia has proinflammatory actions. Glucose ingestion (75 g in 300 mL water) in healthy human subjects resulted in an increase in intranuclear nuclear factor kappaB (NF-kB) binding, the reduction of inhibitor kappaB alpha (IkBα) protein, and an increase in the activity of inhibitor kappaB kinase (IKK) and the expression of IKKalpha and IKKbeta, the enzymes that phosphorylate IkBα in mononuclear cells.

Glucose intake caused an increase in the expression of TNF-α messenger RNA in mononuclear cells. Membranous p47(phox) subunit, an index of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase expression and activation, also increased after glucose intake (Aljada et al. 2004, 2006). These data are consistent with the prediction that hyperglycemia initiates and perpetuates inflammation.

Rat pancreatic islets or clonal rat BRIN BD11 β cells incubated with 16.7 mmol/L glucose for 1 h produced significantly increased amounts of free radicals that were inhibited by NADPH oxidase inhibitor (Morgan et al. 2007). Pre-exposure of U937 histiocytes to high glucose concentrations markedly increased the lipopolysaccharide-induced secretion of proinflammatory cytokines--> and chemokines and the cellular inducible nitric oxide level compared with pre-exposure to normal glucose (Nareika et al. 2007). Similarly, exposure of human microvascular endothelial cells to various concentrations of glucose from low to physiological levels (0–5 mmol/L), production of G6P (glucose-6-phosphate), lactate, NAD(P)H, and CO_2 increased as expected, while oxygen consumption rate was reduced. These changes were found to be oxidative stress mediated endothelial inflammation induced by excess glucose as a result of G6P accumulation (Sweet et al. 2009). These results clearly suggest that glucose is proinflammatory in nature.

164.4 Hyperglycemia Induces Oxidative Stress in Adipose and β Cells

It is interesting that hyperglycemia induced adipose tissue developed severe insulin resistance and produced a number of acute phase reactants at high levels (Lin et al. 2001) that is mediated by the induction of reactive oxygen species (ROS). Hyperglycemia induced a significant increase in ROS in adipocytes isolated from streptozotocin-treated diabetic mice. Hyperglycemia-induced proinflammatory response in adipose tissue was reduced significantly by agents that lower the mitochondrial membrane potential, or by overexpression of uncoupling protein 1 or superoxide dismutase. On the other hand, hyperpolarization of the mitochondrial membrane, such as overexpression of the mitochondrial dicarboxylate carrier resulted in increased ROS formation and decreased insulin sensitivity, even under normoglycemic conditions (Lin et al. 2005). These results highlight the importance of ROS production in adipocytes and the associated insulin resistance and inflammatory response.

Both hyperglycemia and the proinflammatory cytokine IL-1β induced up-regulation of c-Myc and heme-oxygenase-1 in β cells. Hyperglycemia stimulated islet (β cell) c-Myc and heme-oxygenase-1 expression without affecting NF-kB activity or iNOS and IkBα mRNA levels. Fas mRNA levels only increased after prolonged incubation with 30 mmol/L glucose. Short (such as overnight) exposure to hydrogen peroxide mimicked the effects of hyperglycemia on heme-oxygenase-1 and c-Myc mRNA levels without activating NF-kB, while the antioxidant N-acetyl-L-cysteine inhibited the stimulation of heme-oxygenas-1 and c-Myc expression by 30 mmol/L glucose and/or hydrogen peroxide. These results suggest that hyperglycemia and hydrogen peroxide do not activate NF-kB in cultured rat islets, suggesting that the stimulation of islet c-Myc and heme-oxygenase-1 expression by 30 mmol/L glucose results from activation of a distinct, probably oxidative, stress-dependent signaling pathway (Elouil et al. 2005). Thus, hyperglycemia-induced proinflammatory event in different cells may follow different pathways. This proposal is supported by the observation that both TNF-α and glucocorticoid dexamethasone-induced insulin resistance is associated with enhanced levels of ROS, and methods designed to suppress ROS generation improves insulin resistance in obese, insulin-resistant mice and restored glucose homeostasis (Houstis et al. 2006). Since insulin resistance is one of the hallmarks of obesity, type 2 diabetes mellitus, and the metabolic syndrome, it suggests that ROS plays a significant role in these conditions. Hyperglycemia induces

oxidative stress not only in pancreatic β cells and adipose tissue but also in endothelial cells. This enhanced oxidative stress in endothelial cells could be responsible for endothelial dysfunction seen in metabolic syndrome.

164.5 Insulin Is Anti-inflammatory in Nature

In contrast, insulin has anti-inflammatory properties (Das 2000, 2001). Insulin suppresses the production of proinflammatory cytokines, ROS, MIF (macrophage migration inhibitory factor), and augments the production of anti-inflammatory cytokines and eNO. In thermally injured rats (30% total body surface area, TBSA), insulin administration significantly decreased dose dependently serum proinflammatory cytokines IL-1β at 1, 5, and 7 days, IL-6 at 1 day, MIF at 5 and 7 days, and TNF at 1 and 2 days after injury when compared with controls. Insulin increased anti-inflammatory cytokines IL-2 and IL-4 at 5 and 7 days after trauma and IL-10 at 2, 5, and 7 days after trauma when compared with controls. Proinflammatory signal transcription factors STAT-5 and C/EBP-beta mRNA were significantly decreased 1 and 2 days post-trauma; insulin increased anti-inflammatory signal transcription factor mRNA expression of SOCS-3 and RANTES 7 days after the injury (Jeschke et al. 2002). These data lend support to the original hypothesis (Das 2000, 2001) that insulin attenuates the inflammatory response and thus restores systemic homeostasis that could be critical for organ function and survival in critically ill patients. Furthermore, insulin significantly improved hepatic protein synthesis by increasing albumin and decreasing c-reactive protein; decreased the hepatic inflammatory response signal cascade by decreasing hepatic proinflammatory cytokines mRNA and proteins IL-1β and TNF levels; and increased hepatic cytokine mRNA and protein expression of IL-2 and IL-10 at a pretranslational level when compared with controls in rats that received thermal injury. Insulin increased hepatocyte proliferation along with Bcl-2 concentration, while decreasing hepatocyte apoptosis along with decreased caspases-3 and -9 concentration and thus improved liver morphology ($P < 0.05$). Thus, insulin attenuates the inflammatory events (Kelin et al. 2004). Similar results have been noted in thermally injured children who received insulin (Jeschke et al. 2004).

High-dose insulin treatment (short-acting insulin 1 IU/kg/h with 30% glucose 1.5 ml/kg/h administered separately) that was targeted to maintain blood glucose levels at 6.0–8.0 mmol/L produced a significant fall in C-reactive protein and free fatty acid levels postoperatively in patients with unstable angina pectoris who underwent urgent coronary artery bypass surgery. Though the proinflammatory cytokine response [interleukin-6 (IL-6), interleukin-8 (IL-8) and TNF-α] levels did not differ between the insulin group and the controls and no beneficial effects on myocardial injury were detected, these results suggested that high-dose insulin treatment has potential anti-inflammatory properties independent of its ability to lower blood glucose levels (Koskenkari et al. 2006). Similar attenuation of the systemic inflammatory response was noted in infants undergoing cardiopulmonary bypass who received intensive insulin therapy (Gu et al. 2008).

In a nonhyperglycemic mouse model of endotoxemia, continuous administration of a low dose of human insulin induced phosphorylation of Akt in muscle and adipose tissues but did not exacerbate lipopolysaccharide (LPS)-induced hypoglycemia. Insulin decreased plasma levels of IL-6, TNF-α, monocyte chemotactic protein 1 (MCP1)/JE, and keratinocyte chemoattractant, and decreased mortality. The PI3K inhibitor wortmannin abolished the insulin-mediated activation of Akt and the reduction of chemokine and interleukin-6 levels suggesting that insulin reduces LPS-induced inflammation in a PI3K/Akt-dependent manner without affecting blood glucose levels (Kidd et al. 2008). In a study designed to evaluate whether insulin attenuates TNF-α induction in acute myocardial ischemia/reperfusion

injury both in vitro and in vivo, we observed that insulin inhibited ischemia-reperfusion-induced TNF-α production through the Akt-activated and eNOS-NO-dependent pathway (Li et al. 2008). These results strongly suggest that insulin has cardioprotective and prosurvival effects in the critically ill and, in general, possesses cytoprotective actions. But it should be noted that in some studies the protective effect of intensive insulin therapy in patients after cardiac surgery could not be related to a change in cytokine balance from a proinflammatory to an anti-inflammatory pattern (Hoedemaekers et al. 2005). This discrepancy in the results could be attributed to the differences in the study population, the insulin protocol used, and the underlying clinical conditions.

The fact that glucose and insulin have opposite actions on inflammation and since food intake is regulated by the hypothalamus, a function that is possible only if the hypothalamus is able to sense blood glucose levels and regulate gut function and insulin secretion, it is likely that the glucose-sensing mechanism of the hypothalamus may involve ROS signaling. Vagus seems to facilitate cross-talk among the gut, adipose tissue, pancreas, and hypothalamus, while cytokines modulate hypothalamic neuronal firing rate. In addition, the presence of insulin receptors in the brain and the known interactions between insulin, ROS, cytokines, and glucose homeostasis (as discussed above) suggest that hypothalamus function is regulated by ROS. For a better understanding of the existence of low-grade systemic inflammation in metabolic syndrome and the role played by hypothalamus in glucose homeostasis, it is important to briefly review the role of the hypothalamus in food intake and glucose homeostasis.

164.6 Hypothalamus Regulates Food Intake

Appetite is controlled by an appetite stimulating neuropeptide Y (NPY), an agouti-related peptide (AgRP), and the appetite inhibitory molecules pro-opiomelanocortin (POMC), the precursor for α-melanocyte stimulating hormone (α-MSH), and cocaine and amphetamine-regulated transcript (CART), which are expressed within the hypothalamus and act together to regulate energy balance. NPY is predominantly localized in the hypothalamic arcuate nuclei (ARC) and NPY neurons project to the paraventricular nucleus (PVN), dorsomedial nucleus (DMN), the perifornical region, and the lateral hypothalamic area (LHA) (Grove and Smith 2003). NPY neurons respond to alterations in the concentrations of plasma glucose, insulin, and leptin. Increased food intake increases the circulating concentrations of leptin that are sensed by the leptin receptors expressed on ARC and DMN neurons leading to a fall in hypothalamic NPY mRNA that results in decreased food intake. AgRP that is coexpressed with NPY in the ARC is an endogenous antagonist of anorexigenic melanocortin receptors MC3-R and MC4-R in the PVN and other hypothalamic regions. α-MSH is an endogenous anorexigenic peptide that acts on the melanocortin receptors to suppress food intake. CART, localized within the POMC neurons in the hypothalamus, also suppresses food intake (McMillen et al. 2005).

164.7 Appetite Regulatory Centers Develop During the Perinatal Period

Hypothalamic appetite regulatory centers develop predominantly during the perinatal period. For instance, NPY is present within the fetal ARC from as early as 14.5 days gestation; NPY/AgRP projections between the ARC and DMN develop around 10–11 days after birth whereas NPY containing projections to the PVN develop around 15–16 days (Grove and Smith 2003; McMillen et al. 2005). Hence, factors that influence the growth and development of the brain will have a significant

impact on the development of appetite regulatory centers that, in turn, could determine food intake in later life.

For instance, postnatal over nutrition in rats led to an increased early weight gain and fat deposition, hyperphagia, obesity, hyperleptinemia, hyperglycemia, hyperinsulinemia, and insulin resistance. These indices of the metabolic syndrome were accompanied by decreased mean areas of neuronal nuclei and cytoplasm within the PVN, VMN, and ARC and a significant increase in the number of NPY containing neurons within the ARC, and decreased immunostaining for both POMC and α-MSH (McMillen et al. 2005; Davidowa et al. 2003; Fahrenkrog et al. 2004). In contrast, when rats are undernourished during the perinatal period the offspring develop significant hyperphagia and obesity when maintained on a high fat diet and showed an increase in the relative mass of retroperitoneal fat. Thus, the amount and type of food consumed during the suckling period determines food intake and preferences in later life.

The neuropeptides NPY, AgRP, POMC, and CART showed significant changes in their concentrations in the hypothalamic nuclei of fetal sheep in response to intrafetal infusion of glucose between 130 and 140 days of gestation by which time these peptides are highly expressed (Muhlhausler et al. 2005). These results suggest that neuropeptides that regulate appetite centers and their responses to stimuli are "programmed" in the fetal and perinatal stages of development. This ultimately influences the dietary preferences and the development of obesity and the metabolic syndrome in later life. This implies that early life feeding pattern and growth "program" the hypothalamic centers and their neurotransmitters that could have a life-long impact on food intake and thus influence the future development of the metabolic syndrome in a given subject.

164.8 Ventromedial Hypothalamic Lesion Produces Features of Metabolic Syndrome

Hyperphagia and excessive weight gain, fasting hyperglycemia, hyperinsulinemia, hypertriglyceridemia, and impaired glucose tolerance, which are features of the metabolic syndrome are seen when the ventromedial hypothalamus (VMH) is injured in rats (Axen et al. 1994; Keno et al. 1994). Intraventricular administration of antibodies to neuropeptide Y (NPY) abolished the hyperphagia and *ob* mRNA (leptin mRNA) in these animals, suggesting that enhanced NPY is responsible for hyperphagia and obesity seen in VMH lesioned animals, and the *ob* gene is upregulated even in nongenetically obese animals (Dube et al. 1995; Funahashi et al. 1995). Paraventricular, ventromedial (VMH), and lateral hypothalamic areas showed increased NPY concentrations in streptozotocin-induced diabetic rats. These diabetic animals also showed a significant decrease in extracellular concentrations of noradrenaline (NA), serotonin (5-HT), and their metabolites. and a pronounced increase in extracellular GABA, in the VMH. Long-term infusion of norepinephrine plus serotonin into the VMH impairs pancreatic islet function inasmuch as VMH norepinephrine and serotonin levels are elevated in hyperinsulinemic and insulin-resistant animals (reviewed in Das 2008). Streptozotocin-induced diabetes caused an increase in NA concentrations in the PVN with a concurrent increase in serum corticosterone and an increase in the concentrations of NA, dopamine, and serotonin in the ARC. It also increased NA concentrations in the lateral hypothalamus, VMH, and suprachiasmatic nucleus that reverted to normal with insulin treatment, while leptin treatment was ineffective (Das 2008).

The activity of glucokinase (GK), the critical glucose sensor of pancreatic β cells, is high in the arcuate nucleus; moderate or low in the ventromedial nucleus, lateral hypothalamic area, and paraventricular nucleus; and very low in the cortex. GK activity and GK mRNA level in the arcuate

nucleus of streptozotocin-treated rats were lower than those of control rats, suggesting that prolonged hyperglycemia induced by diabetes decreased the activity of GK in the arcuate nucleus. This decrease in glucokinase activity in the hypothalamic neurons may interfere with the central regulatory mechanisms of insulin secretion by pancreatic β cells. Thus, hypothalamic neurons and neurotransmitters and GK play a critical role in the regulation of insulin secretion and in the pathobiology of the metabolic syndrome, suggesting that the latter may very well be a disorder of the brain (Das 2008).

164.9 Insulin and Insulin Receptors in the Brain

Brain is rich in insulin receptors especially in the olfactory bulb, the hypothalamus, and the pituitary, and insulin signaling has a role in the regulation of food intake, neuronal growth, and differentiation; it also regulates neurotransmitter release and synaptic plasticity in the CNS (Wan et al. 1997; Bruning et al. 2000; Hill et al. 1986). Insulin infusion into the VMN and PVN increased body temperature and energy expenditure and reduced food intake (Menendez and Atrens 1991; McGowan et al. 1992). Infusion of insulin-specific antibodies or antisense oligonucleotides directed against the insulin receptor in the third ventricle reduced hepatic sensitivity to circulating insulin and increased hepatic glucose production, suggesting that insulin in the brain regulates liver glucose metabolism (McGowan 1992). IRS-2 is abundant in the arcuate nucleus, and insulin administration induced tyrosine phosphorylation of IRS-2 and increased the production of phosphatidylinositol 3,4,5-trisphosphate (PI_3). Mice lacking IRS-2 in the hypothalamus exhibited hyperphagia and enhanced body fat deposition (Lin et al. 2004). ICV insulin infusion blocked the effects of both fasting and streptozotocin-induced diabetes to increase expression of NPY mRNA in the arcuate nucleus, while insulin increased hypothalamic POMC mRNA content. The melanocortin receptor antagonist, blocked the ability of ICV (intracerebroventricular) insulin to suppress food intake (Benoit et al. 2002). Subthreshold doses of insulin and leptin showed additive effects on short-term food intake, while both insulin and leptin suppressed NPY/AgRP neurons in the arcuate nucleus and concomitantly activated POMC/CART neurons. These results suggest that there is a cross talk between insulin and leptin apart from sharing the common ability to suppress anabolic, while activating catabolic, regulatory neurocircuitry.

164.10 Mechanism(s) of Action of Insulin in the Brain

Insulin activates ATP-sensitive K^+ channels (K_{ATP} channels) of hypothalamic neurons, especially in the mediobasal hypothalamus (Spanswick et al. 2000). Activation of K_{ATP} channels is suppressed by increased intracellular ATP levels in response to oxidation of glucose or other substrates. This raises intracellular concentrations of K^+, leading to membrane depolarization and increased firing rate. Thus, glucose-excited neurons are those that are activated (i.e., depolarized) by increased local concentrations of glucose. However, some studies showed that these effects are not seen at physiological glucose levels, suggesting that these neurons are downstream of NPY and POMC neurons and potentially play an integrating role for peripheral and central energy homeostasis. Leptin, like insulin, activates K_{ATP} channels in glucose-responsive hypothalamic neurons (Mirshamsi et al. 2004). Glucose-responsive neurons from Zucker fatty (*fa/fa*) rats that develop obesity, which have a leptin receptor mutation, are insensitive to both insulin and leptin. This may explain why ICV insulin inhibits neither food intake nor NPY gene expression in these *fa/fa* rats.

GLUT-4 and GLUT-8, the glucose transporters, and glucokinase, the glucose sensor of the β-cell, are present in several areas of the brain. In the arcuate nucleus, >75% of NPY-positive neurons express glucokinase (Lynch et al. 2000). Intracarotid glucose infusions increased hypothalamic glucokinase expression (Dunn-Meynell et al. 2002), suggesting that glucokinase could function as a glucose-sensor in both glucose-responsive (also referred to as glucose-excited) and glucose-sensitive (also referred to as glucose-inhibited) neurons. Since many glucokinase-expressing neurons coexpress K_{ATP} channels, and coexpression of GLUT-4 with insulin receptor mRNA is reported in glucose-responsive neurons, interactions among glucose-sensors, K_{ATP} channels and various neuropeptides is expected.

Thus, insulin interacts with neuropeptides and regulates food intake that may have relevance to the development of obesity and metabolic syndrome. Disruption of the neuron-specific insulin receptor gene (NIRKO) in mice increased food intake, developed diet-sensitive obesity with increases in body fat and plasma leptin levels, insulin resistance, hyperinsulinemia and hypertriglyceridemia, features that are seen in metabolic syndrome without interfering with the development of brain and neuronal function (Bruning et al. 2000) lending strong support to the concept that a decrease in the number of insulin receptors, deficiencies in the functioning of insulin receptors, and insulin lack or resistance in the brain leads to the development of metabolic syndrome even when the pancreatic β cells are normal (Table 164.2). This is further supported by the observation that intraventricular injection of insulin inhibits food intake (McGowan et al. 1992).

Food-deprivation induced increase in NPY levels in the paraventricular nucleus (PVN) returned to the control range following insulin injections, which did not alter blood glucose levels. Both insulin and insulin-like growth factor-II (IGF-II) decreased the release of NPY in a dose dependent fashion from the PVN *in vitro*, suggesting that the site of insulin action on the hypothalamic NPY network is at the level of NPY nerve terminals and that both insulin and IGF-II decrease NPY release from the PVN (Sahu et al. 1995). Since NPY is a potent orexigenic signal and as insulin and IGF-II decrease hypothalamic NPY, it is suggested that presence of adequate amounts of insulin, insulin receptors, and IGF-II in the brain reduces appetite, and thus controls obesity and hyperglycemia. This interaction among insulin (and insulin receptors), IGF-II, and neuropeptides depends on the health of the neurons in the brain, their receptors, and the presence of adequate synaptic connections among them.

Plasma concentrations of proinflammatory markers are increased in metabolic syndrome. These proinflammatory molecules: TNF-α, IL-6, and CRP, cause endothelial dysfunction. Mice with targeted disruption of eNOS are not only hypertensive and insulin resistant but also showed features of the metabolic syndrome such as hyperlipidemia, hyperleptinemia, hyperuricemia, and hyperfibrinogenemia and glucose intolerance but were not obese (Cook et al. 2003). These features are similar to those seen in the NIRKO mice. Since insulin stimulates the production of eNO and inhibits TNF-α production (Das 2008) and NIRKO mice show several features of the metabolic syndrome, it is postulated that a decrease in the number of insulin receptors, defects in the functioning of insulin receptors, and insulin lack or resistance in the neuronal cells lead to the development of

Table 164.2 Neuron-specific insulin receptor knockout (NIRKO) mice

1. Brain is rich in insulin receptors
2. Insulin and insulin receptors are necessary for normal growth and development of the brain
3. Insulin is also essential for neuronal growth and synapse formation
4. Insulin receptors in the brain are particularly rich in the hypothalamus
5. When these neuron-specific insulin receptors are knocked out by genetic manipulation these animals develop all the features of the metabolic syndrome
6. This suggests that insulin receptors in the brain have the ability to signal pancreatic β cells to secrete adequate amounts of insulin as the situation demands.

metabolic syndrome even when pancreatic β cells are normal. Thus, metabolic syndrome could be a disorder of the brain.

But the major question is: "When and how is metabolic syndrome initiated?" Evidence is available that suggests that the metabolic syndrome may have its origins in the perinatal period.

164.11 Perinatal Programming of the Metabolic Syndrome

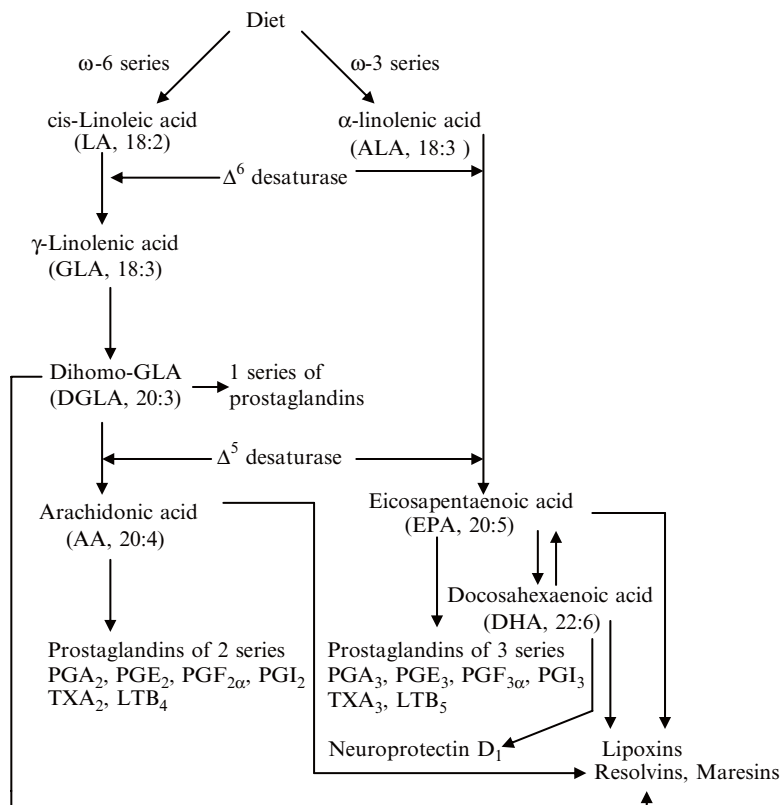
Stimuli or insults induced during the perinatal period can have lifetime consequences and is called "programming". Hormonal signals or nutritional factors may serve as programming stimuli. Smallness and thinness at birth, continued slow growth in early childhood, followed by acceleration of growth so that height and weight approach the population means is considered as the most unfavorable growth pattern that results in fetal adaptations that may programme the development of metabolic syndrome in later life (Das 2008). This implies that perinatal nutrition is a crucial determinant of adult diseases. Since the development of brain occurs during the period between second trimester to 5 years of age and again during adolescence, it is likely that nutrition during these periods plays a significant role in this process. Factors that are essential for brain growth and development, regulation of synapse formation, and neurotransmission include: polyunsaturated fatty acids (PUFAs) and their metabolites, various cytokines, insulin and various neuropeptides, and monoaminergic neurotransmitters.

164.12 Essential Fatty Acids

Essential fatty acids (EFAs) are important constituents of all cell membranes. EFAs confer on membranes properties of fluidity and thus determine and influence the behavior of membrane-bound enzymes and receptors. There are two types of naturally occurring EFAs in the body, the ω-6 series derived from *cis*-linoleic acid (LA, 18:2) and the ω-3 series derived from α-linolenic acid (ALA, 18:3). LA and ALA are converted to their respective long-chain metabolites and several eicosanoids that have significant biological actions (see Fig. 164.1 for metabolism). The long-chain metabolites of EFAs (also called as polyunsaturated fatty acids, PUFAs) can give rise to both pro- (such as prostaglandins, thromboxanes, and leukotrienes) and anti-inflammatory (such as lipoxins, resolvins, protectins, and maresins) molecules. Hence, the balance between these mutually antagonistic compounds could determine the final outcome of the disease process.

164.13 PUFAs, Insulin, and Acetylcholine Function as Endogenous Neuroprotectors

Human infants accumulate PUFAs such as arachidonic acid (AA), eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA) from maternal/placental transfer, consumption of human milk, and synthesis from LA and ALA. AA regulates energy metabolism in the cerebral cortex by stimulating glucose uptake in cerebral cortical astrocytes and enhances acetylcholine (Ach) release in the brain (Das 2002b). DHA also enhances cerebral ACh levels and improves learning ability in rats. ACh modulates long-term potentiation and synaptic plasticity in neuronal circuits and interacts with dopamine

Fig. 164.1 Metabolism of essential fatty acids. Resolvins, protectins, lipoxins, and maresins formed from PUFAs have anti-inflammatory actions and participate in the resolution of inflammation. Neuroprotectin D_1 formed from DHA has anti-inflammatory and cytoprotective actions. EPA can be converted to DHA. DHA can be retroconverted to EPA


receptor in the hippocampus. In obesity, a decrease in the number of dopamine receptors or dopamine concentrations occurs and obesity is common in type 2 diabetes and metabolic syndrome (reviewed in Das 2008).

Insulin augments the activities of desaturases, enzymes involved in the desaturation and elongation of LA and ALA to their respective long-chain metabolites, and this increases the formation of AA, EPA, and DHA. Insulin-like growth factor-1 (IGF-1), insulin and AA, EPA, and DHA antagonize neuronal death induced by TNF-α and thus show neuroprotective and cytoprotective actions (reviewed in Das 2008). Furthermore, PUFAs are potent inhibitors of IL-6 and TNF-α production (Kumar and Das 1994), and they also regulate superoxide anion generation and enhance the production of eNO. NO is anti-inflammatory in nature and quenches superoxide anion. IGF-I and insulin enhance ACh release from rat cortical slices. ACh inhibits the synthesis and release of TNF-α both in vitro and in vivo and thus, has anti-inflammatory actions and is also a potent stimulator of eNO synthesis. These data suggest that insulin enhances the formation of PUFAs that, in turn, enhance ACh levels in the brain and inhibit the production of TNF-α. Thus, insulin, ACh, and PUFAs suppress TNF-α production and augment the synthesis of eNO. ACh and eNO are not only neuroprotective in nature but also interact with other neurotransmitters. Thus, insulin, ACh, and PUFAs protect brain from insults induced by TNF-α and other molecules. In addition, incorporation of significant amounts of PUFAs into the cell membranes increases their fluidity that, in turn, enhances the number of insulin receptors on the membranes and the affinity of insulin to its receptors. Thus PUFAs can attenuate insulin resistance (Das 2008).

Since human brain is rich in AA, EPA, and DHA, one of their important functions in the brain could be to ensure the presence of adequate number of insulin receptors and protect

neurons from insults. Hence, it is reasonable to propose that when adequate amounts of PUFAs are not incorporated into the neuronal cell membranes during growth and development it may cause a defect in the expression or function of insulin receptors in the brain that could lead to the development of metabolic syndrome as seen in the NIRKO mice. Furthermore, systemic injections of insulin in rats resulted in an increase in extracellular ACh in the amygdala (Hajnal et al. 1998). ACh modulates dopamine release that, in turn, regulates appetite. As already discussed above, ACh inhibits the production of proinflammatory cytokines (IL-1, IL-2 and TNF-α) in the brain and thus protects the neurons from neurotoxic injury.

AA and DHA activate syntaxin.-->3, a plasma membrane protein that has an important role in the growth of neurites (Darios and Davletov 2006). AA, DHA, and EPA bind to RAR-RXR, LXR, FXR and other nuclear receptor heterodimers and thus modulate development of the brain.

164.14   TNF-α, AA/EPA/DHA, Insulin, and Neuronal Growth and Synapse Formation

Perinatal supply of ω-3 fatty acids influences brain gene expression later in life and is critical to the development and maturation of several brain centers that are specifically involved in the regulation of appetite and satiety. Supplementation of AA and EPA/DHA increased the expression of serotonin receptor in the hypothalamus (Berger et al. 2002). 5-HT$_4$ receptor increases in expression have been shown to augment hippocampal acetylcholine outflow. It was reported that AA and EPA/DHA feeding enhanced the expression of POMC in the hippocampus, suggesting that AA/EPA/DHA influence appetite and satiety and thus control energy metabolism.

TNF-α produced by glial cells enhances synaptic efficacy by increasing surface expression of AMPA receptors. Continued presence of TNF-α is required for preservation of synaptic strength at excitatory synapses (reviewed in Das 2008). TNF-α production is suppressed by EPA/DHA, whereas excess TNF-α induces apoptosis of neurons. Insulin is not only needed for neuronal growth and differentiation and synaptic plasticity in the CNS but also stimulates the formation of AA/EPA/DHA and suppresses TNF-α production. Both insulin and AA/EPA/DHA stimulate eNO formation. This close interaction and feedback regulation among TNF-α, EPA/DHA, insulin, and neuronal growth and synapse formation suggests that growth of neurons and synaptic formation will be optimum only when all these factors are present in physiological concentrations. In contrast, when AA/EPA/DHA concentrations are suboptimal, TNF-α levels tend to be high. High TNF-α concentration are neurotoxic and hence could cause damage to VMH neurons that could lead to the development of the metabolic syndrome.

164.15   Maternal Diet Influences Fetal Leptin Levels

Low birth weight is associated with high prevalence of metabolic syndrome in later life (reviewed in Das 2008). Babies with low birth weights have 10 times greater chance of developing metabolic syndrome compared to those whose birth weight was normal. In addition, postnatal nutrition and growth also play a role in the development of metabolic syndrome in later life. Maternal protein restriction or increased consumption of saturated and/or trans-fatty acids and energy rich diets (maternal overnutrition) during pregnancy decrease the formation of PUFAs. Perinatal protein depletion leads to almost complete absence of activities of the enzymes in fetal liver and placenta that are

necessary for the elongation and desaturation of LA and ALA. Thus, both protein deficiency and high-energy diet leads to maternal and fetal deficiency of EPA, DHA, and AA.

A diet rich in PUFAs increases leptin levels in diet-induced obese adult rats, suggesting that variation in the type of diet during pregnancy and lactation might significantly modulate fetal and neonatal growth and development by leptin-associated mechanisms since leptin influences NPY/AgRP and POMC/CART neurons and their connections (reviewed in Das 2008). Plasma leptin levels were found to be low in the lactating dams fed an EFA-deficient diet and their suckling pups compared with controls. The suckling pups showed decreased concentrations of leptin even in their adipose tissue, suggesting that maternal EFA deficiency can produce a decrease in leptin levels in several tissues, possibly even in the hypothalamus. These low leptin levels during the perinatal period alter NPY/AgRP and POMC/CART homeostasis that may lead to the hypothalamic "body weight/appetite/satiety set point" set at a higher level that is long-lasting and potentially irreversible onto adulthood. Thus, maternal malnutrition, low perinatal PUFAs, and consequent low leptin concentrations could lead to the development of metabolic syndrome in adulthood (Das 2008).

164.16 Gastric Bypass-induced Weight Loss Could be due to Changes in the Hypothalamic Neuropeptides and Monoamines

If it is true that metabolic syndrome is a disorder of the brain, then it is necessary to show that diet-induced obesity and weight loss are due to changes in hypothalamic neuropeptides and monoamines. Roux-en-gastric bypass (RYGB) and other bariatric operations are being increasingly adopted to induce weight loss. RYGB produces on an average 49–65% weight loss within 2–5 years and ameliorates diabetes, hyperlipidemia, and other obesity-related metabolic abnormalities. In order to understand the molecular mechanisms involved in weight loss and amelioration of metabolic abnormalities in diet-induced obese animals that shed weight after RYGB operation, we developed a surgical rat model of human RYGB (Meguid et al. 2004; Middleton et al. 2004 and Xu et al. 2004).

Weight loss achieved by RYGB and PF (pair fed rats that received the same amount of diet that RYGB animals consumed) in obese rats was accompanied by a decrease in NPY in ARC, pPVN (parvocellular part of paraventricular nucleus of hypothalamus), and mPVN (magnocellular part of PVN) and an increase in α-MSH in ARC, pPVN, and mPVN compared with obese controls. 5HT-$_{1B}$-receptor in pPVN and mPVN increased in RYGB and PF compared to obese control (Romanova et al. 2004). Thus, weight loss seen after RYGB and diet control in PF groups is due to specific changes in hypothalamic peptides. Serotonin innervation is widely present in the hypothalamus and it innervates NPY neurons both in the ARC and PVN. Serotonin suppresses food intake. Hence, weight loss seen in RYGB and PF groups could be attributed to alterations in the concentrations of specific hypothalamic signaling peptides that regulate appetite, food intake, and satiety.

Even in tumor bearing anorectic rats, which showed significant weight loss due to tumor burden, similar results were seen: an increase of serotonin in PVN and VMN and a concomitant decrease of dopamine in PVN, VMN, and LHA (lateral hypothalamus), and of NPY in LHA, VMN, and PVN; a decrease in NPY in ARC and of POMC (proopiomelanocortin) in ARC and PVN (Romanova et al. 2004; Ramos et al. 2004); these abnormalities reverted to normal after tumor resection. Even the concentrations of IL-6 and TNF-α that were found to be elevated in ARC in tumor-bearing rats reverted to near normal in tumor-bearing rats that were fed fish oil (a rich source of EPA and DHA). In addition, a significant decrease in the concentrations of NPY and POMC in ARC were noted in fish oil fed nontumor-bearing rats, indicating that EPA/DHA regulate the levels of hypothalamic neuropeptides and monoamines.

164.17 Conclusions

Based on the preceding discussion, it is evident that availability of adequate amounts of EPA, DHA, and AA during the perinatal period is crucial to prevent the development of metabolic syndrome in later life. This could be in the form of supplementation of PUFAs to pregnant and lactating women, adequate breast-feeding to the newborn, followed by EPA, DHA, and AA supplementation to infants, children, and adolescents. The negative correlation noted between breast-feeding and insulin resistance and type 2 DM supports this view since human breast milk contains significant amounts of PUFAs. When infants receive inadequate amounts of PUFAs, optimal neural development is unlikely. As a result, the development, expression, and maintenance of NPY/AgRP, POMC/CART neurons, and insulin receptors will be defective; plasma, tissue, and hypothalamic concentrations of leptin will be inadequate, whereas the concentrations of proinflammatory cytokine TNF-α will be high, which may affect neuronal plasticity. A high TNF-α level may result in inadequate development of the critical hypothalamic neurons predisposing to the development of metabolic syndrome as seen in the NIRKO mice, VMH lesioned rats, and Lep^{ob}/Lep^{ob} mice. Thus, a marginal deficiency of PUFAs during the critical phases of fetal and infant growth can have a major effect on subsequent health. This is analogous to the observation that DHA deficiency in the perinatal period results in hypertension in later life, even when animals were subsequently replete with this fatty acid (Weisinger et al. 2001).

PUFAs also regulate food intake by modulating the concentrations of endogenous lipids *N*-acyl-ethanolamine (NAEs, anandamide) and 2-acylglycerols, and the ligands of cannabinoid (CB) receptors. These polyunsaturated NAEs bind to CB1 and CB2 (cannabinoid) receptors and regulate food intake. Furthermore, defective leptin signaling elevated hypothalamic levels of endocannabinoids in obese *db/db* and *ob/ob* mice and Zucker rats. Leptin treatment reduced anandamide and 2-arachidonoyl glycerol concentrations in the hypothalamus. EPA and DHA modulate leptin gene expression and levels both *in vitro* and *in vivo*. This suggests that PUFAs, endocannabinoids, and leptins act in concert with neurotransmitters NPY/AgRP and POMC/CART to control food intake, obesity, and metabolic syndrome.

Direct support to the concept that unsaturated fatty acids regulate hypothalamic neurons involved in the control of food intake and energy homeostasis comes from the observation that infusion of oleic acid (18:1 ω-9) in the third ventricle resulted in a marked decline in plasma insulin concentration and a decrease in the plasma glucose concentration compared with control within 1 h from the start of the infusion (Obici et al. 2002), suggesting that intracerebroventricular (ICV) oleic acid enhances insulin sensitivity. These results confirm that unsaturated fatty acids decrease systemic insulin levels and markedly stimulate insulin action on glucose homeostasis. Oleic acid suppressed the rate of glucose production by activating K_{ATP} channels in the hypothalamus similar to leptin and insulin.

Fatty acid synthase inhibitors reduced food intake and hypothalamic NPY mRNA levels (Loftus et al. 2000) by increasing the concentration of malonyl CoA, an inhibitor of the entry of long-chain CoAs into the mitochondria via inhibition of the activity of the enzyme carnitine palmitoyl-transferase-1. This results in elevation of cytoplasmic long-chain fatty acyl CoAs and diacylglycerol that play a role in signaling to the cells about the availability of fuels. Malonyl-CoA mediates nutrient-stimulated insulin secretion in the pancreatic β cell. Since glucose-sensing neurons and β cells have several similarities, such as expression of glucokinase and the ATP-sensitive K^+ channels, it is likely that malonyl-CoA may also signal fuel status in the hypothalamic neurons as it would in the β cells. In addition, both fatty acid synthase inhibitors and ICV injection of oleic acid inhibited hypothalamic expression of NPY, indicating that PUFA content of the hypothalamic neurons regulates the expression of NPY and other neuropeptides and, thus, modulates food intake, glucose homeostasis, and the development of metabolic syndrome.

Regulation of ATP-sensitive K$^+$ channels seems to be a common pathway by which nutrients modulate neuronal sensing of fuels. A primary increase in hypothalamic glucose levels lowers blood glucose through inhibition of glucose production and this effect of glucose requires its conversion to lactate followed by stimulation of pyruvate metabolism, which activates ATP-sensitive K$^+$ channels. Pyruvate has antioxidant and anti-inflammatory actions (pyruvate inhibits NF-κB activation, TNF-α, IL-6, MIF, and HMGB1 production) and is an insulin secretagogue (Das 2006b). This implies that glucose and pyruvate influence neuronal glucose sensing by a free radical dependent process since both modulate free radical generation.

Although ATP production and consequent closure of ATP-sensitive K$^+$ channels and calcium influx is considered as the main metabolic signal for this purpose, glucose-excited signaling in β cells and hypothalamic neurons is not totally dependent on ATP generation. In some hypothalamic arcuate neurons, ATP-sensitive K$^+$ channels function independent of ATP level and glucose-independent depolarization might occur through an ATP-sensitive channel-independent mechanism. Transient increase in glucose metabolism generates NADH and FADH$_2$ from the mitochondria and their use increases superoxide anion production (also called mitochondrial reactive oxygen species, mROS). Hypothalamic slices *ex vivo* exposed to 5–20 mmol/L glucose generated ROS. Glucose-induced increased neuronal activity in arcuate nucleus and insulin release are suppressed by antioxidants, suggesting that the brain glucose-sensing mechanism involves ROS signaling (reviewed in Das 2008). This is supported by the observation that ATP-sensitive K$^+$ channels control transmitter release in dorsal striatum through an H$_2$O$_2$-dependent mechanism and as several ROS-sensitive and nonselective cationic channels are known to exist. It is likely that glucose-sensing mechanisms could be similar, if not identical, in glucose responsive cells: pancreatic β cells and hypothalamic neurons. Thus, hypothalamic pyruvate, a metabolite of glucose metabolism; ROS; and PUFAs not only play a significant role in the regulation of nutrient sensing by hypothalamic neurons and β cells, but may interact among themselves. Ghrelin-induced feeding behavior that is controlled by arcuate neurons that coexpress NPY/AgRP also seem to be mediated by free radicals (Andrews et al. 2008). Thus, free radicals seem to be the common mechanism by which ghrelin, NPY/AgRP, glucose, and insulin (and possibly POMC neurons) act on hypothalamus to bring about their actions on food intake, satiety, appetite, and finally glucose homeostasis (Fig. 164.2).

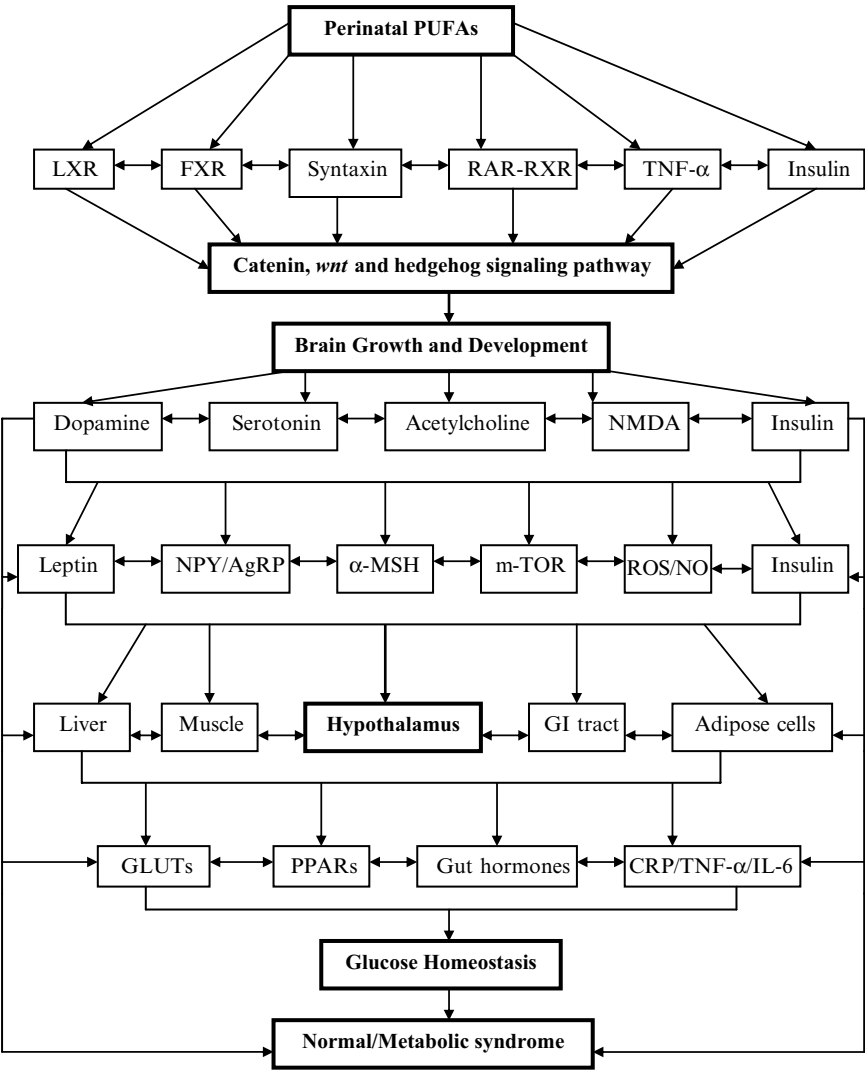
Peripheral tissues (such as muscle, adipose cells, etc.), pancreatic β cells, and the hypothalamic neurons need to communicate with each other to maintain energy homeostasis. For instance, immediately after food intake gut peptides such as ghrelin, cholecystokinin (CCK), etc., are released that interact with hypothalamic neurons and signal hunger and satiety sensations. CCK reduces food intake by acting at CCK-1 receptors on vagal afferent neurons. Leptin mRNA has been reported in vagal afferent neurons, some of which also express CCK-1 receptor, suggesting that leptin, alone or in cooperation with CCK, might activate vagal afferent neurons and influence food intake via a vagal route. A much higher prevalence of CCK and leptin sensitivity amongst cultured vagal afferent neurons that innervate stomach or duodenum than there was in the overall vagal afferent population was reported. Almost all leptin-responsive gastric and duodenal vagal afferents also were sensitive to CCK. Leptin, infused into the upper GI tract arterial supply, reduced meal size, and enhanced satiation evoked by CCK, indicating that vagal afferent neurons are activated by leptin, and that this activation participates in meal termination by enhancing vagal sensitivity to CCK (reviewed in Das 2008). Injection of adeno-associated viral vectors encoding leptin (rAAV-lep) rAAV-lep injection increased hypothalamic leptin expression in the complete absence of peripheral leptin in *ob/ob* mice; suppressed body weight and adiposity; voluntarily decreased dark-phase food intake; suppressed plasma levels of adiponectin, TNF-α, free fatty acids, and insulin concomitant with normoglycemia and elevated ghrelin levels for an extended period. Leptin administration rapidly decreased plasma gastric ghrelin and adipocyte adiponectin but not TNF-α level, thereby demonstrating a


Fig. 164.2 Scheme showing the relationship among PUFAs and various tissues and factors involved in the pathobiology of the metabolic syndrome

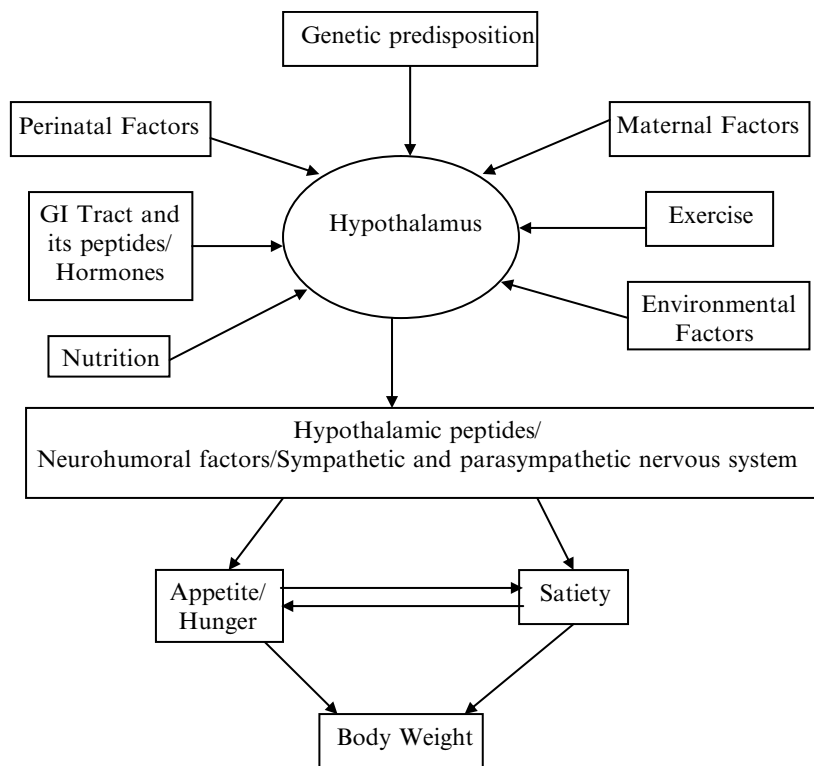
peripheral restraining action of leptin on the secretion of hormones of varied origins. Whereas ghrelin administration readily stimulated feeding in controls, it was completely ineffective in rAAV-lep-treated wt mice. Thus, leptin expressed locally in the hypothalamus counteracted the central orexigenic effects of peripheral ghrelin, suggesting that leptin and ghrelin interact with each other and thus regulate energy homeostasis and metabolism. It was reported that incubation of the hypothalamic explants with ghrelin significantly increased NPY and AGRP mRNA expression, suggesting that ghrelin and NPY interact with each other. Ghrelin facilitates both cholinergic and tachykininergic excitatory pathways, consistent with activity within the enteric nervous system and possibly the vagus nerve (reviewed in Das 2008). These evidences suggest that sympathetic and parasympathetic (especially vagus nerve) nerves carry messages from the peripheral tissues and β cells to the hypothalamus and *vice versa* where all the messages are integrated, codified, and relayed to the target tissues to maintain overall energy balance (Fig. 164.3).


Fig. 164.3 Scheme showing the simplified relationship between genetic factors, maternal factors, diet, GI tract, and hypothalamus to body weight

This is supported by the observation that adenovirus-mediated expression of PPAR-γ2 in the liver induces acute hepatic steatosis while markedly reducing peripheral adiposity, changes that were accompanied by increased energy expenditure and improved systemic insulin sensitivity. Interestingly, hepatic vagotomy and selective afferent blockage of the hepatic vagus reversed these changes, whereas thiazolidinedione, a PPAR-γ agonist, enhanced these changes (reviewed in Das 2008). Thus, a neuronal pathway consisting of the afferent vagus from the liver and efferent sympathetic nerves to adipose tissues is involved in the regulation of energy expenditure, systemic insulin sensitivity, glucose metabolism, and fat distribution between the liver and the periphery. In this context, it should be noted that proinflammatory cytokine production is regulated by the efferent vagus nerve. Acetylcholine (ACh), the principal vagal neurotransmitter, has been shown to inhibit the production of TNF, IL-1, MIF, and HMGB1, and activation of NF-κB expression (reviewed in Das 2008). Since ACh is both a neurotransmitter and regulates serotonin, dopamine, and other neuropeptides, whereas PUFAs influence ACh release and insulin sensitivity (Das 2008), it is clear that a complex network of interaction(s) exists among all these molecules in the regulation of energy homeostasis. Furthermore, brain insulin resistance exists in peripheral insulin resistance, especially in regions subserving appetite and reward; exercise enhanced the sensitivity of hypothalamus to the actions of leptin and insulin and the appetite-suppressive actions of exercise are mediated by the hypothalamus (Das 2008). These evidences emphasize the role of hypothalamus in the pathobiology of metabolic syndrome.

Summary Points

- The incidence of metabolic syndrome is assuming epidemic proportions in almost all countries in the world.
- Low-grade systemic inflammation occurs in metabolic syndrome.
- Glucose has proinflammatory actions while insulin is anti-inflammatory in nature.
- The anti-inflammatory nature of insulin suggests that hyperinsulinemia seen in insulin resistance may be a protective phenomena and this also explains its cardioprotective and cytoprotective actions.
- The hypothalamic centers that regulate appetite, food intake, and satiety are formed during the fetal period; enhanced maternal and early perinatal nutrition programs the hypothalamic centers and this influences food preferences in later life.
- Features of metabolic syndrome are seen when ventromedial hypothalamus is damaged suggesting that it could be a disorder of the brain.
- Insulin receptors are present in the brain and intracerebroventricular injection of insulin reduces food intake and suppresses NPY/AgRP and activates POMC/CART neurons.
- Insulin activates K_{ATP} channels in the neurons and modulates the levels of reactive oxygen species and nitric oxide, and thus regulates glucose homeostasis.
- PUFAs are essential for brain growth and development and modulate the production and actions of acetylcholine, dopamine and other neurotransmitters and monoamines. PUFAs are also neuroprotective in nature.
- Maternal diet influences plasma leptin levels that, in turn, modulates NPY/AgRP and POMC/CART homeostasis
- Gastric bypass and diet restriction induced weight loss could be due to alterations in hypothalamic neuropeptides and monoamines.

Key Points

- Glucose is needed for the energy needs of all tissues of the body.
- Glucose needs to enter the cell for its conversion to ATP (adenosine triphosphate), the main source of energy to all cells of the body.
- Insulin has the property to push glucose into the cells.
- Insulin to produce its actions binds to its receptor, insulin receptor, which leads to the generation of a series of signals that bring about the actions of insulin in the cell.
- Once the glucose enters the cell, though its receptors called GLUT (glucose transporters) receptors plasma glucose levels decrease.
- When glucose fails to enter the cell due to a defect in insulin action and abnormalities in GLUTs, plasma glucose will increase while the cells are starved of glucose.
- Insulin is produced by pancreatic β cells in response to food intake and increase in plasma glucose levels.
- Failure to produce adequate amounts of insulin leads to inadequate utilization of glucose by cells and this results in an increase in plasma glucose. Called hyperglycemia, this is a key feature of type 2 diabetes mellitus and the metabolic syndrome.
- Other features associated with metabolic syndrome are obesity, abnormities in plasma lipid levels, and low-grade inflammation.

- Metabolic syndrome is considered a low grade systemic inflammatory condition.
- Hyperglycemia enhances the production of free radicals, and proinflammatory cytokines.
- Insulin shows anti-inflammatory actions.
- Lesions of the ventromedial hypothalamus (VMH) in experimental animals produce all the features of the metabolic syndrome
- Neuron-specific insulin receptor knockout (NIRKO) mice also show many features of the metabolic syndrome.
- Mice with targeted disruption of endothelial nitric oxides synthase (eNOS) are not only hypertensive and insulin resistant but also show features of the metabolic syndrome.
- The brain is rich in insulin receptors, including the hypothalamus.
- Administration of insulin into the hypothalamus reduces food intake and plasma glucose.
- Hypothalamic centers that regulate food intake, appetite, and satiety are formed during the perinatal period.
- Maternal diet and perinatal nutrition programs the hypothalamic centers, hypothalamic neuropeptides, and monoamines.
- Polyunsaturated fatty acids (PUFAs) are essential for brain growth and development and can modulate the production of leptin and other neuropeptides.
- Intraventricular administration of oleic acid decreases food intake, reduces plasma glucose and leptin levels, and ameliorates diabetes mellitus.
- Cross-talk among gut, liver, pancreas, and hypothalamus occurs through vagal fibers.
- Acetylcholine, the principal vagal neurotransmitter, shows anti-inflammatory actions and regulates various hypothalamic monoamines.
- Insulin, PUFAs, and acetylcholine enhance endothelial nitric oxide generation, and have anti-inflammatory and neuroprotective actions.
- Glucose, insulin, and PUFAs act on K_{ATP} channels in glucose-responsive hypothalamic neurons.
- Brain glucose-sensing mechanism involves reactive oxygen species (ROS) signaling that act on ATP-sensitive K^+ channels.
- The strategy of providing adequate PUFAs during the perinatal period may prevent the development of the metabolic syndrome by suppressing low-grade systemic inflammation, ensuring the presence of adequate number of insulin receptors in the brain, and adequacy of hypothalamic neuropeptides and monoamines.

Chapter 165
Schizophrenia and the Metabolic Syndrome

Jared Edward Reser

165.1 Introduction

It has been well known for at least 2 decades that schizophrenia is associated with excess mortality, premature death, and increased standard mortality from both natural and unnatural causes (Allebeck 1989). Patients with schizophrenia are at high risk of death from unnatural causes such as suicides and accidents; however, unnatural causes do not account for even half of the excess mortality. It is increasingly recognized that patients with schizophrenia are at increased risk for natural causes of death, primarily life-shortening illnesses (Marder et al. 2004). Epidemiological data have for decades evinced that natural causes afflict patients with schizophrenia much earlier than they do people in the general population. In fact, one meta-analysis concluded that at least 60% of the excess mortality in patients with schizophrenia is attributable to physical illness (Brown 1997). This well-received study also found that only 28% of the excess mortality is attributable to suicide and only 12% to accidents, leaving even more room than initially expected for the contribution of illness. Individuals with schizophrenia have been shown to die younger from a variety of cardiovascular, infectious, gastrointestinal, respiratory, urogenital, and metabolic conditions. It is not clear if there is a common contributing pathological factor that underlies these epidemiological correlations. Probably the best candidate for such a unifying factor is the metabolic syndrome, a cluster of commonly comorbid metabolic derangements that tend to exacerbate one another and tend to afflict individuals with schizophrenia. It is not clear why the metabolic syndrome is relatively prevalent in populations with schizophrenia, but taken together, various points of evidence regarding this association are beginning to elucidate how the two are related and what can be done in regard to prevention.

Most medical professionals do not think of the metabolic syndrome when they hear the word schizophrenia. Schizophrenia is a psychiatric diagnosis that is characterized by abnormalities in the perception or expression of reality. It can present in different ways but commonly manifests as auditory hallucinations, paranoid or bizarre delusions, or disorganized speech and thinking. The impairment in sensory gating, emotional inhibition, and the organization of complex behaviors cause individuals with schizophrenia to have significant impairments in social and occupational abilities. Onset of symptoms typically occurs in young adulthood with between 0.4% and 0.6% of the worldwide population affected (Bhugra 2006). It has become clear that the psychological symptoms are accompanied by a variety of somatic symptoms and health issues. In a study of over 168,000 affected

Table 165.1 The key features of schizophrenia

Thought	Hallucinations, delusions, paranoid ideation, bizarre thinking
Behavior	Disorganized speech, emotional outbursts, social and occupational dysfunction, long term unemployment, homelessness, poverty
Causes	Both genetic and environmental, high heritability, stress, prenatal stress, drug abuse, social disadvantage
Brain physiology	Increased dopamine activity in the mesolimbic pathway, hypometabolic states in the prefrontal and temporal cortices and hippocampus
Comorbid conditions	Major depression, anxiety disorders, metabolic disorders, substance abuse

The key features of schizophrenia with selected aspects

patients in Sweden, schizophrenia was associated with an average life expectancy of approximately 80–85% of that of the general population (Hannerz et al. 2001). It is currently thought that a large proportion of this excess mortality can be attributed to metabolic disease.

Before the explicit ties to the metabolic syndrome were made, it was noted by epidemiologists that cardiovascular disease plays a large role in the premature deaths of schizophrenic patients. It was estimated that cardiovascular disease was responsible for as much as 50% of the excess mortality (Osby et al. 2000). Moreover, nearly 20% of deaths in schizophrenia can be attributed to ischemic heart disease, the most common cause of death in both sexes (Newman and Bland 1991). Today it is thought that even though there may be many contributing factors to cardiovascular disease in schizophrenia (such as cardiac arrhythmia and toxic cardiomyopathy), the major contributing factors may be metabolic disturbances – shared, common comorbidities in cardiovascular disease and schizophrenia. Since this realization, it has been well documented that individuals with schizophrenia are markedly susceptible to a specific group of metabolic disturbances that tend to present together in human and animal populations as the metabolic syndrome. It is thought that susceptibility to metabolic disease may be due to many different aspects common to schizophrenia, the most probable include inactive lifestyle, poor dietary choices, severe stress, and the side effects of psychotropic medications (Wirshing and Meyer 2003) (Table 165.1).

165.2 The Metabolic Syndrome in Schizophrenia

The metabolic syndrome has been a significant construct in the field of cardiology and endocrinology for at least 2 decades, but has become of interest to a variety of different fields in the last decade because of the ongoing, worldwide epidemic of obesity and diabetes. The metabolic syndrome is comprised of a group of clinical features that include atherogenic dyslipidemia (low high density lipoprotein (HDL) and elevated fasting triglycerides), hypertension, increased abdominal or visceral adiposity, and impaired fasting glucose or diabetes mellitus (Expert Panel on Detection 2001) (Table 165.2).

In 2005, the Adult Treatment Panel III of the National Cholesterol Education Program defined diagnosis as the presence of three or more of the five states listed in Table 165.3. The International Diabetes Federation, the European Group for the Study of Insulin Resistance, the World Health Organization, and others have each identified unique sets of diagnostic criteria. This disparity in diagnostic definition has created some concern and confusion; however, all three systems are relatively similar. There is broad overlap between the definitions, especially those of the World Health Organization and National Cholesterol Education Program. These similarities led researchers to find that, using data from the third National Health and Nutrition Examination Survey, NCEP and WHO criteria led to identical diagnoses for a group of 8,608 subjects in 86.2% of subjects. Not surprisingly,

Table 165.2 The key features of the metabolic syndrome

Obesity	Increased total body fat, abdominal or central fat distribution, increased visceral fat
Insulin resistance	Hyperinsulinemia
Dyslipidemia	Hypertriglyceridemia, decreased HDL cholesterol, increased LDL cholesterol
Impaired glucose tolerance	Type 2 diabetes mellitus
Hypertension	High or deranged blood pressure

The defining disorders of the metabolic syndrome and their components

Table 165.3 Criteria for the metabolic syndrome

Increased waist circumference	>102 cm in men, >88 cm in women
Elevated triglycerides	>150 mg/dl or 1.7 mmol/l
Decreased HDL cholesterol	<40 mg/dl in men, <50 mg/dl in women
Blood pressure	>130/85 mgHg or active treatment for hypertension
Fasting glucose	>110 mg/dl or active treatment for hyperglycemia

The National Cholesterol Education Program's criteria for diagnosis of the metabolic syndrome and their defining measures. Three of the five risk factors must be present for a diagnosis

differences in susceptibility to individual features caused the prevalence estimates between the two definitions to differ for some subpopulations, including sex and race (Ford and Giles 2003). It is not known if schizophrenia is another subpopulation whose prevalence might be affected arbitrarily by differences in susceptibility to certain features over others, although it is certainly possible.

The metabolic syndrome is highly prevalent in the general population. Based on the estimates derived from the third National Health and Nutrition Examination Survey it is thought that around 47 million people in the US meet the diagnostic criteria (Ford and Giles 2003). The age-adjusted prevalence in the US is 23.7% with the lowest prevalence of 6.7% for individuals between the ages of 20 and 29 and the highest prevalence of 43.5% for individuals aged 60 and higher. Both schizophrenia and a closely related psychiatric illness, schizoaffective disorder, are associated with a drastically increased risk for the metabolic syndrome and together have an age-adjusted prevalence of 42.6% for males and 48.5% for females (Cohn et al. 2004). Ethnicity as a predictor persists even after controlling for age, BMI, and socioeconomic status. For instance, Hispanics have the highest age adjusted prevalence of 31.9%. The age adjusted prevalence for schizophrenia is thought to be above 40%, significantly higher than the highest prevalence by ethnicity (Cohn et al. 2004).

McEvoy et al. (2005) confirmed in a large and well-controlled study that the metabolic syndrome is much more prevalent in patients with schizophrenia than among individuals from the general population, even after controlling for body mass and a variety of demographic variables. The order of the significance of this finding persuaded researchers to state that schizophrenia patients may represent a patient population with one of the highest metabolic syndrome prevalence rates of the major patient groups studied today. This study also showed that female patients with schizophrenia may constitute one of the subpopulations most vulnerable to central obesity and type 2 diabetes mellitus. Despite this and other fine studies in this area, there is no consensus about the prevalence of the metabolic syndrome in schizophrenia, in it subsets, or in associated psychotic disorders. It will be very informative to have the cross-sectional, longitudinal, and component feature data, and this may be available in a more reliable form in the near future.

The etiology of the metabolic syndrome, like that of schizophrenia, is still mysterious and controversial. There are a large number of secondary factors, aside from the key features, that are closely associated with the metabolic syndrome (Ryan and Thakore 2002), see Table 165.4. A review of these by Hansen (1999) identifies a wide assortment including: autonomic neuropathy, altered adipose tissue

Table 165.4 Secondary associations with the metabolic syndrome

Adipose tissue abnormalities: hyperleptinemia, altered lipoprotein lipase activity
Alcohol consumption
Pituitary adrenal abnormalities: hypercoritisolemia, impaired glucocorticoid receptor function
Reduced physical activity
Reduced ability to cope with stress, elevated stress hormone levels
Genetic predisposition, high heritability
Smoking
Increased food intake: hyperphagia, increased dietary fat content
Sex hormone abnormalities

A brief list of some of the secondary abnormalities associated with the diagnosis of the metabolic syndrome

physiology, difficulty coping with stress, excess alcohol consumption, hypercortisolemia, hyperphagia, impaired glucocorticoid receptor function, increased dietary fat content, reduced growth hormone, reduced physical activity, sex hormone abnormalities, and smoking. Factor analyses of the key and secondary features suggest that there is no unifying etiological feature (Zimmet et al. 1999). Many of these features are known to be quite commonplace in schizophrenia (Ryan and Thakore 2002). There has been very little research though, on whether populations of nonschizophrenic individuals with the metabolic syndrome exhibit symptoms particular to schizophrenia.

Individuals with schizophrenia may have increased risk for the metabolic syndrome because of patterns of unhealthy lifestyle choices common to schizophrenia and other psychotic disorders. Heavy alcohol (Mortensen and Juel 1993) and cigarette (Masterson and O'Shea 1984) use, along with poor diet, high fat consumption, lack of exercise and low physical activity (Brown et al. 1999) are all strongly associated with schizophrenia and have been for decades. These lifestyle factors are also powerful risk factors for the metabolic syndrome. It is clear that there is an increased need for lifestyle therapy intervention in this population. Diminishing substance abuse and increasing physical activity have long been treatment goals in schizophrenia therapy designed to ameliorate the psychological symptoms and improve mood. Now it is obvious that these goals will do more for this population than previously appreciated because they will also help to treat the metabolic symptoms.

It is becoming clear that the high prevalence of the metabolic syndrome in schizophrenia is due to more than just the behavioral propensities of patients or the antipsychotic drugs that the majority of patients have been prescribed. Several family history studies, and even decades old historical studies have found weighty, positive associations between schizophrenia and diabetes. Studies have also shown that first episode drug-naïve patients have an increased prevalence of central obesity, impaired fasting glucose, and insulin resistance suggesting that metabolic disturbances may be an inherent genetic component of the schizophrenia phenotype (de Leon and Diaz 2007; Spelman et al. 2007). Some well controlled studies have even shown that diabetes is more common in patients not taking antipsychotics than in those that were receiving them (Mukherjee et al. 1996). This represented powerful evidence suggesting that the association between schizophrenia and the metabolic syndrome is due to more than just the commonly accepted environmental influences. Some recent articles have even stated explicitly that there is evidence indicating that, "patients with schizophrenia might have an inherent predisposition towards the metabolic syndrome in a similar manner seen with certain ethnic groups" (McEvoy et al. 2005). In fact, genes responsible for schizophrenia and the metabolic syndrome seem to transmit together across generations. There is an increased frequency of the metabolic syndrome in the nonschizophrenic relatives of patients with schizophrenia (Mukherjee et al. 1989). Also, many of the individual facets of the metabolic syndrome have been closely tied to first episode or drug naïve schizophrenia as Table 165.5 demonstrates.

Table 165.5 Metabolic disorders and schizophrenia

Cardiovascular disease	Kendrick (1996); Davidson (2002) Ryan and Thakore (2002)
Insulin resistance	Felker et al. (1996); Ryan and Thakore (2002); Ristow (2004)
HPA axis up-regulation	Walker et al. (1996); Walker and Diforio (1997)
Metabolic syndrome	Ryan and Thakore (2002); Heiskanen et al. (2003)
Obesity	Allison et al. (1999); Davidson (2002)

A list of some of the features of the metabolic syndrome that have been associated with drug naïve or first episode schizophrenia

165.3 Schizophrenia and Diabetes

Studies indicate that diabetes mellitus may be twice as prevalent in schizophrenia (14%) as it is in the general population (7%) (Dixon et al. 2000). Additionally, impaired glucose tolerance and insulin resistance are also more common (Jeste et al. 1996). It is still not clear to what extent schizophrenia and diabetes present comorbidly because of shared genetic backgrounds, or if they are associated environmentally through weight gain. Prior to the onset of schizophrenia, there is not strong evidence for preexisting obesity (Weiser et al. 2004), an observation which provides some support for the latter assumption given that susceptibility of children and adults to the metabolic syndrome increases with worsening obesity. This does not necessarily detract from the significance of genetic contribution though, especially since individuals with schizophrenia are more likely to have obese parents. Furthermore, some studies have shown that even though there may not be a predisposition towards obesity prior to onset, it seems there is a prodromal predisposition for visceral adiposity (Zhang et al. 2004). It is possible that this inclination becomes fully expressed as obesity and diabetes after onset due to epigenetic factors, lifestyle, medications or interactions between all three.

The number of published prevalence studies of the metabolic syndrome in schizophrenia patients is not large, but it documents that the association is probably larger than the association between schizophrenia and diabetes mellitus (Heiskanen et al. 2003; Basu et al. 2004). Why this might be is unclear. The association between diabetes mellitus and schizophrenia has come under scrutiny recently because of new data associating atypical antipsychotics (also known as second generation antipsychotics) with new onset diabetes and the dangerous state of diabetic ketoacidosis (American Diabetes Association et al. 2004). Atypical antipsychotics have been known to work well to alleviate the symptoms of schizophrenia, and other forms of psychosis, but have received negative attention in the literature because of the significant weight gain liabilities associated with certain drugs (Meyer 2001).

165.4 Antipsychotic Medications

Atypical antipsychotics have been immensely effective in treating schizophrenia. Ironically though, they have been implicated in greatly accelerating the progression of the metabolic syndrome. More specifically, they have been heavily associated with cardiac irregularities, dyslipidemia, glucose intolerance, and weight gain (Ryan and Thakore 2002). The proportion of patients on antipsychotics with the metabolic syndrome ranges between 20% and 60% and in most cases is double the prevalence in the general population (De Hert et al. 2006; Haupt 2006). The evidence is the strongest for clozapine and olanzapine (Shirzadi and Ghaemi 2006) and suggestive but weaker for other antipsychotics (Newcomer and Haupt 2006).

It has been difficult for researchers to come to conclusions about the adverse effects of antipsychotics without the much needed randomized, controlled trials with prospective designs. Prior antipsychotic treatment and other medications confound the findings of many of the studies. Recent studies done with first episode schizophrenia avoided some of these confounds because all of the participants were drug naïve and had no prior antipsychotic prescription. One such study, using historic data, found that even though there was no difference in prevalence of the metabolic syndrome between first episode schizophrenics from 15–20 years ago compared with first episode moderns, the incidence of the metabolic syndrome was three times higher in the modern group that took atypical antipsychotics compared to the historic group that took first-generation antipsychotics (Hert et al. 2008). A number of findings have reinforced the consensus that first generation antipsychotics were far less likely to lead to metabolic complications. Another first episode study compared individual medications and showed that the test groups receiving olanzapine had the highest prevalence of the metabolic syndrome at 20–25%, followed by risperidone at 9–24% and finally haloperidol at 0–3% (Saddichha et al. 2008). Other studies have identified clozapine as being among the worst of these agents.

There are still many unknowns in this arena but fortunately there are also some thoughtful articles aimed at educating health professionals about what is known. The American Diabetes Association published a consensus paper on antipsychotic drugs and metabolic outcome that provides clear and helpful guidelines for health monitoring and medication selection for patients needing atypical antipsychotic drugs (American Diabetes Association et al. 2004). Despite many strong findings, it is important to point out that the influence of antipsychotic drugs comprises only a piece of this puzzle. As stated earlier, metabolic abnormalities have consistently been associated with schizophrenia even before the era of antipsychotic medications (Raphael 1921; Homel et al. 2002).

165.5 Schizophrenia and Cardiovascular Disease

As stated earlier, cardiovascular disease is one of the primary causes of morbidity and mortality in patients with schizophrenia (Meyer and Nasrallah 2003). Patients are known to commonly exhibit several different markers for cardiovascular risk. Both individuals treated with atypical antipsychotics and those who are drug free have a high propensity for platelet aggregation differences which makes them more likely to produce thrombus. Thrombus production is crucial during wound healing but overproduction can lead to life-threatening pathology including myocardial infarction. Exactly why and how this increased platelet aggregation occurs is unclear. Other unhealthy cardiac features that are associated with schizophrenia include: abnormal heart variation, prolonged phase of cardiac depolarization, decreased variations in cardiac rate, high sinus rhythm resting heart rate, long periodicity of endogenous ultradian rhythm of heart rate, and others. Interestingly, most of these features were abnormal in both individuals treated with antipsychotic drugs and those that were never treated. These findings lead one to conclude that there are multiple sources of evidence for abnormal autonomic control of heart rate, each of them related to cardiovascular risk, and many of them particular to the condition of schizophrenia specifically because they seem to be independent of the effects of antipsychotic medication.

The autonomic basis for these cardiovascular effects may be related to the extreme liability of both the sympathetic and parasympathetic divisions of the autonomic nervous system in untreated schizophrenia. It has been found that treatment with antipsychotic drugs actually has the effect of normalizing these swift autonomic swings. Such major autonomic dysregulation in untreated individuals could be inextricably tied to the development of the metabolic syndrome for several reasons including the following three: insulin is known to stimulate sympathetic activity, habitually elevated

Table 165.6   Therapeutic intervention for the metabolic syndrome

Obesity	Behavior modification, caloric restriction, regular exercise
Atherogenic diet	Reduce trans fats, saturated fats, dietary cholesterol and total fat
Cigarette smoking	Complete smoking cessation
Low HDL	Advise adding fibrate or nicotinic acid to diet
Hypertension	Lifestyle therapy, advise antihypertensive drugs
High LDL	Advise LDL cholesterol lowering drugs
Elevated glucose	Lifestyle therapy, advise hypoglycemic agents
Physical inactivity	Sixty minutes of moderate-intensity exercise daily
Prothrombotic state	Advise low-dose aspirin therapy

A very brief summary of clinical recommendations for individual facets of the metabolic syndrome

levels of sympathetic activity induce insulin resistance in skeletal muscle, increased sympathetic tone is associated with obesity and visceral fat deposition. The autonomic dysregulation may also lead to risk factors for the metabolic syndrome via a separate route. Chronic arousal of the sympathetic branch of the autonomic nervous system causes upregulation in the hypothalamic-pituitary-adrenal axis which in turn increases levels of circulating cortisol. Chronically elevated cortisol levels, a major finding in schizophrenia, influence and accelerate, at multiple etiologic stages, insulin resistance, abdominal obesity and dyslipidemia. An article by Rosmond and Bjorntorp (2000) provides compelling support for the wealth of evidence tying autonomic and hypothalamic-pituitary-adrenal axis dysregulation to risk factors for the metabolic syndrome.

Physician efficacy in moderating lifestyle risk factors for cardiovascular disease such as physical activity, diet and smoking can be very low even in healthy populations. Due to their psychological symptoms such as high levels of emotion and low capacity for inhibition, influencing lifestyle factors is probably more difficult in populations of patients with psychiatric histories, especially ones with schizophrenia. This makes it even more important to treat the other risk factors: hyperlipidemia, obesity, and glucose intolerance. In other words, because patients with schizophrenia can be relatively resistant to lifestyle therapy, the medications and the role of the prescribing physician are of upmost importance. There are a daunting number of antihypertensive, hypoglycemic, and cholesterol lowering drugs to keep track of, each with multiple contraindications and implications for medication evaluation. Table 165.6 summarizes some of the major therapeutic interventions for individual features of the metabolic syndrome, including behavioral goals and medications. These are forms of intervention that any medical professional treating schizophrenia should be aware of.

165.6   Applications to Other Areas of Health and Disease

It is clear that patients with schizophrenia are susceptible to a variety of medical illnesses and that these are responsible for a large proportion of the excess mortality observed. A large proportion of these disturbances map on neatly to the various features of the metabolic syndrome. It is not obvious whether the metabolic disorders are an integral part of schizophrenia or whether both are caused by a third, unidentified mechanism. The close association probably has at least a small genetic foundation and is further exacerbated by unhealthy lifestyle choices and the commonly prescribed antipsychotics. The existence of serious metabolic disease in schizophrenia has major implications for public health. It is very important that mental health professionals are made cognizant of the metabolic issues in patients with schizophrenia and instructed in how to address them proactively. Serious efforts should

be made to instruct and educate psychologists and psychiatrists to investigate, recognize, and actively monitor metabolic conditions in their patients with schizophrenia as well as readily refer these patients to primary care physicians. It is also important to increase awareness among psychiatrists of the fact that these conditions can be iatrogenically exacerbated during antipsychotic therapy.

A great deal of evidence suggests that the existence of the metabolic syndrome in schizophrenia, as in other populations, is contingent upon a high fat diet and living in a Westernized culture (Thakore et al. 2002). The metabolic syndrome is reaching pandemic proportions worldwide and this is thought to be closely related to the absence of physical exercise and abundant and cheap supply of calorie dense foods. Another chapter in this book, "Nutrition, Behavior and the Developmental Origins of the Metabolic Syndrome," discusses how immoderate eating habits and reductions in physical activity have the capacity to greatly exacerbate metabolic disturbances in humans from Westernized cultures. Now that we no longer forage throughout the day for lean meats, fruit and vegetables we are susceptible to obesity and metabolic disease, just like laboratory animals that are caged and fed ad libitum. Many of the topics highlighted by that chapter, including the Westernization of diet, the genetic associations between different metabolic abnormalities, the discussion of "thrifty genotypes" and the influences of epigenetic programming may also be relevant to the present discussion.

There are several well refined animal models of schizophrenia. Most of these induce schizophrenic symptoms in rats or mice by using the same cues thought largely responsible for inducing schizophrenia in humans stress and hypercortisolemia. Rats that are stressed, either prenatally or postnatally, exhibit many of the fundamental symptoms of schizophrenia including impulsivity, habituation deficits, sensory gating deficiencies and reduced hippocampal size. There is truly a paucity of research on the metabolic abnormalities in these animals and the present literature on schizophrenia and the metabolic syndrome has all but ignored this model. Researching the metabolic features of the animal models of schizophrenia should be far less expensive and easier to control and manipulate than many of the current studies looking at these features in humans. Of course, further studies with people are urgently needed as well though, and an emphasis should be placed on drug-naïve, longitudinal designs.

Comprehensive reviews in clinical endocrinology have established that, as our population ages, the metabolic syndrome will be an increasingly important concern. The incidence of schizophrenia does not increase with advancing age yet very little is known about the incidence of the metabolic syndrome in aging individuals with a past diagnosis of schizophrenia. As this chapter has illustrated, we know a good deal but there are still many unknowns. The formulation of treatment standards for the metabolic syndrome remains a highly contentious topic even in individuals without schizophrenia. Increasing the efficacy of lifestyle therapy, decreasing the metabolic disturbances associated with antipsychotics and disentangling people from their genetic propensities for schizophrenia and the metabolic syndrome all remain formidable and complicated problems for the future. It is clear; however, that the careful monitoring of metabolic health in patients with schizophrenia, especially those on atypical antipsychotics, could help markedly in early detection and prevention of the metabolic syndrome.

Summary Points

- Schizophrenia is a life-shortening illness with excess mortality attributable to increased frequency of specific natural and unnatural causes.
- Schizophrenia carries increased risk of a variety of metabolic disorders.
- High visceral fat, type 2 diabetes mellitus and cardiovascular disorders occur with increased frequency in schizophrenia.

- Unhealthy lifestyle, poor diet and lack of exercise probably contribute to the metabolic syndrome and metabolic abnormalities in schizophrenia.
- An inherent susceptibility to stress and elevated levels of cortisol probably exacerbate both psychiatric and metabolic disturbances.
- Atypical, or second generation, antipsychotics have been largely implicated in the onset of obesity, diabetes mellitus and the exaggeration of metabolic complications.
- New findings in this literature have important implications for public health and the treatment of schizophrenia.

Definitions

Antipsychotics: Medications used to treat schizophrenia or other psychotic conditions often manipulating dopamine function to decrease hallucinations, delusions, and other symptoms. Also referred to as neuroleptic drugs.

Dyslipidimia: A disruption of the levels of lipids in the blood. In western societies, most dyslipidemias are hyperlipidemias; an elevation of lipids often due to diet, lifestyle or prolonged elevations of insulin.

Glucose tolerance: The ability of the body to adapt to a relatively large dose of glucose. This ability is usually diminished in diabetics and is used to diagnose diabetes mellitus. A fasting subject ingests around 75 g of glucose and blood glucose is measured at intervals. In diabetics the concentration is higher and takes longer to return to baseline value.

Hypercortisolemia: A state marked by elevated levels of circulating cortisol, an essential glucocorticoid steroid hormone, the major hormone secreted by the adrenal glands.

Hyperglycemia: A complex metabolic condition characterized by high levels of blood glucose in the circulation, usually a result of insufficient or ineffective insulin production in either type 1 or type 2 diabetes mellitus.

Hyperphagia: An abnormal appetite or increased consumption of food, often associated with abnormalities in the hypothalamus.

Hypertension: High blood pressure or force of blood on the vessel walls of the arteries.

Hypothalamic-Pituitary-Adrenal axis: This is a neuroendocrine system in the body responsible for regulating stress physiology. Brain areas that sense threat, signal the hypothalamus which communicates hormonally to the pituitary which in turn signals the adrenal glands to secrete adrenaline and cortisol.

Insulin resistance: A condition in which cells, especially those comprising muscle, fat and liver tissue, fail to be properly receptive to the messages of the hormone insulin. Because insulin promotes the extraction of glucose from the blood, allowing cells to meet their metabolic needs, insulin resistance is associated with elevated levels of blood glucose.

Metabolic syndrome: A combination of metabolic disorders that commonly present together and increase the risk of developing diabetes and cardiovascular disease.

Schizophrenia: A group of psychotic disorders characterized by impairments in sensory gating, emotional inhibition and the organization of complex behaviors.

Visceral fat: The accumulation of fat around the internal organs of the torso. It is associated with the "apple shape," belly fat, central obesity and a high waist to hip ratio.

Chapter 166
Nutrition, Behavior, and the Developmental Origins of the Metabolic Syndrome

Jared Edward Reser

Abbreviations

LDL   Low density lipoprotein
FOAD   Fetal origins of adult disease

166.1 Introduction

A handful of unifying perspectives have guided theory and even research related to the metabolic syndrome and its associated abnormalities. A broad look at the most popular of these adds another dimension to the clinical knowledgebase that we have and also helps us to better characterize findings and unknowns. This chapter will take such an approach and attempt to highlight some of the outstanding perspectives in an attempt to reconcile the metabolic syndrome with the goals and frame of reference of this book. First, of course, it is important to have a handle on what the metabolic syndrome represents nosologically and why it can be such a difficult construct to get a firm grip on.

The metabolic syndrome is a combination of medical disorders that present in a clustered fashion and result in increased risk for cardiovascular disease and diabetes. Also known as syndrome x, and the insulin resistance syndrome, this multifactorial disease was identified over 80 years ago but has shown a striking increase, worldwide, in the last 2 decades. The rise in international prevalence and clinical interest is closely associated with the global epidemic of obesity and diabetes; however, the metabolic syndrome includes other comorbid disorders, including cardiovascular disease. Symptoms and features include: glucose intolerance (type 2 diabetes, impaired glucose tolerance or impaired fasting glycemia); high blood pressure (hypertension); central obesity (visceral adiposity); increased LDL cholesterol; and dyslipidemia (elevated triglycerides) (Table 166.1). These conditions have a tendency to co-occur in individuals more often than they present alone. For this reason, they have been grouped into the encompassing diagnosis of the metabolic syndrome which is known to present in a variety of different ways in different people. Partly because the constellation of metabolic abnormalities can be slightly different for virtually every person, there is still some contention over which features are central etiologically.

Table 166.1 The key features of the metabolic syndrome

Obesity	Increased total body fat, abdominal or central fat distribution, increased visceral fat
Insulin resistance	Hyperinsulinemia
Dyslipidemia	Hypertriglyceridemia, decreased HDL cholesterol, increased LDL cholesterol
Impaired glucose tolerance	Type 2 diabetes mellitus
Hypertension	High or deranged blood pressure

The defining disorders of the metabolic syndrome and their components

Table 166.2 Diagnosis of the metabolic syndrome

Increased waist circumference	>102 cm in men, >88 cm in women
Elevated triglycerides	>150 mg/dL or 1.7 mmol/L
Decreased HDL cholesterol	<40 mg/dL in men, <50 mg/dL in women
Blood pressure	>130/85 mgHg or active treatment for hypertension
Fasting glucose	>110 mg/dL or active treatment for hyperglycemia

The National Cholesterol Program requires that at least three of the above five criteria be met for a diagnosis of the metabolic syndrome

In 2005 the Adult Treatment Panel III of the National Cholesterol Education Program (2001) defined diagnosis as three or more of five states listed in Table 166.2. The International Diabetes Federation, the European Group for the Study of Insulin Resistance, and the World Health Organization, and others have each identified unique sets of diagnostic criteria. This disparity in diagnostic definition has created some concern and confusion, although all three systems are relatively similar.

Making comparisons of prevalence for different populations is difficult because different published studies utilize different diagnostic criteria, although a standardized, international definition should abet these difficulties. Sex and ethnic origin predict large amounts of variation in prevalence. The prevalence is also highly age-dependent. Prevalence in the USA (in the national health and nutrition examination survey) increased from 7% in participants between the ages of 20 and 29 to 44% in participants between 60 and 69 (Ford et al. 2002). The majority of diagnoses are given to older, obese individuals who have a degree of insulin resistance. Until recently, the metabolic syndrome was regarded as a disease of old age, yet now, with increasing rates of obesity and diabetes in young people, it is commonly diagnosed in children. As in adults, susceptibility of children to the metabolic syndrome increases with worsening obesity.

The etiology and pathophysiology of the metabolic syndrome are extremely complex and have only partially been elucidated. Currently, it is debated whether obesity or insulin resistance is the cause of the metabolic syndrome, or if it can be attributed to a more obscure metabolic derangement (Table 166.3). The disorder, like its features, is highly heritable, and the large genetic component helps health practitioners to identify at-risk individuals if their family medical history is known. The main treatments include calorie restriction and dieting, physical exercise, and occasional drug prescription. The individual diseases that make up the metabolic syndrome are usually treated individually; diuretics and ACE inhibitors for hypertension, cholesterol drugs for elevated LDL cholesterol, and triglyceride levels and various drugs for insulin resistance. More information about treatment and clinical recommendations is given in Table 166.4.

The prevalence of the metabolic syndrome has increased severalfold in the last few decades. In these same decades, fast food and processed foods have become internationally ubiquitous, and physical exercise has been engineered out of our daily routines. It is clear that the metabolic syndrome is a product of the modern environment which has done much to increase sedentary behavior and the overconsumption of unhealthy foods. It is thought that humans were not "designed" to live this type of lifestyle, which is to say that we were not naturally selected to have genes that prepare us for it. Our hunting and gathering ancestors were probably only rarely afflicted by such unhealthy lifestyles or their metabolic consequences.

Table 166.3   Behavior and the metabolic syndrome

Pituitary adrenal abnormalities: hypercortisolemia, stress behavior
Reduced physical activity, sedentariness
Reduced ability to cope with stress, elevated stress hormone levels
Substance abuse: smoking, alcohol, others
Increased food intake: hyperphagia, increased dietary fat content
Sex hormone abnormalities

A brief list of some of the behavioral abnormalities closely associated with the metabolic syndrome

Table 166.4   Therapeutic intervention for the metabolic syndrome

Obesity	Behavior modification, caloric restriction, regular exercise
Atherogenic diet	Reduce trans fats, saturated fats, dietary cholesterol, and total fat
Cigarette smoking	Complete smoking cessation
HDL	Advise adding fibrate or nicotinic acid to diet
Hypertension	Lifestyle therapy, advice antihypertensive drugs
LDL	Advice LDL cholesterol-lowering drugs
Elevated glucose	Lifestyle therapy, advice hypoglycemic agents
Physical inactivity	60 min of moderate-intensity exercise daily
Prothrombotic state	Advice low dose aspirin therapy

A very brief summary of clinical recommendations for the individual disorders of the metabolic syndrome

166.2   The Thrifty Genotype

The same genes that cause humans to be susceptible to diabetes, heart disease, and obesity in modern times may have protected us from starvation and famine during ancestral times. This hypothesis was first put forward in 1962 by James Neel in an article entitled: "Diabetes mellitus: a 'thrifty' genotype rendered detrimental by 'progress.'" Neel coined the phrase "thrifty genotype" referring to the probably very large complement of genes that would have helped our ancestors' metabolisms to be economical and prudent with the foods that they hunted and gathered (Neel 1982). Not only did their meals contain a smaller proportion of sugar and fat, but our ancestors also had to engage in prolonged physical activities to obtain them. Interestingly, adopting a "paleolithic diet" consisting primarily of fruit, vegetables, and meat is an increasingly popular dietary regimen. Neel pointed out that not only are our bodies engineered to expect a different diet, but they are also probably expecting extreme food shortages, something modern people only very rarely encounter. His thesis, refined in subsequent articles, was that adaptations that allowed organisms to minimize metabolism and providently lay down fat reserves would produce a survival advantage during periods of nutritional scarcity (Neel 1999). A good deal of research has indicated that the environment of human adaptedness, and wild environments in general, are marked by periods of "boom and bust" where periods of plenty are interspersed among periods of food shortage or famine. This concept was initially generated to allow an evolutionary explanation for the existence of diabetes, but has since been generalized toward the metabolic syndrome and become widely adopted. The mainstay of this conceptual standpoint is that our inherited propensity for energy conservation probably only translates into obesity and metabolic disease in modern times and may have protected individuals, particularly those with the "thriftiest genotypes" from starvation in ancestral times (Table 166.5).

Thrifty benefits have been attributed to the individual components of the metabolic syndrome. A smaller, weaker, yet less energy-expensive heart may confer the ability to minimize energy expenditure in the heart in order to mitigate the risk of starvation (Barker 1998; Barker et al. 2002). In modern times people that express this once adaptive phenotype no longer enjoy the benefits because the excess of fat and cholesterol consumed by these individuals puts a serious strain on their "thrifty" heart, making

Table 166.5 Diet and behavior, then and now

Prehistoric foraging individual	Modern day individual
Caloric uncertainty	Caloric stability
Moderate to high physical activity	Low physical activity
Dietary balance	Dietary excess
Insulin sensitivity in muscle cells	Insulin resistance in muscle cells
Metabolic efficiency	Metabolic dysregulation
Reproductive advantage	Presumed reproductive disadvantage

A comparison of health and ecological features between a typical forager and modern individual on a Westernized diet with an inactive lifestyle

them susceptible to heart or cardiovascular disease (Ridley 2003). A similar tradeoff is presumed to exist for insulin signaling. The beta cells of the pancreas release insulin in response to carbohydrate intake facilitating the metabolism of carbohydrates. An exaggerated pancreatic response (seen in the metabolic syndrome) results in hyperinsulinemia (high circulating levels of insulin) that leads to increased lipogenic activity and ultimately the storage of fats in adipose tissue. Such metabolic tendencies for increased adiposity may have helped individuals in the past to be frugal with fats and to store more fat, yet today they lead to obesity. Type 2 diabetes mellitus has been characterized as a disorder that is a prototypic example of this kind of evolutionary tradeoff. It has been thought for decades now that, on a cellular and organ system level, the disorder represents a thrifty condition – insulin resistance – that would have only rarely manifested as disease in the ancestral environment, because at that time individuals had no access to refined sugar or processed foods. The current literature holds that insulin resistance, brought about by genes for type 2 diabetes, represents a finely tuned physiological state and that its cellular and molecular pathways have been refined by natural selection over millions of years to help organisms conserve blood sugar. Insulin causes cells to rapidly take up blood sugars and increase the rate of their cellular processes thereby increasing total metabolic output. The defective insulin receptors, seen in cells of people with insulin resistance, might have helped to conserve these blood sugars in the past, but now that our diets feature dramatically higher levels of refined sugar; insulin resistance results in blood sugar levels that are vastly too high. Elevated blood sugar, hyperglycemia, can cause a variety of systemic and organ problems through the glycation and damaging of important biomolecules, seen frequently in diabetes. In all of these examples, biological mechanisms malfunction badly once they are forced to face our unhealthy modern diets (Table 166.6). It is now thought that many individual physiological pathways involved in the metabolic syndrome may represent ancient methods of energy conservancy (Eriksson et al. 2001).

Population genomics has identified some very interesting trends in geographic susceptibility to the metabolic syndrome, which provide corroborating evidence for the thrifty genotype theory. This widely accepted interpretation emphasizes that populations of preagricultural, foraging individuals who live in areas where, until recently, food has been relatively unpredictable have much higher prevalence of thrifty genes (Neel 1982). The traits that these genes code for probably helped these individuals survive during prolonged periods of scarcity or were maintained because historically these individuals were not exposed to high calorie diets (Valencia et al. 1999). Today, the incidence of the metabolic disease remains highest among populations where an economy of foraging existed until recently. Unfortunately, people in these areas such as Native Americans, Aboriginal Australians, and Pacific Islanders have an unusually high prevalence of the metabolic syndrome now that they have been exposed to the modern "diet of affluence." This genetic variation between human populations is akin to other known forms of anthropological adaptation to environment. Unknown to many, there are several examples of selective pressures acting on humans even in the last 50,000 years. Lactase persistence is one example, where populations in Europe and elsewhere

Table 166.6 Medical risks associated with a westernized diet

Metabolic state	Implications for foragers	Implications for moderns
Adiposity	Healthy fat retention	Excessive fat retention
Insulin resistance	Healthy levels of blood sugar	Excessive levels of blood sugar
Beta cell Responsiveness	Metabolism of carbohydrates	Hyperinsulinemia
Thrifty heart	Healthy, efficient heart	Heart burdened by high body fat
Glucose intolerance	Normoglycemia	Hyperglycemia

A comparison between a typical forager and an obese modern individual with respect to the end result of individual metabolic states

retained the ability to digest lactose into adulthood because of the domestication of cattle and the importance of the ability to derive calories from milk.

The Pima Indians in Arizona and the Nauru people from the Micronesian South Pacific Islands appear to have particularly thrifty genotypes (Dowse et al. 1991). Both populations are thought to have endured repeated episodes of food shortage and starvation. They live and have long lived in relatively isolated, unpredictable, and in the case of the Pima, desolate areas. Fascinatingly, the Nauru people have traveled among remote islands in the Pacific during many, several-week-long canoe voyages. Historical accounts attest that many individuals in these canoes died of starvation during the trips, perhaps creating a Nauru founder population of highly starvation adapted people. When exposed to a Western lifestyle in the twentieth century, obesity and type 2 diabetes increased drastically in the Pima and Nauru. For some time, these two groups had among the highest age and sex-adjusted incidence rates of type 2 diabetes, around 25 per 1,000 people per year for the Pima (Schulz et al. 2006).

A variety of animal studies echo these genographic studies in humans. Diabetes commonly afflicts zoo animals, and an epidemic has been described of captive populations of primates, whose lifestyle approximates the sedentary, high-calorie lifestyle of First World urban humans (Diamond 2003). Ecological support for the thrifty genotype hypothesis comes from studies with leptin-deficient (ob/ob) and leptin receptor-deficient (db/db) mice (Coleman 1979). Heterozygous animals, which have a significant tendency toward obesity and diabetes when fed ad libitum, survived longer during fasting than the wild-type animals, even when matched for body weight. This trend has been observed outside of the laboratory too. Certain animals that are well adapted to frequent food shortages, such as desert mammals, show increased susceptibility to the features of the metabolic syndrome when they are able to feed ad libitum. The Israeli sand rat is a prime example. It is highly predisposed to developing metabolic disease including insulin resistance, obesity, and diabetes when put on the western lab rat diet. The symptoms reverse quickly when its food is restricted or it is placed back in its natural environment (Haines et al. 1965). Fascinatingly, it is known that the facets of the metabolic syndrome in humans, including diabetes, can be reversed by diet, exercise, and weight loss. This decline and even disappearance of diabetes symptoms happened to thousands of Parisians during the 1870–1871 famine associated with the siege of Paris (Zimmet 1997).

Even though the thrifty gene hypothesis has been challenged in its particulars, the aspects discussed here have been well accepted in the medical and ethological literatures. The thrifty genotype model is not meant to account for all instances of metabolic disease, but does seem to offer a high degree of explanatory power for the metabolic pandemic of modern times. Far from being a liability, a tendency to be fine tuned for having a lower metabolism would have been an asset to survival in the Plio-Pleistocene because it would have helped individuals to conserve calories. That individual species, or some individuals within a species, have this tendency has important biomedical ramifications, and further research and experimentation in this area should help to clarify the underpinnings and tradeoffs involved in energy homeostasis. Several successful animal models, like the ones mentioned,

are thought to have helped to elucidate some of the key genes and pathways involved in impaired energy balance regulation. Interestingly, the genes that one is born with are not the only predisposing factors, as the next section will illustrate; the environment can play a large role as well.

166.3 The Developmental Origins of the Metabolic Syndrome

It is now widely accepted that the risk for a number of metabolic diseases may be affected by circumstances before birth. Professor David Barker and colleagues have produced a large amount of data, since 1994, showing that low birth weight increases susceptibility to noninsulin-dependent diabetes mellitus, hypertension, and coronary heart disease (Barker 1998) later in life. By analyzing epidemiological data for cohorts whose birth records are available, and following these individuals into adulthood, Barker, Hales and others have shown that birthweight, length, body proportions, and placental weight are highly associated with later metabolic disease incidence (Philips 1998) or risk factors for those diseases (hypertension, glucose intolerance, hyperlipidemia) (Barker, 1994, 1998). In addition to having increased adipose tissue mass in adulthood, low birth weight individuals have a tendency to store adipose tissue centrally and have a lower lean mass. Reduced muscle has been reported to contribute heavily to a lowered basal metabolic rate and is expected to reduce capacity for exercise (Kensara et al. 2005). These associations between birth size and disease are often apparent from childhood, hold in a large number of different populations, and have given rise to the term "fetal origins of adult disease" (FOAD) (Law and Shiell 1996; McKeigue 1997).

The biological changes responsible for metabolic alterations are attributed to epigenetic programming, also called phenotypic plasticity. Epigenetic programming occurs when an environmental cue creates a change in gene expression. Even small changes in gene expression and protein regulation, early on, can cause large phenotypic changes with time. Developmental geneticists closely adhere to the idea that a single genotype can give rise to, or canalize, a variety of different phenotypes depending on the programming effects of the early environment. Intrauterine programming is a well-established biological phenomenon, and there are many well-known examples, affecting organisms from plants to humans. In this case, an environmental stimulus, experienced during gestation, is thought to lead to impaired fetal growth and diminution in size at birth, although "catch-up" growth in childhood is the norm. This stimulus or cue also leads to altered homeostatic mechanisms such as the regulation of blood pressure or insulin sensitivity, which in turn results in susceptibility to the metabolic syndrome later in life. Exactly what this cue or stimulus is, has been open to debate. The majority of models in this literature point to undernutrition (Langley 1997) but some emphasize the contribution of other forces, such as placental dysfunction, or excessive fetal exposure to glucocorticoids.

Evidence for undernutrition as the underlying, environmental stimulus in this association comes from three sources: (1) the aforementioned epidemiological associations; (2) animal models; and (3) historical pseudo-experiments. Birth weight is readily altered in experimental animals by manipulating maternal nutrition during fetal development. A reliable way to decrease a rat's size at birth is by reducing the proportion of protein in the diet of their pregnant mothers. Like humans and other mammals, these rats show catch-up growth in youth, but soon thereafter exhibit tendencies toward obesity, elevated blood pressure (Langley and Jackson 1994), and impairments in glucose tolerance (Desai et al. 1995). Glucose intolerance seen in low-protein exposed offspring is contributed to by a reduction in pancreatic beta cell mass, reduced insulin secretion, and peripheral tissue insulin resistance. These symptoms are worsened by the presence of obesity in an additive manner (Petry et al. 1997) and, as in humans, worsened symptoms lead to reduced longevity in rats and mice (Ozanne and Hales 2004).

Restriction of total calories during pregnancy, without respect to protein composition, has been shown to result in rat offspring that are hyperphagic, hyperinsulinemic, obese, hypertensive, and significantly less physically active (Harding 2001). Again, analogous to what we see in our own species, these symptoms are accentuated by a highly palatable or high-fat diet later in life. High levels of catch-up growth after early deprivation have been shown to be related to skeletal muscle insulin resistance, reduced thermogenesis, and increased insulin sensitivity in adipose tissue (Cettour-Rose et al. 2005). Another parallel in this domain that is directly relevant to human health is the finding that diets of saturated fats lead to detrimental effects on glucose homeostasis in fetally deprived rats whereas diets containing polyunsaturated fatty acids had beneficial effects (Siemelink et al. 2002). Similar studies designed to reduce maternal nutrition during pregnancy have led to comparable results in rats, mice, guinea pigs, and sheep.

Peripheral signals that indicate the size of adipose stores such as circulating factors and the hormone leptin are received and integrated by the central nervous system, primarily at the hypothalamus and brainstem. If adipose stores are sufficient or large, changes in these signaling systems, such as the increase in leptin hormone, induce the nervous system to inhibit feeding and promote energy expenditure. Offspring of undernutrition pregnancies have been shown to demonstrate leptin insensitivity, high body weight, and increased food intake in adult life (Harding 2001). Whether early food restriction acts at the level of the hypothalamus to predispose to this "thrifty behavior" is currently not clear. There is very little doubt though that maternal undernutrition in animals leads to diminished size, altered behavior, and permanent alterations in metabolism, and that this is consistent with disease susceptibility observed in human studies.

The second source of evidence for the efficacy of maternal undernutrition in the programming of the metabolic syndrome comes from historical pseudo-experiments. A popular example, the Dutch Hunger Winter, was a season of extreme food shortage in the Netherlands between 1944 and 1945. Ravelli and colleagues compared data on 300,000 19-year-old males that were born before, during, or after this famine (Ravelli et al. 1976). The study revealed that the nutritional limitations imposed by severe nutritional deprivation lead to offspring with reduced birth size, and increased risk of glucose intolerance, and obesity in adult life. The cohorts that were most affected were the offspring of the mothers whose first two trimesters of pregnancy coincided with the famine. Similar historical pseudo-experiments, with well documented medical data that are consistent with the findings of the Dutch Hunger Winter, have occurred in Asia and elsewhere.

Another body of literature has taken this programming concept a step further and attributed adaptive or evolutionary value to sensitivity to programming (Barker et al. 2002). Evolutionary significance has been attributed to the programming that occurs due to nutritional deprivation, and even to altogether different programming models, such as early life stress. Neonatal rats, when exposed to various stressors, show permanent changes in hypothalamic structure and systemic responses to stress (Barbazanges et al. 1996; Francis et al. 1996) and these responses have been characterized as representing predictive actions to better prepare the animal for predation risk and environmental adversity (Zhang et al. 2004). In a similar manner, the thrifty phenotype hypothesis contends that the permanent changes in metabolic homeostasis represent evolutionarily adaptive programming that decreases susceptibility to starvation.

166.4 The Thrifty Phenotype

It is clear that Hales and Barker, like Neel before them, appreciated the evolutionary implications of their hypotheses. They explicitly proposed that this metabolic response to a nutritionally poor early environment was a predictive, adaptive response that would maximize chances of surviving postnatally in conditions of ongoing deprivation. Also, like Neel, they appreciated the fact that this prediction represents a

tradeoff and is subject to being inaccurate. If, unexpectedly, the postnatal environment provides plentiful nutrition these individuals will be at increased risk of metabolic disease.

The phenotypic characteristics of many organisms ranging from plants to insects to mammals are known to show plastic responses to environmental events, many of which are thought to represent adaptive, defensive responses, or reproductive strategies (Via and Lande 1985). This phenotypic plasticity through differential gene expression is often cued by maternal condition and is known to create profound alterations in the phenotypes of developing organisms. The thrifty phenotype hypothesis (Hales and Barker 1992, 2003 2001) has been used widely by researchers from different disciplines to interpret studies showing that maternal malnutrition is a strong risk factor for the metabolic syndrome (Wells). According to this hypothesis, phenotypes that are programmed by prenatal malnutrition to express low metabolic rates enjoy a survival advantage under deprived circumstances; however, if such a thrifty fetus is born into an environment marked by nutritional abundance, it will face increased risk of negative health consequences (Bateson et al. 2004). Conversely, robust phenotypes that express larger size and rapid metabolism are thought to increase reproductive success when resources are more plentiful, but are more susceptible to starvation if exposed to nutritional shortage. Specialists now believe that the association between maternal malnourishment and the offspring's proclivity for a low metabolism is adaptive specifically because the mother's deprived condition during pregnancy is often predictive of the environment into which the fetus will be born. It has been established that many animals share similar metabolic responses to environmental cues and this requires us to concede that our own tendency to react plastically may derive from phylogenetically earlier forms because of a shared evolutionary history (Crespi and Denver 2005).

Epigenetic processes are the biological basis for programming effects. Chemicals such as acetyl or methyl groups attach themselves to promoter regions of genes in specific tissues. Fine and intricate control of gene expression has been taken to suggest that the programming effects have been maintained through evolution because of their adaptive advantage rather than representing maladaptive effects of developmental disruption such as teratogenesis (Hanson and Gluckman 2008). It has been shown that, in animals, these epigenetic effects, for instance DNA methylation, can be passed down to successive generations along with the altered phenotypic expressions. In fact, due to alterations in the epigenome that are maintained during the creation of gametes, the effects of early life undernutrition may be transmitted to subsequent generations without repetition of the immediate insult in the second generation (Drake and Walker 2004). Many researchers believe that there may be an adaptive advantage in long term intergenerational programming, and that information about a grandparent's environment will help a developing animal in its "environmental forecasting."

Many fully grown animals are well known to demonstrate consistent adaptive responses to starvation that help to minimize energy expenditure, even of the order of a few days. Starvation evokes several immediate physiological changes, the most dramatic of which include suppression of metabolic rate, increased adiposity, reduction of thyroid and growth hormone levels, a reduction in fertility (through the suppression of gonadal function), and an increased activation of the hypothalamic–pituitary–adrenal axis (Schwartz et al. 1995; Flier 1998). Unlike animals programmed prenatally for thrift though, these predictive metabolic measures reverse largely after the animal resumes its normal diet. It is also well accepted that seasonal cycles of metabolic alterations occur in hibernating mammals. Many animals that hibernate are insulin insensitive for months before they go into hibernation and exhibit increased adiposity. When they wake up in the spring they are lean and insulin sensitive once again (Scott and Grant 2006). These other examples of phenotypic plasticity are comparable to intrauterine programming in many ways and researchers could potentially learn much from contrasting these models.

The brains of experimental animals that were exposed to early nutritional deprivation seem to be buffered from growth restriction in moderate cases, but can show definite changes in severe ones.

Reductions in the number of cells in certain regions as well as in synapses and white matter evince that programming effects, that may involve thrift, take place in the brain as well. Recent studies using imaging techniques show that gray matter is reduced in humans subjected to intrauterine growth restriction, and that catch up growth may not occur (Tolsa et al. 2004). The present author has offered explanatory hypotheses for these and related observations elsewhere (Reser 2006). It is possible that a large number of different metabolic and organ systems may be affected by epigenetic programming involving predictive adaptive responses. Further, integrative research, incorporating the viewpoints from different levels of biological and medical analysis, should help to provide a clearer picture of what we refer to today as "thrift."

166.5 Applications to Other Areas of Health and Disease

The thrifty genotype hypothesis posits that certain human genes that are associated with increased risk for metabolic disease today were naturally selected in the past because they helped their bearers to be more "thrifty" with energy stores. According to this hypothesis, phenotypes that express low metabolic rates enjoy a survival advantage under deprived circumstances. However, they face increased risk of negative health consequences when sugars and fats are artificially abundant, as they are in many countries today. The thrifty phenotype hypothesis posits that all of us have windows of susceptibility to thrifty programming that enable us to create permanent readjustments in homeostatic systems in an obsolete attempt to aid survival.

Today, the costs of the metabolic syndrome are well documented and well understood, but the prehistoric, defensive manifestations are obscured, at least at first glance, because of discrepancies between the ancestral environment and the modern environment. Many traits that are known to have been defensive in the ancestral environment are now seen as maladaptive in the present (an "environmental mismatch") and the science of evolutionary medicine attempts to identify and characterize these traits. Researchers have identified many such "pathological" conditions such as anxiety, cystic fibrosis, diarrhea, fever, inflammation, pain, sneezing, sickle cell anemia, and vomiting and have helped to show that they actually represent evolved defenses that would have promoted survival and the likelihood of reproductive success (Williams and Nesse 1998).

The merits of the thrifty genotype and phenotype hypotheses include the implications that they generate for understanding past, current, and future trends in disease (Pollard). The historical and evolutionary forces that are apparent are still largely abstract when measured against our biomedical knowledge, and it is clear that during our journey of reconciling the two, they will continue to influence and provide predictions for each other. The notion that the human genome bears witness to past struggles for survival against starvation allows us a new context within which to view the responses of the human body. A person's physiological response to dieting will reflect our ancestors' adaptive responses to seasonal hunger, just as their response to abundant calories and fats will reflect our ancestors' beneficial responses to harvest seasons. Furthermore, the thrifty phenotype hypothesis informs us that early, prenatal effects and even effects that were inherited from grandparents can cause the same anachronistic responses.

The cause of fetal malnutrition in present day populations is different from what it used to be. In the ancestral past the majority of examples of fetal malnutrition and intrauterine growth restriction probably would have come from starvation. Today, especially in affluent countries, it primarily stems from circulatory problems that are secondary to uteroplacental dysfunction, a relatively rare but epidemiologically constant condition. These modern fetuses, restricted by uteroplacental dysfunction, misinterpret their situation and prepare for nutritional scarcity when they will, in fact, encounter the opposite scenario.

Anthony Philipps explains that these findings have important implications for obstetrics and prenatal nutrition. It is imperative that circulatory assessments be made earlier in pregnancy, that more reliable ways to ascertain placental villous blood flow are developed, and that more sophisticated fetal growth measures are devised and used widely.

The identification and mapping of both thrifty genes and epigenetic markers will help to evaluate these hypotheses, but more importantly, will help inform medical research. Many critical aspects remain to be explored: (1) Where are the alleles for thrifty genes? (2) At what points during development do these windows of susceptibility exist? (3) What are the signaling pathways through which an environmental cue is translated into a developmental response? (4) Which developmental responses persist beyond a single generation and how? (5) How long do we have to wait, and how many people have to die prematurely from the metabolic syndrome for natural selection to remove the thrifty genes from our gene pool?

The observations discussed here have been extensively replicated and the theories discussed have been widely espoused but both are – and perhaps for good reason – still discussed, questioned, and debated. Many of these observations are not invariable and the causal pathways are still quite far from being transparent. It is thought that the concepts of the "thrifty genotype" and "thrifty phenotype" can be consistent and reconciled with one another. Sometimes, though, it is clear that they are mutually exclusive explanatory alternatives such as when it is not known if a low birth weight is inherited or acquired. Validity and applicability of these hypotheses is certainly open for dispute. Thrifty genes may not be identified for decades and even given the recent advances in genetic analysis are a rather nebulous concept today. One would assume that thrifty alleles would influence processes such as lipolysis, fuel oxidation, and skeletal muscle glucose metabolism, but it is difficult to say. The 2007 genome-wide association studies on type 2 diabetes mellitus provided promising data, and more refined genetic tools will provide a more complete picture of the genetic and epigenetic complexity of the metabolic syndrome.

Animal models are not always directly comparable to the human situation, but should continue to offer insight into mechanism. Long-term studies in humans are expensive and time-consuming but they will help to clarify the pertinent issues too. It is evident that this line of research has major ramifications for public health policy. Health care funding may be more prudently spent on informing and improving pregnancy care rather than on the contingent metabolic disorders which manifest decades later and cost many times more to treat. If overeating and sedentary behavior are determined during prenatal development to the degree that this literature implies, this may explain why public health initiatives to improve exercise and dieting in adults with metabolic symptoms are largely ineffective.

There is a large literature that addresses these concepts from different angles, and much is known about the similarities in predisposition for metabolic disease between people and animals (Gluckman and Hanson 2004). There is still much that is unknown though, and whether the broad, ultimate, evolutionary hypotheses have to be largely altered or just fine tuned, it is becoming clear that metabolic disease may very simply stem from the fact that our behavior, diet, and nutrition are so different from the way they used to be.

Summary Points for the Developmental Origins of the Metabolic Syndrome

- The metabolic syndrome represents a cluster of metabolic derangements that are risk factors for obesity, type 2 diabetes mellitus, and cardiovascular disease.
- There is currently a worldwide epidemic of obesity and diabetes that is due to unhealthy eating and poor exercise. These are probably issues that our hunting and gathering ancestors would rarely have been exposed to, because they were probably rarely exposed to excess, but commonly exposed to famine.

- The human gene pool probably contains many thrifty genes that would have helped our ancient ancestors to survive food shortages and starvation. For example, a tendency to efficiently take up ingested fats into fat stores would have increased the likelihood of survival.
- The physiological states that cause us to be susceptible to facets of the metabolic syndrome probably all had ecological utility in the past. This is supported by animal models.
- Many mammals and it seems humans too can be programmed for thrift if they are exposed to severe undernutrition early in development. This programming may be a predictive adaptive response to environmental cues signaling that the environment is nutritionally poor.
- The thrifty phenotype that is created from these programming effects is highly susceptible to metabolic disease.
- Future findings in this literature should have serious implications for public health and the treatment of the metabolic syndrome.

Definitions

Dyslipidemia: Refers to a disruption of the levels of lipid in the blood. In western societies, most dyslipidemias are hyperlipidemias; an elevation of lipids, often due to diet, lifestyle, or prolonged elevations of insulin.

Glucose tolerance: The ability of the body to adapt to a relatively large dose of glucose. This ability is usually diminished in diabetics and is used to diagnose diabetes mellitus. A fasting subject ingests around 75 g of glucose, and blood glucose is measured at intervals. In diabetics the concentration is higher and takes longer to return to baseline value.

Genotype: The genetic constitution of a cell or organism. The genotype contains the information, in the form of DNA, which dictates how the cell or organism develops and interacts with its environment.

Hypercortisolemia: High amounts of circulating cortisol, an essential glucocorticoid steroid hormone, and the major hormone secreted by the adrenal glands.

Hyperglycemia: A complex metabolic condition characterized by high levels of blood glucose in the circulation, usually a result of insufficient or ineffective insulin production in either type 1 or type 2 diabetes mellitus.

Hyperphagia: Refers to an abnormal appetite or increased eating of food, often associated with abnormalities in the hypothalamus.

Hypertension: High blood pressure or force of blood on the vessel walls of the arteries.

Hypothalamic–pituitary–adrenal axis: This is a neuroendocrine system in the body responsible for regulating stress physiology. Brain areas that sense threat signal the hypothalamus, which communicates hormonally to the pituitary which hormonally signals the adrenal glands to secrete adrenaline and cortisol.

Insulin resistance: A condition in which cells, especially those comprising muscle, fat, and liver tissue fail to be properly receptive to the messages of the hormone insulin. Because insulin promotes the extraction of glucose from the blood, allowing cells to meet their metabolic needs, insulin resistance is associated with elevated levels of blood glucose.

Metabolic syndrome: A combination of metabolic disorders that commonly present together, and increase the risk of developing diabetes and cardiovascular disease.

Phenotype: An observable characteristic of an organism, such as a trait, property, or behavior. Phenotypes develop from the interaction between an organism's genes and its environment.

Visceral fat: The accumulation of fat around the internal organs of the torso. It is associated with the "apple shape," belly fat, central obesity, and a high waist to hip ratio.

167.1 Introduction

Data collected worldwide point to an increase in childhood overweight and obesity. Studies in both developed and developing countries [for example, Australia (Bauer 2002) and Peoples' Republic of China (PRC) (Jiang et al. 2006)] show that the proportion of children who can be considered obese has continued to increase over the past three decades. It is often proposed that outcomes of early obesity can predispose children to life-long health problems, including the early onset of Type II diabetes, and early onset of risk factors associated with the later-life development of cardiovascular disease (Teran-Garcia et al. 2008). Additionally, obesity in early childhood has been linked to ostracism and early development of low self-esteem (Schmitz et al. 2002), with the critical factor being peer acceptance (Iobst et al. 2009). Parallel to this rise in overweight and obesity among children of all ages is the apparent increase in sedentary leisure pursuits, such as watching television (TV), surfing the Internet, and playing computer games, because of increased access to all forms of electronic media. Watching TV is a low-level activity and is ubiquitous among young children in both developed and developing countries (see, for example, Larson and Verma 1999). For Australian children's TV consumption see for example, Jenvey (2003) in which

Australian children's usual play and leisure patterns in different social contexts were surveyed, and the Australian Bureau of Statistics (ABS) Survey of Australian children's usual leisure activities (ABS 2004). It is not surprising, therefore, that researchers have attempted to identify an association between TV viewing and increasing levels of obesity among children in those countries. While some studies have investigated relationships between the amount of time children spend accessing all forms of electronic media (computers, computer games, electronic games, TV, and watching DVDs) (for a review, see Marshall et al. 2004), the majority of research has focused on adverse health outcomes associated with frequent TV viewing by children from an early age (Anderson et al. 1998; Landhuis et al. 2008).

167.2 Children Who Are Overweight and Obese

Obesity is assessed by calculating body mass index (BMI). To calculate children's BMI, their weight and height are measured, and BMI is derived from dividing children's weight (in kilograms) by their height (in meters squared). Children whose BMI is more than or equal to 25 kg/m^2 are classified as overweight or obese if BMI is more than or equal to 30 kg/m^2 (Cole et al. 2000). Children's weight and height are compared with established international norms, so that meaningful comparisons of children's growth can be made across different countries (Bar-On 2002). There are separate norms for boys and girls, and each child's weight and height are compared with norms established for children of the same age. While BMI provides a quick and internationally agreed-upon means of determining which children can be classified as overweight or obese, other parameters of children's growth should be considered to determine obesity [World Health Organization (WHO) 1995]. In addition to weight and height, measurement of children's mid-upper arm circumference and skin fold thickness (subscapular and mid-upper arm) should be taken to ascertain, respectively, children's muscle mass and fat stores (WHO 1995). Table 167.1 displays recommended anthropometric measures to most reliably characterize children's growth relative to a normative sample.

Consistency or change in children's and youth's BMI measures throughout development continue to be used as dependent measures to investigate associations between amount of TV viewing and obesity in early childhood. Despite this widespread practice, other researchers point to the inappropriateness of BMI measure to detect individual gains in body mass that result from inherited differences in body composition and bone structure among different ethnic groups. Additionally, even successive BMI measures do not adequately characterize individual differences in children's growth rates, particularly during the early childhood period (Lloyd et al. 2009).

Table 167.1 Anthropometric measures used to characterize overweight and obesity in early childhood

Anthropometric measure	Utility and source
Body Mass Index (BMI)	Efficient, shorthand way to characterize growth/ changes in growth in young children (Weight/Height^2) (Cole et al. 2000)
Mid-upper-arm circumference	Measures muscle mass – better to characterize changes in young children's growth over time (Kanda et al. 1997)
Skin fold thickness (Triceps, Subscapular)	Argued to be most reliable measure of young children's fat stores (WHO Expert Committee 1995)

This table displays the most commonly used and internationally agreed upon measures to characterize changes in children's growth over time, including measures of children's height, weight, muscle mass, and fat stores

167.3 Amount of Time Children Spend Watching Television

In a cross-national investigation of children's leisure pursuits it was found that time spent by children of different ages, including young children 5–8 years, in different countries ranged between 1.5–2.5 h/day (Larson and Verma 1999). Australian parents report similar amounts of TV viewing (average of 15 h/week) among their children, including preschool and early school-age children (Wake et al. 2003). This latter study also included time spent in computer-based activity, which was still less than the time spent watching TV. Additionally, results from a survey of frequency and type of leisure activities of a sample of more than two million 5–15 year-old Australian children (ABS 2004) showed that watching TV and videos was the most popular leisure activity of young Australians, with 98% of children engaged in that activity during their leisure time. In a 2-week period during school term, children spent, on average, 22 h per fortnight watching TV and videos. Time spent watching TV and videos exceeded time spent in other leisure pursuits such as reading or playing electronic games (8 h/fortnight) and more physically active pursuits such as bike riding (6 h/ fortnight) or skateboarding and rollerblading (5 h/fortnight).

When these data are considered in addition to time spent by children accessing other more recent forms of computer-based activities, it is reasonable to assume that young children are spending a sizeable proportion of their leisure time in sedentary, electronic media consumption. In fact, children persist in TV viewing even with the advent of more personalized, interactive media such as Internet and computer games. Thus, time spent accessing these more recent forms of electronic media occurs *in addition to* time spent watching TV (Roberts et al. 1999; ABS 2004). Owing to the fact that TV has been part of children's leisure for several decades, there is a larger body of research investigating the impact of TV viewing on young children's development than exists on more recent forms of computer-based technology taken up by contemporary children. Table 167.2 shows estimated daily or weekly TV viewing among children from different countries.

167.4 Potential Adverse Impact of Watching Television on Young Children's Growth and Development

It is argued that the amount of time young children spend watching TV, displaces time that otherwise might be spent in more physically active leisure pursuits (Dietz and Gortmaker 1985). The second concern is related to the program and advertisement content of TV watched by young children. Television content said to be associated with adverse developmental outcomes for children include programs containing advertisements for food products of poor nutritional quality, which are placed strategically during peak viewing times by children (Kelly et al. 2008; Taras et al. 1989). A third hypothesis proposes an interaction of sedentariness of TV viewing and susceptibility of young children to the persuasive intent

Table 167.2 Estimated hours of television (TV) viewing in early childhood

Estimates of hours of TV viewing	Population and source
22 h/fortnight	Australian children 5–15 years (ABS 2004)
1.5–2.5 h/day	Cross-national comparison (Larson and Verma 1999)
15 h/week	Australian children 3–6 years (Wake et al. 2003)

This table summarizes research estimates (in hours) of amount of time spent by children watching TV across different populations. Estimates are fairly consistent across different populations of children worldwide

Table 167.3 Main explanations and underlying processes associating time spent watching (TV) in early childhood and the development of overweight and obesity

Explanation and source	Proposed underlying processes
Energy displacement (Dietz and Gortmaker 1985)	Time spent watching TV supplants time available for more physically active leisure activities, and energy intake (in the form of food) exceeds energy expenditure (in the form of physical activity) and results in overweight and obesity
Exposure to saturation amounts of TV advertisements for foods of poor nutritional quality (Wilson et al. 1999)	Amount of time spent watching TV ensures high level of exposure to certain food products.
	Young children become familiar with the product brands and pester parents, who, in turn, buy those products, to be eaten by their children
In addition to energy displacement, young children's cognitive immaturity impedes detection of the persuasive intent of the food advertisements (Kelly et al. 2008)	Reduction in physical activity relative to energy requirements coupled with an increase in consumption of food products advertised on TV. Such products consistently high in saturated fats, sugars and excessive amounts of salt.
	Young children, because of their cognitive immaturity are susceptible to the persuasive intent of the advertisements

This table outlines the three main explanations of associations between amount of TV viewed by young children and the development of overweight and obesity in childhood. Specifically three main explanations are (a) energy displacement, (b) cognitive immaturity of young children and their susceptibility to persuasive intent of advertisements for *snack* and *junk* foods, and (c) combination of energy displacement and vulnerability to persuasive messages in *snack* and *junk* food advertisements broadcast during children's TV programs

of advertisements for foods of poor nutritional quality, that are frequently advertised during designated children's TV viewing time (Kelly et al. 2008). Each of these explanations will be discussed more fully in the following sections, and they are presented in Table 167.3.

167.5 Relationship Between Young Children's Television Viewing and Low Physical Activity Levels

A relationship has been found among overweight and obesity, hours of TV viewing, and reduced physical activity among young (3–6 years-old) children (Jago et al. 2005). The more time children spent watching TV, the more overweight or obese they were, and this effect was more pronounced among older children (6–7 years-old) in the cohort. Researchers explained these findings by proposing that TV viewing supplants time spent in physical activity, thereby leading to reduced energy expenditure relative to energy intake, and the development of obesity (Jago et al. 2005). Key features of the energy displacement hypothesis are presented in Table 167.4.
