and Palliative Care, San Diego, California, USA

Hachette Livre UK's policy is to use papers that are natural, renewable and recyclable products
and made from wood grown in sustainable forests. The logging and manufacturing processes
are expected to conform to the environmental regulations of the country of origin.

Whilst the advice and information in this book are believed to be true and accurate at the
date of going to press, neither the author[s] nor the publisher can accept any legal
responsibility or liability for any errors or omissions that may be made. In particular, (but
without limiting the generality of the preceding disclaimer) every effort has been made to
check drug dosages; however it is still possible that errors have been missed. Furthermore,
dosage schedules are constantly being revised and new side-effects recognized. For these
reasons the reader is strongly urged to consult the drug companies' printed instructions
before administering any of the drugs recommended in this book.

What do you think about this book? Or any other Hodder Arnold title?

Dedication to Dr Cicely Saunders
OM DBE FRCP FRCN FRCS

The purpose of this Textbook of Palliative Medicine is to disseminate the specialist knowledge of palliative medicine to all who wish to learn about it. Yet, to be a competent practitioner, knowledge is not enough. The ability to apply palliative medicine knowledge at a specialist level requires two things: a role model and precepted practice. For thousands of years, physicians have learned in an apprenticeship fashion under the tutelage of wise role models.

A singular individual who was a role model to thousands and a pioneer in palliative medicine was Dr Cicely Saunders. Born June 22, 1918, she first encountered the unmet needs of patients with far advanced cancer while working as a social worker in a busy surgical ward. Initially trained as a nurse, she had moved on to social work because of a bad back. Her encounter with real patients, with real needs for symptom control and psychological, social and spritual support led her to train as a physician in order to further pursue the work. With unmatched zeal and professional focus, she pioneered the interdisciplinary team-based approach we now know as palliative care. Some have observed that, with training in nursing, social work and medicine, and with an evangelical Christian background, Dr Saunders was in herself the first interdisciplinary palliative care team.

In pursuing interdisciplinary patient care, education and research into the needs of dying patients, Dr Saunders founded the modern hospice movement. As part of that movement, she founded St Christopher's Hospice in south suburban London, UK to be an academic hospice. The care provided, the physicians and other health professionals trained, and the research conducted there has changed health care around the world. She died July 14, 2005 knowing that she had left a legacy of a changed way of caring for both the living and the dying.

We dedicate this textbook to Dr Saunders in the year after her death in hope that it will play an important role in disseminating this knowledge to yet more generations of people around the world who want to understand the principles and practice of palliative medicine.

Preface

Palliative medicine emerged in the United Kingdom during the 1960s as a response to the unmet needs of terminally ill patients and their families. This initially British initiative became progressively a global movement. The original community-based services were followed by programs of increasing complexity in secondary and tertiary hospitals and comprehensive cancer centers. Educational initiatives became progressively more sophisticated, ultimately resulting in palliative medicine becoming a full medical specialty. Research in many of the complex problems faced by patients and families has provided a growing body of knowledge on how to conduct our clinical care, education, organization and governance.

Our book has attempted to reflect the growth of our area of knowledge from a global perspective. Internationally recognized leaders have been asked to apply their first-hand knowledge in summarizing the principal issues in our discipline.

Palliative medicine covers a wide variety of subjects ranging from pharmacological interventions to historical, bioethical, and spiritual issues. This state of the art book cohesively addresses the full range of disciplines regularly involved in palliative medicine. We have attempted to produce a scholarly but accessible text following a user friendly format while respecting the needs of specific authors to deviate from the more traditional biomedical format when their area of content required them to do so.

We believe that this book will become a very useful resource for physicians, nurses, and other health care professionals involved in the clinical, academic, and administrative aspects of palliative care delivery worldwide.

Reference annotation and evidence scores

REFERENCE ANNOTATION

The reference lists are annotated, where appropriate, to guide readers to primary articles, key review papers, and management guidelines, as follows:

- ● Seminal primary article
- ◆ Key review paper
- ✱ First formal publication of a management guideline

We hope that this feature will render extensive lists of references more useful to the reader and will help to encourage self-directed learning among both trainees and practicing physicians.

EVIDENCE SCORES

Supporting evidence has been graded in the main body of the text for each clinical intervention as follows:

- ∗∗∗ Systematic review or meta-analysis
- ∗∗ One or more well-designed randomized controlled trials
- ∗ Nonrandomized controlled trials, cohort study, etc.

1

The development of palliative medicine in the UK and Ireland

DAVID CLARK

INTRODUCTION

This chapter offers a brief history of palliative medicine in two of the countries where it gained rapid strides in the course of the later years of the twentieth century. It begins, however, by recognizing the nineteenth century legacy which was inherited by those later pioneers of the modern field who first carved out an area of sustained medical interest in the care of the dying. The chapter goes on to show how in the UK and Ireland, palliative medicine grew out of the activities of the voluntary hospice movement, how it built on the work of a small number of activists who had to struggle against indifference if not hostility and how, relatively quickly, it gained recognition from the medical establishment as a legitimate field of specialization. Of course, such developments have not been without their tensions, and the chapter concludes with some discussion of the argument surrounding the medicalization of death, the role of palliative medicine within it, and also the likely future of a specialty that makes its main focus the management of complex symptoms at the end of life.

NINETEENTH CENTURY BEGINNINGS

As the nineteenth century advanced, many industrialized countries saw the beginnings of an epidemiological transition wherein a shift took place in the dominant causes of death: from fatal infectious diseases of rapid progression, to chronic and life-threatening diseases of longer duration. As this transition became more marked, the departure from life for many people became an extended and sometimes uneven process. Consequently, people called 'the dying' began to emerge more clearly as a social category; and over time, the most common place to end one's life began to shift from the domestic home to some form of institution. For the first time in history special institutions were formed, often the work of religious orders or religiously motivated philanthropists, that were uniquely concerned with the care of dying people. Several of these were established in Cork, London, and Dublin in the closing decades of the nineteenth century and the beginning of the twentieth century.[1,2]

Another important antecedent to modern palliative medicine in the UK and Ireland at this time can be seen in the writings of key physicians and nurses who began to draw attention to the needs of dying patients. Outstanding among these in the UK context was the English physician, William Munk,[3] who has been described by one historian of the period as 'the most influential Victorian writer on the care of the dying'.[4] In 1887, exactly 100 years before palliative medicine was recognized as a specialty in the UK, Munk published a detailed treatise, 105 pages in length, on the care of the dying.[5] It was entitled *Euthanasia: or, Medical Treatment in Aid of an Easy Death*. In this work Munk uses the word 'euthanasia' in its classic sense to describe the goal of the physician in helping the sufferer to a more comfortable death. His work can be viewed as a precursor to the modern medical textbooks on the care of the dying that came to proliferate over a 100 years later.

In general Munk's book was favorably reviewed in a range of medical journals at the time (see for example, *British Medical Journal* 1861; **ii**: 231–2; *British Medical Journal* 1884; **i**: 1155–7; *Dublin Journal of Medical Science* 1884; **78**: 38–9). *The Lancet* printed a glowing account of *Euthanasia* calling it a 'treatise by a thoughtful and experienced

physician' and supporting fully both Munk's aim in bringing the subject to the notice of the medical profession and his execution of important instruction in the medical management of the dying.[6] In 1888 it was also reviewed favorably by the famous Canadian physician William Osler, who praised its many valuable suggestions to practitioners and sound advice as to the medical management of the dying.[7] Indeed it has been argued that *Euthanasia* remained the authoritative text on medical care of the dying for the next 30 years,[4] but its influence was at best patchy and did not last beyond Munk's own generation. By 1926 the American physician Arthur Macdonald was still calling for a scientific study of death which would enhance the sum of knowledge and enable 'a general picture of the dying time, based upon a sufficient number of observations and with instruments of precision where possible' so that fear of death would be diminished and pain eliminated.[8] And as late as 1935 his fellow countryman, Alfred Worcester was arguing that the previous half-century had seen a deterioration in related medical practice, rather than progress, in the art of caring for the dying.[9]

Unfortunately this trickle of medical writings on the care of the dying found little interest in UK and Ireland in the decades following their publication and there is no evidence that they had an influence in the institutional homes for terminal care which were being created in the same period. If they did, it was insufficient to set in train any broader movement of reform; for the time being these writers and the founders of the homes remained isolated from one another and there was an absence of the kind of synergy which could lead to more widespread change.

A TWENTIETH CENTURY SEA CHANGE

In fact, it was not until the 1950s that some broader concerns about improving care at the end of life did begin to surface in the UK. This began when attention focused in a sustained way on the medical 'neglect' of the dying. Four particular innovations can be identified.[10] First, a shift took place within the professional literature of care of the dying, from idiosyncratic anecdote to systematic observation. New studies, by doctors, social workers, and social scientists provided evidence about the social and clinical aspects of dying in contemporary society. By the early 1960s leading articles in *The Lancet* and *British Medical Journal* were drawing on the evidence of research to suggest ways in which terminal care could be promoted and arguments for euthanasia (as medicalized killing) might be countered. Second, a new view of dying began to emerge which sought to foster concepts of personal dignity, autonomy, and meaning at the end of life. Enormous scope was opened up here for refining ideas about the dying process and exploring the extent to which patients should and did know about their terminal condition. Third, an active rather than a passive approach to the

care of the dying was promoted with increasing vigor. Within this, the fatalistic resignation of the doctor ('There is nothing more we can do') was supplanted by a determination to find new and imaginative ways to continue caring up to the end of life, and indeed beyond it, in the care of the bereaved. Fourth, a growing recognition of the interdependency of mental and physical distress created the potential for a more embodied notion of suffering, thus constituting a profound challenge to the body–mind dualism upon which so much medical practice of the period was predicated.

One particularly important development was a national survey carried out by a joint committee of the Marie Curie Memorial and the Queen's Institute of District Nursing, and chaired by the surgeon Ronald Raven.[11] The Marie Curie Memorial had been established in 1948 and held among its objects the promotion of the welfare and relief of patients with cancer. The joint committee first met in 1950 with the purpose of investigating the needs of domiciliary cancer sufferers and its report was published 2 years later. District nurses in 179 out of the 193 local authorities collected data on 7050 people living at home with cancer. They considered that 2195 were enduring a severe degree of suffering at the time they were visited. The report concluded with a series of recommendations, including the need for more residential and convalescent homes; the importance of better information for cancer sufferers; and greater provision of night nursing, home helps, and equipment. Within a year of the report's publication, the Marie Curie Memorial itself had begun opening homes for terminally ill cancer patients. In 1958 this was further extended by the provision of a night nursing service; and by the early 1960s 24 authorities in the provinces and 15 London district nursing areas were being served by over 200 Marie Curie nurses.[12] There is no evidence, however, of any systematic response to the report from elsewhere within the health and welfare system.

A second report, prepared by Dr H L Glyn Hughes at the request of the Calouste Gulbenkian Foundation was based on inquiries carried out between November 1957 and December 1958, and was published in 1960.[13] It contained a description of current provision for the care of the dying, together with recommendations for development. Like the joint committee, Glyn Hughes, himself a former army doctor, gave considerable attention to the social conditions of the terminally ill, but his report was more wide ranging in character and gave greater prominence to matters of policy and service organization. The report showed that two-fifths of all deaths in 1956 occurred in National Health Service (NHS) hospitals, with under a half of all deaths taking place in the home. Almost 46 000 cancer deaths (approximately a third of the total) took place at home and it was considered that many of these should have required continuous medical and nursing care. Similar needs were thought to be in evidence among some of the 121 000 who died at home from diseases of the circulatory system.

Overall Glyn Hughes estimated that some 270 000 people in need of 'skilled terminal care' died each year outside NHS hospitals. While dying at home was seen as the preferred alternative for most patients, Glyn Hughes stressed the importance of calculating the total number of inpatient beds which would be needed for terminal care. He was eager to stress the value of special terminal care beds within the curtilage of acute hospitals. At the same time the independent homes for the dying which did exist should develop closer links with hospital services to reduce their isolation.

Like bookends at the start and finish of the decade the reports of the joint committee and of Glyn Hughes had highlighted the deficiencies of terminal care in the welfare state of the 1950s. The joint national cancer survey committee had drawn attention to the abject social and economic conditions of many older people suffering with advanced cancer. Glyn Hughes had revealed the absence of a serious policy commitment to terminal care provision; indeed his recommendations highlighted the need for voluntary and for-profit organizations to work in conjunction with the NHS to achieve the necessary results.

During the same period and into the early 1960s a number of studies appeared that threw further light on the problems of terminally ill people in the UK. These included Margaret Bailey's survey of patients with incurable lung cancer conducted at the Brompton and Royal Marsden hospitals[14] as well as a study of delayed help seeking among patients with cancer, which noted that: 'The fact of palliative treatment is not understood, and hospitals appear to be trying to cure all their patients and failing in a high proportion of cases'.[15] Notable also was the early psychiatric work of Colin Murray Parkes on bereavement and mental illness.[16] By the mid-1960s research papers by Eric Wilkes, the Derbyshire general practitioner who later founded St Luke's Hospice in Sheffield, were appearing on terminal cancer at home[17,18] and in the second of these it was observed: 'There seems to be no valid reason why hospital provision for terminal care is so inadequate, or for the National Health Service to lean so heavily on the few Curie Foundation Homes and the devoted but over-worked religious institutions specialising in this work'. Closely associated with these research endeavors was Dr John Hinton, who had qualified in psychiatry from London's Maudsley Hospital in 1958. As a trainee doctor he had developed an interest in the psychiatric problems of terminally ill patients. His paper on the physical and mental distress of the dying was written in 1962 and published the following year, based on research conducted at a teaching hospital in 1959–61.[19] Hinton pointed out the need for more carefully designed research studies relating to terminal care and the need to get beyond anecdotal commentary. He noted in a 1964 editorial in the *Journal of Chronic Diseases* that: 'The large number of articles in which remembered experience is distilled into advice on the management of dying awesomely overshadows the few papers attempting to measure the degree of success or failure of treatment'.[20]

Hinton was inclined to a conversational approach to data collection and his 1963 research paper is based on interviews with 102 patients thought unlikely to live for more than 6 months, with controls. The dying group were more commonly depressed and anxious and half were aware that their illness might be fatal. Physical distress was more prevalent in those with heart or renal failure (57 percent) than those with malignancies (37 percent) and was in general more severe and unrelieved for longer within the dying group. The work was praised in an editorial in the *British Medical Journal*.[21]

In particular, however, it was the growing activities of Cicely Saunders, first developed in St Joseph's Hospice in Hackney, East London, that were to prove most consequential, for it was she who began to forge a peculiarly modern philosophy of terminal care combining a powerful religious and moral conviction alongside a rigorous approach to observation, research and clinical innovation. Through systematic attention to patient narratives and by listening carefully to stories of illness, disease and suffering, she evolved the concept of 'total pain'.[22] This view of pain moved beyond the physical to encompass the social, emotional, even spiritual aspects of suffering – captured so comprehensively by the patient who told her: 'All of me is wrong'.[23] But this was also linked to a hard-headed approach to pain management. Her message was simple: 'constant pain needs constant control'.[24] In a ground-breaking series of papers published in the late 1950s and early 1960s,[25] Cicely Saunders demonstrated that powerful analgesics could be used safely and with confidence. Despite considerable medical skepticism at the time,[26] she argued that if a method of regular giving of analgesia was employed, then pain could be prevented in advance, rather than alleviated once it had become established and the appropriate drug regimen was to work progressively, from mild, to moderate to strong.

When Cicely Saunders founded St Christopher's Hospice, in South London, in 1967, it quickly became a source of inspiration to others. As the first 'modern' hospice, it was at the time unique in combining three key principles: excellent clinical care, education, and research. It therefore differed significantly from the rather more modest goals of the other homes for the dying which had preceded it and sought to establish itself as no less than a center of excellence in a new field of care.

In particular, St Christopher's was associated with some major clinical and organizational studies that did a great deal to advance the field. Much of the former focused on the science of pain control and the underlying pharmacokinetic mechanisms at work in the administration of strong opioids. It began with close scrutiny of some of the methods of pain relief favored within the early hospices and terminal care homes, in particular the use of the so-called 'Brompton Cocktail',[27] which had been gaining popularity throughout the twentieth century and had appeared in print for the first time in the 1950s – a mixture of morphine hydrochloride, cocaine hydrochloride, alcohol,

syrup, and chloroform water but with many local variants and names. Cicely Saunders, in her early writings, was eager to promote this rather exotic mixture but it was the St Christopher's research fellow Robert Twycross who set out to scrutinize it in detail, in what became a series of classical studies, among the first of their kind to be undertaken in the hospice setting. He concluded that the Brompton Cocktail was no more than a traditional British way of administering oral morphine to cancer patients in pain and urged that its use should be quietly abandoned in favor of simpler approaches.[28] But the actions of morphine, the development of new approaches to its administration and the teaching of healthcare professionals about its appropriate use alongside other analgesics and adjuvant drugs – all of these became a rich territory of both research and teaching in the modern hospice and palliative care context. Of particular importance was the work that compared the actions of morphine and diamorphine. Here Twycross reported a controlled crossover trial between the two drugs and showed that given regularly at individually optimized doses in an elixir with cocaine and a phenothiazine there was no clinically observable difference between the drugs.[29] As diamorphine was at that time (and remains) unlicensed for medical purposes in most countries, this was an important finding. Following these results, in 1977, St Christopher's changed its practice and morphine was prescribed for all oral narcotic medication, amounting to some two-thirds of doses given.[30]

Evaluation research at St Christopher's began before the first patient was admitted. The psychiatrist Dr Colin Murray Parkes embarked upon his detailed study of the memories of the carers of dying patients in the locality as the hospice opened and over time built up a cohort of cases. This consisted of 276 married patients under the age of 65 years who died of cancer in two London boroughs, 49 of whom were still under active treatment at the time of death; although the length of time after the end of such treatment varied greatly, the median length of stay for terminal care was 9 weeks. Parkes divided these patients into 'home based', including in this group all who died within a week of a final hospital admission, 'hospital based', and 'St Christopher's based'. He found much unrelieved pain, whether the patient died in a hospital or at home. As patients came into the study he was able to show that people with serious pain problems were referred from the start to the hospice and were largely relieved.[31] The study was repeated 10 years later as part of the ongoing evaluation of the work of the hospice. Although pain and symptom control improved in the hospital setting over time, psychosocial needs and continuity of care continued to be better approached in the hospice.[32]

The success of St Christopher's was phenomenal and it soon became the stimulus for an expansive phase of hospice development. In the UK there was a golden period of hospice expansion which peaked in the 1980s, when about 10 new hospices came into existence each year. But the ideals and practices developed in the hospices were also being disseminated into other settings, so that by the mid-1990s there were over 1000 specialist Macmillan nurses working in palliative care in the UK, approximately 400 home care teams, and over 200 day care and 200 hospital-based services as well as some 5000 Marie Curie nurses providing care in the home. From the outset, ideas developed at St Christopher's were applied differently in other places. Within a few decades therefore it had been accepted that the principles of hospice care could be practiced in many settings: in specialist inpatient units, but also in home care and day care services. Indeed hospital units and support teams were established that brought the new thinking about the care of the dying and those with advanced disease into the very heartlands of acute medicine. In 2004 there were 196 inpatient units in the UK, comprising 2730 beds, albeit just 19 percent of which were within the NHS with the remainder under the governance of independent hospices. There was also a large array of other services: home care (n = 341); day care (n = 237); hospital-based (n = 324); hospice at home (n = 97).[33] The UK has a population of 60 441 457 (July 2005 estimate). Its age structure is as follows: 0–14 years, 17.7 percent; 15–64 years, 66.5 percent; 65 years and over, 15.8 percent (male 4 063 357/female 5 472 683). The rate of death is 10.18 deaths/1000 population. Life expectancy at birth is 75.94 years (males) and 80.96 years (females). The principal ethnic groups, as derived from the 2001 census, are: white (English 83.6 percent, Scottish 8.6 percent, Welsh 4.9 percent, Northern Irish 2.9 percent) 92.1 percent; black 2 percent, Indian 1.8 percent, Pakistani 1.3 percent, mixed 1.2 percent, other 1.6 percent.

The expansion of hospice and palliative care quite quickly led to important considerations of workforce training and development. Even by the 1980s a growing cadre of doctors was developing an interest in the care of terminally ill patients and their families. While many had transferred into this work in mid or even late career, others were interested in dedicating an entire professional life to it. But without more formal recognition, the pathways into and routes through a training program for specialized work in the care of the dying, remained unclear.

SPECIALIZATION

In the context of this expansive period of hospice development in the 1980s, three factors conjoined to build a platform for the broad consolidation of the new field of activity: a medical association was formed to support its practitioners; a scientific journal was established; and recognition was given to palliative medicine as an area of specialization. (The following section draws on oral history interviews conducted by the author with Dr Gillian Ford [June 6, 1996] and Dr Derek Doyle [December 28, 1995 and February 13, 1996], as part of the hospice history program of the

International Observatory on End of Life Care, Lancaster University.)

By 1985, plans were being developed in the UK for the creation of an association to represent the interests of physicians working in palliative care. Cicely Saunders wrote enthusiastically about it to Edinburgh doctor and independent hospice pioneer Derek Doyle[34] who together with Robert Twycross and Richard Hillier (both of whom had developed hospice services within the context of the NHS) made up a key group of early protagonists. Following some early discussion about whether the term 'hospice' should appear in the name, the group soon came to be known as the Association for Palliative Medicine for Great Britain and Ireland. The executive committee of the new association quickly became aware of a paper written by the then Deputy Chief Medical Officer for England, Gillian Ford, in which she outlined the potential for this new field of medicine to gain recognition as a specialty in its own right. Discussions got underway with a number of key committees within the Royal Colleges, including the Intercollegiate Committee on Oncology and ideas were developed about how a training program for the field could be put together. It proved that the most influential group in this regard was the Joint Committee on Higher Medical Training (JCHMT). At the time, a growing number of universities and medical schools were calling on those working in hospices to teach students about pain control and about communications issues, although at that stage no formal curriculum on palliative medicine existed. Gillian Ford, a long-time friend of Cicely Saunders and close associate of St Christopher's, prepared a paper for the JCHMT and at the same time encouraged the chairman of the Specialty Advisory Committee in General Medicine and other senior medical colleagues to visit St Christopher's for an appreciation of the work being done there. These senior medical colleagues found themselves impressed by the research of Robert Twycross on the actions of morphine and diamorphine[29] and by Colin Murray Parkes' evaluations of the impact of hospice care.[35] There was also considerable interest in the multidisciplinary approach that was being adopted at the hospice and the way in which the efforts of the team were focused on the 'total pain' of the patient, seen in a multifactorial light. Yet there was still a sense up to the late 1970s and early 1980s that the constituent elements of what came to be called specialist palliative care, had not yet been teased out. This made for difficulties in devising a training program for what at that time were known as the senior registrar years within medical training. It was also necessary to determine the specific background experience that would be necessary for entry into the new field.

The outcome of these deliberations was enormously important for the history of palliative care in the UK and Ireland, and arguably much further afield too. In 1987 palliative medicine was established as a subspecialty of general medicine, initially on a 7-year 'novitiate', which once successfully concluded, led to the creation of a specialty in its own right. Indeed the specialty broke new ground in accepting as an appropriate qualification for entry, membership of the Royal Colleges of Physicians, Radiology, and Anaesthetics; initially membership of the Royal College of General Practitioners was not a recognized mode of entry, though considerable protest and further campaigning led to its recognition within a few years.

At the same time as these wider developments were taking place, discussions were also underway about the creation of a journal to publish research, reviews, and debate relating to the work of the new field. Following some discussion about its name (again revolving around whether the word 'hospice' should be included) and orientation, the first issue was published in 1987. It bore the title *Palliative Medicine*, under which a 'strap line' appeared on the cover stating: *a multi-professional journal*. The wording was crucial and did a fair amount to antagonize colleagues in other professions, but the message was clear: medical practitioners had seized hold of the new field of caring for those with advanced disease at the end of life and over time, the medical model would exert a growing influence on thinking and practice.

Developments in Ireland took a similar path when in 1989 the first post of consultant physician in palliative medicine was created in the form of a joint appointment between Our Lady's Hospice and St Vincent's University Hospital, Dublin. Then in the mid-1990s, the Irish Medical Council considered the inclusion of palliative medicine in its list of recognized specialties. Such recognition required evidence of a significant corpus of knowledge specific to palliative medicine, over and above that which would be within the competence of any registered medical practitioner, as well as the existence of a recognized body to oversee developments in the new specialty, including training and education. The Minister for Health and Children approved the inclusion of palliative medicine among the list of recognized Irish medical specialties in June 1995.[36]

Within an intensive period of activity lasting just a few years, both the UK and Ireland had succeeded in establishing palliative care as a medical specialty, with a training program leading to consultant status. Arrangements for representing the interests of the field were now in place and an appropriate scientific journal had been established. Subsequently there was considerable expansion in the palliative medicine workforce.

A survey of the membership of the Association of Palliative Medicine (APM) in 2004[37] revealed that 58.1 percent were in full-time appointments in palliative medicine and 70.4 percent of the workforce was female. There were 325 consultants, 49 associate specialists, and 78 staff grade postholders as well as 160 specialist registrars, of which 83 percent were women. Some 60 consultants held honorary NHS contracts, but despite an APM recommendation, there were few NHS consultants holding honorary contracts with hospices. In Ireland specifically there were in 2005 seven consultant physicians in palliative medicine, with seven further consultant posts in the process of being filled.[38]

Trainees in palliative medicine undertake a 4-year program of professional development, which involves periods of 'rotation' through a variety of care settings – hospital based and community services, as well as hospices and departments of oncology. Most take advantage of a period for research, sometimes linked to academic departments, though numbers undertaking research degrees for MD and PhD appear to remain rather low.

Such expansion in the infrastructure of palliative medicine has been made possible by wider service developments and policy changes. During the 1970s and 1980s, as we have seen, a major program of hospice expansion had taken place in the UK, gaining wide geographical coverage. The expansion in charitable hospices was also reflected in a growing number of NHS inpatient units, although the ratio between the two has remained fairly constant at roughly 3:1. Indeed it is the 'mixed economy' of care between the nongovernment and government sectors that is such a distinct hallmark of the development of palliative care in the UK and Ireland. From the later 1980s onwards, hospice and palliative care services in the UK also benefited from special government funding streams, enabling the consolidation and expansion of provision and providing ring-fenced monies initially for independent hospices and then for palliative care more generally.[39] There were some other specific policy innovations at this time. In 1992 an expert group of physicians and nurses reported to the UK Minister of Health and was instrumental in making a case for palliative care to be provided on the basis of need, rather than diagnosis; the report called for wider education in palliative care for all health professionals and greater emphasis on matching services to needs identified at the population level.[40] Three years later the Expert Advisory Group on Cancer produced what came to be know as the 'Calman Hine Report' on the commissioning of cancer services in England and Wales.[41] It was crucial in giving a prominent place to palliative care within the different tiers of cancer care provision and in giving guidance on the staffing levels required in relation to a population of specific size. The report was seized upon by the palliative medicine community as an opportunity for development.

In the early 1990s the UK also saw the creation of the first university chair in the palliative care field. A professor in palliative medicine was appointed to it and this set the tone for subsequent academic developments, which tended to focus on the clinical disciplines. By 2005 there were in the UK some nine chairs in medicine and nursing relating to palliative care as well as three chairs occupied by social scientists with a major interest in the field. The academic departments of palliative medicine have developed varied cultures and strands of interest. In some cases the emphasis has been predominantly on clinical studies focused on pain and symptom management. In others there has been a leaning towards matters of policy, service organization, and evaluation. Social science perspectives have had considerable prominence in some departments, focusing around wider questions of social inequality, cultural values, ethnicity, spirituality, and the psychosocial dimensions of palliative care. The perspectives of the medical humanities have also been visible. A major boost to development came in 2005 with the creation of two major research collaboratives in supportive and palliative care supported by a consortium of funders coordinated through the National Cancer Research Institute. These will combine the efforts of multiple academic groups, along with a variety of other partners to advance the field and build the future infrastructure for research.

Other developments have also taken place in the education of healthcare professionals in matters relating to palliative care. During the 1980s and 1990s the curricula of medical and nursing schools as well as courses for occupational therapists and physiotherapists, social workers, and others began to include elements on the principles and practices of palliative care. A comparative survey to determine the presence of end-of-life issues in the undergraduate medical school curricula of the UK and USA found almost universal coverage of dying, death, and bereavement, and most addressed the topic of palliative care. Hospice involvement was found in 96 percent of UK medical schools.[42] Similarly, a survey of senior tutors coordinating entry level degree and diploma nursing courses showed that diploma students received a mean of 7.8 hours and degree students 12.2 hours of teaching in palliative care, compared with the mean of 20 hours of teaching offered to undergraduate medical students in the UK.[43] A 2002 study sought to examine changes in formal teaching about death, dying, and bereavement in undergraduate medical education in UK medical schools and was based on earlier surveys conducted in 1983 and 1994. It found that the amount of such teaching varied widely and appeared in the curriculum in a variety of aspects, times, and places. Specialists in palliative medicine, general practitioners, and nurse specialists were most frequently involved in teaching, with decreased involvement of nonpractitioners since 1983. Most schools covered a wide range of topics, with all addressing attitudes towards death and dying and symptom relief in advanced terminal illness. Some schools used terminally ill patients directly in their teaching and most included hospice participation. Changes in undergraduate medical education, especially in terms of more integrated curricula, mean that for many schools, palliative care teaching is integrated into learning in other areas. This should help students apply their palliative care learning to other contexts. The increase in teaching about the management of physical symptoms that had occurred since the previous surveys seemed to reflect the establishment of palliative medicine as a specialty and the current emphasis within palliative care practice in the UK.[44]

Such achievements have often been looked upon with admiration by others elsewhere, but palliative care in the UK and Ireland continues to face many challenges. In the British context, a health committee of the House of Commons reporting in 2004 took a critical view of palliative care provision. Its 30 key points included concerns about the

lack of early referral to palliative care, the limited potential for those wishing to die at home to be enabled to do so, the continuing problem of matching provision to need, the concern that acceptance of the current diversity of provision could also entail tolerance of continued inequity – particularly in relation to age, ethnicity, and complex needs, and the lack of access to palliative care on the part of patients with diseases other than cancer. It also urged the Royal Colleges to ensure that training in palliative care becomes part of continuing professional development, and to consider making such modules a mandatory requirement for revalidation. Notably, the committee applauded the Government's ambition to double the number of palliative care consultants by 2015 based on the figures for 2002 – a point seen as particularly important in relation to the growing needs for palliative care resulting from population aging and a rising incidence of chronic disease and comorbidities. The findings of the committee provide an important agenda for UK palliative care development in the first decade of the twenty first century.

SPECIALIZATION AND ITS DISCONTENTS

In the early years modern hospice and palliative care in the UK and Ireland had many of the qualities of a social movement supported by wider forces. This movement may well have contributed to a new openness about death and bereavement which was in evidence in the late twentieth century. The first person ever to be seen dying on television in the UK, for example, was a patient in the care of an Irish hospice.[45] The hospice movement condemned the neglect of the dying in society and called for high quality pain and symptom management for all who needed it. At the same time it sought to reconstruct death as a natural phenomenon, rather than a clinical failure and marshaled practical and moral argument to oppose those in favor of euthanasia.

At the same time specialty recognition can be seen as a turning point in hospice and palliative care history.[46] For some, specialization is seen as the key to integration of palliative care into the mainstream health system and a major platform from which to develop an 'evidence-based' model of practice and organization that is crucial to long-term viability. Others mourn the loss of the early ideals of the hospice movement and condemn the emphasis upon physical symptoms at the expense of psychosocial and spiritual concerns. In short, there have been claims that forces of medicalization and routinization[47] are at work or even that the putative 'holism' of palliative care philosophy masks a new, more subtle form of surveillance of the dying and bereaved in modern society.[22] Even by the early 1990s, one Irish palliative medicine physician could raise concerns about palliative medicine developing into a specialty narrowly bounded by the practice of 'symptomatology' and thereby failing to create the conditions for deeper, personal 'healing'.[48]

In a later work he went on to emphasize the need for palliative medicine to draw upon Greek traditions associated with Asklepian healing and for these to be integrated with the modern science of symptom control.[49] As the specialty develops, its medical attention tends to focus on pain and symptom management as a bounded set of problems within the relief of suffering – giving weight to the charge of creeping medicalization. At the same time it is precisely in this biomedical area of palliative care that measurable and striking successes are to be found in the use of pain relieving and symptom controlling technologies, some of which seem not yet to have percolated into the wider healthcare system.

By the end of the twentieth century a growing commitment to the evidence base was emerging in palliative medicine, although several reviewers found this still a rather fragile enterprise and made claims for the particular problems faced by palliative care in assessing its practice by such means.[50,51] Two forces for expansion were, however, clearly visible. First was the impetus to move palliative care further upstream in the disease progression, thereby seeking integration with curative and rehabilitation therapies and shifting the focus beyond terminal care and the final stages of life. Second there was a growing interest in extending the benefits of palliative care to those with diseases other than cancer, to make 'palliative care for all' a reality. The new specialty was therefore delicately poised. For some, such integration with the wider system was a *sine qua non* for success; for others it marked the entry into a risky phase of new development in which early ideals might be compromised.

In the UK and Ireland hospice care and palliative care have a shared and brief history. The evolution of one into the other marks far more than a simple change of nomenclature. It signifies a transition which, if successful, could ensure that the benefits of a model of care previously available to just a few people at the end of life will in time be extended to all who need it, regardless of diagnosis, stage of disease, social situation, or means. Much remains to be done, however, if that goal is to be achieved.

Key learning points

- Some evidence of interest in the care of the dying began to develop in the late nineteenth century, but its influence was limited in extent.

- By the mid-twentieth century attention was beginning to focus on the social denial of death and medical neglect of the dying.

- As the new field of hospice care emerged a multi-disciplinary approach to pain and symptom management was promoted.

- Attention was also given to the wider definition of suffering: physical, psychological, social, spiritual.

- A tripartite model of hospice care emerged: clinical care, education, and research.
- Modes of care delivery began to diversify.
- Specialty recognition was achieved for palliative medicine and the workforce grew accordingly.
- Palliative medicine sought to extend care to earlier stages of the disease progression and to nonmalignant disease.
- Attention focused on the establishment of an evidence base.
- While the development of the specialty of palliative medicine has been widely welcomed, there are some concerns about the medicalization of care at the end of life and the role of palliative medicine within the process.

The development of palliative medicine in Europe

FRANCO DE CONNO, HEIDI BLUMHUBER, JAVIER ROCAFORT

INTRODUCTION

First of all it is important to consider what exactly constitutes 'Europe'. The World Health Organization (WHO) describes Europe as representing 52 different countries.[1] The Council of Europe, the oldest political European organization, has 46 member states.[2] The European Union linked 15 independent nations until 2004, when this number increased to 25.[3] These three different definitions of Europe clearly illustrate the diversity of 'Europe': countries with different languages, history, cultures, economies, and education and healthcare systems.

This variety is also reflected in the organization and development of palliative care in Europe. It is still impossible to talk about common development in Europe, but it is possible to present some snapshots and details that give an idea about palliative care in Europe. Of the 53 countries listed in Table 2.1, 34 countries[4] can be identified as having at least one palliative care association at the national level. Yet among these 34 countries there are distinct differences. The UK has six different palliative care associations (four for professionals, one common research society, and one umbrella organization). France and Italy have one multiprofessional association each (Société Française d'Accompagnement et de soins Palliatifs [SFAP] and Società Italiana di Cure Palliative [SICP], respectively) that collaborates closely with a federation of the supporting volunteer associations (Jusqu'à la mort accompagner la vie [JALMALV] and Federazione Cure Palliative Onlus [FCP]). In Germany there is the German Palliative Care Society, mainly formed of physicians, and a hospice association. In the Netherlands, the national association the called the 'Network of Palliative

Care Services'. Belgium has different palliative care associations catering for the different languages spoken in the country, whereas in Switzerland there is one multiprofessional national association for professionals speaking any of the three languages of the country.

HISTORY

The development of modern palliative care started in the 1960s with the hospice movement in the UK, offering continuous care for incurable patients. Dame Cicely Saunders introduced this change with her vision of holistic medicine, combining a humanistic and sensitive approach to continuing care with the use of recent knowledge and advanced techniques in symptom control. For some years palliative care remained the 'exclusive property' of the UK.

In the rest of Europe two events were significant for development of palliative care. The first was the dissemination of WHO's *Cancer Pain Relief* in 1986.[5] This booklet, and its validation study, induced a change in the interest paid to the problem of cancer pain and heralded an increase in the consumption of opioids. Through attention to pain, an awareness of the multifaceted problems and needs of the patients with advanced disease crept into the daily practice of many healthcare professionals. Another significant event was the first international congress organized in Milan, Italy, thanks to the initiative of Professor Vittorio Ventafridda and the Floriani Foundation. As a consequence, the European Association for Palliative Care (EAPC) was created in December 1988, with the aim to increase awareness and promote the development and dissemination of palliative

care at scientific, clinical, and social levels. This could be best achieved through the implementation of existing knowledge, training of those who, at any level, are involved with the care of patients with incurable and advanced disease, and promotion of study and research (offering patronage to scientific and educational events promoting the dissemination and development of palliative care). In addition, the promotion and sponsorship of publications or periodicals concerning palliative care was endorsed, bringing together those who study and practice the disciplines involved in the care of patients with advanced disease (doctors, nurses, social workers, psychologists and volunteers). Finally, it was hoped that the EAPC would unify the national palliative care organizations and establish an international network for the exchange of expertise and addressing the ethical problems associated with the care of terminally ill patients.

In 1992 the first national palliative care associations joined the EAPC collectively and in 2004, the association became a federation with 31 associations from 22 countries representing a movement of about 50 000 persons (Figs 2.1 and 2.2).

THE EAPC DEFINITION OF PALLIATIVE CARE

In 1998, on the occasion of the revision of the bylaws to ratify its status as a 'nonprofit' organization (EAPC Onlus),

the EAPC also revised its definition of palliative care, first set out in Spring 1989 and published in the EAPC newsletter of that year:[6]

3. Palliative care is the active, total care of the patients whose disease is not responsive to curative treatment. Control of pain, of other symptoms, and of social, psychological and spiritual problems is paramount.

4. Palliative care is interdisciplinary in its approach and encompasses the patient, the family and the community in its scope. In a sense, palliative care is to offer the most basic concept of care – that of providing for the needs of the patient wherever he or she is cared for, either at home or in the hospital.

5. Palliative care affirms life and regards dying as a normal process; it neither hastens nor postpones death. It sets out to preserve the best possible quality of life until death.

RECOGNITION OF PALLIATIVE MEDICINE/ CARE BY GOVERNMENTAL BODIES

In 1998 the EAPC was awarded the status of nongovernmental organization (NGO) of the Council of Europe. In June 1999 the Parliamentary Assembly of the Council of Europe adopted a document on the: 'Protection of the human rights and dignity of the terminally ill and the dying'.[7] This document mentions and underlines the need for palliative care. Toward the end of 2003, the Council of Europe released a second document entitled 'Recommendation REC 24 (2003) of the Committee of Ministers to member states on the organisation of palliative care',[8] which was approved and adopted on by all ministers of health. In 2004, the EAPC promoted a project for the translation and dissemination of those recommendations in many different languages.

Delivery of palliative care

In view of the strategic developments taking place in the healthcare systems in Europe, we consider it timely to cite the

following items from the above mentioned document (reproduced from CM(2003)130 Addendum[9] with permission).

Settings

67. Palliative care takes place in the following settings:
   - home
   - nursing home
   - home for the elderly
   - hospital
   - hospice

Services

71. A distinction is useful between non-specialist and specialist palliative care services. Non-specialist or conventional services provide palliative care without making this into their core business. They include: district nursing services, general practitioners, home care teams, general internal medicine wards, and nursing homes.

72. The large majority of palliative care is, and will probably always be, provided by non-specialist services. In many cases, non-specialised professionals provide the care without the intervention of specialists; in many other cases, specialised intervention may be needed in the context of non-specialist care, while in a small proportion of the cases, specialists will need to take over the care entirely.

73. Non-specialised services also include services that are involved only incidentally, such as radiology and radiotherapy departments, surgery. Such services sometimes have waiting lists that may be especially detrimental to palliative care patients because of their short remaining life span in which they could benefit from the treatment. Therefore, the concept of a 'palliative bus lane', involving preferential access for palliative patients, has been proposed.

74. A specific area where the concept of palliative care has received increased attention over the last years, is the intensive care unit.

75. Non-specialists may build up sufficient experience in relatively uncomplicated palliative care but, due to the limited number of palliative patients they see (in the Netherlands, for example, general practitioners on average see between 2–6 [*sic*] palliative care patients per year), the experience with complex palliative care cannot be acquired. Experiments with easily accessible consultation services show good possibilities

of support for non-specialised professionals while the patient can remain within their care.

76. Specialised services denote services fully devoted to palliative care, whose teams are specially trained in this area of care. Such services do not take the place of the care provided by front-line professionals (home care, hospital or rehabilitation facilities), but support and complement such care according to the needs identified and the complexity of the situation. Wherever they are, patients must be able, if necessary, to access such services at all times and without delay.

77. The most common services are specialist in-patient units, hospital palliative care teams, home care teams, day care facilities, hospitalisation at the home, and out patient clinics.

78. There is very little good evidence as to what type of palliative care services are preferred by patients. In a review, Wilkinson *et al.* noticed a trend toward greater satisfaction with specialised services, both in hospitals and in the community, as compared to general hospitals. (Wilkinson *et al.* 1999). Again, these results should be interpreted with caution.

79. Non-specialist services include the following:
  - informal caregivers
  - volunteers (?)
  - district nurses
  - general practitioners
  - non-palliative care specialists.

80. Specialist palliative care services are those services with palliative care as there [*sic*] core activity. They will require a higher level of professional skills from trained staff and a high staff/patient ratio. Such services should be available in all care settings and should be able to support a patient wherever the patient may be: at home, in hospital, in residential care, in nursing home, in day centres, in out-patients or in a specialist palliative care unit. Specialised palliative care services also have an important role in supporting other health care professionals in the delivery of palliative care services at hospital and community level. All health care professionals should be able to access, advise [*sic*] and support from specialised palliative care providers when required.

81. The key characteristics of a specialist palliative care services have been described by the National Council for Hospice and Specialist Palliative Care Services in the United Kingdom and are endorsed by the National Advisory Committee on Palliative Care (Ireland). These are summarised as follows:

  - the provision of physical, psychological, social and spiritual support, with a mix of skills delivered through a multi-professional, collaborative team approach;
  - at least the lead person in each professional group within the multi-professional team should be a trained and acknowledged specialist in palliative care;
  - patients and families are supported and involved in management plans;
  - patients are encouraged to express their preference about where they wish to be cared for and where they wish to die;

  - carers and families are supported through the illness into bereavement, and the needs of the bereaved are recognised and addressed;
  - there is cooperation and collaboration with primary health care professionals, hospital and home care services to support patients wherever they might be;
  - the contribution of volunteers is recognised and valued;
  - the service has either indirectly or directly a recognised academic external educational role and in-service education provision;
  - standards are set for the education and training provided;
  - quality assurance programmes are in place and are constantly used to review practice;
  - clinical audit and research programmes exist to evaluate treatment and outcome;
  - staff support arrangements exist which are appropriate to meet the needs of those working in specialist palliative care, whether fulltime or part-time.

We can summarize the characteristics described in the above citation as follows:

- A hospital-based palliative unit (specialist) can be composed of:
  - Ambulatory service (outpatients)
  - Day hospital (day care)
  - Beds (inpatients)
  - Intra-hospital consultation team
  - Home care team or home care support teams
- Hospices (free-standing) can be composed of:
  - Day hospital (day care)
  - Beds (inpatients)
- Home care can be delivered by:
  - Specialized teams
  - Support teams
  - General practitioners
- Nursing homes
- Homes for elderly people (long-term inpatients)

NATIONAL LEGISLATIONS

With the exception of the two documents of the Council of Europe, there is no unified European policy for the implementation of palliative care. In 2003, the EAPC decided to organize a survey on the situation of palliative care in each European country, with the aim to collect reliable information on the delivery of and to explain the current organization of hospice and palliative care in Europe, taking into account political, social, healthcare policy and related factors. This project will be carried out in form of a task force chaired by the Spanish EAPC Board Member Carlos Centeno Cortes, in collaboration with other institutions. From the literature review, the first step of the work of this task carried out by Javier Rocafort, we present an example of the data (see Appendix 2.1 for data sources) collected about the legislation of five different countries (Boxes 2.1–2.5).

Box 2.1 Palliative care in Belgium

Political system: Constitutional monarchy
Capital city: Brussels
Total area: 30 158 km^2
Population: 10.2 million
Currency: Euro
Laws:

- July 15, 1994: Law on the organization of palliative care units in hospitals, with the scope of symptom control, and psychological and bereavement support

- July 21, 1994: Law stating that employees can request unpaid leave of 2 years to care for a family member with an incurable (terminal) disease and receive economical support from the state

- October 30, 1996: Law defining need of 10 palliative care beds per 10 000 inhabitants

- June 15, 1997: Law defining that all geriatric nursing homes with more than 60 beds must have a palliative care unit

- July 15, 1997: Law about implementation of hospital consultation teams with the scope to develop attitudes and disseminate knowledge about palliative care in all hospital caregivers

- July 15, 1997: Law for the creation of regional bodies to coordinate delivery of palliative care. One body for an area of between 300 000 and 1 000 000 inhabitants

- October 13, 1998: Law defining need of one home care team with two nurses and one doctor for 100 patients (per 300 000 inhabitants)

Box 2.2 Palliative care in France

Political system: Republic
Capital city: Paris
Total area: 550 000 km^2
Population: 60.4 million
Currency: Euro
Laws:

- 1986: Law on the creation of at least one palliative care unit in each 'department' (French province)

- November 1994: A high-ranked commissioner of the health ministry identified pain as one of the most important problems in France. Law obliges the health institutions to organize better for the control of pain of their patients

- September 1995: Ethical code includes an item about the relief of suffering

- 1999: Establishment of a 3-year national program for the implementation of palliative care in the healthcare system with a financial budget of €58 million. This program also included that employees can request unpaid leave of 3 months to care for a family member with an incurable (terminal) disease and officially recognized the role of volunteers in palliative care

- 2002: Establishment of a second 3-year national program with the following aims: establishment of home care, guaranteeing a palliative care unit of 10 beds in at least one university hospital in each French region, and organization of a campaign to raise the awareness of the population

challenges. Yet, the need for some form of guideline to set a common ground for educational preparation is now necessary for all disciplines involved in the delivery of high-quality palliative care.

In 1997, the EAPC proposed that the collective member associations in each country should create a national education network, which would link with the EAPC education network. The proposal from the EAPC Board of Directors was to establish minimal recommendations for training in palliative care for both nurses and doctors, and also to identify those training skills most appropriate for palliative care educators. The EAPC has, over the last two years, tried to unify the European voice of palliative care through its initiative 'one voice, one vision'. The creation of task force initiatives to address some of the key issues which pertain to this watchword included the project described here – a proposal to offer some kind of guidelines for the future development of palliative nurse education. This report entitled 'A Guide for the Development of Palliative Nurse Education in Europe' is the culmination of a three-year collaborative project, finally agreed in November 2003.

EDUCATION

In an editorial in *Palliative Medicine*[10] and the *European Journal of Palliative Care*[11] Phil Larkin (Chair of the Nursing Education taskforce of the EAPC) reported:

> One of the most difficult dilemmas for the palliative care educator is to achieve some kind of standardisation across programmes. In Ireland, for example, the proliferation of hospice centres providing essentially the same course led to some agreements about what should take place, why, when and where. In a small country like the Republic of Ireland, such national initiatives are possible. Compare the example of Switzerland with three official languages and the need for simultaneous translation in triplicate. The education recommendations of the Swiss National Palliative Care Society (SSMSP) are a credit to the ability to transcend linguistic

---

Box 2.3 Palliative care in Hungary

Political system: Republic
Capital city: Budapest
Total area: 93 000 km^2
Population: 10.2 million
Currency: Forint
Laws:

- 1997: New healthcare legislation includes the concept of palliative care and informed consent

---

Box 2.4 Palliative care in Italy

Political system: Republic
Capital city: Rome
Total area: 301 263 km^2
Population: 57.6 million
Currency: Euro
Laws:

- 1996: Creation of the Ministerial Commission for the definition of palliative care and its development in Italy
- 1998: Health Ministry recognizes an official palliative care curriculum and the need for at least one hospice per region
- February 1999: Ministerial decree that allocates governmental funding of €200 million for the opening of 200 palliative care units

---

Box 2.5 Palliative care in Spain

Political system: Constitutional monarchy
Capital city: Madrid
Total area: 504 782 km^2
Population: 39.4 million
Currency: Euro
Laws:

- 1990: The government of the region of Catalonia passes law on healthcare that includes palliative care
- 1991: Second law of Catalonia including palliative care
- 1994: Spanish healthcare system recognizes the existence of government-funded palliative care units, private palliative care units, and a combination of both

---

The comments and the full recommendations are published on the EAPC website (www.eapcnet.org/; click on EAPC Publications, and then on Education).

The EAPC considers education of palliative medicine at university of utmost importance for the future of palliative care. During 2003, Marilène Filbet (EAPC Vice President 2003–05 and President from 2005) carried out a survey on the state of education for physicians in Europe. A questionnaire was distributed. Among the questions asked, the following two were deemed the most important:

- Do you have a national program for training in palliative care for medical students in your country or state?
- Do you have a specialty in palliative care?

See Table 2.2 for the replies from 12 countries.

Following the survey the EAPC decided to create a taskforce on medical education of physicians to elaborate the European recommendations for the palliative care curricula for physicians for the three levels:

- A (undergraduate)
- B (post graduate, e.g., masters or special courses)
- C (specialist training)

The group chaired by Dr Marilène Filbet represents a broad spectrum of medical practitioners involved in the preparation and delivery of medical education throughout Europe. The curricula recommendations will be published on the EAPC website (section education in 2006).

Table 2.2 *Palliative care training for physicians: EAPC Questionnaire result*

	National program	Specialty
Belgium	No	No
Cyprus	No	No
Finland	Yes	No
France	Yes (100 hours)	Not yet, but many diplomas
Germany	Yes	Yes
Hungary	Yes (24 hours)	No
Ireland	No	No (national document)
Italy	Yes	No
Norway	No	Yes
Spain	Yes	Yes
Switzerland	No	Yes
UK	No	Yes

EAPC, European Association for Palliative Care.

CHALLENGES FOR PALLIATIVE CARE IN EUROPE

We envisage three major challenges for Europe.

Palliative care delivery

Europe is facing an important demographic change. The United Nations forecast for European countries for 2020 is that 26–32 percent of the population will be over the age of 60 years.[12] This situation implies a range of difficulties for the near future: changing epidemiology of disease, increasing age of caregivers, financial implications for healthcare systems, and the range of settings for care. The Recommendation REC 24 (2003)[8] of the Committee of Ministers of the Council of Europe has not given any particular attention to this. To highlight this problem the WHO has published two booklets (*Better Palliative Care for Older People*[13] and *The Solid Facts*[14]) which were the result of an expert meeting organized by the Floriani Foundation, Milano, and coordinated by Irene Higginson.

Education

Palliative care needs to become a specialty in as many European countries as possible. It was as early as 1988 when Calman[14] wrote that 'A well defined discipline:

- has a clearly defined body of knowledge
- has full-time specialists
- has sufficient patients who require the services of an expert in the area
- has technical procedures which can only be carried out by specialists
- has clear training programmes (plus special qualifications in the subject)
- is seen to have value by patients, the public, and other professionals.'

Palliative care fulfils all these requirements but still is a specialty only in the UK and Ireland. Higher professional training in the UK requires 4 years at senior registrar level:

- Obligatory: 2 years full time in a specialist unit which has a full range of services (inpatient beds, outpatient clinics, home care, bereavement)
- Recommended: an elective period of research or special experience in some aspect of palliative medicine.

Research

Research in palliative care is a complex and controversial subject and is not easy to realize. Physicians and nurses do not want to involve patients in trials, as they believe that the burden placed on the patient will be too high. But in modern medicine a new specialty will develop only if it is supported by scientific evidence to justify its aims and means. Clinical trials enable us to evaluate new treatment options. Obviously research in palliative care is not limited to clinical trials. We also need to enhance research, social assistance, psychiatry, psychology, the approach toward death, bereavement and grief, and healthcare policy and organization. The Board of Directors of the EAPC consider research a key issue for the future of palliative care and therefore decided in 1996 to put together a steering group with the aim of establishing a research network. When the Research Steering Committee (RSC) was first established, it felt it was premature to establish a network with the aim of carrying out multicenter and multinational studies. The committee decided to make use of the considerable information and knowledge that already existed among palliative care experts. Since its creation the group has organized 12 expert working groups on a variety of topics for which a common European position or recommendations are needed. For these, experts were invited from various fields in addition to members of the RSC. The results of the work of eight groups have been published, one of them in six languages, and have been made available to the EAPC members. These are listed below.

Klepstad P, Kaasa S, Cherny N, *et al.*; Research Steering Committee of the EAPC. Pain and pain treatments in European palliative care units. A cross-sectional survey from the European Association for Palliative Care Research Network. *Palliat Med* 2005; **19**: 477–84.

Caraceni A, Cherny N, Fainsinger R, *et al.* Pain measurement tools and methods in clinic research in palliative care: recommendations of an Expert Working Group of the EAPC. *J Pain Symptom Manag*e 2002; **23**: 239–55.

Mercadante S, Radbruch L, Caraceni A, *et al.*; Steering Committee of the European Association for Palliative Care (EAPC) Research Network. Episodic (breakthrough) pain: consensus conference of an expert working group of the European Association for Palliative Care. *Cancer* 2002; **94**: 832–9.

Stiefel F, Die Trill M, Berney A *et al.* Depression in palliative care: a pragmatic report of an expert working group of the European Association for Palliative Care. *Support Care Cancer* 2001; **9**: 477–88.

Cherny N, Ripamonti C, Pereira J, *et al.*; Expert Working Group of the European Association of Palliative Care Network. Strategies to manage the adverse effects of oral morphine. An evidence-based report. *J Clin Oncol* 2001; **19**: 2542–54.

Ripamonti C, Twycross R, Baines M, *et al.* Clinical practice recommendations for the management of bowel obstruction in patients with end-stage cancer. *Support Care Cancer* 2001; **9**: 223–33.

Hanks GW, Conno F, Cherny N, Expert Working Group of the Research Network of the European Association for Palliative

Care. Morphine and alternative opioids in cancer pain: the EAPC recommendations. *Br J Cancer* 2001; **84**: 587–93.

2001 WHO guidelines on cancer pain management: report on international application and current appraisal (in collaboration with Excerpta Medica), 5th Congress of the EAPC, 13 September 1997, London.

The RSC has obtained the right to upload five of the papers in PDF format to be available from our website (www. eapcnet.org/researchNetwork/resnetpublications.asp). (Access to this webpage requires registration with the EAPC.) One paper is ready for publication and another is in preparation.

The RSC has also organized panels and seminars for the fifth, sixth, seventh, and eighth congresses of the EAPC and other conferences.

FORUMS ON RESEARCH IN PALLIATIVE CARE

The RSC held its first forum on research and development for selected groups of carers interested in research in Berlin on December 7–10, 2000 (report available at: www.eapcnet.org/congresses/berlin2000.html). The second forum was held in Lyon, France, on May 23–25, 2002 (report available at: www.eapcnet.org/congresses/lyon2002.html) and the third at Stresa, Lago Maggiore, Italy, on June 4–6, 2004 (report available at: www.eapcnet.org/congresses/research2004.html). The fourth forum was held in Venice, Italy, on May 25–28, 2006.

OTHER RSC ACTIVITIES

The RSC has participated in two Expressions of Interest to the European Community (see www.eapcnet.org/researchNetwork/researchprojects.asp) and has submitted an application for funding to the European Community, which was accepted but with conditions that could not be realized. It organized a cross-sectional survey with two main aims: to create a network of European palliative care centers and services to introduce them to collaborative research and to obtain descriptive data of the practice of palliative care across Europe. At the conclusion of this survey, the Research Network intends to undertake multicenter research. The preliminary results of the survey were presented during the first Research and Development Conference in Berlin. Further results were presented in the session about the activities of the Research Network in Palermo on April 2, 2001. One paper has been published and is available in PDF format from the EAPC website. Others are ready for publication and we are in the process of analyzing the datasets for further papers.

The RSC is in the process of organizing its first European multicenter study: European Pharmacogenetic Opioid Study, which will generate data on clinical characteristics and measures, and serum concentrations of opioids, and collect biological material for pharmacogenetic analysis in an attempt to answer several research questions.

The establishment of a bio-bank for genetic studies has given the study group unique possibilities to explore hypotheses generated by genetic findings related to the pharmacogenetics of analgesics and the genetics of pain.

Key learning points

- The countries making up the continent of Europe have diverse cultures and languages, history, economies, and education and healthcare systems. There is also great diversity of legislation in the different countries.
- The development of modern palliative care started in the 1960s with the hospice movement in the UK by Dame Cicely Saunders but for several years this was limited to the UK.
- In the past 15 years, there has been rapid development of the movement of palliative care in Europe and the EAPC was created in December 1988 and is now a federation of nonprofit organizations. Recently, the EAPC revised its definition of palliative care to include total care of the terminally ill patients to preserve the best possible quality of life until death.
- Palliative care associations in European countries are different in the different countries.
- In 2003 the Council of Europe released recommendations of the delivery of palliative care in Europe. These are available on the Council's website and encompass hospital-based palliative care, hospices, home care, nursing homes and homes for elderly people.
- Several European countries have passed legislation in relation to palliative care.
- Europe faces challenges not only in the appropriate delivery of palliative care but also education of professionals delivering the care and research.
- The RSC has made huge efforts to improve and enhance research in palliative care. Several papers have been published and many projects currently are underway.

3A

The development of palliative care in Canada

NEIL MACDONALD

INTRODUCTION

Relating an account of Canadian palliative care is risky, particularly when the historian has been involved in some of these activities, thus magnifying the possibility of bias. One may be fairly criticized for the failure to account adequately for the fine work of colleagues and groups not mentioned in the history, perhaps only because of the author's lack of familiarity with their work, or because of the lack of a readily available written record.

THE TWIN PARENTS

It is easy to trace the roots of Canadian palliative care; they clearly are evident in the seminal activities of Dr Balfour Mount and Dr David Skelton in the mid 1970s. The first Canadian programs were started within a month of each other in 1974. Dr Skelton opened a 'terminal care unit' at St Boniface Hospital in Winnipeg. Shortly thereafter the 'palliative care unit' at the Royal Victoria Hospital in Montreal was launched; from the start it encompassed an inpatient ward, a consult service, a coordinated home care program, and a bereavement service.

St Boniface, a teaching hospital of the University of Manitoba, is a part of the Grey Nuns Hospital network. The Grey Nuns is a religious order which has a long tradition of pioneering hospital and healthcare in Canada. Originally centered in Montreal, the sisters moved in concert with the original settlers of the Canadian West, starting hospitals which were often the only sources of healthcare in the developing towns and regions of the then Canadian frontier. Because of their long history of compassionate care, twinned with a record for innovation, they naturally became leaders in the palliative care field. Following upon their Winnipeg enterprise, the Grey Nuns organized the first inpatient palliative care unit in Edmonton in 1982, again led by Dr Skelton who had moved to the University of Alberta to head a new academic geriatric center.

At St Boniface Dr Skelton was joined by Dr Paul Henteleff in 1975, who took on the directorship of the terminal care unit. St Boniface continues to be an exemplary model of community palliative care linked with a first rate teaching hospital inpatient unit. One notices a strong continuum of leadership, Dr Henteleff served for 17 years, followed by Dr Deborah Dudgeon (now the director of the program at Queens' University in Kingston), and currently Dr Mike Harlos.

The Royal Victoria Hospital is a secular institution, its origin stemming from the support and drive of the men who built the Canadian Pacific Railway, which was the first railroad to traverse Canadian land, thus opening the west and securing the northern Pacific coast as a part of Canada. Reflecting the strong Scottish presence in Montreal and Canada as a whole – if the Scots did not 'invent the modern world'[1] they certainly influenced much of the nonfrancophone culture of Canada – the 'Vic' was modeled on the Edinburgh Royal Infirmary, and became one of the principal adult teaching hospitals of McGill University.

Herein lies an important point which strongly influenced Canadian palliative care – both of the founding hospitals were academic institutions. Elsewhere in the world palliative care usually started outside of the milieu of academic

medicine, and only now is achieving presence and credibility within medical schools. Canada had a 'leg up' in these endeavors because of early acceptance of palliative care by academic colleagues in leadership positions. For example, at the Royal Victoria Hospital, the chairs of surgery and urology and the Director of Nursing sponsored a participant observation on the care of dying patients, a study which in part involved the experiences of a cadaverous appearing, albeit healthy, anthropologist passing as a patient with a cancer of the pancreas.[2] This participant observational study compared patient contacts occurring in the Royal Victoria Hospital Palliative Care Unit and a surgical ward. On the Unit both patient-to-staff and patient-to-patient contacts were considerably higher:[3] this study provided convincing evidence of the effects of palliative care. Based on this 'patient's' hospital encounters, coupled with other relevant studies, Dr Mount made a powerful case for his visionary palliative care program.

At that time Dr Mount was a happily and fully engaged urological oncologist with recent personal experience (a germ cell tumor of the testicle) which no doubt concentrated his thinking on the transience of life and the needs of people during their final passage. In the course of carrying out his initial work, Dr Mount encountered the studies of Elizabeth Kübler-Ross and through her writing learned of the work of Dame Cicely Saunders in London, England. Dr Mount contacted Dame Cicely, and arranged to work with her; a lifetime friendship was soon established. On his return to Montreal, Dr Mount set out to incorporate the principles espoused by Dame Cicely and her colleagues in a hospital-based program with consequent major impact on the life and culture of one of the world's premier teaching hospitals.

Dr Mount soon recognized that he needed a team to meet the expectations which he had established. In 1974 Dr Ina Cummings Ajemian, a highly regarded family physician in the community served as first clinical director. Soon thereafter (1975), another gifted family physician, Dr John Scott, joined the team. Dr Ajemian and Dr Scott in subsequent years held leadership positions in other parts of Canada; Dr Ajemian as Head of the Dalhousie Palliative Care Program, and Dr Scott as Director of the Elizabeth Bruyère Program in Ottawa.

PALLIATIVE CARE: THE ORIGIN OF THIS TERM FOR HOSPICE CARE

Initially a 'hospice program' was planned for the Royal Victoria Hospital. Francophone friends reminded Dr Mount the word 'hospice' had a pejorative connotation in French, conveying a feeling of disengagement from life and termination of hope. Shaving, for some of us a daily ritual, has some merits – while engaged in this onerous task one morning, Dr Mount reflected on the advice he had received

and thought of alternative titles. The phrase 'palliative care' jumped into his mind. Soon at the Royal Victoria Hospital one spoke of the 'Royal Victoria Hospital palliative care program'. Although initially Dr Mount encountered resistance from his respected British mentors, the phrase, conveying a sense of continuing improvement of the quality of existence, came into general global acceptance.

CANADIAN PALLIATIVE CARE SERVICES

Certain features of the Canadian programs are worthy of attention for their potential worldwide influence. Among these one may include team development and the comprehensive home care concept.

Team development

At McGill, Dr Ajemian proved highly adept at putting into practice the team concept initially conceived by Dr Mount. A nonhierarchical team was created, including nurses, psychologists, psychiatrists, music therapists, social workers, physical and occupational therapists, pastoral care workers, pet therapists, grief counselors, and an exceptional team of volunteers. From a distance I was particularly impressed with the Royal Victoria Hospital volunteer program, which placed highly trained volunteers in positions of direct meaningful patient contact, and provided a place at the team table for them. Over time the wisdom of this move became manifest, as it was clear that many patients and families could identify and communicate more openly, in some instances, with the volunteers, while the richness of the volunteer experience enabled the Royal Victoria Hospital to attract a particularly diverse and talented volunteer cadre.

Comprehensive home care

Canada enjoys a healthcare system with full public support for hospital and physician services, and partial support (varying from province to province) for home care, other professional services, and outpatient pharmaceuticals. Home care services are regionalized within large urban/rural districts. This system sets the table for innovative whole population palliative home care programs. A number of Canadian cities now have whole population home care coverage; I will mention two specific programs whose experience and guidance have had major influence throughout Canada.

THE VICTORIA HOSPICE

The influential Victoria Hospice program operates in a small Canadian city without a medical school. It has enjoyed strong leadership throughout the full course of its history (Dr Michael Downing was the first director, and

continues in that role), and it has pioneered a number of community palliative care initiatives which are now widely represented in Canada, in some good part thanks to Victoria. These include:

- Establishment of home services and an inpatient palliative care unit within one organization from the onset of the program in September 1980.
- Development of a unique traveling home chart, facilitating interaction with local physicians.
- In 1989 Victoria pioneered the use of a 'palliative response team' created to provide 24-hour acute care service facilitated by the use of an in-home palliative care drug kit.
- The rate of home death for patients served by the Victoria program continues in the 40–50 percent range.
- The Victoria Hospice approach has had a substantive effect on hospice and palliative care development in British Columbia, a province with over 100 programs today. Aside from personal example and skillful program review which has demonstrated the benefits inherent in their approach, the Victoria program is renowned for its publication of excellent educational guides for both professionals and patients which are widely used and copied throughout Canada.

THE EDMONTON PROGRAM

With a population of 900 000, Edmonton is one of the largest cities in the world with a city-wide coordinated palliative care program. A city-wide home care program was in place in the late 1980s, but there were gaps in the links between institutional activities and the home care system. In 1994, Dr Eduardo Bruera put together an imaginative proposal for a coordinated home care program. On introduction, the program was able to demonstrate a comprehensive approach to the care of palliative care patients at no increased cost to the public purse. This initiative illustrates the benefits of marrying palliative care research and service.[4] The widespread community use of subcutaneous techniques for drug administration, assessment of patient needs, and innovative therapies pioneered by Edmonton colleagues enabled them to predict with confidence that they could successfully link the home and institution in a cost-effective program.[5]

LA MAISON MICHEL–SARRAZIN

La Maison Michel-Sarrazin, a 15-bed inpatient facility in Quebec City, occupies a unique niche in Canadian palliative care. The Quebec City area is almost completely francophone. Maison Michel-Sarrazin has had a major influence on the development of palliative care in the province of Quebec where the population is primarily French speaking. In keeping with its mandate over the years, it has developed written principles which have been published and widely

disseminated in Quebec. It is a teaching institution of l'Université de Laval. The founding director, Dr Louis Dionne was an influential surgeon in that faculty, and well respected throughout Canada. Among other areas of interest, colleagues at la Maison Michel-Sarrazin are spearheading Canadian research in changes in cognitive function associated with illnesses related to advanced cancer.

WHY NO PALLIATIVE CARE SPECIALTY?

Canada stands unique as a home for sophisticated palliative care which has failed to develop a formal specialty in the field. The Royal College of Physicians and Surgeons (Canada) controls specialty development and educational practice. It decided to not act upon a plan presented to the College in 1995 by a representative group of Canadian academic palliative care physicians, which it did acknowledge to be one of the strongest submissions in many years. As a participant in discussions on the proposal, I recall spirited debate with representatives of the sister college, the Canadian College of Family Physicians, which controls family practice educational policy. Anything for peace in the house, or so seemed the perplexing decision of the Royal College. It backed away from support for a fully articulated specialty, and acquiesced to the family practice proposal for a 1-year training program which offers successful candidates a certificate but no true specialty status.

In my view, the decision of the Royal College has grievously hurt Canadian palliative care. Our burgeoning role within medical schools was set back, our ability to sit as equals at the table with academic peers was hampered, our profile as specialists with defined skills and responsibilities was diminished and the creation of well-defined palliative care posts has been limited. To their credit, certain centers with strong leadership and sympathetic deans and hospital administrators have overcome these handicaps.

PALLIATIVE CARE RESEARCH

Canada has a rich pedigree of palliative care research. Except for a few national trials sponsored by the Clinical Trials Unit of the National Cancer Institute this work was primarily localized to a few centers. The major granting agencies showed little initiative in sponsoring palliative care research, and tended to follow, year after year, traditional funding approaches. The story changed dramatically with the inauguration of a major research agency funded by the federal government, the Canadian Institutes of Health Research (CIHR) in June 2000. The CIHR has a mandate to 'foster research relating to the four pillars of health research': basic, clinical, health services and policy, and the health of populations. It was established as a federation of distinct institutes, one of which is the Institute of Cancer Research (ICR).

The scientific director of the ICR is a prominent biochemist (Dr Phil Branton) who has the ability to embrace promising lines of research, traditional and otherwise. With his guidance, the ICR set out to address the task of identifying cancer research priorities in Canada, particularly those which are currently underfunded. Following the completion of a comprehensive national advisory process, the ICR winnowed the list of priority areas to six, and to the surprise of many, palliative and end-of-life care emerged as the top priority area selected for special CIHR funding.

One may conjecture on how this came about, but two themes are clearly apparent:

1   The CIHR–ICR adapted the World Health Organization definition of palliative care which emphasized the importance of prevention (a concept readily understood by cancer researchers) and, most importantly, included the consideration of human suffering. 'Suffering' is a highly evocative word; regardless of whether one's interest lies, with the genome or at the bedside, all can understand that in life's short passage control of suffering is of great import.
2   The CIHR stresses the importance of cross-disciplinary research, and although traditionally associated with cancer care, palliative care clearly is relevant across the broad field of geriatrics and chronic diseases.

The CIHR inaugurated a dedicated pilot research program; it also provided support for a network of training programs in palliative care research. The largest initiative, entitled 'Palliative Care – New Emerging Teams' was established to create a series of palliative care research networks across the country. Ten networks have been awarded grants totaling Can$1 500 000 each over 5 years. The nature of these teams, which include colleagues from virtually every Canadian university, vary from those concerned with physical symptoms (a pain consortium and a group interested in anorexia-cachexia are funded) to many dealing with delivery of palliative care services and whole patient care issues.

Palliative care colleagues in all countries have often complained that their research work has been stifled by cynical, uninformed reviewers sitting on grants panels whose interests lay elsewhere. The CIHR addressed this concern through the establishment of dedicated palliative care review panels including colleagues from other countries to avoid conflict of interest.

Quality of life research

The McGill research program is perhaps best known for innovative quality of life studies. The work of Mount, Cohen, and their associates has clearly demonstrated that there is much more to quality of life at the end of life than simple physical wellbeing. Dr Mount frequently quotes, with conviction, his contact with patients who, with severe limitations, have stated that the last period of their life was

also 'the best year of my life'. Drs Mount and Cohen called our attention to the importance of the spiritual/existential domain and the related importance of developing a sense of meaning as one encounters their final illness, a gift that can be enhanced if professional colleagues recognize and sustain patient–family spiritual interests.

The fruits of their research include the McGill Quality of Life Instrument[6,7] which stresses the importance of an existential/spiritual domain, and in 1999 the inauguration of the McGill Programs in Integrated Whole Person Care. This program has the objective to examine the effect of the inner life on healthcare outcomes.

Dr Mount, who once again faced his own mortality following a successfully treated experience with squamous cell carcinoma of the esophagus, recently penned a thoughtful 'personal narrative' called 'The existential moment'.[8] In it he states 'In accompanying those who are dying over the past quarter century I have come to view life as a spiritual experience, that is to say, a search for meaning purpose and personal connection, to something greater and more enduring than the self'. This view has imbued the Royal Victoria Hospital program throughout its existence, and has had a major impact on global palliative care.

Symptom control research

Amongst Canadian centers, Edmonton has been a leader in this field. Dr Helen Hayes, an Edmonton family physician, pioneered early research on hypodermoclysis, a useful technique for delivering both parenteral drugs and fluids in a cost-effective fashion. The Cross Cancer Institute – University of Alberta university hospital palliative care research program flowered with the recruitment of Dr Eduardo Bruera in 1984. Originally joining the program as a Fellow, within a few months he was clearly taking the lead in the development of palliative care research in Edmonton. Areas of particular interest included opioid studies, drug delivery, hydration, dyspnea, appetite, gastric emptying, and delirium. The Edmonton team was among the first to identify aberrations in autonomic function as a contributor to many common symptoms.

Dr Bruera created one of the more creative international research groups, including colleagues from a number of Central and South American countries.

Psychosocial research

For some years, an influential nursing research program at the University of Manitoba studied the palliative care needs of patients and families; work which has stimulated similar research in other centers. Dr Leslie Degner and her collaborator, Dr Linda Kristjanson, have served as mentors for many nurse researchers in addition to their seminal contributions to the palliative care/family care literature.

Dr Harvey Chochinov, a disciple of Dr Jimmie Holland (Memorial Sloan-Kettering Cancer Center), returned to

Winnipeg as a Soros/Open Society Fellow and launched a series of studies in the 1990s that have increased our understanding of the unique features of depression at the end of life. His work has both improved our management of depression and informed the continuing discussion on euthanasia and physician-assisted suicide. More recently Dr Chochinov has published insightful work on 'Dignity',[9] what it means and how it may be maintained (see also Chapter 13).

PALLIATIVE CARE EDUCATION

The Royal Victoria Hospital program from its inception has been a nidus for education, both locally and at a distance. The 1980 Royal Victoria Hospital manual on palliative hospice care was an early influential guide for programs developing in various parts of the world. Perhaps reflecting a personal cultural interest, Dr Mount has always stressed the use of film in teaching. A series of excellent productions, of which *The Last Days of Living* and *On the Edge of Being* are best known, have been widely used around the world.

Arguably the largest international palliative care gathering has been sponsored by the McGill Program since 1976. The biennial International Congress on the Care of the Terminally Ill enjoyed its fifteenth session in the fall of 2004, a meeting which was attended over 5 days by in excess of 1300 registrants from 35 countries of the world. In both of the Canadian founding languages, the congresses successfully integrated sessions on psychosocial issues with those on basic and clinical research, clinical care and teaching, together with team development.

The Canadian curriculum

In 1990, representatives from all 16 Canadian medical schools together developed a palliative care curriculum, in the hope that this cooperative effort would strengthen the respective efforts in their schools to advance palliative medicine education. The product of their work, the Canadian Palliative Care Curriculum, first published in 1991, is one of the first global curricula in our field. The group who developed this curriculum found other initiatives on which it wished to work together, and formally incorporated itself as a National Educational Committee, which continues to exist under the aegis of the Canadian Society of Palliative Care Physicians. In 1997 the committee updated the Canadian Palliative Care Curriculum and published it with an illustrative *Case-Based Manual*.[10] Each case is designed to illustrate the various curricular points. Arrangements were made for a class in each of the Canadian medical schools to be provided with a copy of the manual, a project which continued for a number of years, and, one hopes, with federal government support, will continue. The committee has completed regular surveys on the status of palliative care education in each of the Canadian medical schools. One

hopes that these published reports have helped the deans and curriculum committees to note discrepancies which exist between schools and to take positive action.[11,12]

Currently a major national initiative entitled 'Educating Future Physicians in Palliative and End-of-Life Care' (EFPPEC) is going forward. Its overarching goal is to ensure that by the year 2008 all undergraduate medical students in clinical postgraduate training in Canada's (now 17) schools will be competent relative to their level of training at the completion of that training. Success is probable, as the project enjoys the strong support of the Association of the Faculties of Medicine of Canada.

The first palliative care fellowships came into being in the 1980s in Edmonton and Ottawa. The former has personal meaning for me as it was funded by Mr Overton, a man of modest means who owned a small confectionery in North Calgary, which as a child I frequented, though not always to the owner's delight. Mr Overton did not have a family, but obviously invested well. In his will I was named as the major beneficiary on the understanding that the funds would be used to support palliative care. With private support, other centers added fellowships in subsequent years. With the approval of the College of Family Practice and the Royal College, formal, publicly supported fellowship programs were established in the late 1990s. By the end of the 2005 academic year 68 trainees had completed these fellowships, and there are currently only 16 people in 12 programs across the country. A gap clearly exists between the numbers of trainees, the availability of positions, remuneration for positions, and the needs of the people.

PALLIATIVE CARE – A UNIVERSITY DISCIPLINE

In 1987, with support from the Alberta Cancer Board, the University of Alberta established the first Canadian chair in palliative medicine. Chairs have subsequently been established at three other Canadian schools (McGill, Ottawa, and Toronto). University divisions of palliative medicine are present, by name or in practice, in every Canadian faculty of medicine. The siting of these divisions within university departments seems to relate to the disciplines that offered early support. Many are in departments of either oncology or family medicine. Surprisingly, with only a few exceptions, departments of internal medicine have not been leaders in welcoming and cherishing palliative medicine.

GOVERNMENT INITIATIVES IN PALLIATIVE CARE

The Canadian Senate, an appointed body, formed a committee which framed a report on euthanasia and physician-assisted suicide,[13] *Of Life and Death*, in 1995. This report did not endorse euthanasia, rather it made recommendations for action to improve palliative care services in

Canada. Five years later another Senate committee tabled a follow-up report *Quality End-of-Life Care: the Right of Every Canadian* which added new recommendations related to support for family caregivers, access to home care, pharmacare, and suggestions for greater emphasis on education and research. In what must be a unique decision, shortly after the above report was tabled, the Prime Minister of Canada appointed a Senator, Sharon Carstairs, to be a cabinet minister with special responsibility for palliative care. Under her aegis, a secretariat on palliative and end-of-life care was established which formed a series of national working groups to advise the federal government on palliative care issues. A number of tangible results are already apparent from this federal initiative, including:

- a decision by the Canadian government to establish a formal policy streamlining disability support application for dying patients
- an online directory of Canadian hospice and palliative care services
- a government decision to ensure that 'Canadians can provide compassionate care to a gravely ill or dying child, spouse or parent without putting at risk their income or job'. Workers can now take a temporary absence from work to provide support. The compassionate care benefit is a reality, but is not uniformly applied in each province because of required changes in provincial legislation
- the establishment of a Canada research chair for palliative care (awarded to Dr Harvey Chochinov) and support for one of Dr Chochinov's initiatives, the Canadian Virtual Hospice.

In concert with the Canadian Council on Health Services Accreditation, an agreement was reached on standards for palliative and end-of-life care that encompass all healthcare facilities as well as volunteer organizations to provide this care. At the provincial level, various provinces have taken the lead in specific support of research and physician education. In some cases there is provincial funding dedicated to palliative care. Victoria demonstrates a support mix which is not uncommon across the country – it receives 65 percent of its budget through the Provincial Health Plan, and is expected to find 35 percent from private donations.

Commonly, the care facilities – physician and nursing services – receive public support, but to a variable extent private monies are required for other team members, and for research and education.

SELECT CANADIAN COOPERATIVE PALLIATIVE CARE INITIATIVES

Canada, the second largest land mass in the world with a population spread across four and a half time zones, may not naturally lend itself to national cooperative activities.

Notwithstanding geography, highly successful national organizations (notably the Canadian Hospice and Palliative Care Association and the Canadian Society of Palliative Care Physicians) now exist. Three national projects with international connotations include:

- The *Journal of Palliative Care*. This is our 'made in Canada' international journal. Under the consistent guidance of a single editorial team (Dr David Roy, Electa Baril, and Suzanne St Amour) since its first issue in 1985, the *Journal* has presented the best of Canadian palliative care work, accompanied by many articles from international authors. Although we now have many palliative care publications in the international community, the *Journal of Palliative Care*, one of the first, remains one of the best.
- The Pallium Project. The federal government has provided funding for the 'Pallium Project', aimed at improving the care of patients with advanced illness in rural and remote Canadian communities. This project, cosponsored by the Alberta Cancer Board, and under the direction of Dr José Pereira of the University of Calgary, will coordinate activities and provide a central resource for training people in distant areas of Canada with particular emphasis on health professionals in the Prairie Provinces and the vast northern lands.
- The Canadian Virtual Hospice. Launched in 2004, the Canadian Virtual Hospice is an interactive network designed to promote information, exchange communication, and mutual support among patients, friends and family, health providers, researchers, and palliative care volunteers. It consists of four websites directed toward patients, family, and friends, healthcare providers, and volunteers. One may use a website for specific information or as a two-way resource to share thoughts, ask questions, and learn from the experience of others.[14] This project, directed by Dr Harvey Chochinov, was initially supported by the federal Secretariat on end-of-life care. Other partners include Cancer Care Manitoba and a number of other provincial and city of Winnipeg agencies.

CONCLUSION

The history of Canadian palliative care resembles not a smooth flowing, gradually expanding stream; rather it is more like the rapidly flowing, occasionally turbulent, ever progressing rivers characteristic of the Canadian landscape. Canadian palliative care contributions are, in this parochial Canadian's view, disproportionately large in relation to its modest population. A history is a tale of events and the people who moved these events. Some extraordinary women and men have painted Canada's, all things considered, intricate but bright and positive landscape. One hopes that

the examples cited in this review of Canada's palliative care life suitably honor the thousands of Canadians, only a few of whom are named, who have selflessly built and advanced this field.

Key learning points

- The appellation 'palliative care' was coined in Canada by Dr Balfour Mount.

- Palliative care started in academic institutions, thus enabling research and education initiatives at an earlier time than otherwise would have been possible.

- Canadian colleges of family medicine and specialty associations decided not to support palliative care as a specialty, opting for shorter training periods providing physicians with hospital/university certificates.

- In 1991, Canadians wrote one of the first national palliative care curricula, subsequently updated twice in association with a case-based textbook (*Palliative Medicine – A Case-Based Manual*) which illustrates the curriculum guidelines.

- The Institute of Cancer Research of the major Canadian research agency (CIHR) endorsed palliative care as the top priority for dedicated research funds in 2003, following up with an investment of more than Can$15 000 000, and the introduction of specific palliative care review panels.

- Led by examples in Edmonton and Victoria, several large urban areas in Canada have comprehensive palliative care programs linking home and hospitals.

- The national government of Canada has a dedicated palliative care initiative, as do many of the provincial health agencies.

The development of palliative medicine in the USA

TRUE RYNDES, CHARLES F VON GUNTEN

INTRODUCTION

The development of palliative medicine, the physician discipline working as part of the larger interdisciplinary field of palliative care, can be viewed in three distinct phases in the USA. The first phase lasted until the work of Dr Kübler-Ross and Dr Cicely Saunders became known. The second phase saw the development of hospice programs across the country. The third phase, in which we now find ourselves, is characterized by the development of a distinct and officially recognized subspecialty of medicine. This chapter will discuss each of these phases to the extent that their history is known either in the published literature or in the memories of those who experienced them. We will mainly focus on the physician component of this history which is the remit of this chapter. While we highlight seminal events in the development of hospice and palliative care in the USA, we purposely do not fully describe the larger history and vast army of contemporary pioneers due to space constraints.

EARLY HISTORY

In the USA as elsewhere in the Western world, dying was a routine part of life until the mid-twentieth century when it became medicalized.[1] Dr William Osler reported on the first large series of dying patients during his time at the hospital he helped to found at Johns Hopkins Medical School in Baltimore, Maryland.[2] Interestingly, he found that the majority of deaths he observed were not painful. Osler is also reported to have said that morphine was 'God's own medicine'. In his famous textbook *Principles and Practice of Medicine*, there is no specific mention of the care of the dying, though Cushing reports an anecdote involving Sir William's exceptionally sensitive care of a dying child.[3]

Osler, who firmly based his practice in study of the history of medicine, was presumably referring to what little was written. A British monograph from 1701 refers to the curative and palliative uses of opium as a 'noble panacea'.[4] In 1890 Dr Herbert Snow published a text on the palliative treatment of terminal cancer, with an appendix on the use of the opium pipe.[5] Yet, while the term 'palliate' appears in the title of a medical paper as early as 1802 in England,[6] there was relatively little in the textbooks of medicine, or in formal medical training, to guide physicians in addressing the array of symptoms and issues associated with the care of the dying patient.

In 1935, Harvard physician Alfred Worcester published three lectures on 'The Care of the Aged, the Dying and the Dead,' intending them to serve as outlines of what medical students should be taught because of the 'unpardonable' shifting of care for the dying to nurses and sorrowing relatives.[7] (pp. 342–3) The text was circulated during the early days of the hospice movement in the USA, in part because of its thorough clinical observations and procedural recommendations (referencing Sir Henry Halford, Sir William Temple, the Soeurs Augustines, and Florence Nightingale) and in part because of its specific injunctions that younger physicians not allow science to distract them from the art of medical practice and the

> indispensable qualifications of the physician: tact and courtesy . . . sympathy and devotion . . . [for] in the practice of our art it often matters little what medicine is given, but matters much that we give ourselves with our pills.

The care of the dying as a special or particular focus of activity was carried out in a small number of homes

beginning in the nineteenth century, much like has been described in France, Ireland, Scotland, and England.[8] All of them had Christian roots. They were founded and run by religious orders devoted to the sick dying as a demonstration of their faith. No particular physician component was identified. Rather, they appear to have been founded from a nursing perspective.

One early example in the USA is the Dominican Sisters of Hawthorne.[9] Rose Hawthorne, the daughter of the American novelist Nathaniel Hawthorne, took a 3-month nursing course at New York's Cancer Hospital, then moved into a three-room cold-water flat on New York City's Lower East Side and began to nurse the poor with incurable cancer. She took the religious name of Sister Alphonsa and founded a Roman Catholic order called the Dominican Congregation of St Rose of Lima, later called the Servants of Relief for Incurable Cancer. In imitation of St Rose of Lima, the order 'strives to give their lives to prayer and compassionate service to Jesus, who comes to them in every patient'. In 1901 Sister Alphonsa opened Rosary Hill Home in Hawthorne, New York (now the mother home of the order) as an inpatient facility to care for the dying.[10] The order is now called the Dominican Sisters of Hawthorne and operates six homes in five states.[10] One of the authors worked in their house in Fall River, Massachusetts from 1971 to 1975.

Another example is Calvary Hospital in New York City. In 1899, a small group of widows began caring for destitute women with terminal diseases. They were inspired by the work of Madame Jeanne Garnier in Lyons, France, who founded several homes for the dying poor she called hospices or *Calvaires*, beginning in 1842.[11] These widows first worked out of their own homes, then in two townhouses in Greenwich Village before moving to the Bronx in 1915. The House of Calvary was renamed Calvary Hospital in 1969. Several Roman Catholic religious orders have served Calvary Hospital over the years, but the organization was never owned or run by a specific religious order.[12]

This is not to say that physicians were unaware of the issues facing the dying during this period. However, in the USA, as elsewhere in Europe, the scientific method was introduced in the late nineteenth century as a way out of the fog of anecdote and quackery that passed for contemporary healthcare. Dr William Osler, writing in the late nineteenth century said 90 percent of the pharmacopeia could be thrown out and the worse it would be for the fish. The new idea was that human suffering stemmed from disease. If one could but understand the disease, the suffering would be stopped.

The second world war marked the beginning of the US federal government's unprecedented financial commitment to the expansion of medicine, medical research, and mental health services as well as to the construction and development of hospitals as the primary site of healthcare. In 1945 the research budget for the National Institute for Health was US$180 000. In 1948 the National Institute for Health, advocating a categorical approach to research and treatment of disease, became the National Institutes for Health, with the creation of the National Heart Institute. Two years later the budget had grown to US$46.3 million.[7] [(pp. 358–9)] The percentage of doctors describing themselves as full time specialists grew from 24 percent in 1940 to 69 percent in 1966.[13] [(p. 6)] As advances in medical science were made, the dispassionate, scientific, mechanistic approach to patient problems ironically fostered the unintended consequence where the patient was treated as a disassembled bystander bearing the disease. Patients who complied submissively with 'the system' were deemed 'good' patients and those who sought a high degree of interactivity with their care providers, and challenged routines were often dubbed 'problem patients', deviant and uncooperative.[14] Furthermore, medicine adopted a near sacred duty to combat all the known causes of death.[15]

Organizational theorist William Starbuck has noted that organizations and their environments perform in a fashion described by scientists as 'co-evolution', that is, 'evolving simultaneously toward better fit for each other'.[16] Thus, it could be said that as the practice of medicine in the USA more greatly valued determinism and prediction in the post-war period, the environment changed, causing a need for compensatory medical care embodied in the palliative competencies of hospice care. Some long time observers of this process have referred to this shift as 'a return to good medicine',[17] a medicine that embraces the medical arts, along with appropriate and tailored use of therapeutics, as expressed in the twentieth century by physicians Alfred Worcester, Charles Aring, Eric Cassell, and Ira Byock.[17–19] Although 'good medicine' may sound trite, this evolutionary step heralds a shift in the meaning of the term 'palliate'. Where palliative treatments were formerly advocated to 'cloak' or 'hide' symptoms, newer palliative approaches actually address the etiology of the symptoms and/or modify the disease, not promising cure but the prospect of reduced symptom burden or longer life expectancy.

AFTER 1970

The success of the growing investment in medical research in the first half of the twentieth century produced unprecedented scientific discoveries and a change in the pattern of illness in the second. In the beginning of the twentieth century, Americans usually died of infectious diseases or trauma. This may explain why there was so little attention to it by physicians – it happened quickly. By the second half of the century, Americans were living longer and dying primarily of atherosclerotic diseases (myocardial infarctions, stroke, congestive heart failure) and cancer. Instead of death occurring quickly (in days) there was a new period of 'dying' that occurred over weeks to years. The paradigm of the scientific method was developed to counter the causes of death of the early part of the century, such as pneumococcal pneumonia. From this point of view, the

change in patterns of death without a change in the scientific method leads directly to the physician to perceive death as a medical failure. Suffering, with its physical, psychologic, social, and spiritual components, was the result of the failure of the scientific method. Like most jests, the following statement, appearing in 1975, reflected an uncomfortable element of truth:[20]

> If only patients could leave their damaged physical vessels at the hospital for repair, while taking their social and emotional selves home.

By the end of the 1960s, a lively discussion about American attitudes and practices related to death can be discerned.[13] [(p. 6)] For example, empirical research had demonstrated that patients with terminal illness did want to talk about death when they were given the opportunity to do so.[21] The publication of *On Death and Dying* by Dr Elizabeth Kübler-Ross in 1969 capped this period with a fortuitous combination of media exposure and timely substance.[22] A remarkable feature of her work was that she interviewed real patients facing death in teaching sessions with other students in a manner similar to that used in teaching other medical subjects. More important, probably, was that Dr Kübler-Ross was a highly effective speaker and was soon making personal appearances throughout the USA.

Another charismatic physician speaker in the USA at this period was Dr Cicely Saunders. She founded St Christopher's Hospice in a southern suburb of London, England, in 1967 as the culmination of nearly 20 years of direct observation of the care of terminally ill people. She had been publishing and speaking about her ideas about modern hospice care since the late 1950s. The work of Dr Cicely Saunders and her colleagues at St Christopher's Hospice in London reached the ears of many Americans like so many seeds on fertile ground – ground that was in part prepared by Dr Kübler-Ross. A particularly significant aspect of Kübler-Ross's presentations was the response of nurses,[13] [(p. 7)] whom many credit, along with social workers and occasional lay persons, as the true force behind the modern hospice movement in the USA. The dialog opened by Kübler-Ross helped to give recognition to what they had experienced, and helped coalesce some of the anger they felt at how 'modern' health care approached the care of the dying.

For a short but eventful period of time, death became the media's darling. This exaggerated attention was manifest in newspapers, magazines, television, and public presentations. Two early programs were established during this time. In 1974, Florence Wald, then Dean of the School of Nursing at Yale University in New Haven, Connecticut, led the founding of the Connecticut Hospice with advice from Dr Saunders[23] and two others. Dr William Lamers, a psychiatrist who pioneered much of the early interactions between hospices and medical schools as medical director of one of the country's first hospice programs, Hospice of Marin,

wrote, 'When we gathered in New Haven to talk about hospice care, Dr Bal Mount of Montreal and I were the only two doctors there,' crediting Dr Mount, a urologic surgeon from the Royal Victoria Hospital in Montreal, as 'the true hospice pioneer on this continent' (T Ryndes, personal communication, 2004). Dr Sylvia Lack, a young physician who had just completed training in hospice medicine at St Christopher's was soon recruited to be the medical professional. Connecticut Hospice played a seminal role in the development of hospice care in the USA. In contrast, in New York City, a consulting team began working throughout St Luke's Hospital in 1974, the same year that Connecticut Hospice was founded. In contrast with Connecticut Hospice, this nurse-led team provided support only in the hospital for dying patients in a scattered-bed model.[24]

A grass-roots 'hospice movement' started in the USA at this time, resulting in the founding of a large number of hospice programs. In contrast with the 'flagship' program in New Haven, local circumstances varied greatly. Hospice advocates had to develop positive collaborations as 'outsiders' to the established healthcare system rather than as a part of the system itself. Advocates were united by a vision of care that was defined by a departure from the types of situation that had been increasingly criticized – the patient either subjected to invasive but useless medical care or virtually abandoned. Physicians who played notable local and national activist roles included Tom Licht (Wisconsin), Dan Hadlock (Florida), Bob Brown (Minnesota), and pediatric hematologist/oncologist Doris Howell (Philadelphia and San Diego). Despite the roles that some physicians played, the hospice movement was perceived by the dominant medical system as anti-medical, and countercultural. Those working in hospices at the time do not disown these perspectives, but remember it as a time that was more anti-pain and anti-suffering than anti-medical.

In response to the enthusiasm but lack of consensus on common principles for hospice care in the USA, the Connecticut Hospice in New Haven sponsored a meeting for American and Canadian hospice advocates. From this meeting eventually emerged the National Hospice Organization (NHO). They developed a set of proposed standards and criteria which have been revised at least four times and expanded considerably since they were first developed.[25]

THE NATIONAL HOSPICE STUDY

The National Hospice Demonstration Project was a research study funded by the US federal government to study hospice care in the USA.[13] [(p. 6)] The study aimed to select hospices from each of three models that had emerged in the USA:

- Hospital hospice programs. The majority only had a dedicated inpatient unit without a significant home care component

- Home health agency hospice programs without a dedicated hospice inpatient unit
- Independent hospice programs exclusively serving terminally ill patients, with or without a special inpatient unit, staffed primarily by volunteers (professional and lay).

The Health Care Financing Administration chose 26 existing hospice programs as demonstration projects out of 233 applicants in late 1979 and provided them with funding for their work. The chosen hospice programs were located in 16 states. A comparison sample of 14 hospice programs were chosen from among the three types as controls who did not receive federal demonstration project funding. The chosen hospices were not randomly selected. During the course of the National Hospice Study, 13 374 patients were admitted to participating demonstration and nondemonstration hospice programs between 1980 and 1982. Broadly, the study showed that patients who chose hospice care did not suffer any deprivation of care, often (although not always) required a lower level of expenditure, and had usually been able to spend more time at home.

THE MEDICARE HOSPICE BENEFIT

Interestingly, the US Congress enacted legislation in 1982 authorizing a hospice care benefit to all beneficiaries of the federal healthcare plan designed to cover the hospital needs of people over the age of 65 and those with disabilities. They did this while the National Hospice Study was still in progress. However, the findings were consulted in the subsequent development of the regulations that implemented the congressional action.

The standards and criteria that had been developed by the National Hospice Organization received enough dissemination and favorable reaction in the US Congress that they became part of the Medicare Hospice Benefit. This broad benefit led to rapid growth of hospice care in the USA. This federal funding led to the establishment of a hospice industry in the USA – a group of organizations that receive 80 percent of their funding under the terms of this federal legislation.

Briefly, in order for hospice care to be covered under the Medicare Hospice Benefit, two broad criteria must be met. First, the patient must have a prognosis of less than 6 months (later changed to less than 6 months if the disease follows its usual course) as determined by two physicians. Second, the care of the terminal illness must be palliative. Once a patient is eligible and elects hospice care, the hospice agency receives a fixed amount of money per patient per day for care. In the USA, this was the first federal example of a managed care plan where the hospice agency carried the 'risk' for caring for the population of patients rather than being reimbursed on a cost basis as was the standard for Medicare coverage.

Hospice programs had to have a medical director, but, under Medicare guidelines, the role explicitly did not include direct patient care. The model was that the patient's primary care physician would continue to serve as the patient's physician with the support of the hospice team.

THE PATH TO A SUBSPECIALTY IN PALLIATIVE MEDICINE

As in other areas of medicine, formal recognition by organized medicine enhances professionalism by creating practice standards and well-defined competencies within a specified domain of knowledge and/or practice. In palliative medicine, these competencies center on relief of suffering, promotion of quality of life for patients and families in the context of life-threatening illness, and promotion of the development and growth possible at the end of life. Subspecialists are needed to provide advanced care for patients and families whose needs exceed the capabilities of generalist or other specialist physicians. Subspecialists also have larger responsibilities to the field. They provide training and education, spearhead quality improvement initiatives and undertake the research that will ultimately yield the evidence on which general medical practice should be based. Formal recognition of the unique competencies of physicians practicing palliative medicine by the larger 'house' of medicine lays the foundation for sustained, long-term excellence by establishing credibility and facilitating the recruitment of the 'best and brightest' into the field. The path to formal recognition of the physician component of palliative care began to develop after hospice care grew rapidly with US federal funding.

Dr Kathleen Foley was an early pioneer.[26] A neurologist at Memorial Sloan-Kettering Cancer Hospital in New York, she both researched and advocated for better pain management as part of cancer care. Many of the physicians who trained with her as fellows in pain management have gone on to leadership roles in palliative medicine. For example, in 1987, Dr T Declan Walsh was recruited to the Cleveland Clinic to establish a palliative medicine program as part of the oncology division at the clinic. His program was unique in the USA in that it was a physician-led program that was hospital and healthcare system based.[27] Dr Walsh had received his training at St Christopher's Hospice in London as well as Memorial-Sloan Kettering in New York City. The program initially provided hospital consultation and an outpatient clinic.

Dr Josefina Magno, founder and medical director of Hospice of Southeast Michigan, formed the International Hospice Institute in 1978 as a forum for education and dissemination of research findings.[28] It was also to be a forum for mutual support. In 1988, she instituted the Academy of Hospice Physicians comprising 125 physicians who gathered in Estes Park Colorado at one of the meetings. The group subsequently became independent and changed its

name to the American Academy of Hospice and Palliative Medicine. It has become the professional association for physicians practicing palliative medicine in the USA.

In 1993, Dr David Weissman established a consultation service at the Medical College of Wisconsin in Milwaukee.[29] He subsequently described the elements of palliative medicine consultation.[30] That same year, Dr Charles von Gunten established a consultation service at Northwestern Memorial Hospital in Chicago that was organizationally linked with a 10-bed acute palliative care unit and a hospice program. Their models led to rapid dissemination to other hospitals in the USA.[31]

Progress toward a recognized specialty took an important step forward in 1997 when the Institute of Medicine (IOM), an independent and influential body that advises the US Congress, highlighted deficiencies in the healthcare system's approach to end-of-life care and called for the development of professional expertise in palliative medicine in the USA to make this knowledge widely available in US healthcare.[32] The IOM report recognized the benefits formal recognition of palliative medicine would confer, stating that a formal specialty would:

- 'focus attention more powerfully on an existing knowledge base that is both insufficiently understood and inadequately applied and that is in need of further growth
- recognize more explicitly and publicly that palliative care is an appropriate goal of medicine
- conform to the value and recognition structure of medical professionals – providing credibility with peers (and perhaps patients and others) as a source of knowledge, guidance, and referral
- attract leaders to the field, and
- nurture the development of the field and its knowledge base.'

Palliative medicine needs to be integrated throughout the care system.[33] Primary palliative medicine is the responsibility of all physicians. This includes basic approaches to the relief of suffering and improving quality of life for the whole person and his or her family. Secondary palliative medicine is the responsibility of specialists and hospital or community based palliative care or hospice programs. The role of the secondary specialist or program is to provide consultation and assist the managing service. Tertiary palliative medicine is the province of academic centers where new knowledge is created through research, and new knowledge is disseminated through education. In addition, tertiary palliative medicine centers are likely to care for the most challenging cases.

The need for palliative care at the end of life has been reinforced in concurring opinions from the US Supreme Court that refused to recognize a constitutional right to assisted suicide.[34] The American College of Physicians and the American Board of Internal Medicine have both called for general physician competency in the care of persons with terminal illness.[35,36] Efforts are also underway to improve the skills of practitioners and to introduce palliative medicine training into physician education.[37–41]

Significant philanthropic funding spurred the development of palliative medicine. The Robert Wood Johnson Foundation, under the project direction of Rosemary Gibson and Victoria Weisfeld, invested US$95 million between 1997 and 2004 in projects aimed at improving end-of-life care. The project that most influenced the physician component was the Education for Physicians on End-of-life Care (EPEC) Project led by Drs Linda Emanuel, Frank D Ferris, and Charles F von Gunten. Initially developed in conjunction with the American Medical Association (AMA), the project convened leaders in the field to assemble a core curriculum in palliative medicine and disseminate it through a train-the-trainer dissemination model. The project was successful in reaching its educational targets,[42] but there were several unanticipated effects of the project. First, the AMA's imprimatur lent legitimacy to a cadre of EPEC trainers who felt encouraged to volunteer to teach the material at educational programs in their home institutions and advocate for curriculum change in their medical schools and residency programs. Second, in a survey of palliative medicine physicians, the majority said that the EPEC Project was their entry into the field.[43]

The Robert Wood Johnson Foundation also sponsored the Center to Advance Palliative Care (CAPC), initially led by Drs Christine Cassel and Diane Meier. The focus of this national center was to advance palliative care in hospitals and health systems. Dr Cassel had played an instrumental role in the recognition of geriatrics as a subspecialty 20 years earlier and held leadership positions in organized medicine in the USA.

Another major philanthropic spur was the Project on Death in America (PDIA). The Open Society Institute (funded by George Soros) invested US$45 million between 1994 and 2003 in a variety of projects to 'change the culture of dying' in the USA. One of those projects, the PDIA Faculty Scholars Program led by Dr Susan D Block, aimed to develop academic leaders in palliative medicine in the nation's medical schools. By the conclusion of the US$15 million project, the 89 PDIA faculty scholars had in turn been successful in attracting US$115 million in grants and awards from federal and other finding sources. Many PDIA scholars are now in leadership positions in the nation's medical schools, residency programs, and the committees that are shaping the specialty.

The combination of EPEC (a program of physician education), CAPC (a program to advance the practice of palliative medicine in hospitals and health systems), and the PDIA scholars (a program to develop academic physician leaders) can be viewed as a strategy to stimulate an evolution in American healthcare more rapidly than it would otherwise take. The strategy appears to be working. In 2004, the American Board of Internal Medicine convened a summit of all member boards of the American Board of Medical Specialties to consider an application to formally recognize palliative medicine. Formal recognition is seen as likely.

This strategy has not occurred without strain. The development of palliative medicine could be seen as a bid for physician domination of a field that values interdisciplinary team care using a bio-psycho-socio-spiritual model. Some also worry that widespread dissemination of palliative medicine throughout the healthcare system will lead to a dilution or co-option of some essential essence of good palliative care. For instance, skeptics fear that hospital-based palliative care services will be less likely to help patients return to their own homes and will be more likely to overuse diagnostic tests and procedures. In addition, palliative care as part of the US$200 billion dollar healthcare industry might swamp the US$9 billion hospice industry in terms of power and influence. Finally, some predict that the emergence of a cadre of academic palliative medicine specialists will engender a town–gown rift between community-based clinicians (primarily hospice medical directors – often part time and often volunteer or virtually volunteer) and fellowship-trained specialists practicing within the academic medical center.

These concerns are neither unique to palliative medicine nor inevitable. Subspecialization *per se* neither increases nor decreases the likelihood of these outcomes occurring. The root causes for these potential problems must be sought and prevented or redressed. They do not mitigate the driving rationale for professionalization of a field of new knowledge and practice of importance to the health of the public. In addition, the formal recognition of palliative medicine may lead to a broader change within the culture of medicine where 'whole person care' and the relief of suffering are combined with efforts to cure disease.

Key learning points

- In the USA, the history of palliative care prior to the 1970s mirrors that of England with a few homes for the dying operated from religious commitment.

- Dr Elizabeth Kübler-Ross, a psychiatrist, popularized the experience of dying patients through public appearances describing the results of her communication research beginning in the late 1960s.

- Dr Cicely Saunders, founder of St Christopher's Hospice in London, England, was a charismatic speaker and sparked interest among healthcare professionals in the early 1970s in the USA.

- A large number of hospice programs were formed in the second half of the 1970s in the USA, both hospital and community based.

- The US government funded a hospice demonstration project from 1980 to 1982.

- The US government instituted a funding benefit for Medicare patients (mostly over age 65) with terminal illnesses who were cared for mostly at home by family in 1982. This funding stream led to a large increase in the number of hospice programs, particularly community based.

- The path to a recognized physician specialty began in the late 1970s with the formation of a specialty association of hospice physicians.

The development of palliative medicine in Latin America

ROBERTO WENK

INTRODUCTION

The purpose of this chapter is to describe the development of palliative care in Latin America, accepting that the information could be incomplete because there are scarce updated regional data. The issues in Latin America that will be described here may be similar to those present in other developing countries.

THE REGION

The Latin American region has a total population of 510 million and is made up of 35 countries. Although the region is challenged by common economic, political, and cultural factors, there are differences between the countries and states or cities of the same country: size, natural resources, per capita income, resources allocated to health, development, technical expertise, how the people live, health system, stage of epidemiological transition, etc.[1,2]

The challenging difficulties that are common to all the countries despite the above mentioned heterogeneity underpin the serious deficiencies in the way that most of the health systems care for dying people. Many Latin American patients with advanced incurable diseases suffer in the final stages of their lives and die badly.[3,4]

HISTORICAL OVERVIEW

During 1981–85 several physicians in various Latin American countries started treating pain and other symptoms in patients with advanced cancer. Most of them were anesthesiologists concerned about how to improve the care of these patients. This interest generated a bidirectional flow of professionals – from Latin America to Canada, Italy, UK, and USA to find appropriate models of care, and from other countries to Latin America to teach the World Health Organization (WHO) model for pain and symptom control.[5,6] From different WHO collaborative centers, E Bruera, M Baynes, C Cleeland, K Foley, N Koyle, J Stjernsward, R Twycross, and V Ventafridda came to Latin America to teach.

A new perspective about the care of patients with advanced cancer began to grow in the region. As a result of this activity different professionals started to provide palliative care in different countries while promoting and teaching its concepts. They were from different disciplines, mostly volunteers, working at first independently and alone but then in teams based in their community or in their own hospitals. Their successes were the result of personal motivation and the time and resources dedicated to the development of assistance programs adapted to the needs and limitations of each country. They had different resources and opportunities, they varied in their capabilities to care for the dying patients and their families, and their funds came from multiple sources: charity, grants, research protocols, teaching, international subsidies, etc.[7,8]

This development 'on the ground' generated focal activity and initially operated at the level of motivated healthcare professionals who directly provided patient care. It was a time and energy consuming model, but an effective one. The impact of these individual initiatives stimulated action by the health authorities and generated growing interest in the community and among health personnel, which in turn

resulted in the expansion of palliative care to programs of greater complexity.[9]

The programs and their activities highlighted two issues: the need for a practical and effective way to improve the quality of care at the end of life, and the deficiencies in the assistance provided to dying patients and their families. They demonstrated inadequacies in practice and identified different barriers to palliative care.

The key to success for these changes lay with the program leaders: their efforts, which were followed shortly by other people, had two primary goals:

- to recruit individuals from the community to work in palliative care with limited resources
- to recruit individuals from diverse organizations (governmental, professional, academic, etc.) to build partnerships with diverse resources and skills.

Their efforts had a profoundly positive impact: while seeding palliative care teams, they let the public learn about the benefit of adequate end-of-life care and provided health authorities with information about needs and possible interventions. In some cases the ongoing persuasive recruiting activity resulted in the development of national or regional palliative care associations, and in other cases it resulted in national official palliative care programs.

CURRENT STATUS

Despite the progress made in the past 20 years, there is evidence that in general the quality of life during the dying process is poor, with fragmented assistance resulting in uncontrolled suffering, poor communication between professionals, patients and families, and a great burden on family caregivers.[7] Most of the regional health systems fail to provide appropriate care for dying patients; the failures are clinical, educational, organizational, and ethical.

As a rule, adequate care of the dying is determined by the characteristics and interrelations of the health system, the health professionals and the patient–family unit. Each of them has unique characteristics that, after superimposing and/or mixing, define the guidelines for care.[10] To evaluate the current status of palliative care and the factors that modulate its development in Latin America, it is necessary to describe the different interrelated issues that affect the need and the delivery of palliative care.

Health systems

In spite of the experiences of regional programs with demonstrable positive results, and the availability of international guidelines, with the exception of a few countries care of the dying is not a public health priority and given low importance compared with preventive and curative services.[11]

Many Latin American countries offer some kind of palliative care services, but they are often minimal and access to these is limited. Fragmentation is the key characteristic of the available care: different disciplines interact in a non-organized way, sometimes cooperating but sometimes competing. The three structural factors discussed below can help us to understand the situation.

INSUFFICIENT SUPPORT OF THE HEALTH AUTHORITIES

There are reported national programs in only Chile, Colombia, Costa Rica, Cuba, the Dominican Republic, and Mexico (Latin America is made up of 35 countries).[12] Only three of these (Chile, Costa Rica, and Cuba) provide palliative care throughout the country; in the others the effective activity has not yet started. The difference between active and inactive programs may be that in the former the programs derive from official 'top down'[13] well-established plans based on assessments of the needs with a commitment to make changes. In Chile's program it is known how many teams, what kinds of professional, and how much medication, etc. are needed to have an integrated net of services for caring for patients in different settings across the country.[14] In the rest of the countries the programs are developing as described in the historical overview above.

Data from a survey of 566 professionals from Argentina, Brazil, Cuba, Mexico, and Peru[12] indicated that 70 percent of them considered that palliative care is not a priority in the health policies of their country. Data provided by 17 palliative care leaders of different Latin America countries (Ongoing surveys, personal communication, 2004) indicates that in 80 percent of the countries palliative care is not yet recognized as a discipline, and it is not included by mandate in either the free public health system or the private health system.

FINANCIAL CHALLENGES

Governments fail to allocate resources where they would be most beneficial. They are struggling with underfunding to solve different problems like lack of infrastructure and assistance centers, control of infectious diseases, prenatal assistance, undernourishment, etc. Yet their payment mechanisms reward life-prolonging interventions, even when futile.[15] The health systems have not yet matched and aligned financial incentives with better standards of care, namely palliative care. This situation is reinforced by the lack of capability to quantify the costs of palliative care, so that these costs cannot be compared with other health costs and potential cost savings cannot be documented.

BARRIERS TO OPIOID AVAILABILITY AND ACCESSIBILITY

Some countries have changed their policies with increase in the use of opioids, but in most countries this is below the

global mean of 6.5 mg per capita.[16] Reasons for the well-documented underutilization are: the high cost of opioids and restrictive regulations for their use. There is good availability of different opioids, but the high price of most of them compared with the mean monthly income in the region acts as a barrier to their access and utilization.[17,18] In addition, there are outdated and nonscientific prescribing regulations that restrict the use of potent analgesics: 50 percent of the 566 professionals surveyed[12] (see above) considered them as barriers to utilization, and the Pan American Health Organization (PAHO) has identified definite barriers to opioid use in Colombia, Peru, Mexico, Argentina, and Costa Rica.[19,20]

The Latin America health authorities must intervene to make palliative care accessible to everyone through plans with a three-pronged approach:

- improving the economic, organizational, legal, and clinical environment
- educating professionals in end-of-life care
- educating the people about their right to demand high-quality assistance at the end of the life.

Willingness to modify policies can be perceived in some countries, but making the necessary changes is a slow process due to the inertial resistance in the systems and a lack of interest in individuals at different decision making levels.[9] Although these factors may be found throughout the world, their negative impact is greater in Latin America due to the poor socioeconomic health of the region.

Health professionals

Health professionals are focusing on the idea of a good death and are slowly becoming interested in the care of people at the end of life. This new perception of the dying process has not changed the situation in the region as yet: although there is limited information on the proportion of patients who receive palliative care, it can be estimated to be lower than 5 percent. The different factors discussed below can help us to understand the regional situation.

PROGRAMS AND TEAMS

In most Latin American countries the health authorities have not yet adopted palliative care with standards of assistance, and programs vary between cities and among themselves. The programs are more or less well developed with operational differences related to their degree of development; they are based either in the community or in hospitals, some involve one or more institutions within the same community and a few extend to the whole state. They operate in different settings and each program has unique experiences with regard to its creativity, persistence, and adaptability to changes in its environment. These programs provide treatment to the majority of cancer patients.

In general most palliative care programs provide partial care:[21] teams consisting of one or two disciplines with part-time commitment, with mixed or exclusive home or outpatient care, distance care[22] and institutional activity, but no specific facilities (mobile advisory teams without own beds). Full palliative care programs with dedicated interdisciplinary teams providing 24 × 7 care in the consulting room, at home, and in day care, and hospitalization (with own beds) is not the rule.

In large cities, where 97 percent of the palliative care is primarily available,[12] a few health systems provide complete palliative care. In small cities and rural areas, where only 3 percent of the palliative care is available, all patients receive partial palliative care.

MODELS OF CARE

The traditional medical model is prevalent in the region: for many of the dying, quality of life is secondary to excessive medical interventions that too often are futile and sometimes expensive. The patients suffer needlessly both from errors of omission (they do not receive palliative care) and from errors of commission (they receive futile treatments); it is common to see 'curative' treatments being administered that are not beneficial for the patients, nor always in accordance with their wishes. There are multiple reasons for this situation:

- Most of the decisions about offering and providing treatments are not based on cost–benefit ratio and do not consider the patient's quality of life.
- Physicians favor the principle of beneficence rather than the principle of autonomy and adopt a paternalistic behavior with little regard to patient's preferences.
- There is poor communication between physicians and patients and their families that in some cases blocks the disclosure of diagnostic and prognostic information: physicians and/or families are likely to believe that the bad news should be withheld from patients and thus impede their ability to be decision makers in their own care. In other cases, in the absence of complete information about treatment options patients or their families demand useless or counterproductive treatments or cannot refuse what they see to be futile and/or painful treatments.
- Lack of education and awareness of ethical issues and the fragmentation of care complicate the necessary coordination and continuity of care needed to make ethical clinical decisions toward care that is adapted to the individual patient's and his or her family's needs and wishes.

EDUCATION

Undergraduate and graduate education does not adequately prepare health professionals to recognize the final stages of

illnesses or to provide effective interventions. Their education and training fail to provide them with the attitudes, knowledge, and skills required to provide good care for the dying patient. Teaching for graduate health professionals is different, sometimes inadequate. Instruction with specifically structured content and curricula with clinical practice are limited; learning from tutors along with structured assessments is undervalued. As palliative care is still not recognized as a specialty, there are no residency requirements and licensure examinations.

Of the 566 professionals surveyed (see above) 70 percent considered that palliative care is not a priority in health education and that professionals do not have enough knowledge about symptom evaluation and control;[12] 90 percent of the 17 surveyed practitioners indicated that palliative care is not included in undergraduate education and only 15 percent knew about the possibility of graduate clinical training under tutor guidance; they also reported that possibilities for training are, in decreasing order: courses with lectures, self-capacitating and distance learning (Ongoing surveys, personal communication, 2004).

Many of the deficiencies in the practice of palliative care are based in these failures in education:

- professionals without adequate training provide inadequate services
- different professionals with different training performing the same task (i.e. nurse auxiliaries vs. professional nurses; psychologists vs. counselors) without a uniform standard of care
- inadequate communication skills (making it difficult to discuss end-of-life issues)
- training not including experience in interactive multiprofessional work (making teamworking difficult).

This situation is worsened by the lack of standards in each discipline for self-evaluating the quality of the work and by the difficulty in acknowledging the incapabilities.

The healthcare community is slowly accepting the responsibility for educating itself about end-of-life care issues. Some programs offer teaching opportunities with definite objectives and methods that target practice, improved teamwork, and problem solving, i.e. courses with a significant content of clinical practice and fellowships in clinical units to use and reinforce teamwork and reasoning skills.

LACK OF REWARDS AND INCENTIVES

In many countries palliative care is still not recognized as a medical discipline and palliative care teams and programs are difficult to finance because most of the health systems do not pay, or underpay, for their services. This makes sustainability an issue that has been solved (in most countries) with different approaches: resources from charity, working for free on a volunteer basis, and care paid by the patient (when

it is possible) or by the health coverage (some accept palliative care and pay for it). Most teams, if not all, can deliver assistance because of their high volunteer/paid personnel ratio. This situation can be longstanding and stable with regard to team interventions delivered by nonprofessional volunteers, but the professional volunteer's services are time limited. Professional volunteers usually join a palliative care team because they are both interested in this new discipline and wish to learn its practice. During the time of volunteer work their earnings come from their disciplines, but after some years most of them wish to shift to palliative care as their main discipline. If the team cannot pay for their work, as it usually happens, they withdraw from the team activity. The result is teams with cyclic staffing and effectiveness and trained professionals who do not have adequate job opportunities in this underrecognized and unpaid discipline.

Payment mechanisms for the care of dying patients impede the efficient and effective use of the limited health resources to improve quality of life. The pattern and quality of care is negatively influenced by the unbalanced reimbursement and provider time ratio: financing mechanisms encourage the overuse of procedural services and the underprovision of time consuming services such as palliative care. It is easier and more profitable for a physician to hospitalize a patient or start an aggressive and often ineffectual treatment that may prolong dying process, than to invest time creating consensus about therapeutic alternatives or discussing the dying process.

Health authorities must revise financing and payment mechanisms to encourage good end-of-life care and stop undertreatment or overtreatment of those approaching death.

Patients and families

The care of patients with advanced cancer and their families also depends on both where they live and their resources (effective health coverage and/or money). There are only three Latin American countries (Chile, Cuba, and Costa Rica) with palliative care programs that have reported provision of effective care throughout the country to most of the population (e.g. Chile reports that there are 41 palliative care teams in the whole of the country).[23] What is happening in most of the other countries? There are four different scenarios:

1 *Patients living in a large city with resources.* These patients have the possibility of accessing top interdisciplinary healthcare adapted to the individual patient's needs: at the office, at home, or during stay in hospital. (Resources and living in a large city do not guarantee effective palliative care.)
2 *Patients living in a large city without resources.* These patients have the limited possibility of receiving care in public hospitals. (Not all hospitals have palliative care

teams nor can all the teams provide all the treatment options.)

3 *Patients living in a small city or in a rural area with resources.* If moving to a large city these patients have the same possibilities as the patients in scenario 1.

4 *Patients living in a small city or in a rural area without resources.* These patients have the possibility of receiving some kind of care, characterized by poor control of symptoms.

The difficult, negative health situation of scenarios 2 and 4 is due to and amplified by poverty generated by Latin America's socioeconomic crisis: 200 million people (36 percent) live below the poverty level.[1] Medical, nursing, and social services are not available to them. Assistance and palliative care are often inaccessible and unaffordable, resulting in considerable suffering due to both lack of basic essentials for care and access to symptom control medication. Many people live in absolute poverty with unmet physical needs: without suitable food, drinking water, electricity, indoor toilets, etc., and for some needs are better met in hospital than at home. They spend their last days (sometimes weeks and months) in healthcare institutions under the care of professionals without instruction in palliative care.

Some of the deficiencies in the healthcare systems are solved by the informal care systems that play a central role for many if not most patients and families. Extended families (people with a legal, social, or biological relationship with the patient) collaborate in the care of the patient at home but they become burdened by the difficulty of caring, their lack of knowledge, the lack of drugs in the home, and their fear of not knowing what to do when the patient deteriorates.[24] In the community, voluntary groups and religious communities develop networks to help in the care of patients at home or in hospital by visiting regularly and providing food, medicines, or money. As in other developing regions of the world finding the money for outpatient consultations, medicines, transportation, and paying the funeral is a top ranked task.[25,26]

Notwithstanding even the huge efforts of different groups and institutions, the health situation of patients and families at the end of life is poor. They must be able to expect and receive efficient and skillful care. Educating them about palliative care, a shared responsibility of health professionals and the media, will encourage them to report suffering and to demand palliative care. Increased consumer demand is a powerful factor with the potential for reducing barriers through 'sensitizing' health providers and policy makers.[27]

LOOKING FORWARD

In Latin America, palliative care is impossible to stop because there is growing evidence that it is useful. Every year, in every country, many palliative care teams are formed.

Palliative care health professionals now acknowledge the two basic needs: adequate regional palliative care and changes in the systems of care and individual actions. The new perception of the poor health situation of the dying facilitated the consensus and the urgency to act to satisfy their needs: professionals from different countries funded the Latin American Palliative Care Association (Asociación Latino Americana de Cuidado Paliativo, ALCP) on April 23, 2001, in Buenos Aires, Argentina. The mission of this not-for-profit organization is

> to promote the development of palliative care in Latin America and the Caribbean by communication and integration of all those interested in helping improve the quality of life of patients with incurable progressive diseases as well as their families.

The ALCP has not yet found the way to obtain enough funds to be completely functional, but it has managed to launch three different tools:

- *Latin American congresses.* There is a demonstrable positive tendency to share experiences and results of assistance in regional meetings. The first congress in San Nicolas, Argentina, in 1990, brought together 35 people from seven countries. The last congress, held in Montevideo, Uruguay, in 2004, was attended by 284 people from diverse disciplines and 18 countries.
- *Circular of the ALCP (newsletter).* This is a free electronic monthly or bimonthly publication in Spanish and Portuguese. At present there are 1450 subscribers in 14 countries.
- *Website* (www.cuidadospaliativos.org). This is intended to disseminate information and collaborate in the development of support networks.

One of roles of the ALCP is to help in the identification of real or potential barriers to palliative care in the region and in individual countries. Some of them have been identified and others are suspected; after they are documented and understood different actions can be taken to reduce their impact. There is a need for information to aid in understanding the different professional, organizational, and cultural issues involved to guide the development of palliative care. The ALCP is the tool that will allow palliative care to develop in accordance with regional needs.

Key learning points

- Countries in the Latin American region face several common challenges that underpin the serious deficiencies in the way that most of the health systems care for dying people.

- In the 1980s a growing awareness of the need for treating pain and other symptoms in patients with advanced cancer resulted in visits from several international leaders

in the field to Latin America to teach the WHO model for pain and symptom control.

- The first practitioners of palliative care in Latin America were from different disciplines, mostly volunteers, working at first independently and alone but then in teams based in their community or in their own hospitals.

- Despite the progress made in the past 20 years, there is evidence that in general the quality of life during the dying process is poor, with fragmented assistance resulting in uncontrolled suffering, poor communication between professionals, patients and families, and a great burden on family caregivers.

- Many Latin American countries offer some kind of palliative care services, but they are often minimal and access is limited. Only three (Chile, Costa Rica, and Cuba) provide palliative care throughout the country.

- Health systems face insufficient support of the health authorities, financial challenges, and barriers to opioid availability and accessibility.

- Health professionals and patients and their families face the challenges of lack of education, awareness, robust models of care, and standard programs, and payment mechanisms that impede the delivery of efficient and effective care.

- Despite the challenges palliative care continues to grow in Latin America and the ALCP will play a significant role in its future development.

The development of palliative medicine in Africa

ANNE MERRIMAN

INTRODUCTION

In June 2004, the African Palliative Care Association (APCA) was launched officially in Arusha, Tanzania, during its first annual general meeting and conference.[1] Twenty-two African countries attended. This was amazing progress since 1994, when only four countries (Zimbabwe, South Africa, Kenya, and Uganda) had established palliative care in sub-Saharan Africa. Also in 2004, Zimbabwe celebrated 25 years of palliative care. It was the first country in Africa to commence palliative care in the 1970s, according to the concepts developed through the modern hospice movement (Table 5.1).

This chapter explores the slow start, and then the mushrooming of interest over 10 years in palliative care. Its findings must be seen in conjunction with the economic and social history of the African countries during this time. Of the 46 countries in Africa, by 2005, 26 have shown interest in palliative care including those with established care (five

countries) and those with early initiations without morphine and essential drugs or training in place (10 countries).

The importance of an accurate definition of palliative care in the African context

The African definition of palliative care, as in other contexts, is:

- The active total care of patients whose disease is not responsive to curative treatment.
- Control of pain and of other symptoms and of psychologic, social and spiritual problems is paramount.
- The goal is achievement of the best possible quality of life for patients and their families.

Palliative care combines supportive care (present in support home care teams before the advent of palliative care) and pain and symptom control using the methods researched since 1967. But the following are *not* palliative care:

- Supportive care *without* pain and symptom control using the researched methods. This is only **support care**.
- Pain and symptom control without supportive and holistic care: this is anesthesiology.

Table 5.1 *Development of palliative care in Africa*

Year	Palliative care commenced
1979	Zimbabwe
1982	South Africa
1989	Kenya
1993	Uganda
1994–99	Zambia, Botswana, Swaziland, Nigeria
2000–04	Tanzania, Malawi, Ghana, Sierra Leone, Lesotho

These distinctions are important in Africa today. With donors now funding palliative care, many organizations with supportive care or home care are claiming they offer palliative care. However, they do not have trained health professionals or the affordable medications that have made pain and symptom control possible at affordable prices. This approach is lowering standards. Donors and service providers as well as governments need to be aware of this problem.

Pain and symptom control are now being grafted onto supportive care programs in Africa. Supportive care has always been there in Africa, similar to the support Dame Cicely (Fig. 5.1) found in the UK while deciding to research pain and symptom control before St Christopher's was established (Dame Cicely Saunders, personal communication, June 2003). But in Africa pain control was absent. This is only possible when the knowledge of palliative methods of pain control are taught and practiced. Morphine, the main drug recommended by the World Health Organization (WHO) for severe pain control has not been available (or affordable) in a form that could be used in the home.

Figure 5.1 *Dame Cicely Saunders, founder of the modern hospice movement which introduced researched pain and symptom control as a basis for peace at the end of life.*

THE FIRST HOSPICES IN AFRICA: ESTABLISHED WITH THE NEEDS OF THE WHITE POPULATIONS IN MIND

Zimbabwe (Zimbabwe, Country Report, p 10, Eunice Garanganga, personal communication, September 2004)

In 1977, a young white girl, Frances, died in Zimbabwe, in severe pain from cancer. Her mother, Maureen Butterfield, hearing about St Christopher's Hospice in London, went there to see if she could prevent this suffering from continuing in Zimbabwe. This first move toward palliative care in Africa resulted in the opening of Island Hospice in Harare in 1979. Island Hospice was dedicated to home care and did not have an inpatient facility.

Initially created with the intention of meeting the needs of all Zimbabweans, it was mostly accepted and used by the white community with a large bereavement service and mainly older patients. The Island Hospice model gradually became more acceptable to the African community. In 1986 they took their first acquired immune deficiency syndrome (AIDS) patients in the program and have continued to do this. Island Hospice was modeled very much along the lines of the British hospice model but adapted to the needs of a mixed community. For example, in 1993, we found that Island Hospice had 9 nurses, 9 social workers, 9 cars, and no doctor for the home care service. About 75 percent of the patients were from the indigenous communities. The bereavement service had grown significantly, primarily due to traumatic deaths, and formed the major part of the social workers' work. Many staff at that time were white Zimbabweans. The attached doctor was advisory and attended case conferences only, seldom visiting a patient. The nurses were prescribing morphine with the support of their doctor (J Hunt, personal communication, September 2004). They were doing wonderful work, and had access to oral morphine allowing them to keep their patients comfortable. Training was in place. The hospice had expanded to other branches throughout Zimbabwe and was already networking with support teams to bring in palliative care.

Sadly, since the recent decline in the economy of Zimbabwe, the hospice is floundering for want of materials, which it cannot afford because of the decline in the value of the Zimbabwean dollar. Morphine is often not available. However those trained in palliative care are continuing to do all they can for their patients, are actively taking part in training both within Zimbabwe and other African countries and are active members of the APCA.

Most staff are now indigenous Zimbabweans, although filling and maintaining positions is becoming increasingly difficult. Many health professionals are lured away to organizations and other countries offering much better conditions than this hospice can afford. This is an example of

how economic and political circumstances in a country can affect a humanitarian service.

South Africa[2]

South Africa was the second country in Africa to introduce palliative care. South Africa was brought into the fold of sub-Saharan Africa only since the cessation of apartheid in 1995. However, apartheid has left its mark on the South Africa of today. There is still a wide divide between the Caucasian races and others, although this divide is narrowing. The holistic approach to palliative care in South Africa reveals some terrible problems related to poverty, poor housing, drug and alcohol abuse and sexual promiscuity. More recently, an escalating human immunodeficiency virus (HIV) epidemic has added to the woes. Many of the problems in South Africa are comparable to the problems found in the poorer areas of the developed world and their origins can be found in the social development of the country.

The inspiration for founding hospice and palliative care in South Africa came from Chris Dare (Brief history of the Hospice Palliative Care Association of South Africa, Kath Defillippi, personal communication, 2004), who was in the same choir as Dame Cicely Saunders in London (Dr Mary Baines, personal communication, 2005). She was greatly inspired by the work of Cicely Saunders and how it had changed the face of suffering among patients in London. A physiotherapist, she decided to follow Cicely Saunders' example and become a doctor with the aim of commencing palliative care in South Africa. In 1979, while still a medical student at University of Cape Town, she persuaded Professor J P van Niekerk, Dean of Studies at the University, to invite Dame Cicely to Capetown to speak about her work. This eventually led to the opening of the first inpatient hospice in South Africa, St Luke's Hospice, Capetown, on February 1, 1983. This extended to a community service in 1992, and the service has grown rapidly to meet the needs of the HIV/AIDS epidemic.

Meanwhile, the example of St Luke's was taken up in many areas of South Africa. By the year 2000 there were 40 hospices established, 5 regional hospice associations and a national association (Hospice Association of South Africa [HASA]) was commenced in 1987. This national organization has set up standards, advocacy, and education and has been a resource both within and beyond South Africa.

HOSPICES SET UP WITH THE INDIGENOUS AFRICAN POPULATION IN MIND

Sociocultural aspects of sub-Saharan Africa

Sub-Saharan Africa above South Africa, has, on the whole, kept a stronger African heritage. Cultural beliefs come into play when approaching death, which are often a mix of African religious beliefs and the beliefs of religions

(Christianity and Muslim mainly) new to the African scene (by 'new' meaning 100 years). This has meant that palliative care needs to be adjusted to each country and to the belief systems and felt needs of patients and families.

Nairobi Hospice

In 1988, the wife of a BBC correspondent, Ruth Wooldridge, watched helplessly as a Kenyan teacher returned home from hospital with a diagnosis of terminal cancer and proceeded to die with the family trying to care for her while she suffered terrible pain and symptoms without assistance. Ruth was a nurse and although not trained in palliative care, she knew that there was an answer to this problem; indeed she had witnessed hospice care in South Africa while with her husband in a previous posting.

Ruth started to find supporters for a foundation called Nairobi Hospice Charitable Trust (NHCT). In 1989, they had employed a senior nurse, Brigid Sirengo, who was working with Jane Moore, a volunteer nurse from UK. They were then working by candlelight in a small hut, while a prefabricated building was being set up adjacent to and on land belonging to Kenyatta Hospital (the government teaching hospital). They were already running a small service and had a Board in place, but did not have access to oral morphine. First through contacts overseas and later through the negotiations and advocacy to the Ministry of Health by Professor E Kasili, oncologist and Chairman of the Board of Nairobi Hospice, with the Ministry of Health, oral morphine was obtained, and I took up post as their first medical director in 1990. A training program was also established.[3] At Nairobi Hospice I was overwhelmed with the severe suffering we were seeing among patients dying in the community, with or without previous hospital consultation. Indeed the suffering of the African, with scant curable treatment, is the worst in the world both for cancer and for AIDS.

Nairobi Hospice has continued to carry out pioneer work in service and in training throughout Kenya. It provides patients with cancer a home care service and consultation in Kenyatta Hospital and other hospitals. In the last 2 years they have expanded their care to HIV/AIDS patients. New hospices came up slowly, with the first a branch of Nairobi Hospice commencing in 1993 (Nyeri Hospice). Most of the new services have started due to individual efforts. Today, there are small services in different parts of the country, some as part of an outreach program from hospitals and others as home care programs.

Hospice Africa Uganda

Uganda was the fourth country in Africa to embrace palliative care. There was a felt need for an African hospice that would have the hospice spirit of hospitality without bureaucracy and that would combine culturally acceptable practices and act as a model for other and poorer African countries.[4] After a feasibility study in three of the seven countries requesting hospice care, Uganda was chosen

because of its track record of integrity in handling aid, the severity of the AIDS epidemic, and the willingness of the Ministry of Health to import morphine powder and support the service.

Fazal Mbaraka and I were the initial pioneers of this work. Fazal, a Kenyan of Pakistani origin was a nurse trained in palliative care at Nairobi Hospice. Sadly during the pioneer period, Fazal's father was murdered in Eldoret, Kenya. This resulted in Fazal having to return to Kenya in early 1994 to support her family. By that time we already had a training program in Makerere University medical school and had identified our first Ugandan pioneer nurse, Rose Kiwanuka. Hospice Africa Uganda commenced with three objectives:

1 To provide a palliative care service to patients and families, within a 20 km radius of the hospice and to promote this care throughout Uganda.
2 To provide education programs in palliative medicine, for health professionals at undergraduate and postgraduate levels throughout Uganda so that this form of care can be available to all in need.
3 To encourage the initiation/consolidation of palliative care in other African countries, by providing a facility at Hospice Uganda for training, and experience of palliative care working in the African context.

For the first 5 years, the priority was to simultaneously set up the service and the teaching. Teaching in the medical schools in Makerere University and later Mbarara University, was gradually producing doctors and nurses who understood the concepts of palliative care and could teach others. However, support from the Ministry of Health (MoH) was often difficult to maintain. Some senior physicians, due to earlier teaching, were unaware of the modern research on pain and symptom control and the recognition of palliative medicine as a specialty by the Royal College of Physicians (UK) in 1987.

In 1998, following a conference for senior MoH officials and those managing cancer and AIDS, initiated by the Hospice, the MoH agreed to form a committee to review the role of palliative care for Uganda. As a result of this, in 2000, Uganda became the first country in Africa to include palliative care as an essential service for all in Uganda as part of the 5-year Strategic Health Plan. This essential service came under AIDS, not cancer. Cancer in this country, where life expectancy was only 39 years, (now increased to 45), was not one of the top 10 causes of death; HIV/AIDS was the cause behind most deaths.

By 2000 the three priorities for a palliative care service in an African country were present in Uganda: drug availability, education and government support (Fig. 5.2).[5–8]

Generating government support to other African countries: 2000–2004

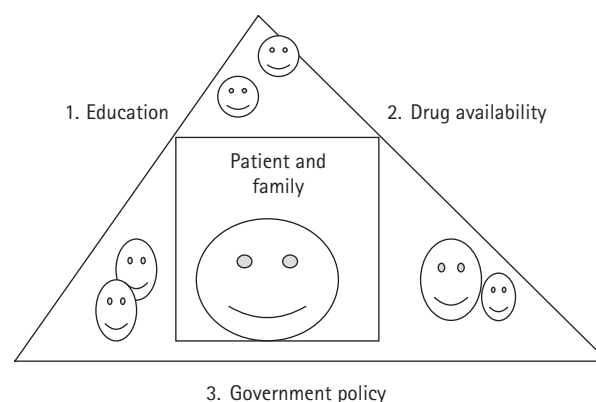
In 2000, the first funding was made available to support our third objective (see above). The training and support


Figure 5.2   *The World Health Organization (WHO) three priorities for a new service in palliative care. Note that the patient and family are at the center of care. Adapted (to include the patient and family as the centre of care) from WHO.[9]*

was offered to teams in Tanzania, through ORCI (Ocean Road Cancer Institute) and PASADA (a comprehensive HIV/AIDS support organization under the Catholic Archdiocese) in Dar es Salaam. Through this experience we developed a three-pronged plan for assisting countries in Africa.

1 Assessment of need, guided by those on the ground requesting assistance.
2 Advocacy with our team and initiators of palliative care in the country to the MoH regarding the importation of powdered morphine for affordable pain relief.
3 Introduction of palliative care training for those who would prescribe medications using the WHO guidelines. We could not envisage the introduction of morphine without this special training being in place. If palliative care is wrongly used, it can cause more pain and discourage health workers in its use as an effective means of care. The introduction of standards is therefore essential from the start.

The advocacy to the governments was successful in Tanzania and Malawi. Powdered and affordable oral morphine was imported for the first time.

Role of the WHO: the public health approach

In 2001, the WHO[10,11] commenced its initiative to assist five African countries. The organization commenced a work which brought experience in Africa to four further countries by introducing country palliative care teams, research in situation analysis and needs of patients and carers in the community with a view to persuading governments to support palliative care and to legalize procurement of essential drugs including morphine.

In the following years this approach was brought from Hospice Africa Uganda in partnership with Diana, Princess of Wales Memorial Fund, to Malawi, Zambia, Ethiopia, and Ghana. Further requests are coming from all over Africa, and have increased since the first conference and annual general meeting of the APCA in June 2004 in Arusha, Tanzania.

PALLIATIVE CARE IN AFRICA AND DRUG AVAILABILITY

In line with most other developing countries, African countries had gradually decreased their requests for class A drugs, particularly morphine, because they were afraid of a back lash from drug trafficking laws (David Joranson at the WHO Collaborating Centre in Wisconsin, USA, personal communication over many years). In 2000, the WHO[12] pointed out the need for balance in narcotic control laws, so that patients would not be denied pain relief due to archaic laws. At Hospice Africa Uganda, more than 7000 patients have received pain control using morphine, without diversion or abuse of drugs.[13] This has been confirmed in other developing countries.[14]

At present, morphine solution reconstituted in a pharmacy, costs less than half a loaf of bread for the average patient to be free of pain for 10 days. The other medications (22 on our essential drug list) are affordable and usually available in any African country. This is a forceful advocacy statement for governments in fear of economic implications of palliative care.

However, there is a further problem in countries with few doctors. Doctors are still the only prescribers for class A drugs, such as morphine. Uganda recognized this problem and in 2004 changed the law so that nurses and clinical officers, who have undergone a 9-month training program in Clinical Palliative Care and are registered with the MoH, can prescribe morphine. It is hoped that this first will be taken up in other African countries.

Nigeria

Nigeria was visited in 1993 by the initiators of Hospice Africa, Mbaraka Fazal, and the author. Nigeria was among several countries that had requested that the model hospice might be in their country. In Lagos that year, a pioneer group was headed by Mrs Fatumnbi and Professor Duncan, a retired radiotherapist. Mrs Fatumnbi had been inspired by her visit to St Christopher's Hospice in London the previous year, and her meeting with Dame Cicely. They were very keen that Nigeria would be the country where we would commence and as we visited the MoH and other teaching centers in Lagos, Ibadan we realized that the problem of corruption was so bad that donors were reluctant to

support nongovernmental organizations, especially new ventures. The MoH promised to bring in powdered morphine, but this was not followed through after we left the country, much to the disappointment of the pioneers.

Today, this same group has registered Hospice Nigeria in Lagos, there is a teaching section in the undergraduate curriculum in University College Hospital (UCH), Ibadan, but it still has no affordable and available oral morphine for control of pain. The government is yet to take on this need. Nigeria is a huge country. I am aware of one or more small groups trying to commence palliative care, but it takes full time commitment by someone with fire in the belly (often due to a personal experience of the need having been fulfilled).

An Advocacy APCA visit to Nigeria in January 2005 brought great interest from many highly positioned medical and nursing leaders in the UCH Ibadan and beyond. Advocacy is now again being brought to the present government and teaching with a community home-based care service is planned for later this year in Ibadan itself.

Note added in proof: Nigeria and Cameroon now have morphine available for use in palliative care since February 2006.

PROBLEMS EXPERIENCED IN INTRODUCING PALLIATIVE CARE

The many problems that have yet to be addressed in the different African countries are as follows:

- How do you bring medications to a patient in pain when they do not have enough to eat? This happens in many countries with extremes of poverty, such as Ethiopia and Malawi.
- How do you ask nurses who come into work hungry in the mornings to bring food to their patients without assisting them and their own families?
- The majority of African patients want to die in their own homes.[15] However some of the laws in African countries were designed by and for sophisticated Western colonialists who occupied the African countries, and have not changed since independence. For example, in Zambia, the law says that if a patient dies in the home the body has to be carried to a doctor (usually in the nearest hospital) to be certified dead. This brings a huge cost to the family in the transport of a dead body. There is also a shortage of doctors in Zambia, as in many poorer African countries, due to a 'brain drain'. Thus families prefer patients to die in a hospital or institution where there is a doctor available.

No doubt as we continue this form of assistance, other hindrances will be discovered and of course this emphasizes the fact that palliative care services must be adapted to the cultural, social, and economic needs of each country.

ROLE OF PALLIATIVE CARE ASSOCIATIONS IN AFRICA

With the registration and recognition of the APCA in June 2004, the role of palliative care associations throughout Africa is highlighted. The APCA aims to:[16]

- promote standards for the quality provision of hospice and palliative care services for adults and children
- be an advocate to Governments for affordable and appropriate palliative care to be incorporated into the whole spectrum of healthcare services
- promote the availability of palliative care drugs for all in need
- encourage the establishment of national palliative care associations in all African countries
- encourage sharing among such associations
- promote training programs suitable to African countries
- make standard guidelines for training at different levels.

This brings tremendous hope to bring together all the expertise now available within Africa. The national palliative care associations have led the way, particularly in South Africa (Hospice and Palliative Care Association of South Africa, [HPCASA]) and Uganda (Palliative Care Association of Uganda [PCAU]), by providing forums for continuing medical education and sharing among palliative care teams and isolated trained personnel. They now have a continental parent organization to support them.

SUPRA–SAHARAN AFRICA

In countries north of the Sahara, development has been mainly associated with the Islamic religion and governments affiliated to this religion. Although these countries have been oil rich for many years and oncology is far advanced, there has been little development in palliative care. We cannot find any palliative care models in these countries although there is a great interest there at present.

WHERE ARE WE TODAY AND WHERE DO WE GO FROM HERE?

We need to maintain up-to-date information on all African countries, e.g. the stage of development of palliative care in each country:

- Country with no palliative care
- Country with some but not all three priorities in place
- All three priorities in place adapted to the needs in your own country

As we move palliative care into the Francophone and Portuguese speaking countries, we need training materials in these languages as well as books for carers in the vernacular languages. How can we scale up to have the best care for our patients and families the centre of our philosophy? Every step to bring comfort and peace at the end of life in the African situation is appreciated.

This is our challenge in Africa over the next 20 years. The way forward is hopeful but it will take a lot of dedication and attention to detail to reach even the poorest with modern palliative care.

ROLE OF MONITORING AND EVALUATION[17]

With palliative care having been provided for up to 25 years now in Africa there are rich resources being recorded. Every service now needs to measure outputs and needs in their own setting. Monitoring and evaluation is now part of all aspects of palliative care. Not only are papers becoming more frequent, tapping on the experiences to date, but also audit with computerized data has come to Uganda and other countries, which many can learn from. The African culture is much better at handling grief and bereavement than most of the developed world. There are many reasons for this but there are lessons to be learnt. There are also differences in metabolic handling of medications and tolerance to pain that need further research as well and research into the best and most economically acceptable ways to deliver quality palliative care. Africa is still trailing behind some countries in evaluation. However, effective auditing has begun and will continue …

Key learning points

- An accurate definition of palliative care is essential to maintain standards throughout Africa.

- Suffering from cancer, AIDS and other noncurable diseases is greater in Africa than anywhere in the world because of lack of resources.

- Palliative care using the researched methods of Dame Cicely Saunders, in Africa, is now affordable to the poorest with introduction of training, drug availability and government will.

- Africa has the greatest need of palliative care because of the HIV/AIDS epidemic and is meeting the challenge on the back of the epidemic.

- There has been rapid growth of palliative care in Africa since 1990. Monitoring and evaluation of this work to date can bring a wealth of experience to those just starting.

- Each country needs its own form of palliative care because of cultural, economic, and social needs which must be met at the end of life.

- Palliative care associations in Africa have a large part to play in setting standards, training, and advocacy.

- African governments need to ensure availability of affordable oral morphine and other medications to bring humanitarian relief in line with the human right of freedom from pain.

The development of palliative medicine in Australia/New Zealand

J NORELLE LICKISS

INTRODUCTION

Australia is the outcome of an ongoing human conversation[1] which began over 60 000 years ago, incorporated Anglo-Saxon and Celtic elements from 1788 onwards, Chinese from mid-nineteenth century (the 'gold rush') and subsequently, especially from the mid-twentieth century onward, contributions from almost every part of the earth. Australians are all immigrants,[2] for even the first indigenous peoples came by boat from across the sea: some came willingly, others were forced to come (as convicts) – until the mid-nineteenth century, and, especially since the second world war, some came as refugees. So, people in Australia have been approaching death and caring for each other for over 60 000 years, in diverse ways. There has been sparse documentation of these matters, though a constant presence of death, if not dying, in Australian art and literature,[3] but there is increasing professional interest (Pollard B. Dr Fred Gunz and the First Five Years of the Palliative Care Association of New South Wales, unpublished manuscript).[4,5] Developments in palliative medicine and of palliative care in Australia in the last 30 years may be the fruits of disquiet, a little reminiscent of patterns articulated by Kuhn,[6] associated with paradigm shifts.

The care and concern for dying persons in the early years of British settlement in Sydney from 1788 onward was quite appalling: grave illness and deaths of convicts at sea during the long voyage from England, and soon after arrival, at what is now Sydney harbor, appeared to have been met with barbarity by today's standards.[7] Serious discrimination was manifest with respect to marginalized, indigent, and dying persons late in the nineteenth century,[8] yet subsequent medical history indicates a continual pattern involving concerned doctors of integrity and other humanitarians seeking to improve the health and welfare of the people.

The early Australian colonies were set up at a time of rapid secularization in Britain, and Kellehear records that during the first 100 years of European settlement Australians began to see their death as a failure of health and not a natural or divine outcome of life. Little is documented, however, about details of the care of the dying. Institutions for the care of the dying, and especially the dying poor, were established in the nineteenth century and early or mid-twentieth century by Christian organizations: Sacred Heart Hospice, Homes of Peace, and later Calvary Hospital in Sydney, Bethlehem Hospice in Victoria, and Mt Olivet Hospital in Brisbane, Queensland. These explicitly religious initiatives were complemented by the medical schools and teaching hospitals established in the mid-nineteenth century in Sydney and Melbourne: there is explicit mention of the concern for the poor in hospital documents.

John Rickard, writing at the time of the commemoration of 200 years of European settlement, wrote tellingly that[9]

> a culture should be identified not so much by any sense of shared values, which may be artificially induced, as by the means it develops to reconcile or at least to accommodate the dissonant forces within it.

The multicultural conversation of Australia embodies not only ethnic diversity but many other forms of cultural difference, with patterns of emphasis in the conversation varying enormously across diverse places: metropolitan (inner, outer) regional, rural, desert … and across the socio-economic spectrum. Cultural differences – and tensions – go far beyond customs surrounding death. Other matters need to be considered and respected; for example, patterns of interpersonal responsibility, modes of decision making and communication, caring styles, responses to loss/grieving, and bereavement customs. … All but the indigenous people in Australia are in a sense 'displaced', with complex cultural roots and current cultural affiliations. English, although widely understood, is the second language (and not usually spoken at home) by over a third of population of major cities like Sydney.

Care of the other involves (at some period of life) most people past childhood (and even children in some circumstances): being human involves sociality, interpersonal bonds, social responsibilities. The philosophical basis of the duty of care is not law, or contract, but the call of the other.[10] People caring for each other (well or poorly) is, everywhere in Australia as elsewhere, the fundamental stratum of what has come to be known as palliative care. People with family or neighborhood bonds for one reason or another need assistance from others including, when available, health professionals. What has changed over the last 30 years in Australia is the nature, competence, and organization of the professional help available to support the family or neighborhood carers. Professional assistance with respect to palliative care in Australia is carried out by clinical staff within the whole healthcare system. The quality of such care depends enormously upon attitude, competence, and efficiency of staff involved as well as organizational factors. But there is no doubt that the burden (and privilege) of palliative care in Australia is dispersed very widely, and the whole population is increasingly in focus.[11]

The recently increased attention to improving care for those with progressive disease and approaching death, so apparent in the UK from the mid-twentieth century[12] and in the USA more recently[13] dates from the early 1970s in Australia. Several brief accounts exist of some aspects of the development of palliative care in Australia[14–16] with further major works in progress. But it is necessary to emphasize that many of the elements within the umbrella term 'palliative care' developed and remain principally outside specialist palliative care services (for example, oncology services, pain services/centers, bereavement services, palliative care within intensive care services, psychooncology, and so on): this trend is obvious in the two largest cities (Sydney and Melbourne) but is perceptible elsewhere. The history of the recent development of palliative care in Australia is truly the history of improvements within the whole health care system … and the stirrings were obvious in the early 1970s, in widely separated parts of Australia, even though the term 'palliative care' was rarely used. The first national multidisciplinary palliative care meeting was held in Canberra in 1989, organized on behalf of the Medical Oncology Group of Australia (MOGA) by Dr Roger Woodruff of Melbourne. The 1-day meeting for the first time brought together doctors, nurses and allied health professionals to discuss the range of issues facing the emerging specialty of palliative care.[17]

Specialist palliative care services are now available in some form in most areas of Australia to assist, when requested, other clinical staff in various aspects of care.[18] The national (Commonwealth) government is explicitly involved, with inclusion of palliative care matters in policy and planning documents, and financial allocations, with devolution of responsibilities to the states for administration.[19] Palliative Care Australia, representing the palliative care associations (multidisciplinary) of each state, is in dialog with the national government on these matters, and has commissioned several valuable projects, including for example, a national census of palliative care services in 1998.[20] The National Health and Medical Research Council is investing targeted funds in both palliative care research and capacity building in palliative care nationally. This includes project grants for research, bursaries for postgraduate research studies and workshops on research. The national government has also produced a handbook on palliative care and the ethics of research. There has been a concerted effort to collect and make available all the completed but unpublished research and scoping that has been done in Australia since 1980 (www.caresearch.com.au). The Chapter of Palliative Medicine (within the Royal Australasian College of Physicians) has now over 200 Fellows (mostly Foundation Fellows) and around 15 supervised trainees. There has been explicit interest in provision of palliative care for children (especially in New South Wales [NSW]), and a recent major document[21] is part of a national strategy to improve all aspects of nursing home care.

Palliative medicine is part of the curriculum for medical schools throughout Australia although patterns of education vary and documentation is scanty. Postgraduate education in palliative medicine, and clinical training for skills enhancement or for progression to specialist status are now available in most states, again, with varying patterns of training and emphases, reflecting local factors. A national curriculum for palliative care in all health sciences is under consideration.

There are major differences between the states with respect to many indices – from ethnicity, to economic status, and to prevailing ethos. Much is related to geographical factors and population levels, but historical factors still have much influence.

NEW SOUTH WALES

In the early 1970s in NSW and Tasmania (historically closely related to Sydney), two academic hematologists, Fred Gunz in Sydney, then Director of the Kanamatsu Research Institute Sydney Hospital, and Albert Baikie,

Foundation Professor of Medicine, University of Tasmania 1967–75, previously in University of Melbourne and originally from Glasgow, co-authors of a major text on leukemia, urged that improvement needed to occur in the care of patients with progressive disease approaching death. These two eminent men were influential as well as innovative: Gunz laid the groundwork for palliative care service development in NSW (Pollard B. Dr Fred Gunz and the First Five Years of the Palliative Care Association of New South Wales, unpublished manuscript).[22] Anesthetists in Sydney – Dwyer (St Vincent's Hospital), Pollard (Concord Repatriation General Hospital), and Laird, internist (Royal Prince Alfred Hospital) – were instrumental in setting up palliative care services in the three teaching hospitals in Sydney by 1982 (around the time of an influential visit by Balfour Mount of Canada). In the mid-1980s decisions were made under the guidance of senior clinicians to restructure the service at Royal Prince Alfred Hospital: a steady evolution of the palliative care service was facilitated.[23]

From the late 1980s there was a focus in Sydney on clinical training for doctors especially through the Sydney Institute of Palliative Medicine (SIPM), based in Royal Prince Alfred Hospital (University of Sydney) and Prince of Wales Hospital (University of New South Wales), with their associated community services and inpatient units. Three domains of clinical experience were available for trainee posts: community, inpatient beds, and hospital consultancies.[24] The concept of these elements under one administration was adopted as the service model for NSW Area-based Palliative Care Services. The NSW Palliative Care Association, NSW Society of Palliative Medicine and the Sydney Institute of Palliative Medicine have continued to be active in education, planning and support for specialist palliative care services, and increasingly in cognate research involving major public funding.

Collaborative research (some with international links) is in progress in areas such as prognosis, care of patients with cardiac failure and communication, in addition to more traditional areas of inquiry. Postgraduates training in internal medicine (Royal Australian College of Physicians [RACP]) commonly undertake 3–6-month terms in clinical palliative medicine as part of their preparation for the RACP examination preceding various strands of advanced training: over 200 registrars (including British registrars) have occupied SIPM posts, either for skills enhancement or for specialist training. Many of the latter were examined by Geoffrey Hanks (UK), who served as external examiner to SIPM for nearly two decades. Particular emphasis in Sydney has been given to the need for recognition of the need for improvements in palliative care in acute hospitals.[25] The recent emergence of doctorate candidates marks a new phase in the development of academic palliative medicine in NSW.

Over the past 15 years in NSW, the University of Sydney and University of NSW fostered the development of medicine not by establishing university-funded chairs, but by conferring professorial status on senior clinicians. The University of Newcastle established a Chair in the 1980s

and this has been crucial in the development of a cohesive palliative care service in the Hunter River region of NSW. Undergraduate medical education in palliative medicine within University of Sydney, University of NSW, and University of Newcastle has been undertaken for over a decade, with increasing formalization over time.

The situation in NSW continues to be challenging not only in the complex cities such as Sydney but also in the sparsely populated rural areas: staff (especially nurses) capable of adapting ideas and practices to the local situations are the sturdy backbone of palliative care in such circumstances, but inequities of resource levels in NSW and adequate provision for professional education and training need urgent attention.

VICTORIA

In Victoria several recent landmark events and strands of activity are noteworthy, building on the efforts of the period prior to 1970. Details of the impressive development of specialist palliative care services in Victoria, which have been largely community based, have been detailed by Redpath, one of the key figures in the whole process.[16] It is noteworthy that an inquiry into issues related to dying with dignity, held in Victoria in 1987[26] gave added impetus to coordinated improvements in palliative care, and led to law which enshrined the right to refuse treatment.

In the late 1970s the first community-based palliative care service, delivering specialist palliative care in patients' own homes was set up by City Mission. A nurse-led palliative care service was established at the Repatriation Hospital in 1988, closely followed in 1989 by the first multidisciplinary hospital-based palliative care service, established at the Austin Hospital.[27]

The University of Melbourne introduced a postgraduate diploma in 1996 and established a chair in palliative medicine. Elsewhere in Melbourne in the 1990s, chairs were also established in Monash and Latrobe University. Melbourne-based academic nurses have also been active in research regarding palliative care – with chairs established relevant to palliative care. Medical education with respect to palliative medicine and palliative care has been well documented by Melbourne-based clinicians.[28]

Palliative care services are well established in the Melbourne teaching hospitals, including the largest cancer center. Melbourne has centralized radiotherapy services in the Peter MacCallum Hospital, and therefore also a tendency to centralization of other aspects of oncology. The first steps were taken in 1980 by Dr Walter Moon who set up a pain clinic for inpatients and outpatients at the Peter MacCallum Hospital, reflecting again the growing concern in Australia during the period 1975–80, to improve seriously neglected dimensions of care. A senior radiotherapist, Dr Ruth Redpath, undertook extensive community consultations, and encouraged the development of community

palliative care in Melbourne and elsewhere in Victoria. Peter MacCallum Cancer Centre (as it is now known), a teaching hospital of the University of Melbourne, has currently a significant multidisciplinary palliative care department with consultative responsibilities within the hospital as well as educational activities (undergraduates, including a 1 week full time attachment, and post graduates), with a special interest in psychooncology, and research programs (including PhD programs) in association with the University of Melbourne.

QUEENSLAND

Queensland is a state with one major city, Brisbane (the capital) several smaller cities, and a large hinterland. Administration is largely concentrated in Brisbane. Mt Olivet, Brisbane, a Catholic institution administered by the Sisters of Charity (like St Vincent's Sydney and St Vincent's Melbourne), was established in the mid-twentieth century (1957), but planned for the preceding 20 years. It was the result of a collaboration of two surgeons, a benefactor, the government and the vision of the Sisters of Charity. It was for many years the only recognized provider of palliative care services in Queensland, and a major contributor to the introduction of contemporary ideas of palliative care into the Queensland scene. Throughout the period of rapid development of palliative care services in several parts of Queensland in 1990s, Mt Olivet has remained a major provider of specialist services, with a 28-bed inpatient unit and formal home care service, and an active focus for education of doctors, especially general practitioners.

In 1992 the Queensland Cancer Fund, a charity, funded the establishment of a palliative care service in Mater Hospital, a teaching hospital of the University of Queensland, and also a service in Townsville, a northern Queensland city. The Queensland Health Department soon followed this initiative, establishing many other services in the south east of Queensland. Another teaching hospital in Brisbane (Prince Charles Hospital) was the site for a 16-bed unit, and provision was made for several other hospital-based inpatient palliative care units. In the city of Ipswich, not far from Brisbane, half of the cost of the establishment of the local hospice is funded by the local meat works – an unusual pattern of collaboration in any area of healthcare in Australia. Palliative care throughout the areas of Queensland distant from major centers continues to be the responsibility of the mainstream health services, assisted where feasible, by the small number of personnel within specialist services.

In Australia, the major teaching hospitals are public (government funded), but private hospitals play an important role in the care of patients with private insurance. In Queensland (as in several other states) the private sector has also established palliative care consultancies at several hospitals. This trend may be expected to strengthen in Australia in the next decade, especially if the concept of mixed management or parallel care becomes more widespread.

Multidisciplinary research in Queensland related to palliative care has been impressive over the last decade reflecting a wide range of interests, including ethical, social and spiritual matters. The University of Queensland has recently (2003) appointed a Professor of Palliative Care based in the Mater Hospital Brisbane, an encouragement to the Brisbane-based Centre for Palliative Care Research and Education.

SOUTH AUSTRALIA

South Australia, especially through the work and encouragement of Ian Maddocks, and more recently his successor, David Currow, has contributed significantly to the development of specialist palliative care services in Australia. Urban Adelaide lends itself to a logical and orderly development of hospital and associated community services (guided by wise leaders), and undergraduate medical education was given due emphasis. Distance learning, organized as a masters program, based in the International Institute of Hospice Studies, has assisted many professionals in Australia and elsewhere to enhance their skills and move into the practice of palliative care. Useful population-based studies, as well as institution-based studies have broadened the focus of studies of palliative care needs. It is noteworthy also that in South Australia, as in other Australian states, leading oncologists contribute significantly to support and investigation of issues relevant to palliative care. There was early recognition of the needs of patients with conditions other than cancer, notably cardiac and neurological conditions.

South Australia contributed significantly to developments in the legal situation. In South Australia, 'Do Not Resuscitate' orders are usually not written, rather, documentation for 'Good Palliative Care' is the norm in appropriate circumstances and the practice is currently under review.

WESTERN AUSTRALIA

In Western Australia, a state with the population much concentrated in the capital Perth, nurses played a crucial role in the development of specialist palliative care services. In the late 1970s oncology nurses at the Royal Perth Hospital were instrumental in arranging for Dame Cicely Saunders to give a lecture in Perth, and this proved a catalyst. Joy Brand, a nurse in an academic position, Rosalie Shaw (a medical graduate who had also been a nurse) and Douglas Macadam (the first medical director of the community-based Silver Chain Nursing service) were highly significant in those crucial years around 1980. The Cancer Council of Western Australia supported the community-based developments. Other influential doctors and nurses were supportive, and the specialist

palliative care services in Perth developed in an orderly and comprehensive manner, with later involvement of the major acute hospitals. In the 1980s, Hollywood, a Veterans hospital, developed under the direction of Rosalie Shaw, an inpatient palliative care unit with significant influence on undergraduate medical education. Dr Shaw subsequently was invited to Singapore to assist in the development of palliative care services in that city and subsequently became Executive Director of the Asian Pacific Hospice and Palliative Care Network.

In the 1990s, the appointment of a nurse researcher Linda Kristjanson as Professor of Palliative Care at Edith Cowan University, led to Perth becoming a significant Australian focus for research activities and for leading impressive projects for improving practice (for example, the recently launched guidelines for palliative care for older people in residential care).[21]

TASMANIA

Tasmania, the smallest state, has a history intimately connected with Sydney. Hobart, the capital, prides itself on having a branch of the Royal Society (the first outside London). A medical school was planned for Hobart in 1854, to be of 3 years' duration with lectures in anatomy, chemistry, and the natural sciences as well as Latin and French, English, and History. There had already been apprentices trained by surgeons in Hobart since 1826. The plan for a medical school was abandoned (because the UK Royal Colleges insisted on 100, instead of the readily available 30, inpatients to be available for teaching). Palliative medicine had no place in training then, despite the prevailing high mortality in the Australian colonies. But in 1974 the University of Tasmania, under the guidance of Professor Albert Baikie, was the first Australian medical school to introduce teaching in clinical palliative medicine (called then 'clinical aspects of the care of the dying') as part of clinical studies (with relevant examination questions), with some joint teaching of medical and nursing students. The teaching of clinical ethics in the University of Tasmania undergraduate curriculum in the 1970s frequently included matter (in case-based format) directly related to palliative care.

The cancer services of Tasmania, developed under the guidance of Baikie, from 1967 until his untimely death in 1975, were, from the beginning, comprehensive, patient-centered, and explicitly multidisciplinary. Although the word 'palliative care' was not used, the elements of palliative care were embedded in the mainstream cancer services. Other clinical services were also deliberately comprehensive, encouraged by and supported by the conjunction of academic clinical staff with private specialists and general practitioners, as well as health administrators.

Collaboration between clinicians, government and the community has been significant in the further development of specialist palliative care services in Tasmania. As in

Queensland, a benefactor was also helpful, but consistent community interest reflects the value system of the island state. Service reviews by independent persons have served to guide the services toward sustainability as well as quality. Gradually, a well-resourced statewide specialist palliative care service evolved, with excellent facilities, multidisciplinary service provision in all areas – city and rural areas – with presence in all hospitals, excellent inpatient units, and availability of consultants to nursing homes, as well as organized home care service provision.

AUSTRALIAN CAPITAL TERRITORY AND NORTHERN TERRITORY

The territories of Australia – the Australian Capital Territory (Canberra) and the Northern Territory – have diverse histories with respect to the evolution of palliative care service. Nurses have for many years been crucial in caring for patients at home in both regions. Palliative medicine provision (in the form of palliative medicine specialists) commenced in Canberra in the early 1990s and more recently in Darwin/ Northern Territory.

In Canberra, the palliative care service is well developed with a comprehensive community service and a purpose-built hospice. The oncology departments of the Canberra Hospital have strongly supported action and research regarding the care of patients with advanced disease.

The heated debate in the mid-1990s and short-lived legislation permitting euthanasia in the Northern Territory accelerated the development of specialist services in that territory. Darwin, the only city in the Northern Territory (total population 200 000), became a world center of interest in 1995 with the passage of the first legislation in the world to permit euthanasia. The Rights of the Terminally Ill Act (ROTI) was passed into law in late 1995 and was accompanied by a Bill to increase palliative care funding in the Northern Territory from about Aus$100 000 to close to 1 million dollars per annum. The ROTI Bill was revoked by the Federal Parliament in 1997 amid much controversy over the intrusion of the Australian Government into Territory affairs: the status of the area as a Territory (not a state) had legal implications. There were seven euthanasia deaths recorded in the time the law was in place[29] and there were also clinical problems associated with the Act.[30]

A specialist palliative care program was commenced in 1989 with the appointment of two palliative care nurses working within the community nursing network. A voluntary board of interested stakeholders was established and continued to function with oversight of the program. Two palliative care teams were established in the Northern Territory, one in Darwin covering the 'top end' (population about 150 000) and one in Alice Springs (population about 50 000) but recruitment of doctors with expertise in palliative medicine proved difficult. An inpatient unit (hospice) was opened in 2005.

The rural and remote area of the Northern Territory encompasses some 200 aboriginal communities, many of which had their own language. The aboriginal communities account for between 25 percent and 30 percent of the total Northern Territory population, with the acute hospital population being up to 65 percent aboriginal. An aboriginal health worker position was created in 1998 (the first in palliative care in Australia), which enhanced the effectiveness of palliative care in the rural and remote aboriginal communities and eventually led to the development of an 'indigenous palliative care model' based on research funded by the National Health and Medical Research Council.

Documentation (even complete) of landmark events is not history. The history of the development of palliative medicine (to be a little more focused) in Australia is above all a history of ideas, and of their expression in diverse contexts. We know something of the values, dreams, courage, and tenacity of the colonial doctors who upheld (on the whole) the best traditions of Western medicine and contributed richly to the transformation of fairly chaotic colonies into modern communities – they had their counterparts elsewhere. We know little of the intellectual constructs, the ideas, the views of the indigenous people prior to European settlement, but we have a rich legacy of art, dance, bush craft, and stories. Proust, in his remarkable compendium of some of the material relating to the history of medicine in Australia,[31] documents some of what is known about aboriginal traditional medicine – ideas about causation of serious disease, the role of traditional healers (combining role of priest and physician). Blackwell[32] recounts that there is little aboriginal literature concerning death and dying, reflecting the importance and secrecy attached to death and dying, but papers by experienced palliative medicine practitioners are appearing.[33,34] Indigenous doctors, now numerous in Australia, with a professorial appointment in University of Melbourne, may assist in articulating and clarifying some of the rich ideas about dying – as well as living – which have flourished in indigenous communities – despite (or possibly because of) their profound experience of loss and grief over the last two centuries and continuing high mortality in some sectors of indigenous life in Australia.

For the rest, Manning Clark, historian, author of a six-volume history of Australia, considered that there were 'three different visions of God and man which Australians bought to the conversation which is Australia: Catholic Christendom, Protestant Christianity and the Enlightenment'.[35] A quarter of a century later he would have to make explicit mention of Buddhism (the fastest growing religion in Australia), and the many other ethnic and spiritual traditions long present in persons and institutions such as Judaism, Bahai, Islam, and the increasing strength of secular expressions of values (and of spiritual matters). Philosophical trends in Australia are not only heirs (or traces) of the Enlightenment: the conversation is very complex, the interplay of ideas vigorous, and both the shape and the content of the discussion vary markedly across the continent, and

within regions. Grand narratives from traditional cultures, and from communities from which Australians come, do not always appear to hold. Ideas are welcomed but tested and accepted or rejected or modified, on the whole courteously, but without grace or favor with respect to their origin.

WHAT DOES THIS MEAN FOR PALLIATIVE CARE?

The British hospice movement, especially embodied in Dame Cicely Saunders, has had profound influence in many parts of the world – and Australia is no exception. Several of the individuals who were influential during the 1970s and 1980s in raising the profile of the care of patients with incurable and especially progressive disease, and particularly when approaching death, had some personal contact with St Christopher's Hospice, London, and often with Dame Cicely in person. Ideas of St Christopher's found fertile soil in which to flourish, soil prepared by men such as Gunz and Baikie, influenced by other strands of thought and experience. Further, the way ideas took root in Australia was influenced subsequently by persons appointed to responsible positions – by their personality, background, medical discipline, resource levels and the environment in which they encountered their patients. Community care patterns are obviously closely influenced by local circumstances, but even the shape of clinical practice in hospitals differs from hospital to hospital, even within one state, as trainees in palliative medicine testify. Diversity in thought and practice is a hallmark of Australian life and the medical environment.

Some of the ideas held to be central by the UK hospice movement have been modified in some parts of Australia: for example, conditions from which patients suffer (with acquired immune deficiency syndrome [AIDS] patients readily seen in consultations and admitted if necessary to palliative care units), the contexts in which patients are seen, the acceptance of episodic involvement and of parallel care, the acceptance of mainstreaming of palliative care, the pattern of funding (government not charity), the concept of team (with specialists in palliative care being members of several teams), the secular basis of service (rather than religious), even the apparently compromising concept of a 'good enough death'.[36]

Documentation is available concerning the processes involved in specialist palliative medicine consultancy and palliative care services in several contexts – community, inpatient units, hospitals. However, outcome evaluation is not extensive – and will become less so in the future as (requested) input of specialist palliative care personnel (singly or as a team) becomes simply part of the common mainstream healthcare effort. The quality of palliative care as a whole may be measurable (best by its recipients), rather than the input of distinct services such as oncology services, specialist palliative care services, bereavement services, pain

services, psychooncology services, etc. The whole is more important than any part.

Have the original ideas of the British hospice movement been betrayed? Or are we seeing the fruits Dame Cecily dreamed of – the incorporation of the core (not peripheral) ideas of palliative care into mainstream, public funded healthcare? These core (not peripheral) ideas are surely:

- Respect for the individuality and the uniqueness of each person.
- Recognition of the significance of the last phase of life – and the value of an individual usually knowing of his or her existential situation.
- The acceptance of the value of the weak in society – and the recognition that a society can be judged by its care of the most vulnerable.
- The understanding of the contribution of essential persons of different professional backgrounds, as well as family, friends, (all only as needed) in improving the quality of life of very ill persons – but with respect for the privacy of individuals and their places of care or residence.

Many in Australia, including this author, would not agree that palliative care should be considered as a social movement[37] but these core ideas are not contested.

WHAT OF THE FUTURE?

The problems of the present are, mainly, those of mismatch, the failure of resources to match inevitably increasing, legitimate needs as the population ages (with rising cancer rates, and multiple morbidity becoming more common), and as anti-disease therapies which control disease (but do not cure) may prolong the time span of serious illness, and morbidity. Increasing competence in palliative care of professionals outside specialist palliative care services may reduce the pressure on the latter by 'heightening the bar', raising the threshold at which personnel from a specialist palliative care service are needed. It is true, however, that the more professionals learn about palliative care, the more they become aware of needs of patients and families previously not noted or given little attention, and the possibilities for improvements in care. If this is true, there may be increased call for specialists in aspects of palliative care – medicine, nursing, or social work to assist with specific matters – and a high level of competence would be expected. Or will specialist palliative care services in Australia become unnecessary if skills enhancement of all other clinicians proceed? Probably not: rather, strengthening and expansion is planned and government support appears firm.

Will specialist palliative medicine survive in its present form in Australia? This is more worthy of discussion. The ratio of palliative medicine specialists to oncologists in Australia is less than 20 percent and a similar ratio applies to trainees following the program of the RACP Chapter of Palliative Medicine. Many oncologists, without specific training in palliative medicine but with increasing expertise, do explicitly undertake palliative care for hospitalized and ambulant patients as part of their responsibilities. In view of the large numbers of oncologists in Australia, this trend may increase with respect to patients with cancer. Or it may be that consultant physicians (internists) wishing to practice palliative medicine especially in hospitals will undertake training in oncology and include a significant period in palliative medicine as the optional (elective) section of advanced training. Or palliative medicine consultants (and even palliative care services) may focus more in the problems of patients with diseases other than cancer, leaving palliative care with respect to patients with cancer more and more in the hands of oncologists. This would, however, also require structural and administrative changes with respect to some aspects of care (notably with respect to community services), and to training programs (in oncology as well as palliative medicine).

Resource allocation will be a critical factor. The current clinical caseload of most palliative medicine consultants and specialists mitigates against a flourishing academic activity of appropriate physicians, although several are courageously undertaking significant research. Financial incentives for research in palliative care related matters are plentiful now, but personnel to grasp the opportunities are relatively few. Experienced formally trained palliative medicine consultants or specialists with academic ability, are to be seen to be moving into fields removed somewhat from the clinical scene of one-to-one medicine for a large part of their time. But palliative medicine is primarily a highly personalized, indeed intersubjective activity. The tendency to objectification of the patients, and the blurring of individual differences even for research or planning purposes, needs careful scrutiny … or there may be a new wave of protest (as well as sadness).

Ethical issues (hopefully not medicolegal issues) will always be part of the stuff of palliative care; and there is a case for more rigor in training in clinical ethics. Palliative medicine specialists are, in general, aware of manifold ethical dimensions of everyday practice and seek to exercise clinical wisdom. End-of-life care is, everywhere, ethically complex – for the folding up of life is as complex as the living of it.

Public debate concerning euthanasia (at its height in the mid-1990s) is not a major feature of the Australian conversation in the early twenty-first century. However, disquiet concerning the quality of care, especially the elderly and about decisions made concerning end-of-life care, do surface from time to time in the media, and much more frequently in private conversations. There is well-based fear not of euthanasia but of life being prolonged (especially in hospitals) beyond the patient's wishes, and advance directives, though promoted now in primary care and by some geriatricians, are not in common use in hospital practice. It appears that despite excellent Australian writing on this theme[38] a balance has not yet been struck at least in some large metropolitan hospitals

between a passion to affirm life – 'save' life where possible by all means possible – and a commitment not to obstruct death, but rather to care competently and comfort the patient and significant others as the end of life draws near. There is much to learn and to do, especially in hospitals, and hopefully palliative care services will have a role as agents of change.

NEW ZEALAND

New Zealand is a cohesive nation (population 3.8 million) with a longstanding interest in medical issues of community significance. The steps leading to the present situation are outlined by MacLeod.[39]

The first (inpatient) hospice in New Zealand, Mary Potter Hospice in Wellington, was opened in 1979, closely followed by Te Omanga Hospice and St Joseph's Mercy Hospice in Auckland. Little has been published concerning the climate of ideas and debate which preceded and undoubtedly prompted the foundation of these institutions, mainly Christian in inspiration. New Zealand has two major ethnic configurations: the indigenous Maori population and Anglo/Saxon/Celtic New Zealanders. The marked ethnic diversity of Australia (especially its large cities) is far less obvious in New Zealand.

Palliative medicine teaching has been limited in medical schools in New Zealand, but there is a well established liaison between the Mary Potter Hospice and the University. A Chair in Palliative Care was established at the Dunedin School of Medicine within the University of Otago in 2003. A national strategy for New Zealand is now in place, with now 37 hospice and around 40 palliative care services set up throughout the country.

The Australia and New Zealand Society for Palliative Medicine has been supportive of the development of palliative medicine in New Zealand. There is support for specialist palliative care from the community and from government, but it is clear that leadership given by a small group of influential clinicians, has – as in Australia – been crucial. There are 25 fellows of the Chapter of Palliative Medicine within the Royal Australasian College of Physicians. These influential senior clinicians in New Zealand have given particular attention to several matters relevant to specialist palliative care: for example, palliative care of patients with neurological disease and the psychiatric dimensions of palliative care.

The differences between Australia and New Zealand are predictable once the vast differences in size, distances between population centers, and patterns of migration and resultant cultural mix as well as political nuances are kept in mind. There has been excellent cooperation between the two countries to ensure that different emphases, attitudes, problems, and possibilities are articulated and understood, with the contribution of each contributing to the improved care of the people … the endpoint surely of all common endeavor.

CONCLUSION

Palliative medicine, as a component of palliative care, is a privilege, sometimes burdensome, sometimes painful, but a privilege nevertheless. If a society can be judged by its care of the weak – and palliative medicine attends to humankind in weakness – palliative medicine, far from being marginal, may be at the heart of the discipline and practice of medicine. There is much to be improved in the care of the dying 'down under'[40] and the whole community everywhere must be involved … but this task may make or remake Australia as it struggles for its soul.

Key learning points

- Australia is an ancient land, with humans caring for each other for over 60 000 years, but with dramatic changes in modes of life and death since the British settlement in the 1790s, and with increasing ethnic and cultural diversity.

- Recent developments in palliative care in Australia reflected Christian influences in the late nineteenth century and early twentieth century (first hospices), supplemented in the late twentieth century (from the 1970s) by broad humanitarian leadership given by leading academics and clinicians.

- It is accepted that palliative care is not a charity-funded optional extra, but part of mainstream care. Governments, national and state, have since the late 1980s given firm support concerning the need for specialist palliative care services and/or professionals to be available to improve palliative care given through the healthcare system, but deficiencies remain, despite extensive efforts. Palliative Care Australia monitors and coordinates many programs and projects.

- New Zealand is a more cohesive nation, with less cultural diversity than Australia, and progress has been steady.

- Outcome measures with regard to the quality of care as a whole remain inadequate, and despite current initiatives the care of institutionalized older people in the last phase of life needs much improvement.

- Research in various aspects of palliative care is being fostered by government.

The development of palliative medicine in Asia

ROSALIE SHAW

INTRODUCTION

The development of palliative care in Asia has been hampered by poverty, lack of resources, the need to address more urgent healthcare needs, issues relating to the availability of opioids, and the unwillingness in many cultures to discuss issues surrounding death and dying. Asia covers about a third of the world's land mass and three-fifths of the world population. The eastern and southern part of this vast continent and the islands to the east of its coastal boundaries can be subdivided into three regions:

- East Asia – China, including Hong Kong, Taiwan, Mongolia, Korea, and Japan
- Southeast Asia – Myanmar, Thailand, Cambodia, Laos, Vietnam, Malaysia, Brunei, Singapore, Indonesia, and the Philippines
- South Asia – India, Pakistan, Bangladesh, Sri Lanka, Nepal, and Bhutan.

Within this region there is great diversity of race, language, religion, and culture as well as economic and political systems. Many countries are grappling with ways to provide basic healthcare in rapidly expanding and congested cities, as well as in isolated rural areas where infant and maternal death rates are high. Infectious disease is still a major cause of illness, and the incidence of cancer is rising. Healthcare staff, especially nurses, often have relatively poor status and very poor remuneration.[1] In most countries, traditional medicines are widely used, either instead of or concurrently with Western medicine.

There is wide variation in the level of development of palliative care services. In some countries (Japan, Taiwan, Hong Kong, and Singapore) services are relatively well developed with trained professional staff and with part or full government funding. However, in many countries, dedicated and committed individuals are struggling to establish credibility and to find resources for hospital-based and home care programs. The following sections review the development in different parts of Asia.

EAST ASIA

Korea

In East Asia the concept of hospice was introduced as early as 1965 when an order of Catholic nuns opened a clinic in Seoul in South Korea.[2] However, following 1982 when hospice services were started by Dr Kyung-Shik Lee at Kangnam St Mary's Hospital, expansion was gradual until a World Health Organization Collaborating Centre for Hospice Palliative Care was established in 1995 at the Catholic University of Korea, College of Nursing. This center has had an important role in the training of professional hospice nurses. By 1996, 90 percent of nursing colleges were teaching hospice palliative care.[3]

There are now more than 100 hospice programs in South Korea. Of these about 37 percent are nongovernmental organizations and 31 percent are in university hospitals. However, few doctors wish to train in the area of palliative medicine, which is not yet recognized as a medical specialty. Although slow-release preparations of morphine are available at government hospitals, there are still no oral immediate-release preparations of morphine available for titration or for the management of breakthrough pain.

Three umbrella hospice organizations have been important in raising public and professional awareness: the Korean Hospice Association (established in 1991), the Korean

Catholic Hospice Association (1992) and the Korean Society for Hospice and Palliative Care (1998). The sixth Asia Pacific Hospice Conference in March 2005 hosted by the Korean Society for Hospice and Palliative Care with 1200 local and international participants gave an impetus to the development of palliative medicine and will further advocacy for palliative care to be eligible for National Health Insurance funding in Korea. A 2-year pilot project was initiated by the government in 2003 to decide on a model of palliative care suitable for Korea so that national policies can be formulated.

Japan

Palliative care was brought to Japan in 1973 when Dr Tetsuo Kashiwagi returned from psychiatry training in the USA and set up an Organized Care of the Dying Patient (OCDP) team at the Yodogawa Christian Hospital, Osaka. Eleven years later a 23-bed inpatient hospice ward was opened at that hospital. By then the first inpatient hospice had been set up 3 years earlier at Serai Mikatabara General Hospital in Hamamatsu, in Shizuoka Prefecture. The first independent freestanding hospice, the Peace House Hospice, was opened in 1993 in Kanagawa Prefecture.

A landmark in the development of hospices in Japan was the publication in 1989 of a report on care of the dying patient by the Ministry of Health. This report resulted in National Health Insurance funding for accredited palliative care units from 1990. At that time there were only three hospices and one palliative care center in Japan. By the end of 2004 there were 131 government-approved hospice and palliative care units with 2449 beds. However, despite this rapid development, it is estimated that only 4.4 percent of cancer deaths occur in palliative care settings (inpatient or at home). In 2000 only 2.3 percent of patients being cared for by palliative care services died at home.[4] Patients are often not told the diagnosis or prognosis, hospice home care services are not well developed, and reimbursement for medical expenses is less for care at home than for care in a hospital.

Several organizations support hospice programs in Japan. The Japanese Association of Hospice and Palliative Care Units (now Hospice Palliative Care Japan) was registered in 1991, the Japan Society for Palliative Medicine in 1996, and more recently the Japan Hospice Palliative Care Foundation was established in 2001. The Japan Society for Palliative Medicine now has over 1200 members. However, palliative medicine is not yet recognized as a specialized area of medicine. The Japanese Association for Clinical Research on Death and Dying has also played a key role in the spread of the hospice movement in Japan since 1977.

People's Republic of China

In the People's Republic of China there had been interest in hospices since 1987 when two nurses from Tianjin Cancer Institute and Hospital (TCIH) went to the Royal Marsden Hospital in London for training in oncology. On their return in 1989 a five-bed palliative care unit was opened at the TCIH. A National Hospice Society was formed in Tianjin in 1992.[5] In the same year the Ministry of Health proposed a program to improve cancer pain relief in China. This included changes in policy to increase analgesic availability and training for healthcare professionals.[6] This was followed by many training programs and seminars at local and national levels and hundreds of hospice and palliative care units were started in hospitals or by licensed private companies.[7]

In 2000 a national network of hospice home care programs was set up by the Li Ka Shing Foundation, which is based in Hong Kong. Following the success of a pilot project in Shantou in Guangdong, the Foundation has been providing funding for hospice home care programs in 20 major hospitals in 16 provinces throughout China.

Hong Kong

In Hong Kong the first palliative care team was formed in 1982 in Our Lady of Maryknoll Hospital. Subsequently, in response to the perceived need for better care for terminally ill patients, the Society for the Promotion of Hospice Care was established in 1986. Six years later the Society secured funding to open Bradbury Hospice, a 26-bed independent inpatient hospice in Shatin. The Hospital Authority of Hong Kong took over management of five hospice units in 1991, established six more in the next 3 years and took over Bradbury Hospice in 1995. This recognition of the role of the hospice in healthcare was a key milestone in the development of hospices in Hong Kong.

There are now 11 palliative care services in Hong Kong under the Hospital Authority. All except Bradbury Hospice are located in hospitals. In 2003 restructuring of healthcare services into clusters resulted in the closure of Nam Long Hospital, a 200-bed inpatient unit. Palliative care services from Nam Long Hospital were then transferred to Grantham Hospital. Efforts are now being made to form consultative teams in general hospitals, to enhance liaison with nursing homes, and to encourage home care services.[8]

The Society for the Promotion of Hospice Care continues to play a major role in promoting public education and providing specialized professional training. The Jessie and Thomas Tam Centre, opened by the Society in 1997 as a bereavement counseling, and education and resource center, has been one of the major projects of the Society.

Professional organizations have been important in the development of palliative medicine in Hong Kong. Palliative medicine achieved specialty status under the Hong Kong College of Physicians in 1998. This was largely due to the efforts of the Hong Kong Society of Palliative Medicine, now the academic body of palliative medicine specialists. Since 1997 the Hong Kong Hospice Nurses' Association has also been active in training and research.

Taiwan

The concept of palliative care first began to attract interest in Taiwan in 1983 when Chantal Co-Shi Chao returned from a nurse PhD program in USA and organized a volunteer hospice home care program in Taipei. However, it was not until 1990 that the first inpatient hospice ward was opened by Dr David Chang and Dr Enoch Lai in Mackay Memorial Hospital. By 2000 this had evolved into a custom-built palliative care center with 63 beds, administrative offices, education facilities, and accommodation for students and faculty.

The Taiwan government became involved in palliative care in 1995 and this led to the setting of standards for inpatient and home care, and the development of guidelines for pain control. National Health Insurance reimbursement was introduced in 2000 for services accredited by the Taiwan Academy of Hospice Palliative Medicine and the Department of Health. This had been preceded earlier that year by the passage of legislation 'The Hospice Palliative Medical Act' which established the patient's right to sign a 'do not resuscitate' order, to choose palliative care, and to designate power of attorney for healthcare. The Act was amended in 2002 to allow for the withdrawal of life-sustaining devices for terminally ill patients.

Three foundations with religious affiliation have been important for the development of palliative care in Taiwan: the Hospice Foundation of Taiwan (established in 1990), the Catholic Sanapax Medical-Social Service Foundation (1993), and the Buddhist Lotus Hospice Care Foundation (1994). The Taiwan Hospice Organization has also been a unifying body for hospice volunteers and profession staff since 1995.

From 1990 the Hospice Foundation of Taiwan has been providing education and training. A multidisciplinary program was started in 1993 and revised in 1999. By 2003 a total of 1767 healthcare professionals had registered for the three-level program. The Taiwan Academy of Hospice Palliative Medicine was established in 1999 and in 2001 palliative medicine was accepted as a medical sub-specialty. By 2003, 172 physicians had been certified as palliative medicine specialists and 14 palliative care units had qualified as teaching units for the residency program. The majority of palliative care physicians have prior certification in family medicine.

By 2004 there were 29 hospice inpatient units with a total of 448 beds. However, it is estimated that less than 20 percent of cancer deaths receive palliative care. The National Cancer Control Program launched in 2003 has included the expansion of palliative care in its 5-year plan. The goal is to increase the coverage of terminally ill cancer patients to 50 percent and to improve the care of patients in nonhospice wards by introducing the concept of shared care.

Mongolia

Development in Mongolia has been more recent. A 10-bed palliative care unit was opened in the National Cancer Centre in 2000 with support from the Soros Foundation. In 2002 the Palliative Care Association of Mongolia was formed with 16 members. By 2005 there were two inpatient units with a total of 20 beds and two home care programs in Ulaan Bataar, all medical schools had teaching in palliative care and palliative medicine had been accepted as a medical specialty.[9]

SOUTHEAST ASIA

Singapore

Singapore has the most comprehensive palliative care services in Southeast Asia. However, early development was hampered by fears that hospices would be death houses like those that – until the 1980s – had sheltered the destitute dying in the back streets of Chinatown. The first 16 hospice beds were set aside in 1985 by the Canossian Sisters at St Joseph's Home. Subsequently, a volunteer hospice group under the Singapore Cancer Centre began providing home care in 1987.[10] In 1988 the Franciscan Missionaries of the Divine Motherhood at Assisi Home allocated 12 beds for hospice care and 4 years later the convent was remodeled to provide 35 beds.

In 1989 the first International Asia Pacific Hospice Conference with 250 participants from 10 countries was a major impetus for hospice development in Singapore and the region. This was followed later that year by the registration of the Hospice Care Association as an independent charity. This organization became the major provider of hospice home care in Singapore. An independent 40-bed inpatient hospice, Dover Park Hospice, was opened in 1995 in a custom-built facility shared with the Hospice Care Association.

When the Singapore Hospice Council was registered in 1995 as the umbrella body for hospice charities it took over public and professional education as well as advocacy with government. It also organized the second International Asia Pacific Hospice Conference in 1996 with Dame Cicely Saunders as keynote speaker and 550 participants from 22 countries.

Partial government funding was provided for hospice inpatient care from 1994 and for home care from 1996. In 2002 the policy was revised and funding is now provided only after means testing of the patient and family. In 2004 community hospice service providers received 2802 new referrals. This represents 74.9 percent of cancer deaths and 19.4 percent of total deaths.[11]

The establishment of a department of palliative medicine at the new National Cancer Centre in 1999 marked another milestone in hospice development in Singapore. This department provides consultancy and outpatient clinics for Singapore General Hospital and Kandang Kerbau Women's and Children's Hospital, as well as the National

Cancer Centre. Since 2002 all medical students from the National University of Singapore have had a 1-day palliative care posting. The Nanyang Polytechnic took the first students for the 1-year Advanced Diploma of Health Sciences (Palliative Care) in 2004.

There are now four inpatient hospices with 125 beds, five home care services, two hospice day care centers and four major hospitals with consultative teams. However, despite the success of the programs it is difficult to recruit medical staff. Efforts are being made to have palliative medicine recognized as a specialty so that there is an accredited training pathway for physicians who are interested in palliative care.

Malaysia

In Malaysia palliative care has developed along two streams: hospice home care provided by non-profit charity organizations and hospital-based palliative care units. In late 1991 home care programs were started by Hospis Malaysia in Kuala Lumpur and by Dato' John Cardosa and Dato' Dr T Devaraj of the National Cancer Society of Malaysia, Penang Branch, the organization that hosted the first hospice conference in Penang in 1993.[12]

The establishment of the palliative care unit at Queen Elizabeth II Hospital in Kota Kinabalu, Sabah, in 1995 was a landmark for hospice development in Malaysia. This unit, set up by Dr Ranjit Mathew Oommen, a surgeon at that hospital, initially had four beds but later expanded to 10 beds. A volunteer group (the Palliative Care Association of Kota Kinabalu) was formed to support patients who were discharged from the unit. This close association between the government hospital and the nongovernment organization providing home care in the community was seen by the Malaysian government as a suitable model for palliative care in Malaysia, and in 1997 the Department of Health announced that by 2000 all government hospitals were to have either a palliative care unit of at least six beds or a palliative care team.

By 2001 there were 11 palliative care units and 49 palliative care teams in government hospitals. In 2004, 20 organizations were providing hospice home care and there were two independent inpatient hospices that had opened in Penang in 2001, each with eight beds. However, despite this development, it is estimated that there is only about 20 percent coverage of cancer deaths and few patients with non-cancer diagnoses are referred for palliative care. In many hospitals the medical care in palliative care units is assigned to junior staff who have no formal training in palliative care and little interest in this area of medicine. Most palliative care services are in urban areas and, although attempts are being made to introduce the principles of palliative care to rural health workers, there is still an unmet need in rural areas.

The Malaysian Hospice Council was set up as the coordinating body for hospice nongovernment organizations in 1998. An annual congress hosted by a different state each year has provided a forum for education and networking. Although some physicians have undertaken distance-learning diploma courses from universities in Australia and UK, these are not recognized by the Medical Board as a specialist qualification. However, in February 2005, the Ministry of Health announced that an accredited training program for palliative medicine would be established.

The Philippines, Indonesia, Thailand, Vietnam, and Myanmar

In other countries in Southeast Asia development has been more sporadic. In the Philippines palliative care was integrated into the Family Health Care Program at Philippine General Hospital in 1989, and in 1991 the Philippine Cancer Society began a hospice home care program. The first National Convention on Hospice Palliative Care was held in Manila in 1995 with Dr Josephina Magno as guest speaker.

There are currently 16 organizations providing palliative care, mainly in or near Manila. These are mostly volunteer-run programs funded by charity. Apart from the Fellowship program at the Philippine General Hospital there are few training programs and palliative medicine is not recognized as a medical specialty. The formation of the National Hospice Palliative Care Council of the Philippines in 2004 is seen as an important step toward better coordination of services and advocacy of palliative care in the Philippines.

In Indonesia palliative care services have been established in Surabaya and in Jakarta since 1992. There are currently six centers providing palliative care: two in Jakarta, one in Surabaya, one in Denpasar, Bali, one in Yogyakarta and one in Makassar, South Sulawesi. These are hospital-based consultancy services with outpatient clinics and home care outreach. However, coverage is poor and accessibility to opioids outside the hospitals continues to be a problem. The Indonesian Palliative Society established in 2000 continues to hold a yearly meeting.

In Thailand, in 1996, a home care program was set up as a demonstration model in the National Cancer Institute in Bangkok, and in 1998 a 16-bed hospice was opened at the Mahavajiralongkorn Cancer Centre in Thanyaburi under the direction of Dr Tanadej Sinthusake. The first palliative care conference was held in 2004 in Hatyai where a consultative team had been operating in the Songklanagarind Hospital from 1999 and where palliative medicine was introduced into the undergraduate curriculum at the Prince of Songkla University Medical Faculty in 2001. A national professional hospice organization was formed in early 2005.

In Vietnam, since 1996 funding has been provided by Ms Elaine Magruder from Volunteers International, an American-based organization, for professional education in Ho Chi Minh City, Hanoi, and Hue, and for doctors and nurses to visit palliative care programs in Australia and USA. Other courses have been provided by experts from Australia, USA, and Singapore. At present there are three palliative care

units in Vietnam: one in Cho Ray Hospital in Ho Chi Minh City (25 beds established in 2003), one in the Hue General Hospital in Central Vietnam (10 beds established in 2001), and one in the National Cancer Institute in Hanoi (40 beds established in 2000). Since 2005, a 3-year Train-the-Trainers project for doctors and nurses in Ho Chi Minh City, Hue, and Hanoi is being funded by the Singapore International Foundation.

In Myanmar two 40-bed independent inpatient hospices have been established by a private charity, the U Hla Tun Hospice (Cancer) Foundation, one in Yangon and one in Mandalay. Another is to be built in Taunggyi. However, there has been no further development of home care or hospital consultancy. Oral morphine is not available in Myanmar.

SOUTH ASIA

The first Indian hospice, Shanti Avadna, opened in Mumbai in 1986. Subsequently, other independent hospices were built and some hospitals established pain clinics and home care services. However, the development in South Asia has been largely centered in the southern Indian state of Kerala where 64 of the known 87 palliative care services in India are to be found.[13]

Dr M R Rajapopal, Dr Suresh Kumar, and others have attempted to develop a model of care adapted to the Indian situation where most patients are in late stage of disease when diagnosed, where there is shortage of resources, and where patients prefer to be cared for at home. In 1986 a pain and palliative care clinic was started in the Regional Cancer Centre in Trivandrum, Kerala. This was followed in 1993 by the registration of a nongovernment organization, the Pain and Palliative Care Society and the opening of a Pain and Palliative Care Clinic at the Calicut Medical College. The focus was on outpatient management of pain using trained volunteers for nursing and administrative duties, empowering families to provide care at home, and development of a network of clinics funded by the local community.[14]

The Pain and Palliative Care Clinic was declared a World Health Organization demonstration project in 1996 and became a major teaching resource for physicians in India and nearby countries including Nepal. In 2003 this function was taken over by the Institute of Palliative Medicine opened in Calicut (now Kozhikode) with accommodation for students and faculty as well as an inpatient facility with 40 beds. A 6-week intensive Basic Certificate Course in Palliative Medicine is recognized by the Edith Cowan University in Australia and students who compete the certificate course are eligible for three of the six study units of the postgraduate diploma offered by the University. In 2004 the Institute of Palliative Medicine launched a 1-year post-graduate fellowship program in palliative medicine. The AIIMS Hospital in Cochin now offers a 2-year diploma in pain and palliative medicine as well as a 6-week certificate course. The Indian

Association of Palliative Care, established in 1994, holds a conference in a different state each year.

FUTURE ISSUES

In Asia two issues continue to cause concern: the resistance to the use of opioids for symptom management and the reluctance to disclose diagnosis and prognosis to the patient. Only in Hong Kong, Taiwan, Japan, Singapore, the Philippines, Malaysia and in some states of India is oral morphine readily available for pain management. Barriers at every level limit access to cheap oral opioids and, even when available, doctors are disinclined to prescribe and families are reluctant to take the medication because of fear of addiction or toxic side effects.[15] Much public and professional education is needed before better pain management can be achieved.

In many countries in East and Southeast Asia, families are often unwilling to inform patients of a cancer diagnosis or of a poor prognosis. Doctors follow the wishes of the family even when the patient is asking for more information.[16,17] Reasons given are that the patient will not understand the information or will become depressed after disclosure.[18] This issue of truth telling creates conflict for professional caregivers, especially when there is need to obtain informed consent for investigative or treatment interventions.

The Asia Pacific Hospice Palliative Care Network (APHN) was established in 2001 to promote networking among those involved in palliative care in the region. By the fifth annual general meeting in 2005 the APHN had recruited 831 members from 26 countries (697 individual members and 134 organizational members). A visiting faculty scheme encourages experts from more developed countries to visit countries where services are being established and a directory of palliative care organizations in the region is published every 2 years with an updated copy on the APHN website (www.aphn.org).[19] The concept of APHN as a regional organization grew out of discussions during the first Asia Pacific Hospice Conference in Singapore in 1989 and the APHN is now having an increasing role in the conferences that are held biennially. The seventh conference will be held in Manila in 2007.

Even though the need for palliative care is becoming more widely accepted both by the public and healthcare professionals, there is still great variation in the quality of services and the coverage of patients in need. The lack of manpower and funding continues to limit the scope of services in many countries. Only in Hong Kong, Taiwan, Mongolia, and Malaysia has palliative medicine been accepted as a medical specialty. Underlying the struggle to have palliative medicine acknowledged as an accredited specialist field is the recognition that only when there is a trained workforce and a clear career path will it be possible to provide services for the growing numbers of patients with end-stage disease.

Professional education in palliative care is still sporadic and relies heavily on overseas faculty and distance-learning courses from UK and Australia. Little research has been published in English language journals apart from the work of Cecilia Lai-Wan Chan and her colleagues at the Hong Kong University. The extent of relevant research in non-English speaking countries such as Japan, Taiwan, and Korea is not known.

Key learning points

- The hospice concept was first introduced into Korea in 1965 and into Japan in 1973.

- National hospice and palliative care organizations have played an important role in the development of palliative care in Asia.

- Continuing resistance by patients, families and healthcare professionals to the use of opioids for symptom management contributes to the nonavailability of oral morphine in many countries.

- Reluctance by families to disclose diagnosis and prognosis to patients creates conflict for professional caregivers.

- Recruitment of medical staff is hindered by the lack of a clear career path with specialist accreditation.

Palliative care versus palliative medicine

EDUARDO BRUERA, ELLEN A PACE

INTRODUCTION

The development of palliative medicine in different regions of the world has been discussed in Chapters 1–7 of this book. In Chapter 1 David Clark discusses the origins of the modern hospice movement in the UK, and the other chapters discuss the progressive integration of these principles to other areas of the world.

Palliative care programs have three distinct characteristics:

- *Multidimensional assessment and management*. This includes the assessment and management of a large number of physical symptoms, psychosocial distress, and functional, spiritual, financial, and family concerns.
- *Interdisciplinary care*. This includes the pivotal role of a team including physicians, nurses, social workers, pastoral care, occupational therapy and physiotherapy, pharmacists, counselors, dieticians, and volunteers who work together in an integrated fashion for the delivery of care.
- *Emphasis on caring for patients and their families*. In the first palliative care programs it was realized that the majority of physical and emotional care near the end of life is provided by the patient's family. Thus programs were developed that aimed to support those families with counseling, education, respite, and bereavement care.

Physicians have had a major role in the development of palliative care programs in the UK and other areas of the world. They came from multiple specialties including family medicine, oncology, pain medicine, surgery, neurology, psychiatry, and geriatrics. These physicians integrated with the other medical disciplines to establish palliative care teams in programs that were mostly based in the community.

During the first two decades of the development of palliative care there was an impressive and global expansion of clinical programs. It soon became clear that some of the most seriously ill patients died in acute care hospitals and cancer centers, and palliative care programs progressively expanded from the periphery into major academic centers. The body of knowledge of palliative care started to progressively develop and the need for research became apparent. The growth in clinical programs, the variety of settings where palliative care was delivered, and the expanding body of knowledge and need for research led a number of physicians in the UK, Australia, and Canada to advocate for the development of the specialty of palliative medicine.

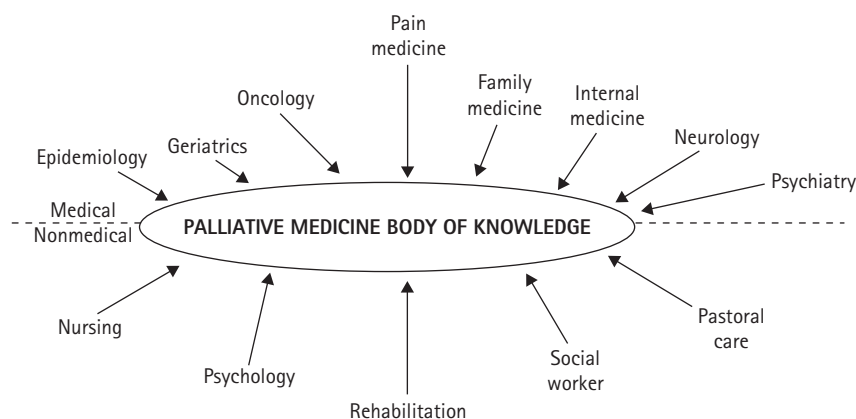
THE EMERGING MEDICAL SPECIALTY

During the late 1980s and early 1990s there was a strong debate regarding the potential advantages and disadvantages of palliative medicine as a specialty. In many countries around the world this debate continues. Box 8.1 summarizes some of the arguments for and against the development of

> **Box 8.1 Perceived advantages and disadvantages of palliative medicine specialists**
>
> **Perceived advantages**
>
> - Access to specialist training
> - Development of a career path
> - Protected time for academic orientation
> - Increased credibility among other medical professionals
> - Access to acute care hospitals, cancer centers, and universities

a palliative medicine specialty.[1–3] At the present time palliative medicine has achieved specialty or subspecialty status in the UK, Canada, and Australia. In addition, there are active efforts to establish palliative medicine as a subspecialty in the USA, many European countries, and a number of countries in Latin America and Asia.

The original heated debate that accompanied the establishment of palliative medicine as a specialty in the UK in 1987 has continued in all other countries where the effort has been made to develop this specialty. Most of the debate has been centered around how to maintain the three main principles of palliative care delivery and how to avoid excessive medicalization of palliative care, but at the same time being able to make a major contribution to the body of knowledge by appropriate research and contributing to the education of future generations of physicians and other healthcare professionals.

The only nation where the specialty of palliative medicine has existed long enough to allow for some evaluation of its impact is the UK. David Clark, in Chapter 1, eloquently summarizes the current debate and also the major growth in the medical components of palliative care including education and research, which have resulted from the emergence of palliative medicine in the UK. The consensus among physician groups in most of the world is that the development of the specialty of palliative medicine is of great importance for the further development of the field, particularly in acute care institutions and universities.


THE ROLE OF PALLIATIVE MEDICINE

Figure 8.1 illustrates the main disciplines involved in the palliative circle of care. Each of these disciplines is responsible for developing its own body of knowledge and for contributing to the integration of this body of knowledge with that of the other disciplines within the circle. The effective growth of each of these disciplines and the successful interaction results in the collective body of knowledge of palliative care being increased, that is then provided to patients and families. In this theoretical model palliative medicine is the medical component of the multidimensional and interdisciplinary domain known as palliative care.

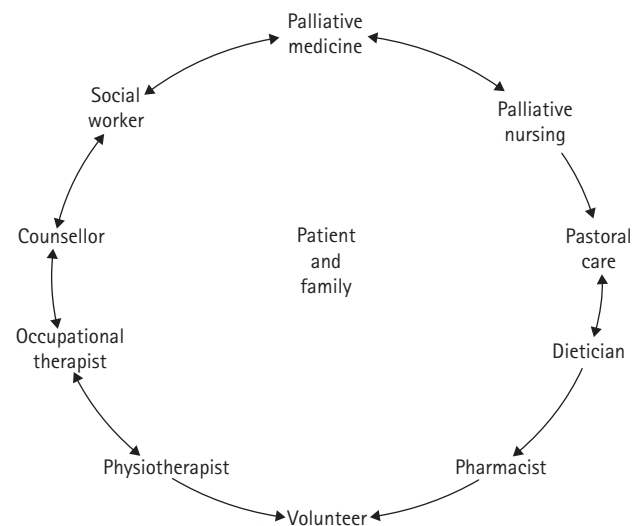
Figure 8.2 summarizes some of the most important contributors to the body of knowledge of palliative medicine. These contributors have not only included subspecialties of medicine but a large contribution to the palliative medicine knowledge has also been made by disciplines such as nursing, rehabilitation, psychology, social work, pastoral care, and nutrition. It is desirable to have representatives of these disciplines as part of the research and education in palliative


Figure 8.1 *The palliative circle of care.*

Figure 8.2 *The main medical and nonmedical disciplines that have influenced the body of knowledge in palliative medicine.*

care. It is likely that with the regular interaction as part of the palliative care circle these disciplines will continue to influence the growth of palliative medicine in the future.

Box 8.2 summarizes the role of palliative medicine specialists in the areas of clinical, educational, and research palliative care delivery. Palliative medicine specialists are not necessarily expected to see all patients with progressive, incurable diseases or their families. In most cases the physician in charge of the primary care of the patient, either their family physician (such as in Canada, the UK, Australia[4]) or their primary specialist (such as in USA,[5,6] most of continental Europe, and the developing world[7,8]) can deliver the principles of palliative care assessment and management. These primary care physicians can access a number of other palliative care disciplines for the patient including nursing, social work, pastoral care, counseling, rehabilitation, or volunteer services.

When patients present with physical or psychosocial distress that can not be appropriately controlled by their primary care physician, the palliative medicine specialist can be involved in secondary care. They can provide episodic care, such as consultations or collaborative care by following up with the patient in an integrated manner with the primary physician.[9,10] The palliative medicine specialist will then be able to access all other members of the palliative care team as required.

Box 8.2 The roles of the palliative medicine specialist (PMS)

Clinical

- Primary palliative care: by family physicians and primary specialists
- Secondary palliative care: PMS – episodic care (consultation)
- Collaborative care (joint follow-up)
- Tertiary palliative care: PMS – primary care (palliative care unit)

Education

- Undergraduate and postgraduate training of other physicians
- Palliative medicine specialty training
- Continuing medical education

Research

- Development of new assessment and management interventions
- Audit
- Epidemiological research
- Translational research

A small percentage of patients are severely distressed, and this requires that the palliative medicine specialist becomes the primary care physician. This will take place both in the ambulatory care setting and particularly in palliative care units.[11–13] In many cases the most important contribution of the palliative medicine specialist is to provide the sophisticated assessment and correct management plan that will help the team develop the most effective interventions.

These different levels of delivery of palliative care by palliative medicine specialists are not different from the role of other medical specialists in the management of different diseases. For example, it would not be reasonable to expect that cardiologists should be in charge of delivering primary care of all patients with arterial hypertension or that endocrinologists should be in charge of the primary care of all patients with type 2 diabetes. In most countries in the world their own primary care physician provides the majority of care for these patients. However, the specialist is available for consultation for a major proportion of these patients and for primary delivery of care in the most refractory situations.

The degree of use of the palliative medicine specialist as a consultant will be linked to the level of expertise of the primary physician. Some primary physicians will have acquired enough education and experience in palliative care to be able to resolve a large proportion of clinical problems whereas others will have a much lower threshold for consultation. The best monitoring for the appropriate utilization of palliative medicine specialty services will be the level of physical and psychosocial distress in patients and families in each institution and/or region.

Palliative medicine specialists are extremely important for undergraduate and postgraduate education.[14–17] They are also responsible for the continuing medical education of those primary care physicians already working in the community. The adoption of new assessments, pharmacological and nonpharmacological interventions by primary care physicians will heavily depend on the clinical and educational leadership of palliative medicine specialists in every community. Physicians adopt new diagnostic tests, medications, and procedures mostly as a result of the clinical leadership and education of those who have specialized in these specific areas of knowledge.[18]

Finally, palliative medicine specialists are responsible for the development of the body of knowledge that will result in changes in the assessment and treatment of patients and families. Although most physicians will use analgesics, antiemetics, and drugs for the management of delirium on a regular basis, there is a huge need for a small number of specialists with great dedication to the discovery of new assessments and treatments for pain, emesis, and delirium in palliative care. Individuals who are fully focused on palliative care research will ensure that there is progress in this field.

In summary, palliative medicine specialists are able to deliver clinical care to those patients and families with the most difficult problems, to educate colleagues about the appropriate delivery of palliative care, and to actively conduct

research on new developments in assessment and management of clinical problems. Ideally, a significant proportion of palliative medicine specialists should operate within academically organized departments in medical schools. Such departments already exist in a number of universities in the UK, North America, and Europe. The university affiliation will allow palliative medicine specialists to have the necessary protected time for conducting academic activities, the possibility to influence the development of undergraduate and postgraduate curriculum, and the possibility to establish research teams by interacting with experts in methodology, content, and biostatistics affiliated with different universities.

CONCLUSIONS

Since the establishment of the specialty of palliative medicine in the UK in 1987 similar efforts have been made in a number of countries. Palliative medicine specialists have been instrumental in the development of scientific organizations and meetings, peer-reviewed journals, textbooks, and in the development of a curriculum for the undergraduate and postgraduate teaching of palliative medicine for physicians. These specialists have also linked with other healthcare professionals and volunteers to maintain the multidimensional and interdisciplinary nature of palliative care.

The nature and content of the teaching curriculum, the financial viability of the different palliative specialist positions in different countries, and the overall body of knowledge are not completely defined for this young medical specialty. As palliative medicine is progressively adopted by acute care facilities and academic institutions the need for palliative medicine specialist is likely to grow exponentially during the next decade in most of the world.

Key learning points

- Palliative care programs have three main characteristics: multidimensional assessment and management, interdisciplinary care, and emphasis on the patient and their families.

- Palliative medicine was initially established as a specialty in the UK in 1987.

- Palliative medicine specialists integrate with multiple other disciplines in the delivery of palliative care.

- Palliative medicine specialists provide clinical care in the most complex situations, graduate and postgraduate education, and research.

Palliative care as a public health issue

JOSEPH F O'NEILL, R CAMERON WOLF

INTRODUCTION

Palliative care is an important public health issue that has been markedly shaped over the past 20 years by the changes in society, especially the acquired immune deficiency syndrome (AIDS) pandemic and aging in many countries. With the emergence of human immunodeficiency virus (HIV)/AIDS, and the ever-increasing need to mobilize communities, adopt prevention measures, and increase access to services, an integrated public health model that spans the continuum of the illness and addresses not only clinical, but also material, psychosocial, and spiritual needs of the patient is needed. The discipline of palliative care offers, in addition to addressing pain and suffering and improving quality of life, an important means of meeting this need.

WHAT IS A PUBLIC HEALTH ISSUE?

The European Observatory on Health Systems and Policies defines public health as 'the science and art of promoting health, prevention disease, and prolonging life through organized efforts of society'.[1] The US Institute of Medicine further defines the role of public health as:[2]

> what we as a society do collectively to assure the conditions in which people can be healthy. This requires that continuing and emerging threats to the health of the public be successfully countered. These threats include immediate crises, such as the AIDS epidemic, enduring problems, such as

injuries and chronic illness, and growing challenges, such as the aging of our population. . . . These and many other problems raise in common the need to protect the nation's health through effective, organized, and sustained efforts led by the public sector.

In a broader vein, the Public Health in the Americas Initiative, sponsored by the World Health Organization (WHO), the Pan American Health Organization, and others defines public health as:[3a]

> a collective action of State and Civil Society to protect and improve the health of individuals. It is a notion that goes beyond population or community-based interventions and includes the responsibility of ensuring access by citizens to quality health care. It does not approach public health as an academic discipline but rather as an interdisciplinary social practice.

These and other definitions recognize that public health is targeted at communities and accomplished through social and political action, which distinguishes the field from, for example, clinical care where the target of activity is the individual patient or family. Public health actions have included the establishment of municipal health authorities, sanitation departments, new healthcare practices, community and professional education, research, reform of public laws impacting on health, and many other societal interventions.

The definition of what constitutes a public health issue has evolved with time. In its earliest Western incarnation after John Snow closed the famous London water pump and ended a cholera outbreak, public health's purview did not

extend much beyond what is now considered basic infectious disease epidemiology. As, however, understanding of the determinants of health have become more sophisticated so has the perspective of public health practice. Disciplines of sociology, economics, psychology, nutrition, anthropology, and others are now considered by many to be important in understanding the health of individuals and, hence, populations and societies. The Acheson report commissioned by the UK Minister of Public Health to review and summarize health inequalities and to recommend priority areas for policy development and interventions to reduce them, noted that their work was based on a 'socioeconomic model of health' that recognized that the main determinants of health could be described as layers of environmental and social influence over the fixed individual constitutional factors.[3b] Similarly, the US Institute of Medicine in its seminal report on the future of public health defined health as a 'public good' because 'many aspects of human potential such as employment, social relationships, and political participation are contingent upon it.'[4] One area of action identified by this report was to adopt a population health approach that considers multiple determinants of health.

PALLIATIVE CARE AS A PUBLIC HEALTH ISSUE

As a health issue that significantly impacts a large number of people, that is amenable to population-based and public sector interventions, and that has the potential to reduce suffering on a massive scale, end-of-life care is an important public health issue. The discipline of palliative care, with its understanding of the interrelationships between physical, spiritual, emotional, and practical domains of human existence and suffering, fits quite comfortably into an approach to population health that recognizes multiple determinants of health and enduring health problems. It has made this philosophy the cornerstone of clinical practice for decades.

Palliative care encompasses, but extends far beyond, end-of-life care. The WHO has defined palliative care as:[5]

> an approach which improves quality of life of patients and their families facing life-threatening illness through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychological and spiritual.

A palliative approach then should be applied along all stages of serious illness regardless of the immediacy of death. To do otherwise can rightly be considered a failure to provide quality care. In this light, the public health mandate of palliative care becomes even larger and more complex: The target for palliative interventions is not just the result of a calculation based on incidence of death but, rather, on prevalence of life-threatening and serious disease in a defined population or geographical area.

PALLIATIVE CARE IN THE DEVELOPED VERSUS THE DEVELOPING REGIONS OF THE WORLD

Global trends

Between 2002 and 2050 the world's population is expected to grow from 6.4 billion to 8.9 billion and the 50 poorest countries will triple in size.[6] By 2050, however, the population of the developed world will have been in decline for 20 years.[7] Therefore, all of the world population increase will be in the developing world. The WHO estimates that there were 57 million deaths in 2002,[8] 85 percent of which occurred in the developing world. Assuming that each death affects five other people, end-of-life issues are estimated to affect about 5 percent of the world's population each year.[9]

The world's aging population brings palliative care to the forefront in disease management. Today, the world's population of those who are 60 years and above is 600 million, and by 2050 this number will reach 2 billion. Eighty percent of these people will be living in the developing world.[10] Aging is associated with increased incidence of chronic noncommunicable diseases including cancer, cardiovascular disease, and other conditions.[11] As recent guidance from the WHO demonstrates,[11,12] increased longevity in many countries brings with it an increase in chronic diseases as a cause of death and older people who can have complex, multiple conditions. It can be difficult to diagnose with certainty any one disease as the main cause of death, as many older people have several conditions together that might all contribute to death and to symptoms. Indeed, it is estimated that 22.4 million people are living with cancer today and that 12.6 percent of all deaths are caused by cancer.[13] There is evidence in some countries that access to palliative and hospice care is less among older people than their younger counterparts.[11] This is another example of where palliative care is a public health issue, which is concerned with ensuring access to care according to need.

An important global trend that has affected the need for palliative care is the HIV/AIDS pandemic. Some 38 million are people now living with HIV/AIDS, 2.1 million of whom are children under the age of 15 years. In 2003 there were 4.8 million new infections and 2.9 million AIDS deaths, of which 490 000 were of children. In total, the epidemic has claimed 23 million lives and is expected to take an additional 22 million by the end of the first decade of the twenty-first century.[14]

Global inequities

The burden of illness requiring palliative care is disproportionately borne by the developing world – regions least able to mount an effective response. Only 1.6 million of the 38 million estimated to be living with HIV today live in high-income countries. Approximately 10 percent of the world's population lives in sub-Saharan Africa, a region that

is home to nearly two-thirds of all persons living with HIV. Explosive trends in HIV prevalence are expected in China, India, and Russia.[15] The US National Intelligence Council has projected that China will have 10–15 million cases of AIDS and India 20–25 million cases by 2010.[16]

Similarly, more than half the world's cancer burden (numbers of cases and deaths) is now borne by the developing world.[17] The 2003 World Cancer Report[13] further documents that:

- In wealthy countries, approximately 50 percent of patients with diagnosed cancer die compared with 80 percent of patients in the developing world.
- More than 80 percent of deaths from cervical cancer occur in developing countries.
- The occurrence of breast cancer in developed countries is >300/100 000 population per year compared to <1500/100 000 in developing countries.
- In wealthy countries chronic infections (such as hepatitis B and C, human papilloma virus, and *Helicobacter pylori* infections) are implicated in 8 percent of all malignancies compared with 23 percent in the developing world.
- Tobacco use remains a global concern and if current rates of use persist will cause 10 million deaths a year by 2005.[18] Moreover, in both developing and developed countries it is the poorest people who tend to smoke the most, and who bear most of the disease burden.[19]

Countries that shoulder the bulk of the world's disease burden and that have the greatest need for palliative care services are fiscally the least well equipped to act to provide it. The World Bank estimates that in 2001, 1.1 billion people consumed less than US$1 per day and 2.7 billion people less than US$2 per day.[20] Variation in spending on health between the developed and developing regions of the world is dramatic: an analysis of 1998 expenditures showed that Africa spent an estimated US$82 per capita per year on health (5.1 percent gross domestic product [GDP]); South Asia spent US$92 per capita per year (4.4 percent GDP) and the Organization for Economic Co-operation

and Development (OECD) countries expended US$2078 per capita per year (9.7 percent GDP).[16]

Only 58 percent of sub-Saharan Africans have access to clean water and 42 percent of the world's population do not have their basic sanitation needs met.[21] Hunger and malnutrition remain the number one risk to global health.[22] It is estimated that there are 800 million undernourished people in the world, that one out of four children are underweight and that, in 2002, 6 million children died from nutritional deficiencies.[19]

The implications of these global inequities are profound. Poverty correlates with disease and disease causes poverty – a vicious cycle resulting in higher and higher levels of suffering and morbidity. Projections of the economic costs of infectious diseases in Africa, for example, have held that for some countries economic growth could be reduced by as much as 25 percent in 20 years.[23] At a time when more health resources are needed than ever before, economies stand in danger of contracting as a result of the deterioration of their population's health and hence will become even less able to respond.

Social and cultural trends

Under the best and most stable of circumstances provision of palliative care requires a wide range of human and fiscal resources. Trained medical professionals are necessary – so are informal caregivers, spiritual healers, families, good nutrition, clean environments, good communication systems, access to medications, transportation, shelter, and, perhaps most important of all, peaceful societies.

In the developed world where populations are aging and rates of fertility have decreased, the availability of caregivers and people who pay for care (generally through taxes or private insurance pools) will decrease relative to the numbers who need care (see Fig. 9.1).[11] In the USA, between August 1999 and September 2000, more than 54 million people – 27 percent of the adult population – served as informal caregivers for people with chronic illnesses or disabilities.[24] A study of the economics of informal caregiving in the USA in 1997 valued it at US$196 billion, an amount equivalent to
Figure 9.1   *The number of working-age people for every elderly person 1960–2020. Source:* Better Palliative Care for Older People.[11] *Redrawn with the permission of the editors. Original data from Anderson GF, Hussey PS.* Health and Population Aging: A Multinational Comparison. *New York: Commonwealth Fund, 1999.*

18 percent of total healthcare spending.[25] This relative level of support cannot be relied on to continue in the face of demographic shifts. The cost to society of supplanting these services will add to the already escalating demands on health resources.

In the developing regions of the world a variety of trends can be expected to impact on the ability to deliver palliative care. The impact of the HIV/AIDS epidemic on family, and hence social stability, is significant. Since 2000, 3.8 million African children have lost one or both parents to the epidemic and by 2010 sub-Saharan Africa will be home to an estimated 50 million such orphans. In 11 African countries, one in seven children are orphans. UNICEF estimates that there are 87.6 million orphans (from all causes) in Asia and 12.4 million in Latin America and the Caribbean.[26]

Social instability is exacerbated by trends in urbanization. Nearly 180 000 people are added to the world's cities each day and it is expected that 60 percent of the world's population will live in urban areas by 2030.[27] In addition, political instability and war in and of themselves cause suffering and hamper the ability of society to mobilize around human service needs such as palliative and end-of-life care. Largely as a result of war and instability there are now some 20.8 million refugees, asylum seekers, internally displaced persons and others of concern.[28] These populations are at high risk for disease, malnutrition, and death.

PALLIATIVE CARE AND THE AIDS EXPERIENCE

The concept of palliative care grew out of pain relief and comfort measures for cancer patients, wherein the traditional trajectory of illness was through a linear projection of diagnosis, growing severity of illness, and death. However, the AIDS epidemic has challenged traditional ideas of end-of-life care, as the trajectory of living and dying in this population has become highly variable and unpredictable. The introduction of antiretroviral drugs (ARVs) to combat HIV has resulted in a wide range of disease progressions, potential complications, and ultimately, survival. An individual's health may improve, then worsen, and then improve again before a terminal state of disease is reached. Some individuals may not respond to ARVs, others may be diagnosed late in the disease, and yet others may never have received treatment, especially those in resource-poor international settings. Therefore, the traditional trajectory of illness through a linear projection is not always an appropriate model for people with AIDS. Moreover, patients using ARVs may experience many other symptoms, including unpleasant side effects of treatment or opportunistic infections. As a result of the variable course of AIDS and its associated symptoms, palliative care in these patients becomes a balance between acute treatment and chronic symptoms and conditions.[29] For many, AIDS more closely resembles a chronic disease than a terminal illness.

Palliative care has been defined as:[30]

> patient- and family-centered care, which optimizes quality of life by active anticipation, prevention, and treatment of suffering. Respectful and trusting relationships are the foundation used by the interdisciplinary team throughout the continuum of illness to address physical, intellectual, emotional, social and spiritual needs and facilitate patient autonomy, access to information, and choice.

The term 'continuum of illness' is a critical part of this definition, and implores public health models to integrate palliative care into the continuum of prevention, diagnosis, and treatment of a disease. Providing palliative care within the continuum of illness has many implications, especially in resource-poor settings. Pain control and symptom management may be given along with curative therapy or when curative therapy is absent. Traditional medicines and spirituality can be, and often are, an important component of a palliative approach.

The burden of grief is compounded among people living with AIDS, families and communities that have experienced losses of many loved ones and, at times, stigma and discrimination from their neighbors.[31,32] This has led to community mobilization of support and advocacy groups. Critical to the definition of palliative care is the inclusion of addressing psychosocial needs in this population. Several factors are important in optimizing clinical outcomes in patients with AIDS. These factors include a wide range of hard-to-control socioeconomic as well as personal characteristics: an understanding of the disease process; empowerment in relation to personal health; a safe place to live; freedom from pain and distressing symptoms; adequate nutrition; treatment for substance abuse, depression, and other mental illness; hope; adequate help of friends, family, and other caregivers, especially when functional status is diminished and disease progression is ongoing. These challenges can be met successfully by using a palliative care framework to approach the patient, providers, caregivers, family, loved ones, and the healthcare system. Conversely, the benefits of community mobilization around palliative care can enhance public health by increasing access to health education, prevention, and care services.

A PUBLIC HEALTH APPROACH TO SUSTAINING PALLIATIVE CARE

In practical terms, a public health approach to making it possible for everyone who needs quality palliative care to receive it must involve a range of activities. The WHO has identified three elements as necessary to further sustainable palliative care:[33,34]

- governmental policy – establishing national policies, making sure that palliative care is harmonized with national health and social service agendas

- education – of health professionals, the public, and media, policy makers, and others
- ensuring access to pain medications.

A public health approach would additionally emphasize the important role of research, and development of a strong evidence base from which to build programs and policies. The responsibility for these activities will vary from society to society, but each in its own way is necessary. Political commitment is a prerequisite for effective action. This, in turn, depends upon community awareness and mobilization. In all cases sensitivity to various cultural perspectives and norms is essential.

Governmental policies: national strategies for palliative care

Government policies can obstruct, permit, or promote an environment that enables palliative care to flourish. Examples can be found of each approach. Relatively few governments have established national strategies promoting palliative care. An outstanding example of forward leaning policy can be found in Uganda. In its Health Sector Strategic Plan 2000/02–2004/05 the Ministry of Health has classified palliative care as 'essential'[35] and has identified indicators, verification measures, and operational activities needed to achieve the goal of increased access to palliative care. The government of Canada has moved in a similar direction by establishing a Secretariat on Palliative and End of Life Care. This group was established by the Canadian government as 'a first step toward creating a Canadian strategy for end-of-life care, including palliative care.'[36]

Strategies like those adopted by Uganda and envisioned by Canada are invaluable in that they provide national leadership, provide a focus for the various activities that comprise a public health response, and set goals and outcome measures for palliative care. Even in the absence of a formal national strategy, however, there is much that the public sector can accomplish. Although the US Public Health Service has not developed a domestic strategy for palliative care, for example, it has promulgated guidelines for pain management,[37] and has made palliative care a key element of its global HIV/AIDS strategy.[38]

A national palliative care strategy must be harmonized with other national health approaches. This is particularly important in relation to national AIDS and cancer programs and with initiatives supporting home- and community-based care. The Canadian Palliative Care Association has developed guidelines for developing palliative care standards[39] that can serve as guidance for the process of strategy development.

FINANCING AND REIMBURSEMENT

Adequate reimbursement for palliative care services is essential if access is to grow. Resources available for healthcare are limited even in the wealthiest societies – finding the appropriate mix of curative and palliative investments is an ongoing challenge for public health policy makers. There is a range of approaches to public financing of palliative care services. In the UK, for example, palliative care, including hospice care, is funded as part of the mix of health services supported by the National Health Service. In contrast, in the USA, public resources do not generally support palliative care apart from the Medicare Hospice Benefit – a mechanism that focuses on care for those who have been determined to have less than 6 months to live. This has had the effect of making integration of palliative care across earlier stages of illness difficult. In many parts of the world, palliative care is only made available through private charitable organizations or international donors.[40]

Although public support through strategic planning, financing, consumer protection, and quality assurance is critical to the expansion of quality palliative care, it is essential that government policies create an environment that allows private sector creativity, participation, and leadership in health policy and program development. Most advances in palliative care and the hospice movement, in the developed and developing world, have begun in nongovernmental organizations and the private sector. Important examples can be found at every point along the way from Dame Saunders' seminal work at St Christopher's Hospice in London in 1967 to the formation of the African Palliative Care Association in 2004.[41]

CONSUMER PROTECTION AND QUALITY ASSURANCE

Development of standards of care and exercise of oversight to ensure that they are met and applied equitably and consistently are important public health responsibilities. In some cases such oversight is conducted through governmental associations. For example, in the USA, the Medicare Hospice Benefit also requires hospices to conduct comprehensive assessments of the quality of care provided.[42] In Uganda, the Ministry of Health has established detailed specifications for implementing palliative care in the healthcare system.[43] Oversight is also conducted through private voluntary associations. For example, in the USA the National Hospice and Palliative Care Organization has developed standards of care for hospice programs that have been widely promulgated.[44] Similarly, the Canadian Hospice and Palliative Care Association developed standards of practice for hospice and palliative care to guide the development of national standards of care.[45] Accreditation programs exist in many countries and typically operate nationally. In the USA, these programs include the Joint Commission on Accreditation of Healthcare Organizations,[46,47] the Community Healthcare Accreditation Program,[48] and the Accreditation Commission for Health Care.[49]

Education

Educational efforts must be directed to the general public, media, policy makers, business leaders, and community leaders as well as to health professionals and others who come into contact with the sick. Public education is necessary to mobilize communities, prompt advocacy, offer hope, and make people aware that there are better ways to approach illness and death than is generally expected. In the USA an initiative supported by the Robert Woods Johnson Foundation, called 'Last Acts', has used various forms of media and outreach to focus on 'educating the lay public, informing medical and health care professionals and promoting social change and policy reform as a means for developing quality care for people nearing the end of life'.[50]

Although education has been a primary focus of the palliative care movement, there is much room for improvement. The need for palliative care education was probably most clearly demonstrated in a 1995 US study that found that over a 5-year period about half of 9105 terminally ill patients being cared for in teaching hospitals spent their dying days in moderate or severe pain.[51] Several studies since then have also documented the poor state of palliative care both in regard to inadequate management of pain or other symptoms[52,53] and in regard to inadequate palliative care education.[54–60] Fortunately, training in palliative care has been identified as a priority over the past decade, and there have been significant increases in the time devoted to palliative care in the basic training of doctors and nurses.[61,62]

Important professional training initiatives are underway in many parts of the world. These range from the creation of academic departments and funded faculty positions in palliative care through distance-based learning programs to practical hands-on training in clinical settings. There will always be a need for specialized palliative care training, but it is important that palliative care education becomes part of the fundamental educational package offered to aspiring health professionals as palliative care is a complementary, not an alternative, therapy. To this end, in 2000 the Liaison Committee on Medical Education, the accrediting board for medical schools in the USA, mandated that every school's curriculum was to include end-of-life care.[63] In an effort to increase the availability of palliative care to all patients with limited prognosis, an International Working Group convened by the European School of Oncology has promulgated the use of both specialized palliative care provided by trained palliative specialists and basic palliative care provided by all healthcare professionals.[64]

The WHO's 1990 report, *Cancer Pain Relief and Palliative Care*,[65] identified several areas that professional education should include: training on attitudes, beliefs and values conducive to a palliative care approach (including ethics, multidisciplinary approaches, personal attitudes toward death and illness, and multidimensional aspects of illness); knowledge base (communication skills, pathophysiology of common symptoms, assessment and management of pain and symptoms, psychological and spiritual needs and their treatment, family and caregiver issues, community resources, and bereavement); and skills (goal setting, care plan development, and monitoring of management).

Ensuring access to medications

Crucial to the successful implementation of an effective palliative care program is a national policy to ensure that drugs are available to care for patients requiring palliative care, especially those used for pain management. The WHO has developed a method of relieving cancer pain that is effective in about 90 percent of these patients.[60] The WHO also recommends this method for people with AIDS because no distinction is made between patients with cancer and patients with AIDS. The WHO guidelines incorporate a stepwise approach whereby the clinician is advised to match a patient's reported pain intensity with the potency of the analgesic to be prescribed (see Chapter 48). As pain increases from mild to moderate or severe, so the medication suggested increases from nonopioids with or with-out an adjuvant medication to opioids or stronger opioids, possibly with this adjuvant medication. Morphine is generally regarded as the gold standard analgesic to control pain that is greater than mild severity, but its availability is sometimes restricted, especially in developing parts of the world (see, for example, Chapters 4, 5 and 7).

The primary obstacles to the availability of these drugs are regulatory and policy obstacles and lack of infrastructure necessary to ensure that these drugs are not misused or diverted. Moreover, in many parts of the world, only doctors can prescribe these drugs. In areas where there are few doctors, access to pain medications becomes especially problematic. Therefore, in these areas, it is imperative that nurses and general practitioners be properly trained and enabled to prescribe opioids. Uganda provides a commendable example of a country that has overcome the obstacle of morphine prescribing only by physicians. Based on a law that allowed midwives to prescribe pethidine (meperidine) for labor, a statute was altered that allowed nurses who are qualified in palliative care to administer morphine. At least one palliative care nurse specialist, who has been trained for 9 months by Hospice Uganda, is planned to be available to prescribe morphine in each district and each district referral hospital.[66] The issue of diversion of these medications to the black market and their subsequent misuse must be taken seriously. Mechanisms to monitor these medications through enhanced drug logistics and supply systems is a critical public health function. Again, we have a synergistic effect of enhanced public health benefiting improved palliative care.

Research

Clearly, tracking the scope of pain and suffering should be a vital concern that benefits public health and the public good. There is a clear need to develop an evidence base for policy and programs. Documentation of chronic illness, pain and symptoms and their management through epidemiological and demographic and health surveys should be integral in both developed and developing countries. Research is needed to identify salient characteristics of successful palliative care programs. Studies must be performed that describe and analyze practice, policy, and advocacy to inform future developments and research for building programs that achieve the varied goals of palliative care, that is, achieving the best quality of life for patients and their families.

To minimize risk of failure, it is important that new or expanding palliative care projects in developing countries understand both the successes and failures of existing programs.[67] Several key issues have recently been identified as research topics for investigation, including: availability of pain relieving drugs, pain and symptom control, access to services, education and training, identification of relevant needs and determination of outcomes for care at the community level, and evaluation of the impact of education of policy makers and program directors about palliative care.[68] Given the magnitude of palliative care required by people living in developing regions of the world, programs must also consider coverage and not simply strive to provide high-quality care to a few patients.

ADDRESSING PALLIATIVE CARE THROUGH AN EXPANDING PUBLIC HEALTH PARADIGM

Public health focuses on health promotion and prevention of disease and has often seen pain and suffering as removed from the public health paradigm, to be addressed by tertiary care in a biomedical/clinical model. Although the WHO[69] and various scholars[70] have long argued a broadening of the concept of health to include how well people are able to perform their daily tasks, only recently has daily functioning begun to be included routinely in the assessment of people's health status through measures of health-related quality of life. Simple measures have been tested and adapted for use in resource-poor settings.[71–73] Investigators are going beyond the traditional paradigm that views health only in terms of adherence to or deviation from physical or biochemical markers. Instead, they are including in their assessment of health, people's own reports of their sense of wellbeing and their ability to perform valued social roles.[74,75] Therefore, pain and suffering should be measured through epidemiological and social science methods, as a critical health condition that should be tracked just as we track infectious diseases. By expanding the public health paradigm to include and promote palliative care, we further the goals of

public health – prevention of disease and prolonging life in society. A redefined model of palliative care is not only applicable to the AIDS epidemic. As life expectancy increases and medical advances are being made, people are living longer with chronic diseases. Therefore, an integrated model of palliative care has practical and pragmatic implications for public health universally. Marginalizing those in need of palliative care services to clinical specialists or ignoring them entirely creates a society in dire need of public health action and intervention.

Key learning points

- Palliative care is an important public health issue that has been markedly shaped over the past 20 years by the AIDS pandemic.

- With the emergence of HIV/AIDS, and the ever-increasing need to mobilize communities, adopt prevention measures, and increase access to services, an integrated public health model that spans the continuum of the illness and addresses not only clinical, but also material, psychosocial and spiritual needs of the patient is needed.

- The WHO has identified three elements as necessary to further sustainable palliative care:[35,36] governmental policy (establishing national policies, making sure that palliative care is harmonized with national health and social service agendas); education (of health professionals, the public, and media, policy makers, and others); and ensuring access to pain medications. A public health approach would additionally emphasize the important role of research, and development of a strong evidence base from which to build programs and policies.

- Pain and suffering should be measured through epidemiological and social science methods, as a critical health condition that should be tracked just as we track infectious diseases.

- By expanding the public health paradigm to include and promote palliative care, we further the goals of public health – prevention of disease and prolonging life in society.

- Therefore, an integrated model of palliative care has practical and pragmatic implications for public health universally.

- Marginalizing those in need of palliative care services to clinical specialists or ignoring them entirely creates a society in dire need of public health action and intervention.

The future of palliative medicine

CHARLES F VON GUNTEN, IRENE J HIGGINSON

INTRODUCTION

A reliable forecast for the future requires a hard look at the present. Therefore, we have structured this chapter in three parts. First, we broadly summarize the current state of palliative medicine in the world. Details of the development of palliative medicine in various parts of the world have been described in other chapters in this textbook. Second, we summarize the case for a future that rests on a response to three features: the needs of patients and families, demographic changes, and the physician's role in palliative medicine as a distinct subspecialty. Last, we describe the challenges that palliative medicine must face in the future if it is to prosper.

PALLIATIVE MEDICINE NOW

The current state of the field of palliative medicine can be summarized as highly variable. In some countries, such as Australia, Canada, Ireland, New Zealand and the UK, the field is a recognized specialty with organized programs for clinical care, education, and research. In the rest of the industrialized world, including the USA, a broad program of clinical care has emerged without the official recognition that grounds the discipline in the academic foundation of healthcare. In the poorest nations, the name is unknown and the most basic tools for the relief of suffering are unavailable.

One way to look at this is from an institutional change model. In such a model, an innovation (such as palliative medicine) is developed in one location (such as England) and then gradually spreads to other institutions as its merits become known. There is good evidence for this. Hospice Information reports that from a handful of hospices worldwide in the 1970s and 1980s the number of hospices and

palliative care programs have grown to involve every continent of the world in around 100 countries. The total number of hospice or palliative care initiatives is in excess of 8000 and include hospice inpatient units, hospital-based palliative care services, community-based teams and day care centers. Unfortunately, change has been slow. In England 96 000 new patients were cared for by palliative home care teams in 2003–04, and 27 000 died in an in-patient hospice or palliative care unit: 95 percent of these patients had cancer. In the same year the number of cancer deaths in England was around 140 000, suggesting that around 65 percent of patients with cancer receive care from a palliative care/hospice home care team, and 18 percent die in a hospice. Over 100 000 new patients are seen by hospital palliative care teams each year, some of these go on to receive home care and/or hospice care. Hospital palliative care teams see more patients with noncancer conditions – on average around 11 percent of patients, but this ranges from 0 percent to almost 40 percent.[1] In the USA, nearly 25 percent of those who die receive hospice care, mostly in their homes.

Another way to look at the current state of affairs is from an economic point of view. Those countries that have most developed palliative care are comparatively wealthy countries where palliative care is paid for after other services are covered. In contrast, in poorer countries where it hasn't yet developed, healthcare funds are spent in other ways. In this world view, any money spent on palliative care in developing countries can be construed as a failure to provide the standard healthcare available in other countries. In other words, patients who can't get standard healthcare are given morphine in order to ease their otherwise preventable death.

Finally, the development of palliative medicine can be viewed from a public health point of view. An argument can be made that the most significant healthcare developments

of the past century relate to health promotion (e.g. nutrition), prevention (e.g. sanitation, smoking cessation), and palliation (e.g. pain relief). In this model, palliative medicine is a basic approach to healthcare that even the poorest countries can assure their citizens.

THE FUTURE OF PALLIATIVE MEDICINE

The future of palliative medicine rests on the responses to three features.

Meeting patient and family needs

People with serious chronic illness, and their families, experience a remarkably similar set of needs that are relatively independent of the specific disease or diseases from which they suffer. These can be categorized in the physical, psychological (emotional), social (practical), and spiritual (existential) domains. The prevalence of symptoms such as pain, breathlessness, and fatigue ranges from 50 percent to 80 percent.[2] Psychological conditions such as depression and anxiety affect both patient and family. The social domain includes family and community relationships and support and the need for services be provided. This includes the patient's and family's need for information and training. Finally, the spiritual or existential domain involves the search for meaning and is often affected by serious illness.

Fortunately, there is growing evidence that palliative care is an effective response to these needs. When pain and symptoms are controlled, information is shared, family and caregivers are supported, and services are coordinated, healthcare outcomes are improved at reasonable cost.

Responding to demographic changes

People in both the developed and developing world are aging and live longer. The proportion of those living more than 65 years into very old age is also increasing rapidly. The pattern of disease from which these people die is now characterized by chronic progressive illnesses, including the frailty syndrome of advanced age. This means there will be more people needing healthcare toward the end of life.

At the same time as there is growth in the numbers of people who need care, there is a decrease in the number of both formal and informal caregivers. Innovative ways of providing care are needed. One component of that plan is palliative care.

Developing a unique physician role

The development of the palliative medicine role within the multiprofessional teams who deliver palliative care within hospitals, inpatient units, nursing facilities, or patient's homes is a significant development of the past 50 years. The future of palliative medicine rests on the strength of the case for the field as a distinct specialty. The specialty of palliative medicine has moved from an emerging discipline to a recognized area of expertise in part of the world. It is formally recognized as a distinct specialty in Great Britain, Ireland, Australia, and Canada (see Chapter 8). Its formal recognition is under active review in the USA.[3,4] We can expect similar recognition in other countries for the following reasons.

A DISTINCT BODY OF KNOWLEDGE

A distinct body of scientific knowledge in palliative medicine has accumulated over the past 40 years. The emergence of specialized journals, well-regarded textbooks, and formal curricula are all indicators. This textbook is but one repository. That knowledge is expressed in a variety of scientific and academic endeavors. For instance, the Cochrane Collaborative has a pain, palliative care and supportive care review group which has produced over 50 reviews and over 40 protocols.[5–10] In 2004, the UK government published guidance from the National Institute for Clinical Excellence on supportive and palliative care in cancer.[11] The guidance had reviewed the evidence for the effectiveness in 13 areas of supportive and palliative care, including communication, information, psychological support, specialist palliative care, end-of-life, care and rehabilitation.[12] Also in 2004, the National Consensus Project for Quality Palliative Care published clinical practice guidelines for quality palliative care based on an extensive evidence review and consensus process with the major US palliative care organizations.[13] Addressing the needs of policy makers, the World Health Organization (WHO) European Office produced evidence-based guidance on palliative care in two complementary booklets: *Palliative Care: The Solid Facts*[14] dealt with general palliative care issues, future needs, and evidence, and *Better Palliative Care for Older People*[15] dealt with the need to address the demographic changes in society and take a public health approach to palliative care. Most recently, the US National Institutes of Health conducted a state-of-the-science conference in December 2004. The literature review for the conference covered over 16 000 references,[16] and built on previous references.

The major skills central to palliative medicine are the assessment and management of physical, psychological, and spiritual suffering faced by patients with life-limiting illnesses and their families. Communication and teamwork are also critical skills in palliative medicine.

PUBLICATION OF SCHOLARLY RESEARCH

New knowledge is being discovered at an expanding rate. Research in the area of palliative medicine appears in at least nine international specialized peer-reviewed journals: *Journal of Palliative Care* (Canada), *Journal of Pain and Symptom Management* (including supportive and palliative care,

USA), *Journal of Palliative Medicine* (USA), *American Journal of Hospice and Palliative Care* (USA), *Palliative Medicine* (UK), *Palliative and Supportive Care* (USA), *Progress in Palliative Care* (Australia), *BMC Palliative Care* (a new web-based rapid publication from biomedcentral.com, an international group), *Supportive Care in Cancer* (Switzerland), and the *European Journal of Palliative Care* (UK). More than one curriculum for palliative medicine has been published.[17–20] Models to guide clinical palliative care have been disseminated[21] and a number of well-regarded textbooks are now available,[22–24] of which the *Oxford Textbook of Palliative Care* is now in its third edition. In fact, Oxford University Press now has a specific division for palliative care, with 96 current offerings (www.oup.com/us/catalog/general/subject/Medicine/PalliativeMedicine/?view =usa; accessed October 27, 2004).

GRADUATE MEDICAL EDUCATION

New specialties are characterized by defined training programs that prepare the holder of an undergraduate medical degree for independent practice. In the UK, individuals begin the 4-year training program in palliative medicine once they have completed their medical degree and around 3 years in general medical posts, including hospital medicine. The Association for Palliative Medicine of Great Britain and Ireland has over 800 members and there are 177 qualified doctors training in the 4-year program to become specialists in palliative medicine (personal communication, S Richards, Association for Palliative Medicine, November 2005). In the USA, there are 47 fellowship programs in operation with a total of 97 physicians in training[25,26] (www.AAHPM.org/fellowship/directory.html; accessed August 21, 2003).

PROFESSIONAL ASSOCIATIONS

New specialties are also characterized by professional associations. The American Academy of Hospice and Palliative Medicine (AAHPM) is the professional association for physicians in palliative medicine in the US. The AAHPM currently has 1900 physician members (AAHPM, personal communication, October 22, 2004). The Association for Palliative Medicine of Great Britain and Ireland has over 800 members. The European Association for Palliative Care is a membership organization composed, in part, by members of the national associations of countries throughout western and central Europe. Similar associations have formed in southeast Asia.

PRACTICE PATTERNS AND PROFESSIONAL ROLE

The 1997 Institute of Medicine report, *Approaching Death: Improving Care at the End of Life*, delineated a three-tiered structure for professional competence:[18]

1 A basic level of competence in the care of the dying patient for all practitioners.

2 An expected level of palliative and humanistic skills considerably beyond this basic level.

3 A cadre of superlative professionals to develop and provide exemplary care for those approaching death, to guide others in the delivery of such care, and to generate new knowledge to improve care of the dying.

These three levels correspond to the primary, secondary, and tertiary levels around which medical care is commonly organized. Primary palliative care (a term used mainly in the USA; in the UK and Europe the term used is 'the palliative care approach') is the responsibility of all physicians. This includes basic approaches to the relief of suffering and improving quality of life for the whole person and his or her family. Secondary palliative care is the responsibility of specialists and hospital or community based palliative care or hospice programs. The role of the secondary specialist or program is to provide consultation and assist the managing service. Tertiary palliative care is the province of academic centers where new knowledge is created through research, and new knowledge is disseminated through education, as well as providing a clinical service. The major competencies of the specialist level palliative medicine practitioner can be summarized under the broad patient-centered goals of:

● relief of symptoms and suffering
● promotion of quality of life for patients and families in the context of life-threatening illness
● promotion of the development and growth possible at the end of life.

While the knowledge domains and skills of palliative medicine overlap to some extent with the knowledge, attitudes, and skills that characterize other disciplines that care for patients with advanced illnesses, the specialty practice of palliative medicine is distinguished from other disciplines by its focus on the common features and symptoms associated with life-limiting disease. Palliative medicine reaches across many disease categories and organ systems to concentrate on relieving the burden of illness.

The palliative medicine specialist acquires and applies:

● a higher level of clinical expertise in addressing the multidimensional needs of patients with life-threatening illnesses, including a practical skill set in symptom control interventions
● a high level of expertise in both clinical and nonclinical issues related to death and dying
● a commitment to an interdisciplinary team approach
● the strong focus on the patient and family as the unit of care.

The specialist level competency required of practitioners in palliative medicine complements the core competency that should be maintained by other disciplines.

The majority of palliative medicine physicians practice as hospice medical directors and/or as hospital-based consultants. There are now more than 3200 hospice programs

in the USA (www.nhpco.org/files/public/Facts_Figures_ Jan_03.pdf; accessed August 21, 2003). Medicare-certified hospices are required to have a paid or volunteer staff medical director. The National and Hospice Palliative Care Organization (NHPCO) recently began an initiative to encourage member hospices to strengthen the role and competency of hospice medical directors.[27] Interest in hospital-based palliative care programs is also growing. The Center to Advance Palliative Care states that 800 hospitals now offer palliative care services and the number appears to be increasing by about 20 percent annually.[28] The Center for Workforce Studies at the State University of New York documented that physicians currently working within palliative medicine support formal recognition of the field.[29]

CHALLENGES FOR THE FUTURE

There are a number of challenges that confront the future of the field. These include the response of healthcare policy makers, the definition of the boundaries of the specialty, and the training of the new physicians who are needed.

Healthcare policy

The future of palliative medicine requires a social and political impetus that is beyond the scope of medicine and firmly in the sphere of government. For palliative medicine to prosper, healthcare policy must place much greater emphasis on the care of people of all ages who are living with and dying from a range of serious chronic diseases. The structure of health care *as if* these prevalent illnesses are acute and curable must be changed. Therefore, publicly funded palliative care services as a core part of health care is needed; it cannot be an 'add-on extra'. Those services must meet the needs in the rural and urban community dwelling public as well as in nursing homes and hospitals, including intensive care. Those services must be based on need rather than on specific diseases or prognosis. Finally, healthcare policy must provide for the development of new knowledge through research. Despite the prevalence of palliative care need, national research budgets are paltry. Surely we don't want to be using the same tools in 50 years that we have now.

Professional boundaries

A significant issue that confronts the future of the field is whether it focuses on a condition (the dying patient) or relates to a broader set of competencies that can be integrated across the spectrum of serious and chronic illness. The roots of palliative medicine in hospice care for the dying would lend itself to the former. The experience of hospital-based and outpatient office based palliative medicine physicians suggests that the skills are more broadly applicable than just for the dying.

Palliative medicine is practiced within the context of a team. Some would say it cannot be practiced without a team. Yet, the broad interdisciplinary nature of palliative medicine makes it more challenging to define the boundaries of the specialty than for those with a disease focus (such as oncology), an organ focus (such as cardiology) or a technical skill (such as surgery). As with other fields, there are areas of overlap with other specialties and subspecialties. Delineating and negotiating those boundaries is an important aspect of the maturation of the discipline. There is little argument that palliative medicine is primarily a consulting specialty to the other primary disciplines. There is no agenda, expressed or implied, that all suffering and dying patients be cared for by physicians board certified in palliative medicine.

Developing new and appropriate models of care in response to the different trajectories of illness and diseases

Although the symptom and problem profiles of patients with different chronic progressive conditions are similar, the trajectory of diseases is likely to vary. In addition, caring for older people, an increasing part of the palliative care population, has specific challenges – notably iatrogenic disease, multiple pathologies, and difficulties in prognostication. The early models of palliative care may have to evolve to care for these patients. In particular the model of consultation and palliative care offered for periods throughout the illness, rather than at a particular prognostic point, may have to develop. It will be a challenge for palliative medicine to develop and test such models of care, while maintaining existing services.

Fundraising and/or remaining part of statutory funded care

Currently much of palliative care is provided within the voluntary sector and not for profit organizations. These have a continued battle to raise funds to stand still – and provide a continued service to the community. The charitable sector is set to become more competitive in years to come and is subject to fluctuations in response to economic changes. Becoming part of the statutory sector or receiving increased statutory funds removes some of the freedom of previously voluntary units, although it provides more security. Achieving the right balance here can be a challenge, especially as national charity organizations in some countries (e.g. the charity commission in the UK) provide guidance that charities should not undertake tasks which should be provided by statutory services. Perhaps more and more the role of charitable organizations will be to innovate and discover better treatments and ways to care, while they advocate for the statutory sector to pick up the funding of the services they have proved, through good research, is effective and cost-effective.

Training

Another challenge to the field is to build enough capacity within training programs to train the next generation of specialists. The current interest in developing training programs is heartening, but financial resources are scarce and competition for them is strong. In England, palliative care posts go unfilled for want of trained specialists. In the USA, where the field is only emerging, a similar shortage is emerging. There is no reason to think this won't be the case in other countries unless the field is recognized and sufficient capacity built into the nation's programs for training medical professionals. There is an inherent challenge here, because the field needs the best dedicated and bright clinicians, who have undergone sufficient training. Therefore, a balance needs to be struck between filling posts and filling them with sufficiently experienced and qualified individuals who have the ability to deliver the services and development needed.

Palliative medicine clinicians often find themselves in leadership roles and so have to not only provide clinical care, but also be versed in managing and motivating staff, strategically developing their services and often negotiating contracts and teaching other doctors. Burnout is likely to be a problem in palliative care, especially if clinicians are isolated and asked to cover services 24 hours, without backup or peer support, as well as to deal with issues of staff management and service development. Equally, problems can arise in academic posts, where filling posts with individuals without sufficiently robust track records or from fields outside of palliative medicine, can lead to loss of respect for the field or a distraction of effort away from palliative medicine patients.

Research

A major challenge for the future of palliative medicine is to become a strong specialty for the future. Knowledge has to be a central key to this. If the specialty is to make a real contribution to the future care of patients and families then the evidence base for the treatment of many symptoms and problems needs to be improved. Unfortunately research has been relatively neglected in the past. There has been inadequate funding in all countries, a hesitancy on the part of some ethics committees and institutional review boards to fully support research, and a reluctance of some staff, who entered the specialty because they felt it did not involve research. There are problems too because of the nature of research in palliative care, which is often difficult because of ethical concerns, the intangible nature of many aspects to be measured (e.g. fatigue, quality of life, quality of death) and the fact that patients are ill and difficult to interview. They may live for unpredictable times. Weighed against this we should recognize that there have been enormous achievements in research in palliative medicine in the past decades, despite these problems and the lack of resources. This is a tribute to the few

centers and individuals who are researching the field. In the future, an improved training in appraising and participating in research is needed for doctors and nurses entering the field. It is not expected that everyone will conduct research, but all will need to appraise it, and may increasingly be part of large studies organized in tertiary centers.

SUMMARY

In summary, there can be a bright future for palliative medicine. There is widespread need within society and this is set to increase in the future. There is now a body of good quality evidence showing that palliative medicine within palliative care programs can meet the need. The challenge is clear. The field needs to grow to sufficient size to be a sustainable response. It also needs to develop mechanisms to meet the challenge of the changing population, and in particular the increase in the older population and changed trajectory of illness, it needs to continually improve the caliber and skills of those in the field, through training, and to invest substantially in discovering and testing better methods of care and treatment.

Key learning points

- Palliative medicine is highly variable in the world.

- The evidence base supports the effectiveness of palliative care.

- The demographic changes in the world's populations (living longer with more chronic ultimately fatal disease) require expanded palliative care services.

- The development of a unique palliative medicine role for the physician within multiprofessional teams is a phenomenon likely to develop in most countries.

- Expanding clinical services to meet the needs of patients and families will require both modifications in patterns of care as well as expansion of the numbers of trained physicians and other professionals needed to provide palliative care.

Principles of bioethics in palliative care

PAULINA TABOADA

INTRODUCTION

Ethical challenges in palliative medicine do not substantially differ from those encountered in other areas of medicine.[1,2] Nevertheless, the recognition of the needs of patients at the end of life demands some moral attitudes, skills, and knowledge that enable adequate decision making in relation to the unique sources of suffering encountered in the dying and their relatives.[3]

> Simply stated, ethical issues in palliative care center around decisions which will enable us to satisfy the criteria for a peaceful death, dignified and assisted by a helpful society.
> Roy and MacDonald, p. 97[3]

Hence, two basic moral attitudes belong to the very essence of palliative medicine:

1 An unconditional respect for human life and dignity even in situations of extreme weakness.
2 The acceptance of human finitude and death.[4]

In this context, other moral attitudes also acquire a special relevance, such as the virtues of truthfulness, prudence, and compassion.[5]

When dealing with concrete moral challenges in the care for terminally ill patients, the application of adequate methods for the systematization of ethical problems (Box 11.1) as well as basic knowledge of some ethical principles may help healthcare professionals.[5–11] In this chapter I shall briefly unfold the basic content of some of the ethical principles that are specially relevant in palliative care (Box 11.2). However, I will emphasize that the fundamental moral attitudes and virtues orienting healthcare professionals when caring for the dying are actually more important than the mere application of ethical principles to particular situations.[4,5,12]

Box 11.1 Systematization of the ethical analysis of clinical cases

1 Define the specific ethical dilemma/s
2 Refer to the ethical principles involved
3 Collect and analyze the 'ethically relevant' clinical information
4 Review alternative courses of action
5 Formulate an ethical solution
6 Consider the best way of implementing the solution

Box 11.2 Ethical principles specially relevant in palliative care

The four basic principles of contemporary bioethics:

- Nonmaleficence
- Beneficence
- Autonomy
- Justice

Other traditional principles generally acknowledged in medical ethics:

- Respect for human life and death
- Therapeutic proportionality
- Double effect
- Truthfulness in communication
- Prevention
- Nonabandonment

ETHICAL PRINCIPLES RELEVANT IN PALLIATIVE CARE

The four basic principles of contemporary bioethics

Beneficence and nonmaleficence have traditionally been the leading principles of medical ethics.[13] They correspond to the first and most general ethical intuition: do the good and avoid the bad (*bonum est faciendum, malum vitandi*). Hence Hippocrates thought that the first medical duty is to benefit or at least 'not to harm' (*primum non nocere*). Moreover, he deduced from this general duty a number of concrete consequences reflected in the Hippocratic Oath. For many centuries the Hippocratic tradition was taken for granted by the medical profession. Ethical principles and values contained in the Hippocratic Oath were applied to solve ethical dilemmas in medical practice without any further questioning of their origin or validity.

With the influence of positivism, this way of doing medical ethics was questioned and regarded as 'naive'. Ross' establishment of *prima facie* duties and its incorporation to ethical analysis was considered as a more 'scientific' approach to ethics, at least in the Anglo-Saxon world.[14] As a result of the application of this approach to medical ethics a trend arose known as *principlism*. This approach claims the existence of four self-evident ethical principles that serve to represent and codify the main values underlying medical ethics: nonmaleficence, beneficence, autonomy, and justice:[15]

- Nonmaleficence – do not harm (minimize the harm).
- Beneficence – do good (always act in the patient's best interest).
- Autonomy – acknowledge the patient's rights to self-determination.
- Justice – allocate healthcare resources equitably, according to need.

It is interesting to note that the principle of autonomy – not contained in the Hippocratic tradition – entered medical ethics much later as part of this system of *prima facie* principles devised to deal with moral pluralism.

Although to some extent useful, the principlist approach to solving moral dilemmas in medical praxis has not been exempt from contradictions and criticisms.[16–18] For instance, the concrete content of the so-called 'four basic principles of bioethics' is neither clearly specified nor secured, since the principlist approach does not provide an anthropological foundation for them. Moreover, in this system each principle is given equal weight. Thus, if two or more of the four basic principles conflict with each other this approach does not provide a clear-cut answer as to which of them should be given priority. In the Anglo-Saxon world, the general tendency is to grant moral hegemony to the principle of autonomy. According to this approach, the priority among principles can be definitively established only when the detailed circumstances of the particular situation are known. It therefore entails the risks of situation ethics.

To solve these difficulties, Gracia proposed that the four principles of bioethics should be placed on two levels, based on the distinction between *perfect* and *imperfect* moral duties.[19–22] This approach is known as *specified principlism*. Perfect duties are moral minimums or negative prescriptions, which ought to be respected always, regardless of the circumstances. According to Gracia nonmaleficence and justice belong to this category. Imperfect duties are ethical maximums or positive prescriptions that allow different degrees of fulfillment and Gracia lists beneficence and autonomy among the latter.

A number of other authors have also criticized principlism. Indeed Pellegrino, for instance, states that current bioethics is undergoing an 'anti-principlist' crisis.[13] Faced with this sort of 'crisis' of contemporary bioethics and looking toward the future, Pellegrino proposed virtue ethics.[23,24] Virtue theory as applied to medicine emphasizes that physicians should acquire good traits of character more than just learning about moral theories and principles.[25] Thus ethical inquiry in particular issues asks about the way in which a good person – a good physician in our case – would act if he or she were confronted with a similar situation.

Presently, a trend is opening in ethics toward a renewed discovery of the value of the person (*personalism*).[26–30] According to this approach, it is not duty as duty, or law as law, or principles as principles, or utility as utility, etc. that defines the content of moral obligations – as has been suggested by other major ethical trends. Personalism proposes that it is rather the dignity and the ontological structure of the person that defines the content of our moral duties.[26] The core of moral reasoning is derived here from the statement that the proper addressee for a moral subject is a concrete person. Hence, the most basic norm of morality is: *Persona est affirmanda propter seipsam et propter dignitatem suam* (the person shall be affirmed because of herself and because of her dignity).[26,28] In other words, the clue for the resolution of ethical dilemmas in medicine is the respect due to each individual person as person, which presupposes a proper understanding of the 'ontological structure' of the person.[26]

Summing up the above discussion, nowadays, besides principlism there are several other major approaches to medical ethics.[31–33] As some healthcare professionals are not familiar with either their essential content or with their potential contributions to clinical decision making, the interested reader is referred to summaries of the main trends in contemporary bioethics (Box 11.3) published elsewhere.[5,13,31]

Other traditional ethical principles especially relevant in palliative care

Besides the abovementioned four basic principles of bioethics, a number of other traditional ethical principles can be applied to solve ethical challenges in the care for the

- Principlism

- Utilitarianism

- Kantian ethics

- Casuistry

- Relational and feminist ethics

- Virtue ethics

- Personalism

dying.[4] I shall refer here mainly to the principles of respect for human life and death, therapeutic proportionality, double effect, and truthfulness in communication.

RESPECT FOR HUMAN LIFE AND DEATH

The duty to respect and promote human life and health is a basic ethical imperative in relation to the self and to others. In palliative care the ethical question arising is: How can this basic ethical principle be applied in the context of dying persons? In defining the specific goals of palliative care, the World Health Organization states that palliative care affirms life and regards dying as a normal process, neither hastening nor postponing death.[34] This definition corresponds to a conception of the so-called 'right to die with dignity' not simply as a right to die, but rather as a right to live one's life to the end. In other words, it refers to the right to be assisted by others in the dying process.[35] Hence, the main idea is that the human process of dying poses certain ethical demands for medical professionals as well as for society as such. Palliative care is conceived as a concrete and active answer to these ethical demands.[36]

To answer the question about what constitutes an appropriate use of medical resources in the care of a dying person presupposes adopting a moral attitude toward imminent death and an understanding of the meaning of the so-called 'good death'.[37,38] There seems to be general agreement about the fact that an artificially prolonged agony is contrary to the dignity of the dying person. The Judeo-Christian tradition, for instance, affirms the existence of a *moral duty to accept death* and regards the so-called 'medicalization of death' as an ethically wrong medical praxis.[39,40] But it is also well known that – in contradistinction to the way in which most proponents of euthanasia and medically assisted suicide understand the expression 'right to die with dignity' nowadays[41–44] – the Judeo-Christian tradition absolutely excludes the possibility of intentionally taking one's own life and/or helping others to do so. According to this tradition, the *right to die with dignity* is considered as a constitutive part of the *right to live*.[39,40]

To speak about a *good* or a *bad* death presupposes an understanding of the human act of dying as an act in which human freedom can be exercised, at least to a certain extent.[29,38,45] Nevertheless, it seems quite evident that dying is not something we can decide about. (The classical moral distinction between physical and moral acts expresses that the mere physical realization of an act (*actus homini*) does not necessarily coincide with the realization of a moral act. Only an action in which human freedom is exercised (*actus humanus*) can be morally qualified.[29,45]) We are not able to choose whether we want to die. But in spite of the inevitability of death proper to the human condition, we are actually free to choose an attitude of acceptance or rebellion in the face of imminent death. Elizabeth Kübler-Ross, for instance, describes five kinds of emotional reactions observed in patients facing death: anger, denial and isolation, pact or negotiation, depression, and acceptance.[46] The existence of various types of attitude toward inevitable death suggests the possibility of exercising personal freedom, at least to a certain extent. Indeed, we are free to adopt an attitude of acceptance or of rebellion in the face of unavoidable death. And it is precisely this inner attitude toward imminent death that becomes ethically relevant for a conception of a 'good' and a 'bad' death.[37,38]

Death certainly has deep cultural, moral, and religious meanings (reference 37 and Dekkers W. Images of death and dying. Unpublished manuscript). Hence, cultural, moral, and religious views of death shape what is considered to be an appropriate behavior toward both the dying person and his or her family. The orientation toward cure that characterizes contemporary medicine may encourage aggressive treatment – even if not clinically appropriate and/or contrary to the patient's wishes – to avoid any perception of under-treatment.[47] To be involved in such a cultural trend, as well as its opposite, i.e. the growing acceptance of the practice of euthanasia and physician-assisted suicide, may impose grave moral dilemmas on dying persons, not allowing them to die in the way they consider to be the right one.[48] Indeed, clinical surveys have shown that healthcare workers too often fall into the temptation of using all available technology to avoid imminent death.[47] They seem to have special difficulties in accepting human finitude and death.

PRINCIPLE OF THERAPEUTIC PROPORTIONALITY

No one is obliged to use all available medical interventions, rather only those offering a reasonable benefit/risk ratio. A more difficult question is whether one can refuse medical interventions in spite of their potential benefits or accept treatments for which the risks are still high or not yet well known. In these situations we are confronted with the question about the limits of our moral obligation to pursue healthcare. In an attempt to distinguish morally obligatory from nonobligatory medical interventions, a conceptual distinction between 'ordinary' and 'extraordinary' means has been proposed.[40,49]

The content of this traditional moral teaching is presently better known as the principle of therapeutic proportionality.[40] This principle states the moral obligation to provide a patient those treatments that fulfill a relation of due proportion between the means to be employed and the expected results. Medical interventions in situations in which this relation does not hold are considered 'disproportionate' (previously referred to as 'extraordinary') and regarded as morally nonobligatory. Hence, to verify whether a given medical intervention is morally mandatory one has to carefully judge the utility of this intervention in the context of the patient's concrete circumstances. It is important to note that the utility/futility has to be referred to the patient's overall clinical evolution and not merely to some isolated physiological effects. Also the risks and 'burdens' associated with the intervention should be carefully taken into account, understanding the notion of 'burden' in its widest sense, that is, including physical, psychologic, spiritual, humane, familial, social, financial, etc. distress.[49]

Judgments about therapeutic proportionality are relative to an individual's unique situation. Nevertheless, this does not mean that they are merely subjective. In fact, to be legitimate, proportionality judgments need to be grounded in an objective state of affairs regarding the clinical condition and the present state of medical art. From a medical point of view, some of the elements that always need to be taken into account to judge the proportionality of a given intervention are the certainty of the clinical diagnosis, the utility/futility of the intervention, the risks and side effects of the different therapeutic alternatives, and the accuracy of the prognosis. Evidence-based data become relevant, even though it is evident that a moral obligation cannot be sufficiently grounded in statistical probabilities.[50,51]

Moreover, judgments about therapeutic proportionality cannot be considered as the result of a mere cost/benefit equation. The way in which the different elements involved in therapeutic proportionality have to be weighted needs to be guided by the virtue of prudence. I am using the word 'prudence' here in its traditional philosophical understanding, that is, the ability to be practically wise or to exercise the right choice in a particular case in the light of moral universal knowledge. In other words, I am not referring to the contemporary understanding of 'prudence' as 'rational self-interest', but rather to the classic moral virtue of knowing what should be done and avoided in concrete situations.[48,49] And the moral relevance of proportionality judgments guided by the virtue of prudence is that the implementation of interventions judged as 'proportionate' is morally obligatory. This means that to omit them would represent an act of euthanasia by omission (sometimes referred to as 'passive euthanasia').

PRINCIPLE OF DOUBLE EFFECT IN PAIN MANAGEMENT AND SEDATION

There are various situations in normal daily life in which one cannot do the good without also causing undesired bad side effects. The traditional ethical principle of double effect sets the ethical criteria for the legitimacy of actions that have well-known, unavoidable, bad side effects.[26,40,52] This principle also sheds light on various ethical dilemmas in palliative care, for instance, when using opioids or sedatives in terminally ill patients, knowing that they *may* negatively affect the patient's state of awareness, blood pressure and respiration. Sometimes, the fear that the occurrence of these adverse effects may hasten the patient's death poses ethical dilemmas to the patient, relatives and even to healthcare professionals, who doubt whether this might represent a form of euthanasia (referred to as 'indirect euthanasia'). In this context, it is important to remember that adequate use of opioids is not necessarily associated with the occurrence of such feared side effects. But even if the undesired effects do occur, the principle of double effect helps to recognize the patients in whom the use of these drugs may be morally legitimate in spite of the risks. Provided that other pain killers have been tried and shown as inefficient in the control of pain, and if opioids are used in the right way and dose, then the use of opioids would represent the only possible way of benefiting the patient and their use is therefore morally justified. Indeed, the principle of double effect states that actions with both good and bad effects are ethically legitimate only if certain conditions are simultaneously fulfilled:[26,40,52]

- The action performed is not itself morally evil.
- The good effect is not caused by the evil effect.
- Only the good effects are directly intended; the bad effects are not intended but only tolerated (as unavoidable).
- There is a due proportion between the good and bad effects.

Thus, the double effect doctrine forbids the achievement of good ends by wrong means. It forbids doctors to relieve the distress of dying patients by killing them, but permits the use of drugs which relieve the distress of the dying, even when they may incidentally hasten an imminent death.

This principle similarly applies to the sedation of terminally ill patients.[53–56] If we consider the actual exercise of mental faculties to be objectively good for the person, then it would be morally wrong to deprive someone of the use of these faculties without a sufficient reason. Hence for sedation to be morally legitimate, the four conditions of the principle of double effect must be fulfilled. It would be morally wrong to sedate a person if there is not a good reason for it. Unfortunately, healthcare professionals are not always completely aware of the seriousness of this issue. Sometimes the scarcity of medical personnel and other related circumstances become the reason for sedating patients. This is a morally intolerable situation.

TRUTHFULNESS IN COMMUNICATION

Perhaps one of the most frequent ethical challenges in palliative care is the question of truthfulness with terminally

ill patients.[57,58] Reluctance to share the truth about diagnosis and/or prognosis with the patient is frequently associated with family pressures related to cultural backgrounds. While medical professionals usually consider truth disclosure to be part of their duty of beneficence and respect for autonomy, relatives sometimes regard truth disclosure as being harmful for the patient. Seemingly, what is beneficent for some appears to be maleficent for others. This contrast in moral perspectives underlies some ethical dilemmas in palliative care.

Usually, a family's request not to disclose the truth to the patient is based on the assumption that truth disclosure will induce serious anxiety and depression, causing real harm to the patient.[59] Indeed, detailed disclosure has been shown to increase anxiety in the short term.[60] Nevertheless, follow-up surveys reveal that the excess anxiety dissipates within a few weeks, whereas the effects of limited information on psychological adjustment may persist.[61] Evasion and lying isolate patients behind either a wall of words or a wall of silence that prevents a therapeutic sharing of their fears, anxieties, and other concerns.

If a physician believes that it is not possible to offer good care without prior commitment to openness and honesty and goes on communicating the clinical information to the patient against the family's desire, he or she may be accused of an 'assault of truth', i.e. of imposing the truth on a patient.[62] The risk thereby is to interfere with the patient's coping mechanisms, as determined by his/her personality or cultural background. In fact, we know that within some ethnic groups the delegation of authority with regard to medical decision making is culturally implicit.[63] Under these circumstances, disclosure of a serious diagnosis to a patient by the physician can be regarded as a socially unacceptable behavior and an untactful act, because the family is considered to have the right to be informed first. In this cultural context an 'assault of truth' may cause irreversible damage to the physician–patient relationship as well as to the physician–family relationship. In such situations, the physician may perceive an apparent dichotomy between holding to the principle of autonomy and respecting the pluralism of different cultures. Nevertheless, a deeper understanding of the meaning of autonomy may help solve the apparent moral dilemma.

As Pellegrino states, the principle of autonomy is grounded in respect for the person and the acknowledgment that as rational beings we have the unique capability to make reasoned choices.[64] Through these choices we plan and live lives for which we are morally accountable. Inhibiting an individual's capability to make these choices is a violation of his or her integrity as a person and thus a maleficent act. Autonomy, therefore, is not in fundamental opposition to beneficence as is too often supposed, but in congruence with it.

Moreover, truth-telling goes far beyond providing mere information.[65] Truth is not just the opposite of lies, not just the sum of correct statements, but a reciprocal state in the patient–physician relationship. Deception appears to be harmful, because it may destroy the foundations of the interpersonal relationship that allows a doctor to 'do good' (beneficence). Thus respect for both autonomy and truth-telling can be regarded as intrinsic beneficent medical acts.

Competent human beings, however, also can freely choose the communication and decision making style they prefer. There are indeed different styles of decision making that can be – in principle – equally respectful for patient's autonomy. One may be called a 'patient-based model' and the other a 'family-based style'. If patients express the desire for personal involvement in the decision making process, they have the right to be informed in spite of the explicit requests of their relatives, who in such a case would in fact be violating the patient's right to autonomy. To respect the patient's autonomous choice it is mandatory to explore carefully his or her preferences with regard to communication and decision making style.

Hence in spite of cultural and ethnic diversities, respect for autonomy can still be said to be valid and universal principle in relation to truth disclosure because it is based on what it is to be a person and in the respect due to each person as a person ('personalist principle').[28] What actually varies among different ethnic groups and cultures is the way in which the respect for a person's freedom is best exercised with regard to communication and decision making styles. The uniformity of a family-based decision-making style within a given culture may suggest that delegation of decision making to family members is an expectation of the sick person that does not need to be made explicit in individual cases. This assumption cannot be taken for granted. The present trend toward globalization may result in a patient's appropriation of values different from the ones that are considered typical for his or her cultural background. One cannot assume that a given patient will prefer one style to the other just because he or she belongs to a given culture or ethnic group. Thus, the physician should tactfully explore the preferences of the individual patient with regard to communication and decision making styles.

FINAL REFLECTIONS

The peculiar needs and features of patients at the end of life demand from healthcare workers – even more explicitly than in other areas of medicine – some fundamental moral attitudes and virtues. These attitudes are an unconditional respect for human life and dignity as well as the acceptance of human finitude. To discover what appropriate palliative care is, a physician shall be dedicated to providing competent medical services with compassion and respect for human dignity.[66] This statement summarizes three central virtues in the praxis of palliative care: medical expertise, compassion, and respect for the dignity of the person – even in situations of extreme debility and suffering. Indeed, these virtues are tightly interconnected. A genuinely compassionate attitude allows healthcare professionals to identify the concrete way in which medical expertise has to be applied to

truly respect the dignity of each person, especially in situations of extreme weakness and unavoidable death.

The term 'compassion' is commonly understood as synonymous of pity. Nevertheless, it can be better defined as 'the virtue by which we have a sympathetic consciousness of sharing the distress and suffering of another person and on that basis are inclined to offer assistance in alleviating and/or living through that suffering. Hence, there are two key elements in defining compassion: (1) an ability and willingness to enter into another's situation deeply enough to gain knowledge of the person's experience of suffering; and (2) a virtue characterized by the desire to alleviate the person's suffering or, if that is not possible, to be supportive by living through it vicariously.[67] Compassion – understood as a moral virtue – entails the willingness to effectively alleviate a person's sufferings. Hence, it demands unfolding the corresponding expertise or 'know-how'.

Human suffering at the end of life has different causes. Thus medical interventions aimed at alleviating suffering in terminally ill patients cannot be narrowly understood as just those having the potential to produce certain physiological effects on the person's body. This is doubtless an important goal of end-of-life care, but the medical commitment toward a dying person goes far further than the body. Indeed, a peculiar cause of human suffering at the end of life is the person's natural fear of imminent death, and healthcare workers should develop a special sensitivity toward this aspect, permitting their patients to reflect on their moral duty to accept death and to receive the necessary psychological and spiritual assistance, if they want. This will require – among other things – to preserve the patient's state of consciousness, as long as the clinical condition and the therapeutic goals allow it.

If compassion is primarily directed to the person in virtue of his or her sufferings and only secondarily to the sufferings, then we can draw another practical conclusion. In situations of extreme and prolonged suffering a truly compassionate attitude will prevent a healthcare provider from the temptation of accelerating death to alleviate their patient's sufferings. To end the life of a person cannot be an act of true compassion, because such an act would eliminate the very object of compassion: the person. On the contrary, a compassionate attitude allows healthcare providers to recognize the way in which their competent medical knowledge can be best used to palliate the person's sufferings in a way that truly respects each person's life and dignity, even in the events surrounding an unavoidable death.

Key learning points

Some ethical principles are especially relevant in palliative care (see Box 11.2). Besides the so-called four basic principles of bioethics (nonmaleficence, beneficence, autonomy, and justice), a number of other traditional ethical principles can be applied

to solve ethical challenges in the care for the dying. These include the principles of respect for human life and death, therapeutic proportionality, double effect, and truthfulness in communication. Fundamental moral attitudes and virtues that help orientate healthcare professionals when caring for the dying are far more important than the mere application of ethical principles.

Ethics in the practice of palliative care

JAMES A TULSKY

INTRODUCTION

Excellent palliative care demands careful attention to diagnostic, prognostic, and therapeutic challenges. The palliative care clinician must demonstrate sensitivity to psychosocial and spiritual concerns, and thoughtful, empathic communication with patients and families. Yet, even when these are done with superb skill, patients and providers will still find that the pathway of life-limiting illness presents ethical dilemmas. Some are subtle and, perhaps, not recognized. Other dilemmas are easily apparent. This chapter discusses several of the more common and vexing ethical issues that arise in care of patients at the end of life. These include truth-telling, when and how to engage in advance care planning, requests for ineffective/unproved treatment and limitation of potentially beneficial treatments, and, finally, consideration of aggressive measures for treating terminal pain and suffering.

The following case raises each of these dilemmas. The case is not unusual and the problems are not profound. However, the problems are common and reflect thorny issues that arise in the real daily practice of palliative care.

SK was a 68-year-old, retired, Korean born university professor who was admitted to the hospital with pneumonia and chest pain. A chest computed tomography (CT) scan revealed a 4 cm lesion obstructing the right upper bronchus and several rib lesions suspicious for malignancy. As the physician approached the patient's hospital room he was pulled aside by Mr K's son and daughter who wished to know the result of the CT scan. They request that the doctor not share the results with their father if it means he may have cancer.

DISCLOSURE AND TRUTH–TELLING

Truth-telling is fundamental to respectful patient care and a necessary component of informed consent. By fully including patients in all decision making, healthcare providers honor patient autonomy. Truth-telling also engenders trust in physicians and the profession and is desired by most patients. Surveys consistently show that most patients wish to receive as much information as possible,[1,2] perhaps as a way to cope with uncertainty.[3,4] In one typical survey of 2850 British patients, over 1000 of them receiving palliative care, nearly 90 percent, stated they would like to be told most or all information about their illness.[5] Yet, patients also wish to have an individualized approach to receiving bad news and discussing prognosis that does not necessarily share all of the information at one time or in the same way.[6] In most Western societies, it is common practice to answer patients' questions honestly and to share relevant information about their medical condition, prognosis, and therapeutic options. However, significant variation exists worldwide.[7,8]

The above work suggests that most patients prefer to participate in decision making but to receive a physician's advice regarding recommended options. Physicians must find the balance between conveying the ambiguity that clouds medical practice and helping patients find the best options for them. There are many good arguments for giving full information to patients.[5] Information allows patients to plan their futures and to make decisions. Lack of information may heighten their fear and anxiety, as the truth is often not as bad as what might be imagined, and they may lose the opportunity to achieve important goals prior to death. In addition, the secrecy and collusion necessary to withhold information may present a significant challenge to providers and families.

Nevertheless, even the most forthright physicians raise questions about the limits of disclosure. When patients don't ask, how much should healthcare providers tell? For example, when starting a new medication doctors rarely describe all of the possible side effects. They judge that this would not be helpful and, instead, mention only the most common, most serious, or most relevant side effects. Disclosure of serious diagnoses and their repercussions appears to be handled similarly. Physicians do not always share prognosis, and when they do, they tend to bias optimistically.[9]

Although withholding information or providing an overly optimistic assessment of illness may be deceptive, legitimate reasons for the practice also exist. Patients may find it too difficult to hear bad news, or may consciously defer all decision making to their families. Although such perspectives may challenge notions of patient autonomy, in fact autonomy dictates that patients also have the right to not hear or to defer responsibility to others.

Cultural issues also play a role. In many societies decision making is localized in the family and individual autonomy is not recognized. Blackhall *et al.* surveyed members of four distinct ethnic groups in the USA and found widely disparate perspectives on whether a patient should be told about a diagnosis of metastatic cancer. Only 47 percent of first generation Korean Americans and 65 percent of first generation Mexican Americans believed that patients should be told, whereas European Americans (87 percent) and African Americans (88 percent) were more likely to want to hear this news directly themselves.[10] In some cultures the delivery of bad news may determine how patients confront illness and being told the wrong information can cause harm. For example, in Navajo society, the concept of 'hozho', or living in beauty, may be violated by statements that are viewed as negative.[11] Such observations imply that, in different cultures, personal autonomy carries different levels of importance. That said, patients' preferences are not simply a reflection of their ethnic background. In Mr K's case, we might expect that Mr K has an approximately 50 percent likelihood of wanting the physician to honor his family's request and to tell the news only to them. However, there exists an equal likelihood that he would want to be told the news himself, and there are no identifiable predictors of such preferences.

In this context, some have argued for 'necessary collusion', or the need to delay disclosure of some specific prognostic information from patients to help maintain their hope.[12] This perspective does not advocate withholding information that is requested, but rather allowing the information to unfold only as requested or needed by the patient in a 'measured series of forecasts'. This perspective appears to strike a common ground that protects those patients who do not want too much information. However, it also risks withholding information from those who would want it, and makes assumptions about patients' needs or preferences that cannot be ascertained simply.

Therefore, a better resolution may be for the clinician to ask patients directly, 'How much information are you interested in hearing about your illness? Patients can declare clearly what they wish to hear and patients will receive only the amount of information they desire. Rather than waiting until the moment that more bad news presents itself, this question is well worth asking early in the care of any patient with serious illness, and certainly at the time of conducting diagnostic and prognostic tests.

ADVANCE CARE PLANNING

> Mr K was treated for his pneumonia and a biopsy revealed nonsmall cell lung cancer, metastatic to rib. He received radiation to his lung and ribs and felt much better. He was seen 6 weeks later in his doctor's office, and the physician wondered whether this was a good opportunity to begin advance care planning.

Advance care planning is the process by which patients, together with their families and healthcare providers, consider their values and goals, and articulate preferences for future care.[13] Written advance directives formalize these preferences and include living wills or other statements of patients' preferences, as well as durable powers of attorney for healthcare, which name healthcare proxies. Do not resuscitate (DNR) orders are written by physicians to operationalize one specific set of preferences articulated by patients and their proxies. In recent years, advance care planning has been promoted widely in the USA and other countries, particularly in response to high-profile cases in which patients in vegetative state have been kept alive despite a presumption that such treatment violated their preferences.[14]

Although it could refer simply to signing a form in a lawyer's or doctor's office, ideally advance care planning creates an opportunity for patients to explore their own values, beliefs, and attitudes regarding quality of life and medical interventions, particularly as they think about the end of their life. Patients may speak with loved ones, physicians, spiritual advisers, and others during the process. This reflective work can help patients make important decisions about issues that may come up even when they still have the capacity to make decisions. When a patient loses decision-making capacity, physicians and loved ones who have been involved in the advance care planning process may feel that they know the patient's goals and values better. This allows them to make medical decisions that are likely to be consistent with the patient's values and preferences.

Advance care planning accomplishes a variety of goals for patients and families.[15] First, patients may use the process to clarify their own values and to consider how these affect their feelings about care at the end of life. Second, patients can learn more about what they can expect as they face the end of life and about various options for life-sustaining treatment

and palliative care. Third, they can gain a sense of control over their medical care and their future, obtaining reassurance that they will die in a manner that is consistent with their preferences. Finally, patients may increase the probability that loved ones and healthcare providers will make decisions in accordance with their values and goals.

Advance care planning may serve other goals, not directly related to medical treatments.[15] Patients may wish to relieve loved ones of the burden of decision making and to protect loved ones from having to watch a drawn-out dying process. Patients also may use the process to prepare themselves for death. Advance care planning may help one reflect more deeply about one's life, its meaning and its goals. Patients may reflect on relationships with loved ones, 'unfinished business', and fears about future disability and loss of independence. In this way, advance care planning may improve patients' feelings of life completion and satisfaction with their treatment in their final days. Advance care planning appears to increase patient satisfaction and, possibly, the quality of death and dying.[16,17]

When a patient's illness has progressed to its final stages, healthcare providers can use the groundwork from these earlier discussions to make specific plans about what is to be done when the inevitable worsening occurs. Among other things, the patient and the healthcare providers can decide the following: Should an ambulance be called? Should the patient come to the hospital? Which life-prolonging treatments should be employed and which should be forgone? Are there particular treatments aimed at symptomatic relief that should be employed?

Healthcare providers have their own reasons for wanting to engage their patients in advance care planning.[15] First, providers may use these discussions to reassure patients that their wishes will be respected. This can enhance a sense of trust. Second, providers may hope that advance directives will help to decrease conflict among family members and between family members and the healthcare team when the patient is seriously ill. Finally, they may hope that advance directives will assist them in making difficult decisions when the patient has lost decision-making capacity.

Physicians are often reluctant to raise the subject with their patients, and often do so later than patients may desire.[18] They may be under overwhelming time constraints. They may have never been trained to discuss this issue and are not sure how to introduce the topic. They may be worried that they will give patients the impression that they are 'giving up' on them or that they think they will die soon. If they have focused in past discussions on interventions rather than patient values and goals, they may have found these discussions frustrating and unhelpful.

Time constraints are difficult to overcome. Physicians could dedicate visits to discussing advance directives; but insurance companies may not pay for such a visit, and many patients may not wish to make a separate trip to the doctor for this purpose. The use of booklets and other tools to introduce the concepts involved in advance care planning may help physicians efficiently use their time to answer specific questions patients may have and to guide patients through the process. Enlisting nurses and social workers to help patients with the advance care planning process may also help.

Although physicians are often worried that patients will be put off by a discussion about advance care plans, surveys show that most patients want to discuss these issues early in the course of their disease, and that they think that the doctor should bring up the topic. Nevertheless, there will be some patients who are not ready to discuss advance directives. Healthcare providers must be sensitive to these patients. Advance care planning is a process that should be offered to patients, not forced upon them. The root cause of much of a physician's reluctance stems from lack of training in how to have these discussions. With training, physicians can feel more comfortable having these discussions, can learn how to deal with a patient's emotional responses, and can have effective discussions that the physician will find truly helpful in caring for patients.

Unfortunately, with few exceptions, the introduction of advance directives has had little demonstrated impact on actual resuscitation events.[19–26] This may be because of several reasons. Discussions often do not occur or are not recorded in ways that may have a lasting effect.[27] Some of the barriers to successful implementation have been procedural when, for example, documents are not available when needed. More importantly, problems arise with deciding in advance about specific interventions,[28] the adequacy of communication,[29] the willingness of healthcare providers to follow patients' preferences,[24,27] and patient and family misunderstandings about the process. Despite these limitations, written advance directives are useful when there is disagreement within a family, conflict between the family and healthcare team, or when the patient assigns a non-traditional family member (for example, a friend or same-sex partner) as the surrogate. In the USA, if the patient's preferences are known and understood by the family and team through an oral advance directive, in most states the written document is superfluous.

Entering these conversations may feel awkward, but if they are viewed as conversations about hopes, fears, and goals rather than decisions for specific preferences, they may be easier to engage. For example, Mr K could be asked how he has been doing since his hospitalization. What was it like to learn of his diagnosis, and how does this make him feel about the future? The clinician can empathize with his emotions and ask about specific concerns he has looking forward. By careful exploration of patients' values, healthcare providers can help patients discover their preferences. This expanded view of advance care planning allows people to think about their mortality and legacy. From such discussions, healthcare providers can help patients consider specifically whether there are certain treatments that they might wish to forgo, and to think about the circumstances under which they might forgo them.

REQUESTS FOR UNPROVEN OR INEFFECTIVE TREATMENTS

> Mr K chose to undergo chemotherapy and received carboplatin and gemcitabine. However, he experienced a significant decline in his renal function and his tumor progressed. He then tried pemetrexed but was hospitalized with neutropenia and fever. Again he had no response and wished to try something else. He was given erlotinib, but he could not tolerate the diarrhea. At this point his oncologist told him that there were no more proven treatments left and that she would not suggest more treatment, given his age and poor responses to previous agents. Mr K asked, 'Isn't there any more chemotherapy? What about an experimental drug or laetrile?'

Desperate patients seek desperate measures. Mr K has exhausted the proved treatments for his cancer and, even though he has experienced significant side effects from his treatment, he does not want to die and is willing to consider other options. Such options generally fall into two categories, clinical trials of promising, but unproven therapies and alternative treatments generally considered ineffective by the mainstream medical community.

Phase I clinical trials are conducted to ascertain the safety of experimental therapies prior to testing for efficacy. Such studies are not meant to be therapeutic and, historically, approximately 5 percent of patients enrolled in such trials of cancer agents achieve a response.[30,31] Nevertheless, most patients enroll with the intent of achieving therapeutic benefit.[32,33] Some have questioned whether this represents a failure of informed consent. Increasingly it is recognized that patients choosing to enroll in phase I trials may have different values from those who do not enroll. Although they understand the prognostic data presented to them, they maintain a more optimistic perspective and believe that they will be the ones to gain benefit.[34,35] In fact, many now argue that hospice care and phase I trials should coexist simultaneously.[36,37] In contrast, requests for alternative, ineffective treatments are viewed differently. Some of these treatments may fall into a category similar to agents used in established clinical trials, but the majority are far less accepted and sometimes considered quackery. Although belief systems vary among patients and clinicians, the primary issue here is one of informed consent and trying to be sure that patients do not encounter more harm than good in reaching out to such treatments.

When receiving requests for unproven or ineffective therapy, physicians should counsel patients openly and not hesitate to give an opinion based upon their knowledge of the intervention and the patient's values. It is important to acknowledge the patient's affect and recognize that requests for unproven or ineffective treatments are frequent proxies for patient distress and difficulty coping with impending death. A common pitfall is responding to such distress by offering more therapy rather than engaging the patient's emotional state. Similarly, others may tell patients that 'We'll wait until you're stronger and can take the chemo then', knowing fully well that the patient will never meet such a goal. A more productive technique to use in this situation is the 'wish' statement.[38] By letting patients know that 'I wish I had more effective treatment to offer you', clinicians can both align themselves with patients, while implicitly acknowledging that this goal cannot be met.

In these settings, clinicians struggle to promote hope in the patient with advanced disease and to support a positive outlook.[1] Incorrectly, they fear that discussing death may distress patients.[9,39–42] As a result doctors frequently convey overly optimistic prognoses or do not give this information at all.[43] Fearing the loss of hope, patients frequently cope by expressing denial, and may be unwilling to hear what is said.[44] Not unexpectedly, patients with more optimistic assessments of their own prognosis are more likely to choose aggressive therapies at the end of life.[45,46]

Physicians should recognize that it is not their job to 'correct' the patient's hope for an unrealistic outcome.[47] Hope is the framework within which patients construct their future.[48] It may be a desire for a particular outcome, or it may be, more broadly, trust or reliance. The key question is whether the patient's construction of hope is interfering with appropriate planning and behavior. Clinicians, at their best, can provide an empathic, reflective presence that will help patients to marshal and draw strength from their existing resources. Together, the physician and the patient can 'hope for the best but prepare for the worst'.[49] Helping the patient and family manage their hope and their resources in a realistic way may leave the family in the best possible shape after their loss.

LIMITATION OF TREATMENT

> Mr K became progressively more debilitated. He decided not to pursue unproven therapies and accepted a palliative approach to care, including a DNR order. He was spending an increasing amount of his time in bed and developed a fever and cough. He stopped eating and drinking. His family wondered whether he had pneumonia again and asked if he could receive antibiotics. In addition, they questioned whether a feeding tube should be placed or if an intravenous drip would be helpful.

Even when patients have elected to pursue a palliative approach to care, they and their care providers may struggle

over the exact limitations of treatment. They may wonder whether treatments such as feeding tubes and intravenous fluids provide comfort, and if their trade-off in treatment burden is worthwhile. Antibiotics are particularly interesting because they tend to be among the least refused of medical interventions.[50,51] Their use is high even in palliative care units, where they are administered to as many as 30–40 percent of patients with comfort care plans.[52–54] The literature suggests that antibiotics can play a role in symptom relief, yet must be balanced against the burdens of needles, side effects, and cost.[52,53] In the case of Mr K, pneumonia may be his terminal event, with or without the use of antibiotics. He and his family will need to decide whether intravenous antibiotics are worth a trip to the hospital, or even whether it is worth trying to administer them at home intramuscularly or orally. His symptoms of cough and fever can be managed with antitussives and antipyretics – it is not clear if adding another few days or weeks to his life will meet his goals at this point. Such decisions become highly individualized with no correct answers.

Tube feeding has not shown a significant benefit for most patients with terminal illness.[55,56] Therefore, there is less controversy on medical grounds. In contrast, considerable debate exists about the benefits of artificial hydration. Recent evidence suggests that subcutaneous hydration can alleviate common symptoms of terminal illness with minimal burden.[57] Guidelines established by the European Association for Palliative Care recommend a three-step approach:[58]

- Step I – includes assessment of a variety of clinical factors.
- Step II – involves an assessment of pros and cons to establish a well-defined goal of therapy and endpoint.
- Step III – requires periodic reevaluation of the decision.

OPTIONS OF LAST RESORT

Mr K's illness progressed and he was bed-bound with fluctuating consciousness. His required large quantities of opioids for pain and dyspnea. His daughter was concerned that the medication might hasten his death, and was resisting the hospice nurse's suggestion to increase the dose further. But his son felt that Mr K had completed all he needed to do and was just lingering uncomfortably. He wanted to know how much longer he would continue to live and if there was anything that could be done to stop the waiting.

One of the major barriers to aggressive symptom management at the end of life is the fear of hastening death. Many clinicians and families are unsure where pain control stops and euthanasia begins. Moral clarity on these issues is critically important to ensure that no inappropriate boundaries are overridden and to give reassurance to ethical providers who are working hard to take the best care of patients.[59]

In situations such as Mr K's, clinicians generally rely on the principle of double-effect to justify their actions. This centuries-old ethical framework allows one to perform beneficial actions with potentially harmful consequences as long as four requirements are met:[60]

- The act itself must not be immoral.
- The act must be undertaken only with the intention of achieving the possible good effect, without intending the possible bad effect even though it may be foreseen.
- The act does not bring about the possible good effect by means of the possible bad effect.
- The act is undertaken for a proportionately grave reason. (Or, stated otherwise, the good effect must outweigh the bad effect.)

The principle of double-effect has been useful in medical practice generally and palliative care in particular. This is because it helps many physicians overcome barriers to prescribing adequate pain relief, and it provides a legal defense for opioid prescriptions at the end of life.[61] At the same time, the principle also allows the community to continue to reinforce prohibitions against directly and intentionally causing death.

Several problems exist with double-effect.[62] It can be difficult to distinguish between intended and foreseen consequences, particularly regarding death at the end of life. Conscientious clinicians not sure of their actions may be tormented by the outcome. Furthermore, the principle of double-effect prioritizes the absolute prohibition against patient death over patient autonomy. Advocates applaud the principle for exactly this reason. Yet those who wish to allow greater flexibility for ending patient suffering at the end of life find double-effect to be constraining.

One practice, termed terminal or palliative sedation, links two acceptable acts in a controversial way. Patients are deeply sedated (double-effect), yet receive no hydration or nutrition (withdrawal of life-sustaining therapy). This intervention is intended for dying patients who have unbearable symptoms unresponsive to other therapies.[63] In the Netherlands, and perhaps elsewhere, the practice precedes a substantial number of deaths.[64] In the USA and most other countries it still remains rare. Because death is certain if sedation is not withdrawn, some people view this as a form of euthanasia, particularly those who believe in an absolute prohibition of hastening death.[65] Yet there is a growing consensus in favor of the practice under appropriate circumstances, and it is legal in the USA and many other countries. Concerns remain about potential abuses,[66] yet the necessity of a team provides some safeguards.

With regard to hastening death, other practices exist, and a detailed discussion of their history, merits, and risks is beyond the scope of this chapter. Briefly, these would include voluntary stopping of eating and drinking, assisted suicide, and euthanasia. Any competent patient who is approaching

the end of life and confronting overwhelming suffering may choose to voluntarily stop eating and drinking.[59] This difficult and potentially unpleasant option takes tremendous conviction.[67] Nevertheless, some take advantage of this because it is legal in most jurisdictions and there is a growing ethical consensus in support of the practice. Furthermore, it does not require physician involvement, which removes a significant barrier.

In contrast with voluntarily stopping eating and drinking, which has received relatively little attention, physician-assisted suicide has been at the center of considerable controversy, including decisions by the US Supreme Court. In the USA and many European nations there is a majority public support for this practice,[68–70] yet considerable controversy exists over its appropriateness.[71,72] Currently, the practice is legal in only one state in the USA, and in one European nation, although it is tacitly approved in others. The practice requires a competent patient – perceived as a safeguard to abuse and somewhat distancing the agency of physicians, which many prefer.

Euthanasia is the practice whereby someone other than the patient, usually a physician, administers a lethal agent to directly hasten a death. This practice is perceived differently in different countries.[73] In the USA, euthanasia is distinguished from physician-assisted suicide and no ethical consensus exists.[68] It is illegal everywhere and likely to be prosecuted. In the Netherlands, Belgium, and some other countries, the public response to the two practices is fairly similar and more accepting. From a practical perspective, euthanasia does not require a competent patient, which has raised concerns about safeguards to abuses of vulnerable patients.[74]

The debate about assisted dying has played out in the press, courts and legislatures. Yet, in the end, individual patients, families and healthcare providers confront real-life situations that must be resolved within the constraints of individual moral values and the law. As Mr K lay dying, his daughter might have been reassured by being told that the aggressive use of opioids is entirely within the accepted standard of care, as the intent is focused on controlling the patient's pain and other symptoms. The son's position is also understandable. It is difficult to sit at such a vigil and wait for a patient to die. In most settings, directly hastening a patient's death will not be an option. Nevertheless, nothing more needed to be done to extend Mr K life, such as giving nutrition, hydration, or antibiotics. All efforts should be focused on the patient's comfort, and helping the family find meaning during the last moments.

CONCLUSION

Ethical challenges lie in the paths of all patients, families, and healthcare providers dealing with a life-limiting illness. At different points in an illness, these may range from truth

telling to requests for assisted dying. Healthcare providers must enter into such issues without assumptions about patient preferences and with an open mind to learn the underlying issues. Careful listening, clear thinking about the ethical issues at stake and empathic communication will help resolve most such dilemmas.

Key learning points

- Truth telling engenders trust and is a central aspect of good palliative care, yet patients very considerably in their preferences for information.

- Patients should be asked how much information they wish to receive early in the course of an illness so that their preferences can be known and honored.

- Advance care planning serves multiple goals for patients, families, and healthcare providers in addition to communicating preferences for future treatment.

- Patients value discussions of advance care planning, but clinicians must initiate them.

- Clinicians should recognize that requests for unproven or ineffective therapies may reflect patient distress and respond accordingly to their emotional state, not just the underlying question.

- When considering limiting therapies such as antibiotics and artificial nutrition or hydration, patients, families, and providers should assess clinical factors, the pros and cons of therapy, and make a plan with well-defined endpoints.

- The principle of double-effect justifies most aggressive therapies for symptom control at the end of life.

- More aggressive options such as terminal sedation and assisted dying must be considered in light of patient values and the local laws.

Dignity in palliative care

SUSAN E McCLEMENT, HARVEY M CHOCHINOV

INTRODUCTION

Scholars from various disciplines are directing increased attention toward understanding the concept of dignity, and its specific application to end-of-life care. Such understanding is neither readily nor easily achieved, so long as conceptual clarity of the term dignity remains elusive. Tension exists in trying to provide care that honors both individual patient conceptions of dignity, and societal constraints on choices concerning a dignified life and death.[1,2] No doubt, ongoing debate and dialog among academics, researchers, and practitioners will enrich our future understanding regarding the issue of dignity in end-of-life care. However, it is within the present morass of complexity and ambiguity characterizing dignity that those providing end-of-life care to the terminally ill must practice their craft.

The work presented here does not purport to be an exhaustive treatise on dignity. Rather, the purpose of this chapter is to examine some of the salient issues healthcare providers must grapple with when notions of dignity in the provision of end-of-life care are invoked. First, conceptual challenges identified in the literature related to the term dignity will be presented. Next, the salience of dignity in discussions regarding end-of-life care will be examined. Finally, empirical work examining the issue of dignity in end-of-life care will be presented, along with suggestions for future dignity-related research.

CONCEPTUAL CHALLENGES: DEFINING DIGNITY

The concept of dignity is ubiquitous, figuring prominently in discussions of bioethics, human rights documents, codes

of research involving human subjects, patients' bill of rights, and decision making in end-of-life care.[3–8] Despite its widespread use, however, the concept of dignity is poorly understood, and consensus regarding both its meaning and utility in end-of-life discussions has yet to be realized. [9–12] The importance of conducting research into the construct of dignity was highlighted in the final report of a Special Committee of the Senate of Canada, mandated to explore the social, ethical, and legal aspects of euthanasia and assisted suicide.[13] That committee concluded health professionals cannot fully understand requests for assisted death and fears about loss of dignity if the construct remains vaguely defined. Far more than an academic exercise, clarification of the concept of dignity is important because our understanding of it appears to guide both healthcare providers and the public about the way they attend to the dying.

Dictionary definitions provide a starting point from which to begin to understand what dignity means. The word dignity is derived from the Latin *dignus* meaning 'worthy'.[14] Webster's *Dictionary* defines dignity as: 'worth or excellence; nobility of manner; quality of commanding esteem, high office, or rank'.[15] Defined in this way, dignity evokes notions of worth, honor, and esteem.[16] It is not clear from these definitions what one is worthy of. There is a tacit suggestion that evaluations of dignity involve a comparative process, however, specification regarding who confers evaluations or judgments of being worthy or esteemed is not clear.[12,17]

Synonyms for dignity include words like self-respect, self-esteem, poise, and pride,[18] suggesting that the concept is a broad one encompassing several meanings. Such 'umbrella' terms are typically difficult to define and operationalize.[19] Because the concept of dignity is not readily amenable to precise theoretical or operational definition, replacing it in favor of other concepts that appear to have greater definitional

precision is tempting.[20] However, alternative concepts such as 'autonomy' are imbued with ambiguity as well.[7] Mere word substitutions, then, will not produce the sought after clarity.

One approach used to clarify the meaning of words is the process of concept analysis; a formal linguistic strategy that facilitates examination of the defining attributes or characteristics of a concept.[19] It is a process used to determine similarities and differences between concepts, and create tentative theoretical and operational definitions.[21] Concept analyses of the term dignity can be found in the literature. Mairis[22] examined dictionary and thesaurus definitions of dignity as well as personal definitions of dignity offered by nursing students and healthcare professionals. Critical attributes of dignity emerging from her work included notions of maintenance of self-respect, self-esteem, and appreciation of what dignity means to the individual. The theoretical definition arising from this concept analysis suggests that dignity exists when individuals are able to exert control over their behavior, surroundings, and the way they are treated by others. Central to this definition is the capability of the person to be able to understand information and make decisions.

Haddock's[17] concept analysis defines dignity as 'an individual's ability to feel important and valuable in relation to others, communicate this to others, and be treated as such by others in contexts which are perceived as threatening' (p. 930). This theoretical definition speaks to the dynamic subjective nature of dignity, the processes involved in maintaining self-regard amid threatening situations or circumstances, and the interpersonal nature of dignity.

Dignity, as defined by Justice Iacobucci of the Supreme Court of Canada speaks to the self-respect and self-worth that individuals or groups feel. This definition is concerned with physical and psychological integrity and empowerment.[23] It not only injects the notion of capacity for self-determination into the concept of dignity, but also evokes what would appear to be critical attributes of dignity, such as autonomy, privacy, reputation, self-image, and intrinsic worth.[22,23] Such a broad range of alternative notions subsumed within this characterization of dignity, while capturing the complexity of the concept, makes definitional precision problematic. And like the theoretical definitions arising from the process of concept analyses of dignity, this characterization, while heuristic, lacks an empirical foundation.

What contributes to the ambiguity surrounding the term dignity? First, dignity seems to be closely intertwined with our ideas about autonomy, with both terms often referred to 'in the same breath'.[24] The equating of human dignity with autonomy is not new and can be traced to the writings of eighteenth century philosopher Immanuel Kant. Kant argued that human beings have an intrinsic worth – that is dignity – because they are rational agents capable of setting their own goals and making their own decisions. Following Kant's reasoning, the basic moral worth of every human being resides in the human capacity for rational choice.[25,26]

The pervasive tendency to equate dignity with autonomy is troublesome, for it assumes that individuals lacking the capacity for autonomous thought also lack human dignity.[27]

Some authors have attempted to effect the distinction between autonomy and dignity by examining the ways in which dignity is used in ordinary discourse. Pullman[7] asserts that the language of dignity embraces two distinct conceptualizations of the word. Basic dignity is the fundamental moral notion that speaks to the intrinsic worth of all human beings. In contrast, personal dignity refers to norms of dignity of the individual or subgroup of individuals.[7] Personal dignity is constructed through complex processes of social interaction and evaluation, and is socially and individually referenced.[7,12] Moreover, given that considerations of what counts as dignified treatment or behavior is variable between individuals and across groups over time, personal dignity should be viewed as a transient rather than an ascribed notion.[7]

Proulx and Jacelon's[28] contention that the concept of dignity rests in a dichotomy, consisting of both internal and external components, echoes Pullman's[7] assertion. Internal aspects of dignity speak to the inherent worth ascribed to all human beings, which is uniquely expressed in their life stories.[28–30] External aspects of dignity are connected to and vary with what matters to the individual person and includes such factors as physical comfort, autonomy, meaningfulness, spirituality, and interpersonal connectedness. This later conceptualization speaks to the subjective way in which individuals discern what is dignified for themselves and for others, and the ways in which dignity is socially constructed.[9]

There is consensus in the literature that dignity is a complex and multifaceted concept. However, the data sources informing definitions of dignity in the context of end-of-life care have largely failed to include an emic, or insider's perspective. Consequently, our understanding of dignity towards the end of life has been largely devoid of the voices of those best qualified to speak about it – terminally ill patients themselves. A patient-centered approach to understanding dignity provides guidance to those caring for the dying regarding what constitutes dignity enhancing or dignity eroding actions.[31] Examining dignity in end-of-life care from this perspective, and making what is tacit more explicit, should reveal dimensions of dignity that are not captured in the existing literature.

THE IMPORTANCE OF THE NOTION OF DIGNITY

Confusion in the literature related to definitions of the term 'dignity', have resulted in some authors characterizing the concept as 'ambiguous', 'euphemistic', 'subterfuge-creating', 'useless', and 'cliché'.[8,12,20,32] While the concept of dignity currently enjoys neither definitional specificity nor consensual meaning,[9,10] there does appear to be agreement

that dignity is foundational to the provision of quality end-of-life care.[33] Indeed, the link between providing palliative care and enabling patients to maintain their dignity is a perspective that Macklin[12] (p. 214) suggests proponents of palliative care are 'wont to emphasize'.

The importance of palliative care being philosophically rooted in an acknowledgment of the inherent dignity of the individuals has been expressed in the literature,[34] and dignity has been identified as one of the five basic requirements that must be satisfied in caring for dying patients.[35] The basic tenets of palliative care, including symptom management, spiritual and psychological wellbeing, and care of the family unit may all be summarized under the goal of helping patients die with dignity.[36–38] When the preservation of dignity becomes the clear goal of palliation, care options expand well beyond the symptom management paradigm and encompass the physical, psychologic, social, spiritual and existential aspects of the patient's terminal experience.[36] Dignity is thus a relevant concept in discussions regarding care of the terminally ill, in that it provides an overarching framework that may guide the physician, patient, and family in discussing and defining the objectives of care at the end of life.[39]

Considerations of helping patients to die with dignity is not, however, the sole purview of advocates of palliative care. Appeals to dignity are frequently invoked as the ultimate justification for euthanasia and assisted suicide – approaches to care of the dying diametrically opposed to the principles and practices of palliative care. For example, both the hospice movement and the Hemlock Society invoke the ideal of dying with dignity in defense of their opposing perspectives.[7,31,40,41] That dignity is used to defend and justify diametrically opposed actions and practices, seems to be predicated on the notion that for some, assisted death is consonant with, and the epitome of, respect for autonomy. This explains why in some circles, the term 'death with dignity' has become synonymous with the right to assisted suicide and euthanasia.[42] For others, however, such actions constitute the ultimate indignity.[43]

That 'loss of dignity' was the most common response of physicians when asked why their patients' had selected euthanasia or some form of self-assisted suicide clearly underscores the importance of better understanding the concept of dignity in end-of-life care.[44] In a Dutch nationwide study on euthanasia and other medical decisions concerning the end of life, loss of dignity was cited by physicians in 57 percent of cases, followed by pain (46 percent), unworthy dying (46 percent), social dependency (33 percent), and tiredness of life (23 percent). Research conducted by Back and colleagues[45] examining physician-assisted suicide and euthanasia in Washington State found that physicians of 207 patients who expressed a preference for hastened death reported that a loss of dignity was a concern for 72 percent of these patients.

A study conducted by Seale and Addington-Hall[46] explored differences in preferences for hastened death between cancer patients and patients with cardiac disease, stroke, and respiratory disease. Approximately 25 percent of the 'significant others' indicated that they would have preferred that the patient die sooner in his or her illness trajectory. Twenty-five percent of respondents also said that the patients themselves had expressed a desire for hastened death. Although these studies provide important insights into healthcare provider and family member perspectives, they did not solicit input from patients directly concerning this issue. Therefore, our understanding regarding patient experiences is incomplete.

Research has been conducted examining the types of physical and psychological concerns that may prompt terminally ill individuals to desire a hastened death. There is some suggestion in the literature that severe pain can result in a heightened desire for death. In their study of terminally ill cancer patients, Chochinov and colleagues[47] found that 75 percent of patients who had a significant desire for hastened death experienced moderate to severe pain, compared with 46 percent of patients with mild or no pain. Similarly, Rosenfeld and associates'[48] research examining interest in physician-assisted suicide among terminally ill patients with acquired immune deficiency syndrome (AIDS) found that pain intensity contributed significantly to the prediction of desire for death in those patients with pain.

Evidence also exists that depression contributes significantly to a desire for death among terminally ill patients. In a review of literature pertaining to physical and psychological distress associate with a desire for early death, Chochinov and Wilson[49] concluded that clinical depression, poor pain control, and low social support are significantly related to desires for hastened death, and that the degree of distress in these individuals is frequently very high. In an examination of desire for death in terminally ill patients, it was found that 8.5 percent of patients reported at least a moderate desire for death that was consistent over time. Slightly more than half of the patients (55 percent) reported no desire for early death and 36 percent of patients reported intermittent desire for early death. Follow-up interviews 2 weeks later indicated that four out of six of the original 17 patients with at least a moderate desire for death had changed their minds. This finding demonstrates that even strong desires for early death can change over a relatively short period of time. Given that requests for euthanasia in the Netherlands are usually satisfied within 2 weeks of the patient's request, efforts to explicate the factors that contribute to a desire for early death must be a continued foci of research.

In their review of terminally ill patients' requests for hastened death, Block and Billings[50] emphasized the importance of detailing the clinical determinants and the meaning of the request for early death, so that the therapeutic options offered by care providers may be broadened. Variables considered important in shaping patients' decisions to hasten death include symptom control, social support, psychological distress, and the meaning of life and suffering. Clearly, the psychological context within which a fear of lost dignity

is fostered needs to be understood empirically. Systematic examination and description of those factors identified by the patient as prompting requests for hastened death provide a solid foundation from which caregivers might implement dignity preserving or bolstering interventions.

Central to the arguments for and against death hastening measures are notions of what constitutes a 'good death' – an experience within which notions of dignity appear to be embedded.[51] Emanuel and Emanuel[52] have examined the construct of a 'good death', describing a detailed framework for this event. Though not empirically validated, these researchers synthesized the dying experience as a process with four critical components including fixed patient characteristics, mutable elements of the patient's experiences, interventions that are available, and overall outcome.

Steinhauser and colleagues[53] used a cross-section stratified random national survey to collect information from patients, families, and healthcare practitioners, with an aim to identifying factors that were most important to them at the end of life. Factors identified by participants include pain and symptom management, preparation for death, decisions about treatment preferences, and being treated in a holistic fashion. Relevant strategies for addressing these factors were not identified in the study.

Turner and colleagues[54] sought to measure dignity in 50 terminally ill patients being cared for in an integrated palliative care service during the final 72 hours of life by focusing on symptom control, level of functioning, and negative events and situations that might compromise dignity. The limitations of this work include inconsistency and confusion regarding the ways in which these criteria were measured, and sole reliance on healthcare provider perspectives in assessing dignity.

EMPIRICAL WORK

Empirical literature examining the concept of dignity in end-of-life care, although limited, is instructive. Street and Kissane's[9*] discourse analysis of palliative patient and family case studies provides insights about how dying people feel about their bodies and the care they receive at the end of life. Results from their work help to further dimensionalize our understanding of dignity as it relates to the embodied experience of dying, and the ways in which abjection of the body might serve as a source of shame and disgust for the terminally ill. Their findings regarding the reciprocal, relational nature of dignity serve as a poignant reminder that patient's perceptions of worth are greatly influenced by the ways in which care providers communicate with and care for them.

Enes[20*] conducted a phenomenological study examining the meaning of dignity from the perspectives of patients, relatives, and healthcare providers in a hospice inpatient unit in England. Thematic analysis arising from this work suggests that dignity concerns issues of relationship and belonging; having control; being human in terms of having
Figure 13.1   *The dignity-conserving model of care.*

rights and being worthy of respect; and maintaining the individual self. Patients, families and healthcare providers, while in agreement regarding the various facets of dignity, placed their emphases differently. For example, whereas healthcare providers emphasized issues of control and privacy, relatives emphasized issues of relationship and humanity. These findings speak to the need for, and challenges inherent in, trying to balance the multiple needs of care recipients and providers.

Chochinov and colleagues have been engaged in a program of research using a combination of qualitative and quantitative research methods to arrive at an understanding of the concept of dignity from the perspective of the terminally ill patient, and to identify various factors that support or erode a patient's sense of dignity.[55*] Inductive analysis of qualitative interviews conducted with 50 palliative cancer patients resulted in the generation of an empirically derived model of dignity in the terminally ill, and direction regarding dignity-conserving care[56*] (Fig. 13.1).

The model suggests that patient perceptions of dignity are related to and influenced by three major thematic areas:

- Illness-related concerns, i.e. those issues deriving from the illness that relate to one's level of independence and symptom experiences
- The patient's dignity-conserving repertoire, i.e. the personal approaches that individuals use to maintain their sense of dignity, and the internally held views or perspectives of their inherent qualities
- Social dignity inventory, i.e. factors external to the patient that influence the quality of his or her interactions with others that may bolster or undermine the person's sense of dignity (Table 13.1).

Quantitative data were collected in conjunction with the qualitative work to examine how various demographic and disease-specific variables were related to the issue of dignity in the terminally ill. A cohort of just over 200 terminally ill cancer patients were asked to rate their sense of dignity and complete measures of psychological wellbeing. Nearly half of the patients in the sample indicated they experienced some, or occasional, dignity-related concerns. Compared with those patients whose dignity was intact, patients with significant dignity-related concerns reported that they had increased pain, decreased quality of life, difficulty with bowel

Table 13.1 *Summary of major categories, themes, and subthemes arising from qualitative work examining the construct of dignity from the perspective of the terminally ill*

Illness–related concerns	Dignity–conserving repertoire	Social dignity inventory
Symptom distress	Dignity-conserving perspectives	Social issues/relationship dynamics affecting dignity
Physical distress	Continuity of self	Privacy boundaries
Psychological distress	Role preservation	Social support
medical uncertainty	Generativity/legacy	Burden to others
death anxiety	Maintenance of pride	Aftermath concerns
	Hopefulness	
	Autonomy/control	
	Acceptance	
	Resilience/fighting spirit	
Level of independence	Dignity-conserving practices	
Cognitive acuity	Living in the moment	
Functional capacity	Maintaining normalcy	
	Seeking spiritual comfort	
Figure 13.2 *Scree plot (see text for details).*

functioning, and were dependent on others [for bathing, dressing and incontinence issues]. These patients also reported a loss of will to live, increased desire for death, depression, hopelessness, and anxiety.[36*] The association between appearance (or the perception of how patients believe themselves to be seen or appreciated by others) and dignity, leads to the assertion that 'the reflection patients see of themselves in the eye of the beholder [care provider] needs to be one that is affirming of their sense of dignity'.[57]

Factor analysis of these data revealed six primary factors with Eigen values ranging from 7.19 to 2.39 (Fig. 13.2). This six factor solution accounted for 40.5 percent of the variance and included distinct aspects of the dying patient's experience: pain, intimate dependence, hopelessness/depression, informal support network, formal support network, and quality of life.[58*] This factor structure supports the model that arose from the qualitative work. Logistic regression analysis retaining those factors identified as being most malleable to palliative care intervention resulted in a highly significant two factor model that included hopelessness/depression and intimate dependency needs.[58*]

Some may argue that the model fails to resolve or dispel confusion around dignity's lack of definitional specificity. What every facet of the model has in common, however, is that each of the domains of concern identified within it

have been raised by terminally ill individuals as having a bearing on their sense of dignity.[33] As such, the dignity model provides an empirically derived theoretical framework which aids our understanding of the notion of dignity in those nearing death. We believe that the model of dignity-conserving care described here represents a new model of end-of-life care that may lead to enhanced palliation and new possibilities in care of the dying. Practical clinical considerations as to how healthcare providers might begin to apply dignity-conserving care approaches in practice are outlined in Table 13.2.

In addition to enhancing our understanding of dignity in those approaching death and providing a foundation upon which to both understand how a dying patient may experience a waning of their dignity, the dignity model also provides direction for how to construct dignity enhancing interventions for patients nearing death.[55] One such intervention is a brief psychotherapeutic intervention called dignity therapy that Chochinov and colleagues have developed and piloted tested. This approach comprises tape-recorded sessions, which give terminally ill patients the opportunity to speak to aspects of life they feel proudest of, things they feel are, or were most meaningful, the personal history they would most want remembered, or words they might provide in the service of helping to look after their soon to be bereft loved ones. These sessions are transcribed, edited, and returned to the patient, thereby bolstering patients' sense of purpose, meaning, and worth. Engagement in this empathic, therapeutic process provides patients tangible evidence that their thoughts and words have continued value. The creation of a 'generativity document' offers comfort in knowing that something of their personhood will transcend beyond the time of death. Preliminary findings suggesting this to be a viable way to address suffering and distress at the end of life has provided the basis for a National Institutes of Health funded international control trial of this novel end-of-life intervention.

Table 13.2 *Application of the dignity model to practice*

Illness–related concerns	Directions for practice
Symptom distress	
Physical distress	Baseline and ongoing assessment of physical and psychological symptoms
Psychological distress	
medical uncertainty	Provision of timely relevant information about the illness and plan of care
death anxiety	Exploration of concerns associated with illness progression
Level of independence	
Cognitive acuity	Baseline and ongoing assessment of cognitive functioning
	Vigilance in detection and treatment of delirium
Functional capacity	Baseline and ongoing assessment of ability to carry out activities of daily living
	Referrals to occupational and physiotherapy as appropriate
	Provision of supports needed to maintain independence (e.g. walker, raised toilet seat)
	Involvement in decision making regarding plan of care, as desired by patient

Dignity–conserving repertoire	Directions for practice
Continuity of self	Communication with patient about those facets of life not affected by their disease
	Learn about the patient's biography, attending to those aspect of life that he or she values most
Role preservation	Exploration of roles important to the patient
	Facilitation of role enactment within limitations of patient's illness
Maintenance of pride	Discussion with patient about those aspects of their life that they are most proud of
	Professional demeanor in provision of care
Hopefulness	Talk with the patient about what is still possible, despite illness limitations
	Encourage redefining of goals and expectations
Autonomy/control	Assess patient's perceived level of control, and explore preference regarding level of involvement in care decisions and planning
	Where possible, provide choices
Generativity/legacy	Facilitate life review, or other activities that foster the sharing of memories that are meaningful to patient
Acceptance	Explore the impact of the illness for the patient
	Appreciate the dynamism of the process of responding to a life-threatening illness
	Support patient in his or her outlook
Resilience/fighting spirit	Identify and promote patient participation in those interactions/activities that are most meaningful, given limited life expectancy

FUTURE DIRECTIONS

The empirical work conducted to date examining the concept of dignity in end-of-life care is still in its early stages. What is clear, however, is that the conceptual challenges related to defining dignity are not easily solved. The multifaceted, dynamic, and subjective nature of the concept seem to preclude exploration of the dignity experience using narrow definitions.[20] This suggests the need for researchers to understand and apply dignity in specific contexts in which it can be 'unpacked'.[31]

There is increasing appreciation for the need of palliative care that is both culturally sensitive and addresses the needs of individuals living with life-limiting illnesses apart from cancer.[59,60] As regards dignity research, future work could include exploration of the concept of dignity from the perspective of diverse cultural groups, various specific vulnerable populations, and those with nonmalignant conditions. Empirical work in these areas would inform us about the currency and relevance of the term dignity in other cultures, and help explicate nuances of dignity and dignity-conserving care that may be disease or group specific.

Little is known regarding the impact of terminal illness on perceptions and experience of dignity from the perspective of family members of the terminally ill. Research documents family members who perceive deficits in their terminally ill relative's care, experience changes in their own physical health and family functioning.[61] Therefore, the provision of care appraised by family as dignity eroding may impact on significant family outcomes. Accessing the perspectives of family members regarding the nature of dignified care of the dying is thus an important first step in meeting their care satisfaction needs.

Research has identified that the attributes of dignity may be emphasized or de-emphasized depending on the needs of the individual.[20] This finding speaks to the dynamic nature of dignity and suggests that longitudinal work indexing patient experiences of dignity across the illness trajectory is

warranted. Such longitudinal work may reveal differences in threats to dignity experienced in early versus advanced stages of disease, and help explicate a range of dignity-enhancing strategies that patients use over time.

CONCLUSION

Becker[62] asserts that a significant psychological factor affecting terminally ill people is the compromising of their perceived personal dignity. Palliative care has been characterized as care that 'honors and protects those who are dying, and conveys by word and action that dignity resides in people'.[63] (p. 1) Palliative care practitioners thus ought to be concerned with the issue of patient dignity and to best support it in the delivery of end-of-life care. In particular, those involved in care of the dying need to understand what dignity means to the recipients of care, bearing in mind the various issues subsumed within dignity related concerns. Such understanding will arm healthcare providers with a range of patient-centered approaches and interventions, aimed at achieving humane care for individuals approaching the end of life.

Key learning points

- Dignity is a complex and multifaceted concept making it difficult to define and operationalize.

- Dignity is foundational to the provision of quality end-of-life care.

- Until recently, an understanding of dignity in end of life has largely been devoid of the voices of terminally ill patients.

- When the preservation of dignity becomes the clear goal of palliation, care options expand well beyond the symptom management paradigm and encompass the physical, psychologic, social, spiritual, and existential aspects of the patient's terminal experience.

- A patient-centered approach to understanding dignity provides guidance to those caring for the dying regarding what constitutes dignity-enhancing or dignity-eroding actions.

Transcultural palliative care

CARL JOHAN FÜRST, SOLVIG EKBLAD

TRANSCULTURAL PERSPECTIVES ON DEVELOPMENT OF PALLIATIVE CARE

> Challenging assumptions based on one's own culture is essential to the development of knowledge and insight into others.[1]

There has been rapid development in palliative care in many countries during the past decades, as witnessed in clinical practice, organization, education, and research. This development has been diverse, depending on the local culture and traditions and the context of the care being delivered.[2–4] The many organizational models for end-of-life care around the world and the meaning of and terminology used in different countries mirror some of these variations.[5,6] The World Health Organization (WHO) 2002 definitions reflect a broadening concept of palliative care as compared with the previous WHO definition of 1990 but still do not specifically address cultural issues.[7–9]

Transcultural palliative care deals with the understanding and evaluation of cultural factors in advanced disease and end-of-life care. It takes into account the different cultural, religious, ethnic, and ethical value systems, and it bridges the gap between different cultural contexts by a more fulfilling communication between the care providers and patients and their families. For patients from immigrant populations, transcultural palliative care takes a dual perspective of the norms of the prevailing culture and of the minority group to which the patient belongs. This is relevant in palliative care services in all parts of the world.

Models of palliative care which have been developed in wealthier societies are not easily transferred to societies where there is poverty, extended family structure, and insufficient health infrastructure. There is a need to adjust to local social and culture contexts.[10] At the same time, spiritual care, which plays an essential part in relief of suffering and pain, is just as important in developing countries where comfort and medical resources are limited.[11] In addition, it should be borne in mind that the basic needs and wishes of patients from ethnic minorities in palliative care are common to all human beings and independent of cultural background.[3] Patients from ethnic minorities try to fit in with the dominant culture, which provides another argument against stereotypical cultural care not being appropriate.[12]

Thus, on the whole, transcultural palliative care includes knowledge of the practices and rites of different religions and cultures and is sensitive to the specific needs of minority groups. The term is used synonymously with intercultural and multicultural care.[13] A cultural perspective may also mean that palliative care can pass on its values to institutions, organizations, or education programs. One of the main findings from reflections from focus groups' interviews with hospice staff regarding cultural challenges in end-of-life care was that 'to better understand other cultures it is important to raise awareness about the staff's own culture and to pay attention to culture especially in the context of the individual'.[14]

In parallel with the development of palliative care the world has experienced unrivaled advancements in medical technology and pharmacology, giving rise not only to hope for new possibilities but also to unrealistic expectations of cure and survival. Another factor that has influenced the development of palliative care has been the needs of patients with nonmalignant diseases.[9] Generally, the prevalence of chronic and life-threatening illnesses has increased due to the aging of populations in many developed countries.[9,15]

We are witnessing a change in social structures, toward smaller numbers of informal caregivers. Families look different, are becoming smaller, and are often dispersed. The pressures of a demanding society often influence the family structure and divorce rates are increasing in many countries. At the same time societies and families have lost many of the rites and rituals that were often based on religion or historical traditions. In the past these served as a support during life events such as dying and bereavement.

The acquired immune deficiency syndrome (AIDS) epidemic, in particular in the developing countries, especially has left large groups of children with little adult support and at risk for disease and early death. At the same time, Western countries have witnessed increasing numbers of immigrants from developing countries, war-ravaged regions, and totalitarian regimes, putting new ethical demands on good quality care at the end of life.

CULTURAL COMPETENCE AND EFFECTIVE COMMUNICATION SKILLS

Culture is a process by which activities acquire moral and emotional meaning for individuals.[16] In the twenty-first century, human beings are interconnected globally in the virtual and physical worlds. From this it follows that traditional definitions of culture are now challenged by globalization, which has led to differences within a cultural setting that may equal or exceed the dissimilarities between cultures.[17]

Cultural competence refers to a clinician's knowledge of various cultures and their ability to apply this knowledge to patient care.[18,19] This competence demands a dual stance: first the clinician's own perspective and then the perspective of the patient and family members. The issues that need to be dealt with by all palliative care clinicians irrespective of their background professions is illustrated by the example case in Box 14.1 and in the proposed assessment model (Box 14.2). The ability to communicate effectively gives the clinician an insight of the ethnic minority patient's immediate medical and psychosocial needs.

Box 14.1 A transcultural assessment

Sophia is 43 years old and mother of three children between the ages of 12 and 19 years. She left Iraq with her husband and children 10 years ago. Sophia was diagnosed as having acute leukemia 2 years ago and has been through several chemotherapy regimens including a bone marrow transplant. She is newly admitted to your hospice from the hematology department. Her blood values and general weakness prevent further chemotherapy. She knows only a few words in your language. Her husband and his brother speak your language to some extent and try to act as

interpreters. Mostly they talk and answer on behalf of Sophia. Sophia is prescribed intravenous nutrition, blood platelets when required, and erythropoietin, and is on intravenous antibiotics because of recent septicemia. Your impression is that Sophia is nearing death and is experiencing severe anxiety. The relatives are expecting a brief stay at the hospice before a new course of chemotherapy.

Questions

- How would you handle the situation?

- What more information do you need?

- Are there differences between the perspectives of the different professionals in the caring team?

Box 14.2 A transcultural assessment model: attitudes, skills, and knowledge of transcultural palliative care

Attitudes – issues to reflect upon:

- Assumptions based on one's own culture and possible prejudices

- Your general standpoints on nutrition and fluids, personal care, drugs including smoking and alcohol, alternative treatments such as traditional medicine, anticancer treatment in end-of-life care

- Beliefs, attitudes and values regarding: diseases and prognosis, death customs and bereavement; patient-centered or authority-centered care; expectations of care by patient, family and staff

Skills – issues to be dealt with:

- Social hierarchical structure, family patterns

- Identify adaptations already made by the patient

- Modification of emphasis in teaching, e.g. targeting one of the parents or an elder family member to obtain accurate information and deliver education such as in home care

- Being supportive toward **religious beliefs** as well as toward profane attitudes

- Appropriately adapt communication and behavior according to family structures, communication patterns, and styles, based on cultural influences

Knowledge – issues you need to know about:

- Beliefs and practices related to illness and health, basic habits around dying, death and bereavement in relation to the major religions

- Where to find 'up-to-date information' on religious and cultural habits

- Biological variations, e.g. genetic variation in susceptibility to disease

- Impact of earlier, untreated, traumatic life events during the terminal stage of life

Organizational issues:

- Space, e.g. for patients and relatives to visit and pray if they wish

- Environmental factors, e.g. food, presence of religious artefacts

- Contacts with religious representatives

Barriers to cultural competence can be in relation to the care providers and to health systems.[18,19] The former barriers arise when individual providers lack knowledge of their patients' cultural practices and beliefs or when providers' beliefs differ from those of their patients. Those who expect their patients to respond as they themselves would to issues such as medical decision making, artificial nutrition and hydration, and death and mourning, will be unprepared when patients respond differently. System-related barriers exist because most facilities have not been designed for cultural diversity, favoring instead a 'one-size-fits-all' approach to care. For example: Can a Buddhist family stay long enough with the dead body of a relative to allow for the spirit to leave by the open window?

Thus, culturally tailored care is an important quality factor,[20] but stereotypical cultural care may be inappropriate, since micro-cultural differences and individual diversifications within cultures are common. When needs are not obvious it is necessary to specifically explore the cultural aspects of care.

THE INDIVIDUAL AND THE FAMILY

The focus for palliative care should be centered on the needs of the unique person and patient whose autonomy and values the staff seeks to respect. At the end of life, everyone should be treated with the same respect, independent of religious, cultural, language, and ethnic background. The fundamental ethical principle is the patient's right to die in the way he or she wants to, regardless of his or her condition, lifestyle, culture, beliefs, and educational background. A culturally competent and ethical decision-making model is based on human rights and the use of ethical principles that include values and assumptions of the patients.

Patient autonomy is a key issue in the interface between the patient-centered care that is common in many Western societies and the cultures where the family and community have a more important role and function as advocates for the patient. In some cultures, the welfare of the community

takes precedence over individual life, e.g. Korean Americans and Mexican Americans have been shown to be more in favor of the family making decisions on end-of-life issues than African Americans and European Americans.[21] In reality, decisions are often made by consensus.[22]

It is common to use an empirical ethical analysis that is based on patient autonomy. Other common and relevant ethical principles of Western cultures include the concepts of nonmaleficence, beneficence, and justice. In European philosophy there is sometimes a belief in absolute ethical principles that are the basis of morals. The two moral principles of nonmaleficence and justice are often seen as absolute.[2] Two other important principles are 'sanctity of life' and 'absence of suffering'.

BREAKING BAD NEWS

I will always prefer not to know, or to know as little as possible. No human being knows when he is going to arrive in this world, therefore I believe that his natural state is also not to know when he will depart.[2]

The ethical dilemma of giving diagnostic information or requesting informed consent for a medical procedure from a patient wishing to remain ignorant challenges the physician to balance respect for the patient's attitude with information which could be beneficial. Truth telling or breaking bad news, as well as communication about impending death, has to be seen in this context .[23–25] The nature and the amount of information given to patients with cancer is still approached differently, depending on the country and culture.[26–31] An important ethical question from a transcultural perspective is: What ethical justification can support the withholding of information or the giving of information to patients about their terminal illness? Culturally competent communication about death and dying is increasingly important once biomedical intervention is shown to fail to cure.

In many cultures, families of the patients still generally prefer to receive the information first. They can then filter the information to the patient. Their often-cited reasons for this include fear that the truth will cause the patient to lose hope, they need to protect the patient from bad news, and a strong religious belief.[32] However, effective communication about terminal prognosis allows patients and families to have realistic hope.[33] An example is the expression of parents' self-assumed duty to protect their child from knowing about a terminal prognosis. To carry out this family obligation, relatives should create a caring environment in which the patient does not have any unnecessary psychological burdens. Conflict occurs when the beliefs and wishes of family members differ from those of the patient, the team members, or both. If the patient desires and is capable of understanding full disclosure, the ethical challenge for the physician is whether to respect the patient's wishes or to follow the cultural views of the family members

which may be different. The focus needs to be the quality of life of the patient,[34] and among the team's responsibilities is helping the family to understand the patient's need for information and teaching them that hope can prevail when life comes to an end.[18,35,36]

DIFFERENCES IN VIEWS WITHIN THE PROFESSIONAL CARING TEAM AND BETWEEN THE TEAM AND THE PATIENT AND FAMILY

Patients' needs may be expressed by themselves, by a family member or by a member of staff. These medical and psychosocial needs must be recognized by the team and be thoroughly discussed. Frustration may occur in the team when views of the patient, family and team differ with regard to acceptance of treatment, for example, of pain and other symptoms. Perceptions of the ethical challenges involved may differ and there may be difficulty in communication about the problems. The challenge is understanding each other's perceptions of the problem. If successful collaboration based on shared trust is to be achieved, which will include the participation and empowerment of patients and their families in decision making, the caring team needs to be sensitive to the unique values of each patient, be empathetic, and have the ability to communicate.

Patients and families may be used to a hierarchical healthcare system and may therefore have difficulties dealing with the democratic values of the palliative care team approach. Some male patients may get a feeling of degradation if seen by a female doctor and vice versa, e.g. a female patient being seen by a male gynecologist.[37] Another issue can be the age of the doctor. Older patients may be critical of younger doctors and the doctors may have to demonstrate the required knowledge in order to be trusted.

Access to a professional interpreter is an important right of patients. There may be some resistance on the part of the family members, who prefer to do the translation themselves. A professional interpreter can draw attention to unexpressed signals that may give important information to the staff, for example: Does the patient understand the questions? How does the patient formulate the answers? Are the answers direct? However, patients may be unwilling to talk about delicate matters through a professional interpreter, even when the interpreter is from the same country, region or ethnic group as the patient. In spite of the fact that the interpreter will give assurance about professional secrecy, the patient or the family may not be fully trustful. The personal attitude and professionalism of the interpreter have a large influence on their ability to communicate and facilitate the meeting.[38,39]

Communication problems, hierarchical processes, uncertainty, scarce resources and competing values are the usual causes for moral dilemmas in healthcare. Physicians and nurses responsible for making medical decisions in end-of-life care can experience moral distress. Every team will have different needs and difficulties when encountering suffering and trying to make the best possible decisions and handling the situation.[40] Some of these dilemmas are listed in Box 14.3.

Box 14.3 Issues causing moral distress in transcultural palliative care

- Communication: breaking bad news; role of interpreter; patient/family; role of different team members

- Uncertainty: role of doctor, role of medical treatment, 'false' hope

- Scarce resources: setting priorities for staff, medicine, hospice/hospital beds

- Competing values and hierarchical processes: Whose values and beliefs are the focus?

RELIGION

The religious map in many countries has changed during the last 20 years. There is a profane wind in several modern (including Western) countries and religious rites and traditions are getting less important. Another large change is the growing number of Muslims, making Islam an important religion in several Western countries. Likewise, due to refugee immigration many Catholics and orthodox Christians have gone to the Lutheran countries of northern Europe.

How a patient identifies him or herself in terms of religious belief usually affects their perceptions of health and healthcare up to the end of their lives. Grief is influenced by the cultural meaning that every culture lends to death and loss.[20] The many different death rituals sometimes have a gender implication. For example it is the Muslim norm that members of the same gender wash the diseased body.[41] A common spiritual belief in some religions is that the body must be as intact and unblemished as possible to facilitate the spirit's course through subsequent incarnations or rest. Box 14.4 gives a checklist of important culturally or religiously dependent practices and rituals. The purpose of this chapter is not to give detailed information about different religions, but to emphasize that it is the responsibility of the team to assess the individual preferences of the patient and their family.

With regard to the immediate handling of the body after death, health professionals need to respect the wishes and, if possible beforehand, gather information from relatives and a religious representative concerning restrictions on who (i.e. gender) will close the eyes and mouth of the deceased adult patient, straighten the legs, and for example, for a Muslim patient, put the face and feet in a specific direction, taking into consideration the location of Mecca.[42]

<table>
<tr><td>

Box 14.4 Checklist of questions concerning cultural and religious practices and rituals. Individual preferences and concerns should always be considered

- *Fasting*: Christmas, before Easter, Ramadan, before funeral, fluids only

- *Dietary practices*: Vegetarian, flesh, meat, shellfish, no fermented, alcohol, kosher

- *Treatment*: Patient versus family, staff of same sex, no handshake, alternative treatment or approach, traditional medicine, shamanism

- *Professional interpreter*: same sex, same religion, local dialect, trust

- *Autopsy*: different levels of restriction, no organs taken

- *The dead body*: rituals, washing, dressing, same sex, cremation, burial, time constraints, bury in home country or host country

</td></tr>
</table>

In addition, washing and shrouding procedures may also be related to religion and customs regarding death. If the patient had no relatives, usually the religious community will arrange the prescribed rituals if desired.

Organ transplantation, although uncommon in palliative oncology care situations, is another issue which may not be allowed due to religious beliefs and therefore it is always of importance that the family of the deceased patient is given the information in a sensitive manner and accurately with due respect, i.e. the family has a choice. In several religions there is a custom to bury the deceased as soon as possible and cremation is usually avoided, for example in Judaism and Islam.[41,43] This may become a problem if death occurs during a holiday in a foreign country, giving rise to anxiety among the relatives. Under such circumstances, a rapid release of the dead body prevents unnecessary and prolonged distress to the bereaved family and friends.[42] In Islam, as a sign of respect for the deceased, the grieving relatives will not eat until the funeral. In Islam, the woman's role is to mourn and the husband's duty is to protect his wife.

Bereavement is the objective state of having lost an important, significant person. Grief, on the other hand, is the emotional reaction following a bereavement. Mourning is the behavioral reaction, reflections that a society expects will follow a bereavement. Family members may have more or less appropriate networks for support and sharing during the care and mourning process. An example of a supportive network is the Jewish practice of 'shiva'. The bereaved family stays at home for some days after the death. Family and friends bring food and help with the necessities of life. Such support may enhance the healing process for the family members.

VULNERABLE INDIVIDUALS

Asylum seekers and refugees with a past history of trauma are displaced from their homelands to new environments. It is hard to die as a stranger in a strange land. These patients have often lost their past and old ways of life, their friends and their own people. So much is destroyed by war and, with the onset of palliative care, much of this will never be regained. To settle in the new host country, refugees need to make many changes, and old ways are not always helpful in the event of advanced disease. A life-threatening disease is likely to bring back suppressed memories of atrocities and of other terrible events. Unresolved traumatic life events may evolve into reactions of a psychiatric nature, such as psychoses, which need to be distinguished from development of actual psychiatric disease and from expected reactions to trauma and crisis. Survivors of the holocaust or concentration camps from the second world war may have severe difficulties in coping at the end of life and may even develop psychotic symptoms. Also, dying prisoners who are confined or are illegal immigrants or who are not permitted to spend their last days in a hospice outside the prison need special attention. It is a challenge to bring competent palliative care to dying prisoners.[44]

It is a challenge in communication having to tell a pregnant mother from an ethnic minority, who is infected with HIV/AIDS that she is at great risk of delivering a baby with life-limiting illness. With regard to the loss of a child, mourning is again related to culture and religious customs. Empowerment of parents including spiritual support, which is often neglected but is of importance to prevent unnecessary suffering.[45] For example, an Islamic family may be reminded that children are innocent and pure and as such assured paradise.[46]

<table>
<tr><td>

Key learning points

- Transcultural aspects need to be included in palliative care.

- Cultural awareness, self-knowledge, and cultural competence are necessary tools for the palliative care team.

- Opposing ethical values and cultural norms may give rise to moral distress.

- Communication difficulties between staff, patient and family or within the professional caring team need to be resolved.

- Transcultural assessment should be made following a proposed structural model.

- Transcultural aspects of palliative care should be included in education and training.

Palliative care: global situation and initiatives

LILIANA DE LIMA

GLOBAL SITUATION

The World Health Organization (WHO) estimates that 56.5 million deaths occurred worldwide in 2001. Approximately 76 percent of these deaths occurred in developing countries, where over three-fourths of the people in the world live. According to the data, the main causes of the total mortality for that year were the following:[1]***

- Noncommunicable conditions, including cancers and cardiovascular diseases – 58.5 percent
- Communicable diseases, including acquired immune deficiency syndrome (AIDS), maternal and perinatal conditions and nutritional deficiencies – 32.5 percent
- Intentional and unintentional injuries – 9 percent

In the past decade, infectious diseases such as malaria, dengue, tuberculosis, and cholera have caused over a fourth of the cumulative deaths in developing nations. In addition, approximately 8 percent of the adult population is infected with the human immunodeficiency virus (HIV) virus in sub-Saharan Africa, and global AIDS deaths totaled 3.1 million during 2003.[2]*** Cancer is among the major noncommunicable causes of death worldwide and accounted for 12.6 percent of the total deaths in 2001.[1]*** The International Agency for Research on Cancer (IARC) projects that global cancer rates will increase by 50 percent from 10 million new cases worldwide in 2000 to 15 million new cases in 2020, primarily due to the aging of population and increases in smoking. Fifty percent of the world's new cancer cases and deaths occur in developing nations and approximately 80 percent of these cancer patients are already incurable at the time of diagnosis.

Access to palliative care

Palliative care includes the management of symptoms and provision of spiritual and psychosocial support to patients and their families from the moment of diagnosis, throughout the course of the disease. Palliative care can be provided simply and inexpensively in tertiary care facilities, community health centers, and at home. However, access to pain relief and palliative care services is often limited, even in developed countries due to a lack of political will, insufficient information and education, and excessive regulation of opioids.

A recent study on advanced cancer care in Latin America of 667 physicians demonstrated that most of the care given to persons with advanced cancer is in hospitals as compared with other facilities or at home, whereas the majority of cancer deaths take place at home. The study also identified the following top barriers to cancer pain management as reported by the respondents: (i) inadequate staff knowledge of pain management; (ii) patients' inability to pay for services or analgesics; (iii) inadequate pain assessment; and (iv) excessive state/legal regulations of prescribing opioids.[3]**

Morphine as an indicator of access to palliative care

For several years, morphine consumption has been used as an indicator of adequate access to pain relief, one of the cornerstones of palliative care. In 1986, the WHO and its Expert Committee on Cancer Pain Relief and Active Supportive Care developed the *WHO Analgesic Ladder*[4]** for the relief of cancer pain. The method relies on the permanent availability of opioid analgesics, including morphine, codeine,

and others. The *WHO Ladder* has been widely disseminated throughout the world. Still, opioid analgesics are insufficiently available, especially in developing countries, and prescription of morphine is limited to a small percentage of physicians and is unavailable in many countries of the world.

The International Narcotics Control Board (INCB) collects the consumption data yearly from government reports.[5] While supply of narcotic drugs for medical purposes remains inadequate, the consumption trends recorded by INCB indicate improvement. The global consumption of morphine has been doubling every 5 years since 1984. In 2002 global consumption amounted for 27.3 tons.[6] The trend is, however, mainly due to increasing consumption in a few countries. For 2002, 82 percent of the total global consumption of morphine occurred in six countries: USA, France, Canada, Germany, United Kingdom, and Australia; the remaining 18 percent was consumed in the other 133 countries for which data are available. There are 51 developing countries for which there is no registered morphine consumption at all.[5]

In the study of advanced cancer care in Latin America mentioned in the section above, over 80 percent of the respondents reported either good or excellent availability of the main nonopioid analgesics and adjuvants in their practice settings. In contrast, the availability of both short- and long-acting opioid analgesics varied greatly across by nations, practice settings, and by specific medication.[7]** The great majority of the countries reported difficulties in access and excessively strict regulations on the use of controlled substances. Other studies have confirmed similar results in the availability and accessibility to potent analgesics and limitations to palliative care in different regions of the world.[8–11]

Socioeconomic and cultural aspects

The developing world varies greatly from country to country and region to region. There are a limited number of excellent facilities in developing countries with the latest technology and medications capable of delivering care similar to that of the developed countries, but the majority of the population does not have access to these institutions, and are cared for in facilities with limited resources. Patients in extremely resource-poor settings pose different challenges which need to be taken into account when developing palliative care programs and strategies.

Palliative care is often perceived as part of the Christian movement. However, there are many palliative care programs and hospices in Islamic, Hindu, Jewish, and Buddhist regions of the world. The main concepts of palliative care – respect for the individual, compassionate care, holistic approach, and the incorporation of the relatives and family members as part of the care team – can be applied to all religions and faiths.

Cultural aspects play a significant role in the provision of care. Research has shown there are major differences in attitudes and beliefs regarding issues such as communication, the role of patients and families in the decision making process, amount of information disclosed in the diagnosis and prognosis, spiritual aspects, discussion of end-of-life issues and other related topics.[12,13] Professionals need to be aware that there is a need for recognition of these differences, especially in multicultural environments, or when traveling abroad to teach or work in another country.

Palliative care for patients in the developing world

The modern palliative care movement originated during the 1960s in the UK as a response to the unmet need of patients with terminal conditions and their families. This movement soon became global and there are now hospices and palliative care units in many countries around the world.

A large body of knowledge has emerged on the assessment and management of the physical and psychosocial problems that occur in patients who develop cancer and other progressive incurable illnesses. The overwhelming majority of the available written material refers to the delivery of palliative care for diseases that occur mostly in the developed world and using resources mostly available in developed countries. But patients in developing countries die younger and of conditions different to those in the developed world. In addition, there are socioeconomic and cultural issues that pose particular challenges for the healthcare team. Communication, disclosure of the diagnosis, active participation in the decision making and treatment, discussion of end-of-life issues and other matters are all influenced by the context in which these occur. Recent publications address these issues and highlight the importance of a global approach sensitive to the different conditions, cultures, and settings. Some of these include *Palliative Care in the Developing World: Principles and Practice*[14] and *Pain and Palliative Care in the Developing World and Marginalized Populations: A Global Challenge.*[15] These publications not only cover treatment of diseases common in developing countries, but also cultural and ethical principles affecting care of patients with varied religious beliefs, ethnical groups, and backgrounds.

GLOBAL INITIATIVES

The World Health Organization

The WHO World Cancer Report calls on all countries to establish comprehensive national cancer control programs aimed at reducing the incidence of cancer through primary prevention; providing earlier diagnosis and curative treatments; and improving the quality of life for patients with cancer and their families through the delivery of adequate palliative care and pain relief.[16]

AFRICA PROJECT ON PALLIATIVE CARE

Palliative care is one of the three main priorities of the WHO Program on Cancer Control (PCC) and is included in the agenda of several other WHO programs.[17] The WHO Program on Cancer Control in collaboration with the WHO Departments of Care for HIV-AIDS, governmental and intergovernmental agencies, nongovernmental organizations and the WHO Regional Office for Africa (AFRO) developed an initiative to strengthen palliative care in southern African countries. The project, called 'A Community Health Approach to Palliative Care for HIV and Cancer Patients in Africa' is being implemented in five countries – Botswana, Ethiopia, Tanzania, Uganda, and Zimbabwe.[18]

The main goal of this project is to contribute to the improvement of the quality of life for cancer and HIV/AIDS patients in southern African countries by facilitating and strengthening the initiation and development of palliative care programs with a public health approach. These programs provide pain relief and holistic care to an increasing proportion of patients with advanced HIV/AIDS.

The specific objectives are:

- To develop/reinforce palliative care programs with a public health approach in response to the needs and gaps identified, considering:
  - a holistic approach to palliative care, giving special emphasis to pain relief
  - a systemic approach to program implementation which considers policy development, provision of care, drug availability, training, and education in the context of HIV/AIDS and cancer health problems
  - integration with the existing health system, involving all levels of care with special emphasis on home-based care
  - a team approach at the organizational and care levels
  - the elements for good quality performance: improving access, acceptability, efficiency, effectiveness, etc.
- To advocate for drug availability and policy development among the governments of the participating countries
- To develop a network among the participating countries that will:
  - promote exchange of information and collaboration
  - advocate for the integration of such programs into national strategic plans for health and social services.

The first part of this project has been completed and WHO is seeking funds to continue with the second phase. Additional information about this project can be found in the Palliative Care Page on the WHO website (www.who.int/cancer/palliative/africanproject/en/).

WHO COLLABORATING CENTERS IN PAIN RELIEF AND PALLIATIVE CARE

The WHO collaborating center forms part of an inter-institutional collaborative network set up by WHO in support of its program at the country, inter-country, regional, interregional, and global levels. The Collaborating Centers in Pain Relief and Palliative Care are a resource for the Organization, professionals, policy makers, and the public in current and relevant issues in the field.[19] One particular collaborating center which has been very active in the field of opioid availability and policy is the WHO Collaborating Center for Policy and Communications in Cancer Care. The center specializes in the assessment of barriers in national approaches to opioid analgesic regulations, seeks to make opioids available for medical and scientific use, maintains a global communication network for the WHO Cancer Pain Relief and Palliative Care Program, and provides assistance to initiatives or country projects regarding palliative care, especially those concerning advocacy for drug availability and policy development. The center is located at the Pain and Policy Studies Group, University of Wisconsin Medical School, Comprehensive Cancer Center at Madison, WI, USA. The center has a website (www.medsch.wisc.edu/painpolicy) which lists several reports on opioid use, policies, and documents which are very useful to palliative care workers, legislators and government representatives from around the world.

The International Association for Hospice and Palliative Care (IAHPC)

The IAHPC is a not-for-profit membership-based organization dedicated to the development and the improvement of palliative care worldwide. The organization works with associations, agencies, and individuals, to improve communications and access to resources, as well as to foster opportunities in education and training. The IAHPC's Board of Directors is composed of recognized leaders in palliative care from 16 different countries.

PROGRAMS

In the last 4 years the IAHPC has become an organization recognized by its leadership and ability to improve the delivery of palliative and hospice care through its teaching and support programs.[20] These include:

- Traveling Fellowship Program: This program covers the cost of travel of an individual who has been invited to teach in a developing country for at least 2 weeks. From 1999 to date, 35 individuals have traveled to programs in 25 different countries.
- Traveling Scholarship Program: The Traveling Scholarship Program provides financial support to individuals from developing countries to cover the cost of travel to an international meeting or congress. They are selected for their outstanding leadership capabilities and past accomplishments in palliative and hospice care.
- Annual Recognition Awards Program: The Annual Awards are given in three categories – individual,

institutional, and university – as recognition to outstanding effort and work in the development, promotion and dissemination of palliative care practices and knowledge.

- Faculty Development Program: The main objective of this program is to promote formal education in healthcare institutions by funding faculty palliative care positions for nurses or physicians in developing countries.
- Clearing House Program: IAHPC has sent more than 4000 kg of donated journals and books to individuals, hospices, institutions, and libraries in developing countries.

The IAHPC website at www.hospicecare.com has more than 2500 pages of information with free universal access to all readers from around the world. IAHPC continues to work and support individuals, agencies, institutions and schools interested in the promotion and dissemination of palliative care.

The International Observatory in End-of-Life Care (IOELC)

The IOELC is located at Lancaster University, UK, within the Institute for Health Research.[21] The IOELC works with a team of researchers and in partnership with colleagues and organizations in many parts of the world. The Observatory concentrates on two streams of activity: global analysis of palliative care development; and historical, sociological and ethical studies of hospice and palliative care in specific contexts.

In addition to the Observatory's project-based research and development program it also houses the digital and paper archives of its Hospice History Program and contains an extensive collection of current reference materials.

The IOELC has done a major review of hospice and palliative care in eastern Europe, Central Asia and western Europe, including current initiatives and history of its development. A review of Africa and Latin America is under way.

OBJECTIVES

- To provide clear and accessible research-based information on hospice and palliative care provision in the international context, incorporating public health, demographic, epidemiologic and healthcare systems analysis as well as ethnographic, historical, and ethical perspectives.
- To disseminate this information through the Observatory website and through published articles, monographs, reports, CDs and other media, in ways that facilitate cross-national comparative analysis and stimulate practical development.
- To undertake primary research studies and reviews to generate such information.

- To develop a small grants program to support academic work relating to the aims of the Observatory in resource-poor regions.
- To work in partnership with key organizations and individuals, nationally and internationally, in order to foster a sense of inclusion and participation in the work of the Observatory.

The IOELC has a growing network of collaborators across several countries and continents and already has key links in India and South America, as well as eastern Europe, Central Asia and Africa. Additional information about the Observatory can be found on its website (www.eolc-observatory.net/).

World Hospice and Palliative Care Day

World Hospice and Palliative Care Day is a new unified day of action to celebrate and support hospice and palliative care around the world. It has been developed in association with Voices for Hospices and hospice and palliative care associations worldwide.[22] The initial date to celebrate the World Hospice and Palliative Care Day is set for 8 October 2005, and will hopefully become an annual global event. Activities will take place worldwide and a collective global voice comprising individuals and associations will raise awareness and understanding of the need and importance of hospice and palliative care.

REGIONAL INITIATIVES

European Association for Palliative Care (EAPC)

The EAPC was established on December 1988, with 42 founding members after an important initiative by Professor Vittorio Ventafridda and the Floriani Foundation. The aim of the EAPC is to promote palliative care in Europe and to act as a focus for all of those who work, or have an interest, in the field of palliative care at the scientific, clinical, and social levels.[23] Since 1990, the Head Office of EAPC has been based at the Division of Rehabilitation and Palliative Care in the National Cancer Institute in Milan, Italy. By 2004, EAPC counted individual members in 40 countries, with collective members from 30 national associations in 20 European countries, representing a movement of some 5000 healthcare workers and volunteers working or interested in palliative care.

AIMS OF EAPC

- Promote the implementation of existing knowledge; train those who at any level are involved with the care of patients and families affected by incurable and advanced disease; and promote study and research.

- Bring together those who study and practice the disciplines involved in the care of patients and families affected by advanced disease (doctors, nurses, social workers, psychologists and volunteers).
- Promote and sponsor publications or periodicals concerning palliative care.
- Unify national palliative care organizations and establish an international network for the exchange of information and expertise.
- Address the ethical problems associated with the care of terminally ill patients

INITIATIVES OF THE EAPC

The EAPC website (www.eapcnet.org) has become a crucial communication tool to update on the latest developments and report in detail on the activities of EAPC.

The *European Journal of Palliative Care* is the journal of the EAPC. It is a multidisciplinary journal, published six times a year in both English and French. The journal concentrates on reviews and current awareness of palliative care on the European scene. *Palliative Medicine* is the leading peer-reviewed research journal of palliative care in Europe. It is published eight times a year and the printed version, with online access to the back issues of the last 5 years, is available by subscription.

The 'Research Network' has organized 11 expert working groups on a variety of topics for which a common European position or recommendations are needed. By the end of 2003, the results of the work of seven groups had been published, one of them in six languages. One of the priorities of the EAPC for the future is the support of development of palliative care in eastern Europe.[24] In 2001 the EAPC coordination center was established at Stockholm's Sjukhem Foundation in Sweden, which hosts and supports the center locally.

EAPC TASKFORCES (PROJECTS)

- The EAPC Ethics Task Force on Palliative Care and Euthanasia: The paper is available on the Web (www.eapcnet.org/projects/ethics.asp) in English, French, Italian, and Hungarian.
- EAPC Taskforce on Palliative Care Standards: A goal of this taskforce is to identify the needs for a European standard and create a checklist that anyone can follow.
- EAPC Taskforce on Palliative Care Development in Europe: This taskforce is in collaboration with EAPC Onlus; the IOELC; Help the Hospices and IAHPC, with the aim to achieve an overall vision of the care activity and development of palliative care teams in Europe.
- Taskforce on Palliative Care for Children: The goal of this taskforce is to enhance the opportunities for knowledge exchange between adult and pediatric palliative care physicians.
- Taskforce on Nursing Education: This taskforce was convened to develop recommendations for palliative nurse education in Europe. Recommendations will be published on the EAPC Website.
- Survey on Medical Education: This taskforce was convened to carry out a survey on the state of the art of education for physicians in Europe.
- Taskforce on Medical Education: This taskforce was convened to create recommendations for curricula for medical education.

EAPC CONGRESSES AND FORUMS

Since 1990 the EAPC has organized nine European congresses and three research forums with the participation of individuals from countries of Europe and other regions of the world. The tenth congress of EAPC is scheduled for June 2007 in Budapest, Hungary. The fourth research forum of the EAPC is scheduled for May 2006 in Venice, Italy.

African Palliative Care Association (APCA)

The APCA was founded in 2003 to help support and promote the development of palliative care and palliative care professionals throughout Africa. Members include professionals, individuals with a special interest in the promotion of palliative care, and national and local palliative care associations/programs. APCA recently held its inaugural conference in Arusha, Tanzania, and a new journal was created.[25] Additional information about this meeting and the association can be found on the internet (www.hospicecare.com/newsletter2004/aug04/regional-africa.htm).

OBJECTIVES

- To promote the availability of palliative care for all in need.
- To encourage governments in sub-Saharan Africa to support affordable and appropriate palliative care which is incorporated into the whole spectrum of healthcare services.
- To promote the availability of palliative care drugs for all in need.
- To encourage the establishment of national palliative care associations in all African countries.
- To promote palliative care training programs suitable for sub-Saharan African countries.
- To develop standard guidelines for training and care at different levels of health professional and care providers.

Hospice Palliative Care Association of South Africa (HPCA)

The HPCA was established in South Africa in 1988. Its mission is to provide a holistic and individually tailored palliative care service to all who require such a service, irrespective of the ability to pay.[26]

The Hospice Association of South Africa (now the HPCA) has been providing palliative care through an ever-developing network of hospices throughout South Africa, Botswana, Swaziland, and Zimbabwe, since 1989. The Hospice Association of South Africa developed the Short Course in Palliative Nursing for Professional Nurses in 1994, which is accredited by the South African Nursing Council. Member hospices provided palliative care for 2900 patients in 2002–03, supported their families into the bereavement period, and provided training for 3000 professional and lay people in various aspects of palliative care. Six thousand AIDS orphans were supported in the bereavement programs. With the increasing number of children infected and affected by HIV/AIDS, the need for pediatric palliative care has been highlighted. A national survey revealed a lack of training curricula in this discipline for members of the multidisciplinary team. The HPCA received a grant from the Diana, Princess of Wales Memorial Fund to develop a curriculum for training doctors, nurses, social workers, and other members of the multidisciplinary team, in accordance with the National Qualifications Framework. This is in the process of development with input from role players from around South Africa. Additional information can be found in the website (www.hospicepalliativecaresa.co.za/index.htm).

Foundation for Hospices in Sub-Saharan Africa (FHSSA)

The FHSSA mission is to support organizations in their provision of hospice and palliative care in sub-Saharan Africa.[27] The foundation is partnered with the National Hospice and Palliative Care Organization (NHPCO) in USA.[28] The FHSSA was incorporated in November 1999 and the 21-member Board of Directors included individuals representing a variety of hospice, AIDS service, and medical disciplines from the USA.

An international consultation, which involved both Africans and Americans, was held in 2000 to map out a strategic plan for the FHSSA's efforts. The consultation produced a strategy paper for hospice and palliative care development in the sub-Saharan region. Action recommendations for funding were approved and supported by standards for African programs seeking assistance. These program standards were modified from those adopted by the Hospice Association of South Africa for its members.

In addition, the FHSSA's International Advisory Council is a multinational body whose members help advise the FHSSA on international efforts to raise awareness of the African hospice movement. The FHSSA has a website (http://fhssa.org/).

Asia Pacific Hospice Palliative Care Network (APHN)

The APHN has been established to link all those who are interested in developing hospice and palliative programs in Asia and the Pacific. There are now more than 700 members. Sixteen percent of these are organizations that have joined as organizational members; the rest are individuals who are working with some of the 500 hospices and palliative care services in the Asia Pacific region.[29] The APHN evolved over a series of meetings between March 1995 and March 2001 when the organization was registered in Singapore. Although the Secretariat has been established in Singapore, the APHN is a regional organization with 14 founding sectors.

OBJECTIVES[30]

- To facilitate the development of hospice and palliative care programs.
- To promote professional and public education in palliative care.
- To enhance communication and dissemination of information among members.
- To foster research and collaborative activities.
- To encourage cooperation with other relevant professional and public organizations.

Additional information about the organization and its activities is available on the internet (www.aphn.org/).

Latin American Association for Palliative Care (*Asociación Latinoamericana de Cuidados Paliativos*; ALCP)

The ALCP was recently incorporated as a legal entity, but for more than 14 years, several Latin American palliative care workers have been meeting every 2 years to discuss problems, review recent developments and establish networks of support. For some years, the participants voiced their interest in establishing a formal organization to represent the needs and goals of the region.

The mission of the ALCP is to promote the development of palliative care in Latin America and the Caribbean by integrating of all those interested in helping improve the quality of life of patients with incurable progressive diseases as well as their families.[31] The Association recognizes palliative care as 'the active total care of patients and their families by a multi-professional team when the patients' disease is no longer responsive to the curative treatment'. Control of pain, of other symptoms, and of psychologic, social and spiritual problems is paramount.

OBJECTIVES

- To associate all those who are interested in caring for patients with incurable diseases and their families.
- To promote regional information exchange of experiences to strengthen the existing programs and help in the development of new programs.
- To promote the implementation of existing available knowledge, study and research.

- To develop a basic system to be adapted and applied in every country for the accreditation of institutions and the certification of health personnel of different disciplines.
- To collaborate with its members in:
  - their relationships with the community and the sanitary authorities
  - the identification and planning of the best healthcare model for their country or region
  - the development of systems of economic retribution applicable to their country
  - the development of norms of quality applicable to their country
  - the procurement of resources
  - training of healthcare personnel
  - obtaining regional information to identify needs and collaborate in the design of strategic plans based on this information
  - publishing guidelines and papers in Spanish and Portuguese
  - providing information on educational activities for healthcare professionals, patients, legislators, and the general public
  - supporting initiatives for changes in public health policies which seek to endorse and ensure adequate palliative care
  - promoting the necessary changes in policies and regulations to ensure that the necessary drugs for pain relief and other symptoms are available in all countries, in rural and urban regions.

THE LATIN-AMERICAN CONGRESSES

The Regional meetings serve as a venue where participants share experiences, disseminate new information, and establish a network of colleagues around the world. The meetings started in 1998 and have been going on every 2 years. The next congress will take place in 2006 in Venezuela.

CIRCULAR OF THE ALCP (NEWSLETTER)

The circular is a free electronic monthly or bi-monthly publication in Spanish and Portuguese. It is sent via e-mail to more than 2000 readers in the region. The publication is available on the internet (www.cuidadospaliativos.org/circular/index.html).

WEBSITE

The ALCP website (www.cuidadospaliativos.org) provides the regional colleagues a tool for the dissemination of information and for the development of support networks.

Open Society Institute (OSI)

The Open Society Institute (OSI) is a private operating and grant making foundation based in New York City that serves as the hub of the Soros Foundations Network, a group of autonomous foundations and organizations in more than 50 countries.[32] OSI and the network implement a range of initiatives that aim to promote open societies by shaping government policy and supporting education, media, public health, and human and women's rights, as well as social, legal, and economic reform. In the last years OSI has played a crucial role in providing support and funding to palliative care initiatives and hospices mainly in eastern Europe and Africa.

NATIONAL ASSOCIATIONS WITH INTERNATIONAL PROGRAMS AND INITIATIVES

National Hospice and Palliative Care Organization (NHPCO)

The NHPCO is the largest nonprofit membership organization representing hospice and palliative care programs and professionals in the United States.[33] The organization is committed to improving end-of-life care and expanding access to hospice care with the goal of profoundly enhancing quality of life for people dying in America and their loved ones.

The NHPCO, founded in 1978 as the National Hospice Organization, changed its name in February 2000. With headquarters in Alexandria, VA, USA, the organization advocates for the terminally ill and their families. It also develops public and professional educational programs and materials to enhance understanding and availability of hospice and palliative care; convenes frequent meetings and symposia on emerging issues; provides technical informational resources to its membership; conducts research; monitors Congressional and regulatory activities; and works closely with other organizations that share an interest in end-of-life care.

The NHPCO works collaboratively with existing organizations and individuals who are advancing hospice and palliative care in several regions of the world. It has recently joined forces with the FHSSA to support the development of hospice care in Africa. The *Journal of Pain and Symptom Management* has recently been named as the official journal of NHPCO.[34]

UK Forum for Hospice and Palliative Care Worldwide

The UK Forum for Hospice and Palliative Care Worldwide is the national umbrella and representative body for organizations and individuals working in the UK to support hospice and palliative care services overseas. The Forum is established within Help the Hospices with the goal of

promoting a national, strategic, and collective response in the UK to hospice and palliative care services overseas.[35]

ACTIVITIES OF THE FORUM

- Development of a UK network of people and organizations interested in working in hospice and palliative care overseas.
- Creating a funding structure to support hospices overseas.
- Facilitating twinning arrangements among hospices in the UK and abroad.
- Providing support for training and education for individuals in developing countries.
- Promoting advocacy and dissemination of information.

Worldwide Palliative Care News

The aim of this service is to provide information and sign-posting of information sources to international palliative care workers and to their counterparts based in the UK. The service is managed by Hospice Information Service and the UK Forum for Hospice and Palliative Care Worldwide which aims to keep people involved in international projects informed about funding opportunities, twinning, publications, disease information, policy, and practice.

LESSONS LEARNED FROM THE GLOBAL SITUATION

Thanks to the advancements in technology, the palliative care community around the world is now able to establish and maintain communication on a global scale. Many initiatives were isolated in their efforts, and knowledge of developments in other countries was scarce and limited. E-mail and the internet have had a huge impact in our ability to stay connected and disseminate information. Some of the most important lessons learned from the global situation are:

- Currently many resources, funding organizations, and professional associations are reaching out to individuals and programs around the world. In this process, it is necessary to keep our focus and avoid duplication of efforts. Each one of the organizations and initiatives described in this chapter has a clear mandate. Our ability to maintain this will keep us from using resources in doing what others may have better experience about and knowledge. This may have a devastating effect and can become quite confusing to individuals and local governments. Ideally, efforts should be coordinated among agencies to ensure maximal effect and better use of resources.

- The best global strategy is by cooperation rather than competition. With the advent of technology and the ability to communicate rapidly, the exchange of ideas and mutual collaboration among agencies and programs is the key to success. Having a unified front of specialized organizations collaborating in achieving the goal of improving access to hospice and palliative care is important as a strategy. Advocacy campaigns, calls for policy changes, integration of palliative care in the mainstream of care have a greater chance of being heard if it comes in a single, loud voice. Several examples of success of mutual collaboration among programs, organizations and individuals include the Declaration of Florianopolis,[36] the Santo Domingo Progress Report,[37] and the recent Korea Declaration.[38]
- At the country level, it is important to support multiple local initiatives as a strategy to develop palliative care worldwide. The provision of training, support, information, and funding to various programs maximizes the chances of success and minimizes risks.
- It is crucial to settle realistic goals for each program or initiative. The goals that may be applicable in Latin American countries can not be applied to Middle Eastern, Eastern European or North American countries. When establishing objectives for a program, taking into account its cultural and ethnical values is critical for an effective use of resources.
- Cultural differences and beliefs need to be remembered when establishing strategies for countries. Issues such as communication, decision making, spiritual beliefs and many others vary greatly from group to group. The communication bridge must be established in order to be able to establish effective programs.

CONCLUSION

Development of palliative care in the world has been an increasing trend in the past few decades. This has been largely the result of the commitment of extraordinary individuals and the financial support provided by generous donors and organizations. Many patients are now benefiting from hospice and palliative care services in developed countries, but services in developing countries are scarce and fragile and more is needed to guarantee their permanence and survival.

Education needs to be incorporated in the undergraduate medical and nursing curricula to guarantee the provision of services by a large body of healthcare providers, especially in developing countries. Services and medications need to be subsidized for those who are unable to pay and should be incorporated in the public healthcare systems and reimbursement plans for providers.

More studies are needed on the status of palliative and hospice care services in the world and should be the focus of future research projects. Many organizations such as the

ones described in this chapter have made an enormous effort and have had a large impact in the development of palliative care globally.

Key learning points

- There were about 57 million deaths in 2001, of which almost 80 percent occurred in the developing world. A large number of patients around the globe can benefit from palliative care.

- Palliative care includes the management of symptoms and provision of spiritual and psychosocial support to patients and their families from the moment of diagnosis, throughout the course of the disease.

- Palliative care can be provided simply and inexpensively in tertiary care facilities, community health centers, and at home. However, access to pain relief and palliative care services is often limited, even in developed countries, due to a lack of political will, insufficient information and education, and excessive regulation of opioids.

- The WHO World Cancer Report calls on all countries to establish comprehensive national cancer control programs aimed at reducing the incidence of cancer through primary prevention; providing earlier diagnosis and curative treatments; and improving the quality of life for cancer patients and their families through the delivery of adequate palliative care and pain relief.

Global initiatives

- 'A Community Health Approach to Palliative Care for HIV and Cancer Patients in Africa' from the WHO Program on Cancer Control in collaboration with the WHO Departments of Care for HIV-AIDS.

- International Association for Hospice and Palliative Care programs to support efforts mainly in developing countries and to increase knowledge and awareness of the needs of patients and healthcare providers.

- International Observatory in End of Life Care: The Observatory concentrates on global analysis of palliative care development – historical, sociological, and ethical studies of hospice and palliative care in specific contexts.

- World Hospice and Palliative Care Day: Day of action to increase awareness and celebrate and support hospice and palliative care around the world. Developed in association with Voices for Hospices and hospice and palliative care associations worldwide. Initial day set for 8 October 2005.

Regional initiatives:

- The European Association for Palliative Care (EAPC)

- African Palliative Care Association (APCA)

- Hospice Palliative Care Association of South Africa (HPCA)

- Foundation for Hospices in Sub-Saharan Africa (FHSSA)

- Asia Pacific Hospice Network (APHN)

- Latin American Association for Palliative Care (ALCP)

- Open Society Institute (OSI)

National Associations with international programs and initiatives:

- National Hospice and Palliative Care Organization (NHPCO)

- UK Forum for Hospice and Palliative Care Worldwide

A global palliative care initiative needs to be developed through the collaboration of the organizations, individuals, and programs which have the expertise and knowledge needed for success. This strategy avoids duplication of efforts and maximizes chances of success. Global strategies need to take in consideration the cultural and social differences among patient populations and ethnic groups. Communication issues, disclosure of information and treatment practices need to be tailored to the needs and resources of each country.

Undergraduate education

DOREEN ONESCHUK

INTRODUCTION

An aim of undergraduate education in palliative medicine is to cultivate competencies in the care of patients with advanced diseases. Encouragingly, medical student surveys reveal that competencies in the areas of attitude, skills, and knowledge can be acquired and fostered by well-developed undergraduate palliative medicine programs with students requesting increased instruction in palliative and end-of-life care. Less positive is the knowledge that students display deficiencies in competency at the time of completing their undergraduate education.[1–10]

This chapter reviews the status of undergraduate palliative medicine education in multiple countries, identified barriers and deficiencies in palliative medicine education, recommended changes, how to develop and implement these changes, and national strategies in progress in palliative medicine education.

WHERE ARE WE NOW

To understand better where changes need to be made and how to implement these changes, we need to know where we are now. Many countries have conducted surveys updating the status of palliative medicine in their country and universities.

Canada

A 2001–02 Canadian survey of the 16 medical schools identified that compared with a similar but less comprehensive international survey completed in 1997, only minor changes have occurred in undergraduate palliative medicine education in Canada. The majority of palliative medicine teaching occurs in the preclinical years of medical school, with supervised patient encounters occurring primarily during electives. The median number of instructional hours increased from 6 to 10 hours. Three-quarters of the schools indicated that learning objectives are identified, although the coverage of palliative medicine topics is inconsistent across curricula. The majority of schools use a combination of lectures and small group/problem-based learning. More than half the schools have an academic division or department of palliative medicine, although faculty with protected time are few in number. Student evaluation methods also vary, with only one school using simulated patients.[11,12]

USA

Between 1975 and 2000, palliative medicine education in the USA had increased slightly. In a 2000 survey, palliative care was directly addressed in 87 percent of medical schools responding and the majority of students were exposed to a hospice patient. The number of schools 'not formally offering anything on dying and death' went down from 13 percent in 1975 to 0 percent in 2000. The average number of teaching hours was about 14 hours. Of 19 end-of-life curricular topics listed, eight topics were identified as being taught by at least 80 of the 112 medical schools. Several of the schools noted that they introduce students to terminally ill patients and their families in rotating clerkships, whereas others indicated that the topic is integrated throughout their curriculum. The majority of schools used seminar/small group discussions and lecture mode of presentation. A multidisciplinary team approach increasingly is the mode of presenting the material in the curriculum.[13]

UK and western Europe

In a 2000–01 UK survey, changes since 1994 involved an increase in the use of role play and a decrease in the use of simulated patients in favor of using dying patients. The mean number of taught hours was 20 compared with overall means of 6 hours in 1983 and 13 hours in 1994. The greatest change since the 1994 survey involved the increased use of nurse specialists in palliative medicine. Assessment and evaluation of palliative medicine learning was still not commonplace. A number of schools were planning on increasing their teaching hours.[14] A 2001 survey of palliative medicine teaching in Irish medical schools identified that in no school is teaching centrally coordinated. All five medical schools in Ireland provide formal teaching in palliative medicine and the majority of topics in the suggested curriculum are being taught. A wide range of departments provide teaching. Most teaching occurs in the clinical years and by didactic lecture. Some teaching occurs in the hospice setting. An extremely low percentage of students participate in elective rotations and assessments are not required in order to advance.[15] In a review of undergraduate medical education in palliative medicine in Ireland, the UK, and Europe from 2002, European undergraduate education in palliative medicine was noted to be underdeveloped.[16] Results of a survey of physicians from Germany, Austria, Switzerland, Great Britain, Denmark and France, revealed that less than 50 percent of the European students receive education in palliative medicine. Whereas 51 percent of the physicians in Great Britain felt sufficiently prepared for the task of caring for the dying, less than 25 percent in all other countries felt the same.[17]

Australia

In most Australian medical schools, concepts of palliative medicine are taught but instruction in this area is still limited, with emphasis on the pathophysiology of disease and its treatment. Medical students are not systematically prepared to assess the clinical and psychological factors. There is a lack of attention to skills in communication, shared decision making, and self-reflection, and minimal interdisciplinary education.[18,19]

AREAS OF DEFICIENCIES, BARRIERS, AND RECOMMENDATIONS

The following are identified deficiencies and barriers in undergraduate palliative medicine education with accompanying recommendations for educational development.[11,20–23]

- Training is largely preclinical and elective.
  Recommendation: Care at the end of life should be taught as a core professional task throughout the continuum of medical education. Training should occur in the clinical years since this is where key attitudes and life long practice patterns are learned.
- Education focuses primarily on knowledge rather than on attitudes or skills.
  Recommendation: Key content areas should be addressed with emphasis on humanistic attitudes and communication skills.
- Limited opportunity for or promotion of self-reflection.
  Recommendation: Students should be encouraged to reflect on personal attitudes about their work.
- Limited involvement and emphasis on an interdisciplinary model of care.
  Recommendation: In all phases of training, students should be exposed to dying patients and interdisciplinary teams of clinicians and other healthcare professionals who are skilled in palliative medicine and can model humanistic functions of medicine.
- Underutilization of hospice settings and home care as teaching venues and aids.
  Recommendation: The best learning grows out of direct experiences with patients and families, particularly when students have an opportunity to follow patients longitudinally.
- Lower profile of palliative medicine compared with other specialties and negative informal teaching. In the 'hidden curriculum'[24,25] death is perceived as representing a medical failure, dying patients are not seen as good 'teaching cases', and students and residents receive little emotional support in dealing with their often disturbing encounters.
  Recommendation: Students should be encouraged to develop positive feelings about dying patients and their families and the role of the physician in terminal care.
- Lack of student assessment and evaluation.
  Recommendation: Student competence in managing prototypical clinical settings related to death should be evaluated using state of the art methods.
- Limited faculty time and lack of faculty role models who often have limited training in palliative medicine.
  Recommendation: Hire and train more educators to provide and demonstrate state of the art palliative care. These educators are needed to serve as role models and teachers. Students need to see physicians offering excellent medical care to dying people and their families, finding meaning in their work, and modeling ideal behaviors and skills.
- Limited financial support from the universities.
  Recommendation: Resources need to be available to implement changes.

DEVELOPING A CURRICULUM

Strategic planning at a national and local level is often required to successfully create and implement curricular reform. Defining an outline or using recommended steps

can aid this process, bearing in mind the uniqueness of each school and the need to individually adapt the process to each school.

To begin, a local champion or faculty committee leader should be identified in each school who would assemble an interdisciplinary committee that would be involved in curricular development. Members of the group could include individual course directors and instructors, undergraduate curriculum committee members, and medical students. Students can be very persuasive in eliciting faculty support for curricular change; their feedback and enthusiasm can help sustain the momentum of change.[26]

Needs assessment

One of the first tasks of the group would be to review the curriculum to identify what is being taught well and how to fill in the significant gaps. This can be achieved by conducting a needs assessment.[27] This is considered fundamental to change the process and the most important step in promoting change. A needs assessment evaluates the educational need for a curriculum, possible content, and instructional strategies. It also provides information so that appropriate and realistic implementation and evaluation plans can be developed based on the needs and resources of a particular institution.[28] It lays the foundation for curriculum design, implementation, and evaluation by answering questions about the clinical and educational needs of patients, families, and learners, available and needed resources, and potential political and logistical problems. Information can be gathered and organized into three categories:[29]

1 what is lacking
2 what is available
3 what would be needed to improve the clinical services or educational climate.

Methods of identifying course content include the Delphi technique, nominal group analysis, and single expert opinions.[30] The Palliative Education Assessment Tool for Medical Education (PEAT) is a flexible self-assessment tool that can be used to examine all required courses in the entire curriculum to uncover those areas where specific aspects of palliative care are taught, including those that are often considered 'hidden'.[31,32]

From the outset, it is beneficial to garner support from administrative staff such as deans and associate deans, pivotal committees that govern medical school content, and affiliated accrediting bodies. Carefully prepared, concise presentations to these individuals related to the need for education and/or awareness of national recommendations for curricular reform can be beneficial.[31,33]

Objectives and goals

Probably the most important determinant of the success or failure of a new curriculum is whether the objectives are clearly spelled out and are realistic. The objectives form the basis upon which the evaluation is designed and provide a clear message of accountability for the teachers, learners, and administrators who will review the curriculum's effectiveness.[29]

A key to writing useful educational objectives is to make them specific and measurable.[34] Objectives should contain five basic elements – *Who* will do *how* much *how* well of *what* by *when*? (Box 16.1).

Box 16.1 Types of objective[27]

- Learners' objectives – include objectives that relate to learning in the cognitive, affective, and psychomotor domains

- Process objectives – relate to the implementation of the curriculum. They may indicate the degree of participation that is expected from the learners and indicate the expected response of learners or faculty to a curriculum

- Outcome objectives – relate to potential outcomes, or effects of a curriculum beyond those delineated in the learners' and process objectives

---

Goals provide desired overall direction for a curriculum. An important and difficult task in curriculum development is to develop a manageable number of specific measurable objectives that do the following: interpret the goals; focus and prioritize curricular components that are critical to the realization of the goals and encourage creativity and flexibility; and nonspecified learning relevant to the curriculum's goals.[27]

Many countries and programs have existing palliative care curricula that include established objectives and goals. These could be used as a resource by newly developing programs. They include the core curriculum from the Association for Palliative Medicine for Great Britain and Ireland (1993),[5,35] the Canadian Palliative Care Undergraduate Curriculum (1991) that is presently being revised,[36] the Australian Multidisciplinary Undergraduate Palliative Care Curriculum Project,[19,37] and the American Board of Internal Medicine.[38]

Educational strategies

It is helpful to keep the following general principles in mind when considering educational methods for the curriculum:[27,39]

- maintain congruence between objectives and methods
- use multiple educational materials and instructional methods and

- choose educational methods that are feasible in terms of resources.

Adult learning principles espouse that adults learn effectively by being actively involved in a problem oriented approach because it promotes intrinsic interest and fosters the activation and elaboration of prior knowledge.[40] Attention to prior experience and to individualized approaches can enhance the learner's participation and understanding.[41]

Methods used to achieve knowledge objectives include lectures, assigned reading, small group discussions, programmed learning or problem solving exercises. When it works well, discussion can allow students to negotiate meanings, express themselves in the language of the subject, and establish closer contact with academic staff than more formal methods permit. Discussion can also develop the more instrumental skills of listening, presenting ideas, persuading, and working as part of a team. Discussion in small groups can or should give students the chance to monitor their own learning and thus gain a degree of self-direction and independence in their studies.[42] In problem-based learning, students use 'triggers' from the problem case or scenario to define their own learning objectives. They do independent, self-directed study before returning to the group to discuss and refine their acquired knowledge. Problem-based learning can be thought of as a small group teaching method that combines the acquisition of knowledge with the development of generic skills and attitudes.[43] Information technology now allows development of interactive exercises and distance learning.[39] Web-based conferencing tools hold promise for educators because of their flexibility and accessibility; not only do they have the potential to enhance discussion already taking place in the classroom and facilitate interactions among students and instructors in a course, but they also provide a platform for distributed learning. In other words, learners are able to learn during times and at venues that are convenient to them.[44] Methods for achieving affective objectives include exposure to readings, discussions, and experiences or views of others; facilitation of openness, introspection, and reflection; and role models.[27]

The current psychological concept 'attitude' has been defined as 'a learned predisposition to respond in a consistently favorable or unfavorable manner with respect to a given object'.[45] Attitudes can be difficult to measure, let alone change. Some undesirable attitudes are based in insufficient knowledge and will change as knowledge is expanded in a particular area. Other attitudes may be based in insufficient skill or lack of confidence. Attitudinal change requires exposure to knowledge, experiences, or the views of respected others that contradict undesired and confirm desired attitudes. Probably more than any other learning objective, attitudinal change is helped by the use of facilitation techniques with individuals and with groups that promote openness, introspection, and reflection. Properly facilitated small group discussions can also promote changes in attitudes by bringing into awareness the interests, attitudes, values, and feelings of learners and by making them available for discussion.[27]

Behavior objectives can be achieved by removal of performance barriers, provision of resources that facilitate performance, and behavioral reinforcements.[39] Instructional strategies for skills objectives include supervised clinical experiences, simulations (artificial models, role plays, standardized patients) and reviews of videotaped clinical encounters.[39] The learning of skills can be facilitated when:[27]

- learners receive an introduction to the skills by didactic presentations, demonstration, and discussion
- have the opportunity to practice the skills
- have the opportunity to reflect upon their performance
- receive feedback on their performance
- repeat the cycle of discussion, practice, reflection, and feedback until mastery is achieved.

Research has shown that students acquire skills best when they are taught in an experiential format and that using case histories and speaking to patients and relatives are all powerful learning tools.[46] Students have commented that the pedagogic technique of 'participant observation' has the effect of removing a defensive stance to the treatment of individual patients, allowing students to be more honest in their assessment of the efficacy of the palliative measures patients actually receive.[47–49] A comprehensive understanding and approach to death, dying, and bereavement is enhanced when students are exposed to the perspectives of multiple disciplines working together.[50] Students should participate in collaborative, longitudinal hospice and nursing home experiences, including interdisciplinary team meetings, patient home visits, telephone contact with patients and families and hospice nurses.[51] With the Structured Clinical Instruction Module (SCIM), an instructional tool, students rotate though a group of stations learning about different aspects of one major topic such as cancer pain; this learning technique involves the use of simulated and actual cancer patients.[52]

Implementation

The following is a checklist for implementation of a curriculum: identify resources, obtain support, develop an administrative mechanism to support the curriculum, anticipate and address barriers, and plan to introduce the curriculum.[27] Most educators would favor palliative medicine integration into the preexisting curricula in both the preclinical and clinical years,[25] the thinking being that there is considerable competition for curriculum time and an additional isolated curriculum in palliative medicine is probably unrealistic.[53] However, others favor stand alone blocks or courses taught by palliative medicine physicians and others who regularly work with dying patients.[54]

Faculty recruitment and training is essential to ensure quality of training and institutionalization of the educational program.[33] Supervising physicians often have no training in caring for a dying patient and are generally unaware of what

they do not know about good end-of-life care.[20] Providing faculty with clear course and teaching outlines ensures uniformity of content delivered specific to objectives of the course.[33] Faculty will often require new teaching skills and knowledge to successfully implement new instructional approaches. Many faculty are limited in their experience in curricular change and an educational consultant may be of benefit.[29] However, if expert consultants are employed, that must be utilized judiciously; staff must not become overly reliant on outside consultants.[26]

The importance of securing funding and support for dedicated time and resources as early as possible in the development cannot be emphasized enough.[29] Internal support may be found among the faculty administration or students and external power alliances may be forged with other medical schools, foundations, unions, professional associations, or community, state or federal governing bodies. Developing the training programs and providing the faculty with release time to acquire new competencies requires support from school leadership at all levels – from dean to department head to faculty leaders.[26] The curriculum committee should be kept informed of trends in state of the art practices in end-of-life education and suggest ways to adapt these practices to local conditions.[55,56]

Evaluation and feedback

Without adequate evaluation, educators will be uncertain whether they have attained the stated goals and objectives.[25,27] The purpose of evaluation is to:

- ensure teaching is meeting students' learning needs
- identify areas where teaching can be improved
- inform the allocation of faculty resources
- provide feedback and encouragement for teachers
- support applications for promotion by teachers
- identify and articulate what is valued by medical schools
- facilitate development of the curriculum.

Similar to curriculum design and implementation, faculty coordinating teaching should consider having colleagues with expertise in evaluation methodology help in this effort from the outset.[25] Planners should demonstrate that different examiners (interrater reliability) or the same examiners over time (intrarater reliability) consistently classify each outcome.[39] The Cancer Pain Objective Structured Clinical Examination is an example of a performance-based tool designed to test individual skills in the essential components of cancer pain assessment and management.[57,58] Finally, the curriculum will need to be disseminated and will require ongoing maintenance and enhancement over the years.[27]

NATIONAL STRATEGIES IN PROGRESS

The Liaison Committee for Medical Education (LCME) which accredits Canadian and US medical schools recognized the importance of physician competence in end-of-life care with a requirement that all accredited US and Canadian medical schools include end-of-life care in their curricula.[59] However, like most such requirements, the LCME does not tell the schools the way they should meet the requirement. Fortunately, a number of efforts are underway, although the best way to accomplish this goal remains to be established.

A Canadian national strategy is titled 'Educating Future Physicians in Palliative and End-of-Life Care' (EFPPEC). This multi-tiered project (www.efppec.ca) will strive to bring palliative medicine education to undergraduate medical students and clinical postgraduate trainees in all Canadian medical schools so that they will graduate with competencies in these areas. There will be emphasis on interdisciplinary education and the development and implementation of core competencies.

In the US, there is no national policy that governs the curricula in the 125 medical schools in the country beyond the requirement for accreditation by the LCME. However, a curriculum called the 'Education for Physicians in End-of-life Care' (EPEC) project was developed in conjunction with the American Medical Association to target practicing physicians and has had a broad reach in medical education.[60] It provided the impetus for a national approach to the subject. The curriculum has been used and adapted by many medical schools in their attempts to meet the LCME requirements.[61]

The Australian Department of Health and Ageing was recently awarded a tender to undertake the National Multidisciplinary Undergraduate Palliative Care Curriculum Project (see www.anzspm.org.au) to promote inclusion of palliative care and its principles and practice into all healthcare training. It will develop a set of educational resources for undergraduate courses and identify strategies to encourage the uptake of palliative care principles and associated resources within tertiary education.

Key learning points

- Undergraduate palliative medicine education remains underdeveloped in many countries.

- Areas of deficiencies and barriers for undergraduate palliative medicine education have been identified with recommendations for change.

- Curricular development is best implemented using a step-wise structured approach.

- This step-wise approach should include needs assessment, development of objectives and goals, educational strategies, implementation, dissemination, and evaluation.

- Numerous countries are in the process of developing national strategies to improve and foster undergraduate palliative medicine education.

Graduate education

ILORA G FINLAY, SIMON I R NOBLE

INTRODUCTION

Healthcare professionals are likely to be involved soon after graduation in the care of patients with life-threatening illness and facing death. An awareness of the problems of these patients, highlighted by the media focus on hospice and palliative care, has created awareness of educational needs for all healthcare professionals. After graduation, in many parts of the world, such education will be building on an undergraduate foundation. Even today, many graduating professionals have an inappropriate fear of prescribing opioids, and are unaware of some of the core methods of symptom control and of ways of encouraging patients to communicate. In postgraduate learning the focus switches from the need to pass examinations to the need to provide competent care for an individual patient. This drive to education from the need to learn is the most important feature of postgraduate education. Although terminology differs around the world, medical learning shares commonalities with respect to stages of training. After a period of school-based learning follows a period of apprenticeship. For those embarking on specialist training, this apprenticeship may continue for longer until a level of competency is achieved, enabling the individual to practice unsupervised. For the purposes of this chapter, the term 'graduate education' refers to training that occurs following the initial apprenticeship, at the point of embarking on a specialist career in palliative medicine. In countries where fully qualified general or family practitioners have an interest in palliative medicine, the term 'graduate education' would appropriately describe their ongoing learning.

DOMAINS OF LEARNING

A graduate program needs to focus around the four key domains in learning:[1]

- Knowledge and understanding
- Skills and competencies
- Attitudes and professional behavior
- Personal and professional development.

Objective assessment of these competencies is easier in the first two domains (knowledge and understanding, and skills and competencies) than the others, although the importance of attitude and professional behavior should be an underpinning ethos in any graduate program. Different teaching methods cover different domains, so a mixture of methods is required. A didactic lecture may impart facts and increase 'knowledge' but understanding does not develop until the application and facts to the clinical scenario is explored and understood. Without understanding, cold 'facts' may be applied inappropriately or even dangerously to a clinical situation. Similarly, communication skills training will not correct a poor underlying attitude to clinical practice; attitude difficulties may emerge during teaching sessions and must be separately addressed. Before a change can occur, learners need to have insight into why their attitudes appear

appropriate, understand the fundamental reasons within themselves behind their behavior and also inherently wish to change. Much work has been done on the way that people change behaviors.[2] Those who feel there is nothing wrong with their attitude or approach may have not even begun to contemplate the need to change. It is only by moving from this precontemplation stage toward contemplating that their attitude may be a barrier to effective practice that they can begin to address areas where change in behavior or in their lifestyle could improve their effectiveness. Many problems of teamworking are linked to attitudinal difficulties; the course tutorials and small group work often reveal such difficulties. However it may be the course administrative and secretarial staffs who are aware first of a student's aggressive or awkward approach.

Learning outcomes on a graduate program are driven by the core competencies that have to be attained, and therefore assessed, by the end of the program. However, as graduate learning is usually driven by a powerful 'need to learn' it is useful to allow the graduates to set their own learning needs and outcomes that they can specify as they go through a program and reflect on what they are learning.[3] Such learning outcomes, particularly when defined by the graduate, may not be easily assessed within the context of the graduate course itself. This will apply particularly to practical skills, such as draining a pleural effusion, although an imaginative curriculum will allow such assessment from the student's work place to be fed into the overall assessment on the program. In addition, the learning needs may be determined by current knowledge and skills as compared to required competencies as applied to the learner's clinical practice. Palliative care graduate programs have been shown to improve knowledge and skills in fellows training in hematooncology,[4*] geriatrics,[5*] and critical care[6*] although their core level of knowledge prior to training varied. In addition small studies have demonstrated the benefits of palliative care education in internal medicine house staff and trainees.[7*,8*,9*,10*] However, there is little evidence that these improved skills are sustained or that reported changes in attitude are applied in the clinical setting.

ADULT LEARNING

Adult learning styles will determine how different graduates learn on a course.[11] Adults are more likely to learn if they wish to learn. Learning must be purposeful, voluntary and the course must provide clear goals and objectives. Adults learn much better when actively participating in learning rather than as passive listeners to a series of didactic lectures. Feedback on any work undertaken is essential and adult learners should be encouraged at all times to be reflective in the way that they approach a topic. Clear goals of learning or learning outcomes should state explicitly the

skills and competencies that the learner is expected to be able to demonstrate.

REFLECTIVE PRACTICE

Reflective practice was described in the early 1930s, but the most celebrated description by Donald Schön has only become integrated into course design during the last two decades.[12] Reflection involves thinking about what we are doing, developing insight into our own approaches to a problem, analyzing the way that we tackle the problem and looking critically at the outcome. It then involves reflecting on that process, paying particular attention to what will be learnt at the end of it. Questions that the learner might ask include:

- What features do I notice when I recognize this situation?
- What are the criteria by which I make this judgment?
- What procedures am I enacting when I perform this skill?
- How am I framing the problem that I am trying to solve?

The learner also needs to think about and draw on related knowledge and experiences to be able to criticize, restructure and apply these principles for further learning. Schön calls this type of thinking 'Reflection on action'. This review of past experiences leads to a critical analysis of what led us to change our way of practice; sometimes reflection during the course of a process (reflection in action) involves modifications while dealing with a problem. It is very important that reflection is encouraged in a nonthreatening way so the learner does not become demoralized. Although mistakes or unsatisfactory outcomes often provide the best stimuli for learning, such events need to be handled sensitively and appropriately. Much learning can be effectively undertaken by reflecting on ordinary situations as they arise, thereby building on good practice. This can be particularly important for the learner who lacks confidence. When mistakes have occurred the learner should be encouraged to reflect on what they would do differently next time, rather than on what they did wrong.

In palliative care, the clinical situation is often extremely complex and many different ways of approaching the problem can have effective, or ineffective, outcomes. Emotionally charged situations can leave the palliative care learner feeling inadequate, upset and sometimes with unrealistic expectations of him or herself as a practitioner. Greenwood has been particularly critical of Schön's module because it failed to recognize the importance of reflection *before* action.[13] In palliative care such a reflective approach before acting integrates all previous experiences, with acquired knowledge and understanding, to empower the practitioner to behave differently to previously.

Boud defines reflection as 'an important human activity in which people recapture their experience, think about it, mull it over and evaluate it'.[14] Here, the reflection focuses on the individual's experience, involving both cognition and feelings as the two are closely interrelated and interact. Feelings, which may be 'positive' or 'negative', will prompt an individual to behave differently at the initial stage of reflecting, so Boud postulates that the individual encounters an experience, responds and at the same time starts to reflect. By returning later to recall what has happened, replaying the experience and reevaluating, additional processes occur:

1 Association – where new experiences relate to existing knowledge and understanding.
2 Integration – where the learner seeks relationship between the new information and what is already known.
3 Validation – where the learner determines validity of his/her feelings in response and the ideas that have resulted from it.
4 Appropriation – where the learner takes ownership of this knowledge and integrates it into long-term learning, to be used in future clinical practice.

These reflective processes underpin changes in behavior. They can be very powerful and underpin many of the teaching methods used for teaching graduates; these will be dealt with later in the chapter.

THE ROLE OF A TUTOR IN A GRADUATE PROGRAM

For the purposes of this chapter, a 'tutor' is defined as a person who facilitates the learning process. This term can be considered synonymous with mentor, teacher, or facilitator. All tutors need clear guidance about what is expected of them, and the time frame in which they are expected to be tutoring. They also need to be clear about the styles of tutoring that will encourage learners and styles that should be avoided as they lead to demoralization. Tutors need to be clear that they should operate within bounds of confidentiality, and explicitly explain to a student issues that would be shared with the course organizers/course directors. Where students are being tutored in groups, confidentiality of the group discussions becomes important and each member of the group must be treated with respect. Each member should have time to participate and care should be taken that no one member of the group dominates. The most effective teaching occurs in a safe environment where the individual feels supported and good practice is reinforced. However, sometimes, where individuals lack insight, the tutor may have to speak one to one with the student to help that student identify particular problems, which they are having. Such difficult conversations should be held outside the group setting.

Pendleton's method (Box 17.1) of feedback provides a useful set of rules by which feedback should be given.[15] It is a particularly useful method of feedback in a small group setting but can be adapted for one-to-one feedback by replacing feedback from other learners with comments from the tutor themselves.

Box 17.1 Pendleton's method of feedback

- Asking the learner what they felt they did well or were particularly happy with

- Learner/tutor feedback – what they feel went well

- Asking the learner what they felt could be improved

- Learner/tutor feedback – what they feel could be improved

THE INDIVIDUAL STUDENT'S SITUATION

In selecting graduates for a training program, it is important to know what has motivated the student to come forward and wish to learn. Some may have been told in their appraisal that they must go on a course to improve, while others may be motivated through their own, often bad, experience within their own friends or family, or a professional situation where they felt that their practice was substandard. Students also come from a wide range of clinical situations. Whereas in western Europe and the USA, libraries, journals and internet abound, in many third world and developing countries there are no journals in libraries and the internet is unreliable or nonexistent.

It is also important to know about the practice conditions of learners. Although it can be useful for learners to be exposed to a wide range of ways of practicing, including some high-tech interventions, for those practicing in much more primitive conditions most of their meaningful understanding and competency development will occur in relation to techniques and actions that they can instigate in their own work environment. This is consistent with the principle of justice,[16] which requires that each patient have the best treatment within the resources available, but also the professional is responsible for the just allocation of resources (equity).

REFLECTIVE CASE STUDY (PORTFOLIO LEARNING)

Reflective learning on an individual case can be a powerful teaching tool. The learner's everyday practice offers many stimuli for reflection as they go about their daily work, noting interesting or challenging situations as they occur. Many palliative care teams now use protected time for reflective practice in small groups. This can be successful within

uniprofessional and interprofessional groups, providing it is conducted in a safe, nonthreatening environment, paying particular attention to confidentiality within the group. It can also be a powerful tool within the realms of team support and clinical supervision.

One of the most useful tools to capture and record reflection and personal development is portfolio learning. Portfolio learning is designed to provide a chronological record of the learning process of the student. The learning process is self-directed; the learner chooses the areas within a subject of particular interest. In the context of graduate education, this enables each learner to meet their own individual learning objectives. For example, a student who identifies a need to develop skills in the management of neuropathic pain can focus on this topic, while another colleague may concentrate on mouth care.

This style of learning varies greatly from the technical rational style encountered at most undergraduate schools. Those unaccustomed to this learning style will require gentle support and supervision. As reflective practice and portfolio and problem-based learning become more widespread within undergraduate curricula, graduates will become comfortable with this style of professional development. The beauty and simplicity of a reflective portfolio, which allows the learner to determine format, learning objectives, and emphasis to the learner may be seen by some as too unstructured and challenging. Most physicians are new to the relative lack of prescribed formal structure in the portfolio. Depending upon the experience of the educational supervisor, even the method of presenting the portfolio can be relaxed if the reasons are clear. The learner should be encouraged to develop the portfolio (Box 17.2) in a way similar to an artist's portfolio, reflecting their freedom of creativity in presentation.

Box 17.2 Most successful portfolios consist of the following elements, which are interrelated and cross–referenced[17]

- Factual case histories around which the learning usually occurs

- References to diverse sources, e.g. textbook reading, literature search, lay press, conversations with colleagues

- A record of the clinician's own decision-making processes including details of decisions made and how the learner came to them

- Documentation as to how the learner felt at the time, sources of stress or doubts are as useful as the outcome since the personal feelings of the learner will influence how they were able to approach a problem

- Ethical considerations

- Illustrative items such as photographs, drawings, quotations, poetry, etc., may clarify points being made. Care must be taken over anonymization and permission from the patient for such items to be used

- Some form of indexing is important, so the learner and supervisor can follow the learning process and refer to specific items at a later date

---

The self-directed learning portfolio acts as a tool for learning and as evidence to the supervisor that learning has taken place. The format of the portfolio can vary widely, allowing creative expression by the learner. Formative assessment between the supervisor and student in an informal setting is essential for learners to have feedback on their progress. It enables the supervisor to give constructive feedback to the student and provide support, especially to those new to the concept of portfolio learning. Summative assessment can help the student identify areas for future learning. Examples of marking schedules are given in Tables 17.1 and 17.2; these are for guidance only as the learning process needs to be as flexible and adaptable as possible.

The supervisor will be aware that some factual clinical details of the portfolio cannot be verified or crosschecked, as the reader will not know patients or episodes described. However, it is better to base a leaning portfolio around real cases and events rather than a fabricated scenario, since the learner will gain more from reflection on action with which they have first hand experience. The suggested marking schedules attribute only a small proportion of marks to the description of the case, awarding the majority of marks to evidence that learning has occurred. Social and personal issues in the case history balance the biological evolution of the disease process. The marking scheme reflects the importance placed upon teamworking within palliative care and the supervisor should actively encourage an appreciation of this if it is felt to be lacking in the portfolio.

For the graduate learner, a portfolio gives an excellent opportunity to focus experience. It can act as documentation

Table 17.1 *Summative portfolio mark schedule*

Contextual description of case	5%
Biologic issues of the case	5%
Individual issues of the case	5%
Teamworking	10%
Clarity of presentation	10%
Decision-making logic	20%
Attribution of evidence	20%
Critical analysis	15%
Index and discretionary marks	10%
Total	100%

Table 17.2 *Learners' guidance*

Academic background	15%
Display appropriate use of academic literature/ research, other influences in learning	
Coverage of topic (total 40%)	
Biology of the disease	10%
The natural history of the disease	
Screening and diagnosis	
Staging and disease progression	
Impact of cancer	10%
Psychological response to disease and the importance of honest communication	
Social impact of disease on patients and their families/carers	
Spiritual response to the diagnosis	
Clinical management	10%
Treatment options and how decisions are made	
Symptom control	
Coordinated care	10%
Multidisciplinary teamworking	
Response to loss and bereavement	
Approach to patient and problems	10%
Warmth	
Caring	
Empathy	
Respect	
Humanity	
Holistic assessment and management	25%
Communication and personal insight	10%
Physical, psychological, social, and spiritual assessment	
Ability to engage and talk to patients and their carers about their experience and develop a relationship with them	
Display insight into their own emotional reactions to difficult and sad situations	
Patient responses	5%
Identification of the patients problems, hopes, and fears	
Critical analysis of care	10%
Process of evaluating the efficacy of care from both the medical and patient perspective	
Display evidence of clear critical analysis and synthesis of issues	
Commitment	10%
Throughout the course, the student should have displayed commitment to learning in tutorials and in self-directed learning time	

of learning objectives, recording clinical situations commonly faced and areas of difficulty. For the supervisor it helps identify any topics requiring further experience or teaching. Often small group tutorials can be organized

around subjects identified by several learners, all in a position to contribute in this environment with experiences to reflect upon and share.

Portfolio learning should be viewed as a dynamic, fluid learning process, which should ideally continue as long as the individual keeps learning. As all medical professionals become more accountable and are required to give evidence of continuing learning, the portfolio may become a more prominent educational tool within the whole of medicine, not just palliative care. The portfolio provides a unique opportunity for learning to occur in the wider context of the humanities. Relevant facets are incorporated and cross-referenced, giving validity to the learned experience described by others through art or literature.

COMMUNICATION SKILLS

The importance of communication skills is widely recognized in palliative care. Communication problems faced by graduates working in cancer medicine are not resolved by time and clinical experience,[18**] and there is strong evidence that training courses significantly improve key communication skills.[19***] It seems insidious to allow any professional to graduate from a course in palliative care without having ascertained that they have developed the appropriate communication skills to deal with the complex difficulties that will be encountered in clinical practice.[20]

Palliative care consultations are often the most challenging, since they may involve breaking bad news and talking about dying and loss.[21] Intrusive observation of such sensitive consultations, with recording devices or the presence of additional observers, may disrupt the flow of the consultation and hinder the patient's openness within discussions. Since the palliative care consultation is potentially difficult and may have wide ramifications if badly handled, the trainer must create a safe learning environment where the trainee can feel comfortable making mistakes without repercussions and protect potentially vulnerable patients. It necessarily follows that the use of real patients is not always appropriate.

Role play

Role play, using either actors or colleagues as patients, has long been established as a useful tool for developing communication skills.[22] It is best done as a small group of learners with one or more trained facilitators. It is important to keep the groups small enough to ensure that everyone has the opportunity to role play in the time allocated. People are initially wary of role play since, for many, it is unlike any other training they may have encountered. Maintaining a small group will help them feel more comfortable in the process.

Role play allows people to train for situations they rarely encounter but need to be ready for. The skills for breaking

bad news or dealing with anger are best learned prior to encounter in practice. In the real world, one will not get a second opportunity to tackle a difficult consultation from scratch over and over again. Role play affords the learner this luxury.

There are several basic principles that should underpin any such learning session:

- Clearly established rules of role play
- Strict adherence to confidentiality
- Safe environment
- Avoidance of role playing situations that are potentially distressing for learners
- Option to call 'time-out' at any point
- Opportunity for all learners to participate
- Nonconfrontational feedback
- Time for those involved to 'come out of role' after a session
- Review of learning points and de-brief at end of each session.

Feedback can be given in several different ways. Pendleton's method[15] is one of the safest ways to give feedback singly or involving other participants and has been discussed earlier in the chapter (see Box 17.1). This approach to feedback has the merit of first highlighting what was done well, thereby reinforcing good practice and offering positive suggestions for improvement. Those members of the group who are not role playing should take an active part in the appraisal system, to observe and learn from peers. More recently the Calgary–Cambridge approach to communication skills teaching has been developed as a facilitation tool.[22] It encourages a far more agenda-led approach to communication skills, encouraging learners to focus those specific areas of the consultation they otherwise avoid through lack of confidence.

The skills to facilitate such sessions are sophisticated, so training is strongly recommended before embarking on this teaching style. Most learning of value will occur from the role play itself and the feedback session, but summative assessment can highlight particular areas of weakness. Selected videotaped consultations can complement role play. Box 17.3 illustrates a suggested marking scheme for the palliative care consultation. Marks are given in each section out of 10, 5 being the pass mark.

Box 17.3 Summative marking schedule for palliative care consultation

- Puts patient at ease
- Establishes problems sufficiently to erect hypothesis
- Prioritizes problems/hypothesis
- Checks back on problem list agreement

- Elicits fears/concerns
- Elicits beliefs/concepts/attitudes
- Establishes physical/psychosocial relationship of complaints
- Explores physical issues appropriately
- Evolves plan acceptable to patient
- Checks back that plan is understood/agreed
- Overall – nonverbals facilitate
- Overall – verbals appropriate
- Overall – patient appears comfortable/safe
- Overall – respects patient's pace
- Overall – closes interview well

TEACHING ETHICS

Ethical dilemmas abound in care of patients at the end of life. Ethical decision making is never straightforward, so mastering reflection will help the learner function better within zones of indeterminate practice or as Schön[12] describes it as 'the swamp'. Ethical decision making needs a sound understanding of the principles of autonomy, beneficence, nonmaleficence, and justice within the patient's clinical context.[16] Gillon has also highlighted the wide issues around each decision, which require the clinician to reflect on the 'scope' of application of the decision-making process and its outcomes.[23] Although a formal lecture may appear useful to inform, the complex decision making around each case requires ongoing reflection in action by both tutor and learner.

THE HUMANITIES AS AN EDUCATIONAL TOOL

Graduate training in palliative medicine should address not only the clinical and psychosocial needs of the patients and relatives but also those of the professional. A purely biomedical education cannot equip someone in their early twenties to understand the reactions of a bereaved person, the behavior of someone receiving bad news, or the devastation of a long-term disability.[24] The past decade has seen an increasing role for the arts and humanities in education although there is no consensus about which disciplines constitute the field of medical humanities. While the humanities have clear established roles in patient care and an emerging place in undergraduate education, graduate training remains an area of particular challenge. Art and poetry therapy are widely used to enable patients contemplate their

own response to illness. A number of medical schools encourage the use of humanities such as art and literature within undergraduate special study modules.[25] However, variable access to expert support in what some will find an unfamiliar area of learning is likely to be a problem in graduate education for the foreseeable future. Like all areas of education, clear learning objectives need to be identified and appropriate assessment of learners and evaluation of facilitators undertaken.

There are three main areas of graduate education in palliative medicine that medical humanities can best address – namely reflection, connection, and support. Reflection enables learners to review their own feelings, practice, and experience, allowing insight into the strengths and weaknesses of their own practice. The response of physicians to a dying patient is more than just a scientific answer to a biomedical question. Recognition of one's own needs and values is essential if physicians are to move beyond their own concerns and place those of the patient at the forefront of their endeavors. Reflection on films, literature, art, and poetry may afford physicians an insight into the doctor–patient relationship not given in the biomedical approach to learning. Most graduate learners in their twenties have little personal experience of suffering and bereavement. An ability to connect with patients and their relatives will be essential in the delivery of patient-centered holistic care. Observing how doctors are portrayed in popular culture gives valuable insights into the expectations and fears that patients have of doctors, and doctors have of themselves.[26] Finally, graduate learners may draw on the medical humanities for their own personal development and support. Stress-related illness of professionals in this area of medicine is well documented and the use of the humanities addresses an ongoing need.

INFORMATION TECHNOLOGY AND INTERNET LEARNING

Progress within information technology (IT) has made a huge impact on the provision of healthcare across the world. The use of e-mail correspondence, computerized patient notes, and digital storage of radiology and patient information initiatives are likely to be ubiquitous applications of IT development within the next few years.

Distance learning postgraduate courses have traditionally been organized as a correspondence course, with course packs delivered regularly and completed assignments duly returned. Some of these courses have now adapted toward web-based learning, where learners are able to, course packs online, with links to relevant articles. E-mail allows students direct access to tutors for guidance and submission of assignments. Web-based chat rooms for students encourage informal sharing of ideas, avoiding the distance learner studying in isolation. The benefits of web-based learning are clear, with reduction in stationary costs, administration time, and

removal of the delay of postage, which for many distance learners can be considerable. More importantly it allows professionals from diverse localities and cultures to learn alongside each other, sharing ideas and experiences under the supervision of a suitably qualified facilitator. There appears to be an expanding role for videoconferencing in palliative care education.[27*,28*] Still in its infancy, learners tend to prefer face-to-face teaching to videoconferencing especially for learning about sensitive subjects. However, research suggests that learning outcomes are similar for both modalities.[29*]

An increasing number of journals are now available online although many require a subscription. In addition to accessing online journals, the ubiquitous personal computer has accommodated the publication of major textbooks on CD-ROM.

Although there are clear opportunities for learning by the internet and IT, it is important that these are focused appropriately and not instigated for the sake of progress. Videoconferencing may link learners across the globe but should never be considered as a complete alternative to traditional conferences, since opportunities to learn informally, develop new ideas, and network will be lost.

DETERMINING THE MARKET

Budget programs can provide learning at different levels. There are some core competencies in care that cut across all professional groups and can be taught in an interdisciplinary setting. Others are discipline specific and some relate to specialized or specialist level practice, so although core level learners should be aware of these, they do not need to have an indepth understanding of higher specialist levels of learning.

Interprofessional learning does not occur by simply putting people in the same room together. It becomes important that individuals can define their own common core skills and responsibilities and recognize the competencies that exist in others. Topics such as bereavement will be seen to be core to all those working in palliative care and is best dealt with in an interprofessional learning environment. However some aspects such as the management of spinal cord compression will vary from professional to professional. The physiotherapist or nurse may be the professional to recognize imminent spinal cord compression, the oncologist will instigate the investigation and indepth management, whereas the nursing aspects and rehabilitation aspects will revert to those initially involved in recognizing the problem, with the additional occupational therapy input.

ORGANIZING A GRADUATE PROGRAM

Whenever a graduate program is organized, there are three distinct phases that need to be addressed: needs assessment and precourse planning, course delivery, and

finally assessment after the course to allow modification and confirm that the course met its own aims and objectives.

Careful precourse planning is essential; fundamental decisions about the course must be made: in particular the curriculum and format of the course. Planning should not be done by one individual in isolation, but rather with the involvement of a committee of potential course tutors/facilitators. Once the course has been established, the committee should invite student representatives to contribute.

The curriculum, specific expected learning outcomes, and course delivery should take account of the needs of the learners and the resources available to meet them.[30*] Graduates have different levels of knowledge and experience of palliative medicine. Some may be general practitioners or specialists wishing to expand their palliative medicine skills whereas others may be following a specialist career in palliative medicine. The number of learners intended on the course and their geographical location will have significant impact on resources and course delivery. Distance learning and Web-based courses are more practical for a cohort of learners from a wide geographical distribution but this will have resource implications.

Many countries have a core curriculum of learning needs and descriptors of competencies that need to be achieved during the course.[31–35] Several courses based upon these competencies have run successfully within the UK, with the Cardiff course training over 900 postgraduates to diploma level within 15 years of activity. Although curricula that have been developed by national organizations can serve as 'guideposts' they may not address the specific needs and culture of an individual.[36*] Nevertheless, a survey of 263 clinicians from a wide variety of clinical, geographic, and cultural backgrounds suggests that the elements of such core curricula are of high relevance to their clinical practice.[37*] Learners considered areas of particular importance to include communication skills, multiprofessional teamworking and psychological aspects of care, subjects that lend themselves best to reflective practice and role play.

Resource allocation and availability will affect the course format. Distance learning courses require dedicated administrative staff and a cohort of course tutors. Some core competencies cannot be facilitated or assessed by distance learning and require face-to-face tutorials. Many distance-learning courses include residential weekends to address communication skills and allow group discussion on challenging topics; administrative staff salaries, teaching honoraria and venue costs all need to be considered.

Delivering a course that encompasses a multiprofessional holistic patient-focused approach to care holds many challenges, especially since some of the core competencies and methods of assessment do not lend themselves well to the didactic exam-focused way many doctors are used to learning by. It is likely that most will be new to reflective practice, portfolio learning, and using the humanities as a learning tool. Role play in communication skills training is often met with trepidation, usually manifest as resistance. The role of experienced, skilled facilitators/tutors cannot be underemphasized to provide the support and input inevitably required, particularly at the beginning of the course.

Any teaching program needs regular evaluation to ensure it is educationally effective. The course must respond to the changing and individual needs of participants, provide competent teaching in theory and practice, and enable students to make a difference in their clinical practice.[38*] Structured feedback should be incorporated throughout the course, giving opportunities for learners and tutors alike to contribute to the continuing development of the venture. Feedback should be collated annually and reviewed by the planning committee, allowing time to act on areas in need of change. Student representatives should be encouraged to participate in this process and liaise directly with fellow learners.

POSTGRADUATE RESEARCH TRAINING

Some graduates may wish to pursue higher research degree training. There are various forms of research degree available, including masters in science (MSc), the Commonwealth doctor of medicine (MD), and doctor of philosophy (PhD). A research degree involves the presentation of a thesis on a research topic in a field of interest appropriate to an individual's training needs. Apart from a wish to improve research skills, a higher research degree is considered in other specialties to be associated with better job prospects. Within palliative care, higher research degrees serve four functions:[39]

- extending personal scholarship
- generating knowledge
- training for the individual
- contributing to the growth of the specialty.

Individuals with higher degrees are likely to be involved in research in the future[40*,41*] and to obtain research funding.[42*] To commence on such a training program, the candidate needs to demonstrate a sound knowledge base in palliative care and proficiency in research methodology. To demonstrate these, prospective candidates will need evidence of basic training within the specialty and involvement in related research. Several masters courses will only enroll candidates once they have achieved qualification to diploma level or will encompass training to diploma standard within the first year of enrollment. It usual for such teaching programs to train the candidate in research methodology at the initial stages of the course.

The likelihood of candidates obtaining a higher research degree does not lie solely upon their own attributes and commitment to the project. There are other essential requirements beyond their immediate control that must be fulfilled to obtain satisfactory completion:

- supervision
- environment conducive to undertaking research
- dedicated research time
- funding.

One of the major barriers to undertaking research in palliative care has been difficulties in obtaining appropriate supervision from senior colleagues.[43*] As a relatively young specialty, palliative care has fewer academic departments and hence available supervisors than other long-established specialties. Successful completion of higher research degrees is more likely to occur if the candidate has dedicated research time in a department with an ongoing research facility and some will need to access other specialties, e.g. oncology, to achieve this.[44] Since completion of a higher research degree is more likely with those in full-time research than part time, funding may be required to cover the trainee's salary as well as the running of the research project. Few charities within palliative care offer substantive grants to cover such costs and drug company research grants are lower than allocations for comparable ventures in other specialties. Consequently the majority of higher research degrees within palliative care are completed by part-time study.

CONCLUSION

As the specialty of palliative care expands so will the need to increase the education opportunities available to graduate healthcare professionals. The special nature of palliative medicine with holistic, multiprofessional patient-centered care necessitates what some will find new learning techniques, alien to the didactic method of training they are accustomed to. Communication skills, bereavement care, ethical decision making, and spiritual care may be better learned by role play and reflective practice. Distance-learning courses will facilitate the growing need for a geographically diverse group of professionals to learn together, particularly when facilitated by residential weekends and online. As well as gaining existing knowledge, it is important to encourage further the knowledge base of the specialty through research. Appropriately supervised and funded higher research training will advance knowledge and improve patient care through the twenty-first century.

Key learning points

- Postgraduate learning in palliative care offers challenges unique to medical specialties.

- Holistic multiprofessional learning may be unfamiliar to previous didactic learning experiences.

- Reflective practice and portfolio learning are excellent methods of adult learning.

- The internet, IT, and the humanities lend themselves well to palliative care learning.

- Communication skills training courses improve key communication skills.

- Completion of higher research degrees will improve the research base of palliative care in the future.

Changing the norms of palliative care practice by changing the norms of education

LINDA EMANUEL

INTRODUCTION

Medical professionalism requires earnest adherence to optimal practices for patient care. Because of the potency of the medical armamentarium, the obligation to restrict medical practices to those that optimize patient care is a solemn duty.[1] Career-long learning and modification of practices in the light of new knowledge or new challenges are a necessary part of that duty.

In the past decades, medicine has generated hitherto unsurpassed capacities in symptom management, as is evident for instance from the chapters in this textbook. Medicine has, however, also struggled with a lost balance between the aim to cure and the need to ameliorate suffering. This imbalance occurred during the culture of scientific enthusiasm that had lost too much of the appropriate emphasis on whole-person context of illness-related suffering in favor of organ and molecular-based attention to diseases. It had overlooked quality-of-life issues and suitable care for those with chronic and serious or incurable illness and those engaged with the processes of inevitable death.[2]

It has therefore been a challenge to the profession to put in place sufficiently effective palliative care education that the balance of curative approaches with symptom management and a culture of care could be returned. The challenge was taken on at a time when the norms of medical education were entrenched in dry didactic methods even though research had demonstrated their minimal impact on practices. This chapter traces the efforts of one project in particular, as it coordinated its activities with that of other projects, to do its part among other key programs in confronting this challenge.

ASSESSING THE CHALLENGE, SELECTING THE STRATEGY

The case-study project used here for illustrative purposes is the Education in Palliative and End-of-life Care (EPEC) Project. How did this project assess its circumstances as it designed its strategy?

Many studies have documented minimal impact on practices of carefully designed and implemented medical educational interventions.[3] More effective programs use multiple education methods and multiple interventions such as clinical reminders simultaneously.[4] Nonetheless, impact remains modest at best. Part of the problem is likely attributable to the fact that continuing medical education had become a ritualized process of information presentation. These forms of information delivery are not designed according to principles of adult education theory and are not much influenced by social science understandings of what can drive changes in social expectations and behavioral norms. A related, practical part of the problem was that it was not accepted in mainstream practices, so that multi-method approaches such as clinical reminders would realistically only be implemented *after* the field had gained acceptance. Given the enormity of the challenge that palliative care needed to rise to and the inadequacy of education as a vehicle for an immediate change, the field faced the

stark choice between becoming highly creative or plodding forward with too little and too late. Choosing the former, palliative care has managed to bring about significant changes in a relatively short time, to the point that it has provided something of a model for other fields seeking to bring about changes in norms of practice.

Starting out in the mid 1990s, the EPEC Project took stock of what it could do best as one among other programs. It was situated, when it began, within a national physicians' organization serving all specialties that also had an international presence. So it chose as its mission to improve the skills of physicians from any discipline; and it aimed for a national and international scope. Aware that the focus on physicians might seem counter-cultural to the hospice and palliative care movement that emphasized the essential role of the interdisciplinary team, it nonetheless wanted to capitalize on its unique ability to reach physicians. It settled on a train-the-trainer approach that would allow physician trainers to reach not only other physicians but nonphysician clinicians.

Other features informing the strategy of the EPEC Project included the following. It would have to address the need to address norms among practicing clinicians, since it would take too long to wait for the gradual infiltration of change by incoming newly trained clinicians. Further, the existing practice norms that did not support palliative care would rapidly eliminate any learning among medical students if the norms were left unchanged. A strategy was needed to address the need for changed practice norms, especially since much of the knowledge that should have driven change was not new; that is, the knowledge was mostly available but not applied in practice. Another problem was presented by the perception that palliative care was nonreimbursable; this appeared to be impeding administrative support for palliative care services in mainstream medical practices. The question of which physicians to target came up early since there was a pressing need for palliative care in virtually all the existing specialties in medicine, whether surgery, cardiology, oncology, or general internal medicine. So the strategy for the project would have to allow for 'uptake' within the cultures of these diverse specialties. Regarding geographical location, palliative care was needed for great swatches of territory on the globe, especially where the human immunodeficiency virus (HIV)/acquired immune deficiency syndrome (AIDS) epidemic had taken root. Finally, the strategy would have to fit with the national nature of the organization from which the program was being launched, and with the reality that one program could not cover the global needs in palliative care.

SITUATING A PROGRAM WITHIN A BROADER STRATEGY, RELIANT ON SOCIAL CHANGE THEORY

What successes the EPEC Project enjoyed were in great part made possible by the existence of a well-crafted and funded, national strategy created by the staff and board of the Robert Wood Johnson Foundation. Their approach was driven by the awareness that even a well-designed program, if it is in a hostile larger social context, will be hard pressed to succeed and even harder pressed to sustain its impact after funding is over.

The Robert Wood Johnson Foundation invited a proposal to create what became the EPEC Project as part of an overall, evolving strategy that included projects in nursing education (ELNEC), in training for physicians-in-residence (EPERC), in faculty development (provided by Harvard's Center for Palliative Care), to promote institutional palliative care programs (CAPC), to reach specific communities, for instance, the African–American community (APPEAL) and numerous projects for public education. Later on, when the time was right, support was also provided to the American Academy of Hospice and Palliative Medicine (AAHPM) to get it to a point where it could sustain specialty educational offerings. Reconstructed in retrospect, the strategy can be mapped approximately as in Figure 18.1.

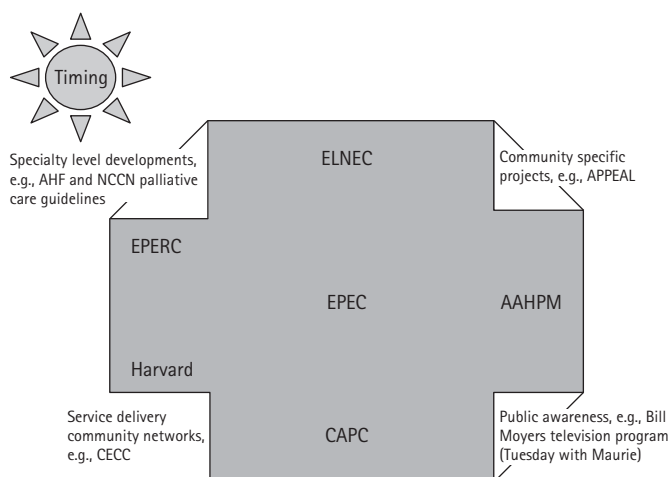
Central to this strategy was a social marketing perspective for each major project that identified how to go about changing the social assumptions in the relevant sectors of


Figure 18.1   *Robert Wood Johnson Foundation strategic programming. AAHPM, American Academy of Hospice and Palliative Medicine; AHF, American Hospice Foundation; APPEAL, A Progressive Palliative Education Curriculum for Health Care for African-Americans at Life's End; CAPC, Center to Advance Palliative Care; CECC, Chicago End-of-Life Care Coalition; ELNEC, End-of-Life Nursing Education Consortium; EPEC, End-of-Life Care; EPERC, End of Life Physician Education Resource Center; NCCN, National Comprehensive Cancer Network.*

society about end-of-life care. Significant involvement of consultative opinion from a social marketing group contributed importantly to the design of several of the major projects. In this fashion, the social taboos and other behaviors of denial that surrounded dying in America at the time, were to be addressed and reversed to the point that a social movement could begin. The programs were also strongly encouraged to achieve programmatic self-sufficiency during their last stages of funding, so that their impact would be sustained after the end of grant funding.

This combination of Robert Wood Johnson Foundation strategies was coordinated with those of the few other funding agencies that were supportive of palliative and end-of-life care. Through meetings of the Grantmakers in End of Life Care and in other settings, the granting agencies were able to coordinate their efforts. All were assisted by the publication of the Institute of Medicine report that called for panoramic improvements in care near the end of life.[2] For instance, the Soros Foundation funded the Project on Death in America, which fostered the career development of young careerists with leadership potential by providing grants and a supportive setting for research and clinical projects in palliative care. Toward the end of the Robert Wood Johnson Foundation's major efforts in end-of-life care, other agencies such as the American Cancer Society, and agencies at the National Institutes of Health such as the National Cancer Institute, were being encouraged to take on funding of what had become successful projects that were nevertheless still being only cautiously accepted in the mainstream of medicine. Leaders had been successfully fostered and a Board of Hospice and Palliative Medicine had been established in association with the AAHPM, leading eventually to the recognition in 2005 of palliative care by the American Board of Medical Specialties as a discipline warranting its own Certificate of Additional Qualification.

Looking back on the decade between 1995 and 2005, the Robert Wood Johnson Foundation can fairly say that the culture of society transformed from one in which death was denied, the dying were shunned, and those who cared for the dying were given minimal support in the practice of medicine. It transformed to become a society in which palliative care has become almost fashionable; it is widely accepted that dying is a matter for open discussion in society and palliative care is a type of service that patients and families demand. Medical institutions throughout the USA are setting up and developing palliative care services, having accepted that every major multispecialty medical institution needs one.

MAXIMIZING DISSEMINATION

Train-the-trainer strategy

The choice of a national and potentially international scope for this project necessitated a highly effective dissemination strategy, especially given the expectation of modest funding. A dissemination format that had enjoyed success in nonmedical settings was the train-the-trainer approach. Effectiveness in bringing about broad social change through the impact of one thought leader through a few opinion leaders to a large number of people who then institutionalize the new norms is a model that has been effective since biblical times and before. It is also well suited to the medical culture, in that there is a strong cultural commitment to the 'see one, do one, teach one' approach in which skills are passed from one colleague to another.

At the same time, this approach was not a common one in medicine at the time that the EPEC Project began. It was an approach more often associated with low-skilled, nontechnical matters. After the initial risk of introducing an unfamiliar format associated if anything with low prestige, the advantage of novelty took over, and this approach seems to have enjoyed enough success that a 'tipping point' was reached so that many train-the-trainer programs in other areas are now also being implemented. It soon became desirable within the medical culture to be a certified EPEC Trainer. Although some other train-the-trainer programs have also enjoyed success, others have not. It may be that the train-the-trainer format just one feature in effective dissemination.

Leadership and professional grassroots buy–in

Attention to the social context and what would drive relatively rapid and sustainable social change was necessary. The platform from which the project was launched was, importantly, the most powerful national medical association, the American Medical Association. It was launched with buy-in and input from leaders in the political and clinical spheres of medicine.

The project chose to simultaneously involve clinicians at the grassroots level. An important mechanism for achieving buy-in at all of these diverse levels was to invite input into the project itself. The curriculum was drafted by a wide range of experts, and suggestions made by participants were taken very seriously in the production of the first edition of the curriculum. Suggestions are still taken at every conference and considered in every new edition of the curriculum.

The commitment of the hospice and palliative care fields to the interdisciplinary team drove a strong focus on how to be maximally inclusive without losing momentum. The difficult choice was made, as noted above, to target the project to physician education; one rationale was that non-physicians would come to physician education programs but not the reverse. This approach acknowledged and even leveraged a social hierarchy within medicine that many members of the interdisciplinary team did not like. The thought was that it was already enough of a challenge to bring about a new popularity for palliative care without

taking on additional challenges to social norms in medicine. As the implementation of the project was tracked, it emerged that most EPEC trainers did indeed teach a full range of clinicians, so the targeting strategy seemed to have been effective.[5]

Individual buy–in

Additional features of the social and cultural context of individual motivation were also considered so that physicians' identification with the program could be achieved. Curricular materials were made to be visually and technologically appealing; that is, the look-and-feel was designed to be meaningful and attractive, and the slides and trigger tapes state of the art. Both conferences and materials were initially provided for free as part of an outreach strategy, with a gradual progression to a cost-recovery nonprofit status kicking in only later. Perhaps most important in this regard, permission was given to the EPEC Trainer to modify the materials to suit his or her teaching style and his or her audience's needs. This allowed individual investment in and career advancement through this curriculum. Every Trainer was able to look and be polished and effective in their presentations when these materials were being used.

Widely applicable curriculum

In order to allow use of the curriculum by Trainers in a wide range of different settings, the curriculum was designed in a modular format. Thus, a 16-module curriculum could be presented in full at a several day conference, over a longer time in periodic presentations or in part at individual seminars or presentations. It was also designed to cover core material that all practitioners need command of. Perhaps also because it was effectively a national core curriculum, EPEC became a de facto normative standard for practice in palliative care.

Venues of discourse

Ultimately, the institutionalization process that moved the EPEC Project from a one-time grant-funded project to a kind of institution was inspired by and molded by its participants. Initially, feedback made clear that the project was satisfying an appetite for collegial connection; so requests for list servs and continuing advice as Trainers conducted their own teaching were readily granted. Soon, Trainers began to want to become members of the smaller group of Master Facilitators who were teaching the Trainers. To allow for that, we instituted a Professional Development Workshop in which principles of education were transmitted and participants learned and practiced teaching skills using the most effective teaching methods known to education that were also suitable for the medical context.

Virtual college

The result of these developments was a transition to something much more than a train-the-trainer program. The project became virtually a college, complete with layers of training opportunities, certification, ways to advance up through the layers, educational materials, and venues for participant socialization.

Tracking dissemination

The dissemination of EPEC teaching was estimated by an external group for a 1-year period between 1999 and 2000. They found that the *EPEC Curriculum* was well regarded and was perceived by most trainers to have provided great improvement in their knowledge and ability to teach end-of-life care. More than 90 percent of trainers were actively using the *Curriculum* to teach; the 184 trainers in the study were estimated to have taught ∼ 120 000 professionals.[5] By extrapolation, it appears that by 2006 the EPEC Project has probably reached about 1 million professionals.

The partnership phase

The next step in the transition had partly to do with dissemination; it was necessary to move beyond the population of clinicians who were well disposed to the idea of palliative care into the population that was skeptical. It also had partly to do with the motivation to help move palliative care 'upstream' from the end of life to include the entire spectrum of illness, bringing the goal of optimizing quality of life to all patients. Both goals were addressed by the transition of the EPEC Project into a partnership phase. By collaborating with specialty societies and institutions, the project has become well positioned to make curricular adaptations with buy-in from the relevant group in medicine. Adaptations for specific communities, such as Roman Catholics or the African American communities, and for specialties such as oncology and emergency medicine are examples that already exist.[6] Dissemination in collaboration with the appropriate community is then possible. The same model has been used for adaptations of EPEC in other countries.

A sustainable, professional institution

To maintain programmatic integrity and reliable standards in the education associated with the project, the EPEC Project retains the exclusive prerogative of creating EPEC Trainers and owns the intellectual property on its materials. To continue the dissemination and accommodate adaptation to suit diverse audiences, automatic permission is granted to adapt the materials for educational, noncommercial purposes and a standard acknowledgment statement that users can apply to adapted material is provided. To

allow for some cost recovery, teaching services are provided for a standard registration fee; costs for adaptation to new programs are covered by grants. The program is maintained within an academic medical institution on the same not-for-profit basis as other academic projects.

MAXIMIZING IMPACT

Change through education

Education theorists, lead by Davis, Dixon, and others, describe different layers of learning resulting in changes to norms of practice. First, attitudes are essential if suitable attention is to be given to the subject matter. Second, knowledge must be acquired. Third, skills that use the knowledge must be acquired. Fourth, behaviors that use the skills must be engaged. Fifth, the behaviors must have the intended outcome. Finally, changes must be brought about in society as a whole so that adjusted norms integrate and sustain the new behaviors and outcomes.[7]

Attitudes and knowledge change

To maximize the change in attitudes and knowledge, EPEC Trainers must use the most effective educational methods and materials possible. Experts in adult education and physician education in particular emphasize the need for several features. Adult education theory notes that the human mind can only take in a modest number of facts at a time if the facts are to be retained and used. After a period of about 45 minutes, the human mind needs to take a break. Visual aids are most effective if the information presented is simple and to the point, with minimal distracting material. At the same time, if the information can be presented through multiple channels – say visual and auditory – that is helpful. For clinicians time is precious so learning must make good use of their time. Like other adult learners clinicians are motivated to learn if they perceive a need. The use of data that identify need and the use of cases that illustrate a recognizable situation with human meaning in which clinical knowledge is needed can be very effective in generating the empathic feeling that in turn provides a teachable moment into which the curriculum can place its 'just-in-time' learning. These and other points guided the design of the curricular materials for EPEC. The resulting materials used accessible language, presented information in simple units, and used slides with clear points using a minimum of words. The modules were all accompanied by a trigger tape describing a case or something similar that would provide the human meaning and recognizable, emotionally and intellectually engaging context for learning.

To provide for the layers of teaching and learning roles in the train-the-trainer approach, materials were provided in the form of a participant's manual and a trainer's guide.

As the curricular content grew, portions were designated as core or optional. For specialty societies where the cultural norm was for more complex information, that was provided and information was identified by its level of evidence.[8]

Behaviors, skills, and practice norms

Among the effective teaching methods, one used above others in the EPEC Project was small-group role-play. The reason for this is that attitude and knowledge gains do not 'stick' without the experience of their implementation.

However, to cross the knowledge–practice chasm will take more than wide dissemination of well integrated attitude change, absorbed knowledge and preliminarily practiced new skills. Davis has recently illustrated again in a commentary on a particularly successful, integrated program of education and practice change, how complex it is to translate knowledge into practice.[9] Knowledge does not translate into practice change without suitable context and motivation. The next adaptations and editions of the EPEC curriculum are being designed so that learning objectives in each module are linked to identified clinical practices, and these clinical practices are in turn linked to measurable outcomes whenever possible. In this fashion, the new curricular materials will be positioned for implementation in systems that can promote and assess the translation of new knowledge into practice improvement. We anticipate that by linking learning to behavioral accountability in this fashion it may finally be possible to cross the boundaries between education and practice change.

MAXIMIZING EFFICIENCY

Long-term, sustainable change requires programs that are not only effective but also efficient and sustainable.

Investing in change agents and opinion leaders

One approach of the EPEC Project, along with that of others such as the Ian Anderson Project in Canada,[10] has been to first use small-group learning for those who will become change agents or opinion leaders.

In the case of the EPEC Project, immersion teaching to create trainers makes use of groups that are optimally sized at about 16 participants and are capped at 25. Although the cost of these immersion courses is large on a per-participant basis, when the Trainers have reached their end-users the cost can be calculated in terms of per-end-user, and the unit cost drops dramatically to about $10 per end-user, depending on the age of the program and other factors. Similarly,

the 'capital outlay' involved in producing a curriculum that is of high enough quality that it will have enduring impact and wide appeal across disciplines and other social groupings is initially high. But the more the curriculum is used the more the per-user unit cost drops.

Distance learning

Another approach to maximizing efficiency in education is to allow for learning from a distance. Among the first palliative care education programs to be offered at a distance was one pioneered by Hospice Africa Uganda.[11] By combining in-person, immersion training with follow-up course work by mail (and later, when it became available, electronic communication), the educational center of Hospice Africa Uganda in Kampala was able to train palliative care leaders from many different African countries. The Pallium Project makes use of a similar paradigm, bringing educational opportunities to widely dispersed locations in Canada.[12]

The effectiveness of distance learning is not well studied. The EPEC Project will be comparing different modalities of distance learning in order to ascertain which types of program are most effective and which are most efficient for different settings. Highly sophisticated versions of learning will also soon be available. Simulations of clinical images are already in use for surgical and other types of education. Additional developments are anticipated.

CONCLUSION

Medicine had become a victim of its own success by the time the hospice and palliative care movement decided to construct a different road to care in which comfort and quality of existence are emphasized. The challenges to the educational arm of this movement were many and the power of traditional medical education was not sufficient for the task. By borrowing heavily from social change theory and adhering closely to proven but little used adult education practices, and by working as one among multiple coordinated projects, the EPEC Project was able to contribute its part to graduate medical education, until eventually the integration of palliative care practices into medical norms was happening throughout medicine. Key features of its design included its train-the-trainer structure with investment of intense education in a relatively small group of trainers; its modular, adaptable curriculum and emphasis on role play as a teaching method; and its establishment of a self-perpetuating college like structure. However, the most important determinant of what impact it has had is probably the synthesis of many effective approaches and collaborations, all occurring in the setting of collaborative projects that could reset the cultural expectations of medicine and society at large.

Key learning points

- Didactic information transfer is a small component of education that, on its own, effects minimal practice change.

- The attitudinal and social context are strong determinants of practice, and educational interventions should include efforts to adjust both to the educational goals.

- Empathic consideration of the relevant situations stimulates attitudinal change and information intake. Use of trigger tapes can facilitate suitable emotional involvement.

- Dissemination programs are most effective if they invest heavily in small groups of opinion leaders and change agents.

- Education programs that seek enduring changes in practice norms must be sustained for many years.

ACKNOWLEDGMENTS

effort to change the norms of education in palliative care could have been achieved without the extraordinary, collaborative approach of these and many other equally fine people.

Public education

SHARON BAXTER, ROMAYNE GALLAGHER

INTRODUCTION

Public education regarding hospice palliative care or end-of-life care has been growing steadily since the movement began 40 years ago. However, there is limited research on the process and outcomes of hospice palliative care education compared with other areas of health education and health promotion. The authors will refer to their experience in Canada as there is little published in this field of palliative medicine.

In Canada, the movement has developed under two names – hospice and palliative care. In a national consensus-building initiative it was decided to adopt the name 'hospice palliative care' to demonstrate that the principles were the same and to reduce confusion among the public and healthcare providers outside the movement.

There are several reasons to pursue public education regarding hospice palliative care:

- Advocacy
- Education of decision makers
- Awareness of hospice palliative care in the general population
- Education of patients and informal caregivers.

The hospice palliative care movement developed over time both within the healthcare system and at the community level, arising from the perceived 'medicalization' of dying. While the community as a whole has embraced the philosophy and practice of hospice palliative care, the healthcare system has not yet fully recognized hospice palliative care as an integral part of the care, including care delivered at the end of life. In addition, knowledge and skills development related to end-of-life care is ongoing in Canada and only recently has palliative medicine become a certified specialty. In 2002 Canada became the first nation to establish standards or norms of practice for hospice palliative care.[1] Advocates have continued to raise public awareness of hospice palliative care services, prompting healthcare systems and providers to educate themselves and effect change in the provision of these services. Ongoing advocacy and the education of decision makers have been essential in the movement of some provincial governments toward legislating hospice palliative care as a core healthcare service within their province.

Increased awareness of hospice palliative care within the general population has several benefits including assisting with advocacy strategies and encouraging preparation for future needs. It is fair to say that there is a public perception that dying is a painful and feared process and therefore little is expected of the healthcare system or providers when someone dies. This is demonstrated when examining pain management where research has shown that most people are satisfied with their pain management despite significantly unrelieved pain.[2] However, it is hoped that having an educated public will enable patients and caregivers to be effective advocates for themselves or their loved ones that they are caring for.

With healthcare systems becoming increasingly complex and having multiple options for care, there is a need for patients to be aware of how to access care and how to navigate the healthcare system. Options for care also entail knowing the rights of patients and families, especially concerning issues of refusal and withdrawal of therapy. Many patients already in the system are not aware of their options or rights as shown by a study of 728 outpatients in an Oregon internal medicine clinic.[3] Only 69 percent were aware of their right to refuse treatment and only 46 percent were aware of their right to the withdrawal of treatment. Interestingly, having an advanced directive in place did not predict for greater knowledge about rights with regard to treatment. A report on the informational needs of

Canadian caregivers[4] cited a number of learning and coping styles of patients and families as necessitating information being provided by oral communication supplemented by a variety of written or electronic media. Similar findings were discovered in a study of primary caregivers of Greek patients with cancer,[5] with those exhibiting high information needs being positively associated with a preference for cancer-specific printed material and negatively associated with satisfaction with the doctor's communication of information and affective behavior.

Lastly, there is a need to educate patients and caregivers who are in the midst of coping with a life-threatening illness. With the rise of chronic illness as a major cause of death, the role of the patient in their illness has dramatically changed. Since chronic diseases are ongoing, it is the patient who must undertake much of the therapy, make behavior changes and learn to cope with the changes that the illness brings. In addition, they must communicate with the healthcare providers and know how and when to access the system for treatment. In the latter stages of illness, informal caregivers take over much of this role. Much of the care in the last year of life occurs at home, according to research from the UK,[6] putting most of the responsibility on the patient and their caregivers. Thus there is a much greater need for education about signs and symptoms, symptom management, coping with illness, and acquiring help when it is needed.

Studies of caregivers have repeatedly noted unmet informational needs.[7] Most of the need for information is related to symptom management, how to care for someone who is dying, and what to expect in the dying process. The best people to provide this information are the healthcare providers which implies that the role of healthcare providers needs to change from that of a 'provider' to the additional roles of educator and collaborator.[8]

Theories of health behavior change

Mainstream health education has evolved dramatically over the last century. There has been a marked decline in infectious diseases in industrialized countries over the last 100 years. While medical knowledge and therapies have advanced tremendously, it is clear from population studies that the declines began before medical interventions such as antibiotics and vaccines were available.[9] It was the improvement in living conditions such as the wide availability of clean water, uncontaminated food, and separation of sewage in these nations that began the reduction in mortality. Heart disease became the major killer of people in these nations and remains so to this day. However, health educators began to see that much of the mortality and morbidity of heart disease and cancer was due to lifestyle factors such as smoking, sedentary lifestyle, and poor diet. Public health evolved into health promotion which combines education with political, regulatory, and system changes that act together to bring about a change in health behavior and disease.

At first glance it may seem a paradox that health promotion should apply to hospice palliative care, but the World Health Organization (WHO) in its Ottawa charter of 1986[10] defined health promotion as 'the process of enabling people to increase control over, and improve their health'. The same document goes on to speak of health in these terms:

> To reach a state of complete physical, mental and social well-being, an individual or group must be able to identify and to realize aspirations, to satisfy needs, and to change or cope with the environment. Health is, therefore, seen as a resource for everyday life, not the objective of living. Health is a positive concept emphasizing social and personal resources, as well as physical capacities. Therefore, health promotion is not just the responsibility of the health sector, but goes beyond healthy life-styles to well-being.

The charter saw three main prerequisites for health promotion: advocacy, enabling equity, and coordinated action between the health sector, government, voluntary sector, industry, and the media. These elements are all essential for equitable access to quality end-of-life care and thus the principles of health promotion are applicable to hospice palliative care.

Health promotion, as well as changing policy and services, also seeks to change individual attitudes and behaviors. Several models of psychological behavior have been developed to explain how behavior can be changed in an individual and a population. The theory of planned behavior was developed by Ajzen and has applied quite well to a number of behaviors in the field. The theory notes that there are three major influences on a person's intention to change their behavior: attitude toward the specific action, subjective norms of behavior around the issue, and perceived behavioral control. For example, applying the model to quitting smoking a person may develop an attitude that it is worthwhile to quit smoking as they will be healthier, fitter, and lower their chance of dying from a smoking-related illness. The subjective norms of behavior around smoking vary with culture and location and have changed dramatically over the past 50 years, becoming unacceptable in some countries and more acceptable in others. As an example of perceived control, a person may feel that they cannot control this behavior as they have too much stress or too much going on at work to quit smoking at this time. These factors act together to influence intention to change behavior and therefore on the behavior itself.

Adapting this model to hospice palliative care education makes it evident where the major challenges and opportunities are in health education regarding hospice palliative care.

Attitude toward specific behavior

An attitude toward a specific behavior depends upon the information given to the public. The individual weighs their vulnerability to the issue as well as the severity of its

effect upon them in developing an attitude toward the issue. Most people perceive serious illness and/or dying as a painful and fearful process. Providing information to counteract this feeling based on what hospice palliative care can do for symptom relief and improving quality of life would be an effective way to present the case for people knowing about hospice palliative care. However, a person's vulnerability to this information likely depends upon their health status. If they have a chronic illness or are caring for someone who does, they are likely to feel quite vulnerable to the fear of a painful death and welcome information on ways in which they can prevent this.

Unfortunately, it cannot be assumed that all healthcare providers and health systems will automatically provide quality end-of-life care for the patient. Therefore, informing the public of what can be done using hospice palliative care services will result in improved overall care once those services are accessed.

Information needs to be provided in a way that the individual receiving it feels that it applies to him or her. However, giving people information that only generates fear (e.g. a painful death) does not change behavior unless the individual has a perception that they can do something about the issue.[11] A meta-analysis of fear appeals[12] indicates that fear appeals motivate positive behavioral change but also maladaptive fear control actions such as defensive avoidance or reactance. It appears that fear appeals must be accompanied by successful intervention messages. Therefore any information about unrelieved pain or symptoms must be accompanied by information about how to access hospice palliative care.

Subjective norms about the behavior

The norms regarding the open discussion of behaviors are dependent on culture. During the sixteenth and seventeenth centuries in Europe it was not uncommon to speak of death and dying openly, in fact there were prescribed practices for dying – the *artes moriendii*.[13] At the end of the nineteenth century, the customs of death changed with the rise of science and the decline of religion. Death became a hidden part of life and thus less acceptable to talk about. Even with the rise of the hospice palliative care movement and the pioneering work of Elisabeth Kübler-Ross in the 1970s there is still a societal reluctance to mention the words dying or death.

However, even in cultures where speaking openly of death or dying may be seen as disrespectful, there are times when speaking of death may be appropriate. For example, a local information fair about hospice palliative care presented in Chinatown in Vancouver, BC is well attended because there is attention to cultural details. The forum is held in the season of Ching Ming, when celebrating and remembering ancestors is commonly done. As well, the forum does not use the word 'death' or 'dying' in its title as this would not be considered appropriate.

Some cultures specifically celebrate death, as Mexico's Dia de los Muertos.[14] It is a festival held on 1/2 November and is a cultural blend of an Aztec festival dedicated to the dead with the Christian tradition of All Saints and All Souls days. During the festival the dead are welcomed back to the family home and commemorated. The festival is a social, festive occasion that is an important way of acknowledging the cycle of life and death as a natural part of human existence.

Perceived behavioral control

It makes intuitive sense that perceiving a capability to change behavior is extremely important in effecting an actual change in health-related behavior. Factors that influence this can be external to the person – factors they have no control over – or internal factors such as self-efficacy or belief in ability to control their circumstances. Factors such as lower education, depression, stress, and personal and situational factors can adversely influence an individual's perceived control.[15]

Death anxiety – the fear of the dying process or being dead – has been studied in a number of groups of people. Interestingly, death anxiety is not a function of illness alone, as older patients have less death anxiety and terminally ill patients' death anxiety varies according to interpersonal factors such as social support and personal resources such as coping styles and spiritual beliefs.[16] As well, higher death anxiety among physicians has been associated with more negative attitudes regarding dying patients.[17]

Public education regarding death and dying needs to be mindful of death anxiety. One way to avoid increasing death anxiety is to raise awareness of the ability of hospice palliative care to help meet the psychosocial and spiritual needs of the individual and their family. As well, highlighting the ability of people to transcend suffering – called 'post-traumatic growth' by researchers[18] – helps to reduce death anxiety and improve quality of life.

ISSUES CONCERNING PUBLIC EDUCATION

Canada is a country of 32 million people with approximately 235 000 deaths per year. In 2000 the Senate of Canada released a report that indicated that an estimated 5 percent of dying Canadians received hospice palliative care.[19] In 2004 it is estimated that this number has grown to less than 15 percent. A number of factors affect the slow growth of access to these services. Currently, Canada has less than 200 practicing palliative care physician specialists out of a total of almost 60 000 physicians. In Canada's 17 medical schools palliative care training is variable, ranging from a mandatory clinical rotation to classroom hours with elective rotations. As well, none of the 91 schools of nursing include hospice palliative care as a core curriculum component. It is apparent that Canada is not training

enough hospice palliative care professionals to provide for an increase in programs and services.

This creates a dilemma concerning issues related to public education regarding hospice palliative care. Should the public be empowered to demand hospice palliative care programs and services that the healthcare system is not capable of providing in the near future? In Canada, the hospice palliative care community continues to advocate for increased programs and services at the same time as working with partner organizations to develop the necessary research and education that will be required in the future. Two examples of this include the recent designation of hospice palliative care nursing as a specialty within the Canadian Nurses Association (CNA) and the Educating Future Physicians in Palliative and End-of-Life Care Project (EFPPEC).

Under the leadership of the CNA standards and core competencies for nurses working in hospice palliative care were developed and the first set of certification exams were held in the spring of 2004. The EFPPEC Project is a 4-year project that began in February 2004. To date all 17 medical schools in Canada have agreed to participate in the project to create interdisciplinary hospice palliative care education curriculum over the next 4 years. This project is working to increase the skill level of graduating physicians in end-of-life care through the use of core competencies. Its goal is to have substantially more family physicians graduating with skills in hospice palliative care.

Making the case for public education

There is a strong case for the need for public education regarding programs and services available at the end of life. Canadians responded positively to the Commission on the Future of Health Care in Canada, indicating that the healthcare system's ability to provide good quality of life at the end of life is a priority.[20] Canadians in favor of hospice palliative care have also overwhelmingly reported (91 percent) that they feel it is important for patients in their last days to be comfortable and in familiar surroundings.[21]

In a 2004 Ipsos-Reid Survey[22] Canadians polled were asked to identify where hospice palliative care services were provided. Not surprisingly 80 percent identified long-term care facilities and/or nursing homes and 76 percent identified hospitals. However, 74 percent of respondents identified the patient's home as a setting of care. If three-quarters of Canadians think that end-of-life care is provided in the home then what is the healthcare system's requirement to address this?

The lack of sufficient research regarding hospice palliative care programs and services and related issues needs to be addressed if education of the public is to be effective. Three key issues which need to be addressed include:

- What does the current healthcare system currently provide with regard to end-of-life care?

- What programs and services does the general public want for themselves and their loved ones at the end of life?
- The economics of hospice palliative care services, i.e. are available hospice palliative care services less expensive than utilizing the current acute care system?

Educating decision makers

Governments are complex organizations where influencing decision making is often challenging. Governments are composed of both political and bureaucratic structures which both have a role in the policy development process. Often new programs and services are created by elected officials due to political pressures, however bureaucrats need to be involved in the development of these programs and services as they are critical to their successful implementation. A strong relationship with both levels of government is critically important.

How healthcare systems are funded varies from country to country. In Canada most of the funds required to pay for the Canadian healthcare system are provided by the federal government with the implementation and ongoing monitoring of health programs being overseen by the provincial or territorial governments. This relationship is complex and at times has been confrontational; however, in order to effect sustainable change an understanding of each player's strengths and weaknesses is necessary. A successful public education plan is based on finding the 'win-win' situation between the various levels of government including the community.

The first step in educating the decision makers is to have the appropriate research and data available; to have an understanding of the healthcare system; and to know what the public expects from the healthcare system. A draft plan outlining the services and programs that need to be developed or augmented is also helpful. Presentations regarding new programs or services can only be presented a limited number of times – it is imperative that organizations are prepared for their presentations by presenting well-thought-out options. Many times, it is the personal experiences of the decision makers that can also drive policy change, so personal experience coupled with an offering of workable options can be very successful in achieving change.

A well-planned multipronged approach is necessary to achieve change in service provision. Support from grassroots stakeholders is imperative because if stakeholders do not support the plan, it will not be supported. As an example, the HIV/AIDS movement in Canada has used the grassroots approach to community development and mobilization extremely well. The voice of People Living with HIV and AIDS has been front and center in all their public education responses.

In Canada, governments are recognized as wanting to act in the best interests of their citizens however they are not always sure what the best interest are. All levels of government depend on advice and input from experts to inform them of the issues and provide possible solutions.

Increasing public awareness of hospice palliative care

Increasing awareness of hospice palliative care services and programs to the general public is imperative. Canadian residents need to know that hospice palliative care is a group of services provided by an interdisciplinary team in a variety of settings (acute care hospital, long-term care facility, hospice or home) that provides care for persons approaching death so that the burdens of suffering, loneliness and grief are lessened. Reaching the public will be discussed under the Process section.

Educating patients and informal caregivers

As mentioned previously in this chapter there is much to be gained by providing education and information to both patients and informal caregivers.

THE PROCESS OF PUBLIC EDUCATION

Building momentum for hospice palliative care

With an aging population it has become apparent that there needs to be an increase in programming in end-of-life care. Data from a recent Statistics Canada report indicate that that the estimated number of deaths in Canada will increase by 40 percent by the year 2020.[23]

Leadership is imperative for sustainable gains. It is also critical that the group or groups leading this plan have the support of stakeholder groups. Division within the hospice palliative care community can undermine any possible gains so it is important to spend time building the partnerships and relationships within the community. It is also critical to have agreement on the key messages being used. A communication strategy needs to be developed for public education no matter which constituents are targeted. Tactics regarding how a communication strategy is implemented will vary depending on the target audience. Public education campaigns targeting the general public may include the following tactics:

- Public awareness campaigns
- Media – placement of personal stories and opinion and editorial articles
- Targeted brochures and pamphlets
- Internet and a campaign to encourage visits to pertinent web sites.

Public education campaigns targeting decision makers may include:

- Briefs and reports
- Presentations to government committees

- Meetings with key decision makers
- Letter writing campaigns
- Petitions.

Models of excellence

There are models of excellence outside the hospice palliative field that should be reviewed when developing a public education campaign. A particularly successful public education campaign in Canada was the *ParticipACTION* campaign. *ParticipACTION* was a campaign aimed at increasing the physical activity levels of school children and young adults. There were many lessons learned from campaigns such as this including the need to keep the campaign fresh, renewed, and sustained. It is also important to look at hospice palliative care campaigns taking place in other countries.

Networks and coalitions have proved useful in Canada, communicating messages to both the general public and to government. The Quality End-of-Life Care Coalition of Canada (QELCCC) established in December 2000 currently has 31 member organizations. QELCCC members represent national health professional organizations, disease-specific organizations, disability awareness organizations, seniors' organizations, and home care organizations and foundations. The QELCCC's main goal is to promote increased access to end-of-life care services for all Canadians. In September 2004 the Coalition published *Dying for Care*,[24] a status report on the state of end-of-life care in Canada that outlines areas of improvement. The Coalition believes it is the right of every Canadian to die with dignity, free of pain, surrounded by loved ones, in a setting of their choice.

The hospice palliative care community has much to learn from the human immunodeficiency virus (HIV)/acquired immune deficiency syndrome (AIDS) community. The HIV/AIDS community has over the last 20 years taken an unpopular health issue and has forced the public and government to act. It can be argued that funding levels for domestic HIV/ AIDS programs continues to be underresourced but on balance they have managed to raise the profile of the disease. Public education regarding hospice palliative care must keep in mind that today's society is death denying and therefore discussions regarding end-of-life issues are often suppressed.

In British Columbia a unique forum has been developed entitled: 'Making Death a Part of Life: a public forum on death and dying'.[25] This forum uses the trade show format with presentations and exhibitor booths featuring local hospice palliative care organizations and related businesses. Presentations deal with practical issues regarding caregiving, pain management, the biological processes of dying, and spiritual issues. The forum is held in a central venue and promoted through local media, hospice palliative care organizations and word of mouth. Funding for the event is generated from sponsorships with government, health authorities, and businesses. This format has been repeated

in other areas of Canada (Winnipeg) as well as the USA and Germany.

OUTCOMES

Outcomes in public education are notoriously hard to measure. One reason for this is that outcomes must be focused on behavioral change evaluated in well-designed randomized controlled trials with standardized outcomes designed for use in the population being studied. So the diligence and experience required to achieve accurate measurement with outcomes that will be sensitive or specific enough to detect a difference is considerable. For example, a Cochrane review of self-management education for chronic obstructive pulmonary disease[26] showed inconclusive results with respect to health-related quality of life, but if a disease-specific instrument was used a better quality of life was seen in the intervention group. The follow-up must be sufficiently long for useful conclusions to be drawn from the studies.

Another major handicap to hospice palliative care outcomes research is that many patients will be too ill to complete questionnaires that are used to self-report. This suggests that those who are experiencing the most problems may be too ill to be included in data collection.[27] Proxy completion is known to have pitfalls as well.

However, there are some outcome studies that can serve as examples in the general healthcare field. Self-management is a common theme in the arthritis diseases. A Cochrane review of patient education interventions on health status in rheumatoid arthritis[28] showed that public education had short-term effects on disability, joint counts, patient global assessment, psychological status, and depression, but these faded after the first follow-up visit and no significant effects of patient education were found by the final visits.

Education interventions on the general population that only has a risk for a disease pose further challenges. A Cochrane review of counseling or education to modify risk factors for cardiovascular disease[29] showed no effect on the mortality rate of the disease. However, among high-risk patients such as those with hypertension, mortality did reduce with medication, counseling, and education. This seems to support the theory that the population must believe they are at serious risk to modify their behavior.

A search of the literature for studies on hospice palliative and end-of-life public education interventions revealed two studies on public attitudes on hospice palliative care and death and dying,[30,31] but educational outcomes seemed to be studied only on healthcare providers. This is likely due to the lack of attempts to undertake a public education intervention to promote thinking and planning for care at the end of life.

There is evidence that public attitudes to death and dying are changing in some countries. A campaign called *Living Lessons*[32] was initiated by a commercial industry foundation – The GlaxoSmithKline Foundation in Canada – in partnership with the Canadian Hospice Palliative Care Association. The campaign included a professionally conducted telephone survey of Canadians' awareness of hos-pice palliative care and what hospice palliative care entails. Additionally, the campaign developed resources to educate policy makers, healthcare providers, volunteers, and caregivers about hospice palliative care and the difference it can make in the living and dying process. This was done through various print media, press kits, and a website (www.living-lessons.org).

In 1997, in the first poll regarding the attitude of Canadians toward hospice palliative care, only 30 percent of Canadians had heard of palliative care.[21] The 2004 survey repeated similar questions and when asked, 60 percent of Canadians had heard of the term palliative care.[22] Fifty-one percent of those people who had heard of it were able to mention what the key attributes of hospice palliative care are.[22] These results indicate a dramatic change in awareness of hospice palliative care. There are numerous reasons that could be postulated for this, including the *Living Lessons* campaign, reports on end-of-life care by the Senate of Canada, as well as high profile legal cases that featured patients requesting the right to physician-assisted suicide. Twenty-five percent of Canadians in the 2004 survey reported that they or someone in their family had used hospice palliative care services.[22]

Canadians were also asked to identify services that they associated with hospice palliative care and the most common services were pain management and psychological support such as dealing with depression and anxiety. Sixty-four percent of Canadians identified hospice palliative care as being available to all people who are dying irrespective of illness.[22] The challenge for healthcare educators was that 90 percent of Canadians would go to their family physician for access to hospice palliative care information.[22] The startling piece of information was that whereas 83 percent felt it was important to discuss end-of-life care with their family, only 49 percent felt it was important to discuss it with their doctor and only 9 percent had actually done that.[22]

Although greater awareness is an excellent start in public education, ultimately the goal is to have increased awareness result in increased access, provision, and quality of end-of-life care. One way to ensure improved provision of care is to link hospice palliative care standards to healthcare facility accreditation. This process has begun in Canada with the Canadian Hospice Palliative Care Association (CHPCA) model[1] being used as a template for healthcare facility accreditation. Accreditation in Canada is a voluntary undertaking but it is customary for every healthcare facility to undergo accreditation approximately every 3–5 years. As well as establishing standards for healthcare facilities such as acute care facilities and residential facilities, standards are being developed which will apply to free-standing hospice facilities and it is expected that these facilities will begin the accreditation process in the next 3–5 years.

The ultimate measurement tool to determine if patients were receiving the care that they expect would be to use a hospice palliative outcome scale of which several have been developed and validated.[33–35] While these scales are subject to biases such as seen in people's satisfaction with pain management although there is still significant pain, they are likely the best indicators available at this time. It would be important to apply these scales to dying patients both in and out of hospice palliative care facilities in order to determine if all patients were receiving the symptom control and psycho-spiritual support they needed through consultative services. Other important outcomes would involve system capacity to handle all the people requiring and requesting hospice palliative care.

The hospice palliative care movement has much to learn from other public awareness and policy-changing campaigns that have pioneered policy change. The need for hospice palliative care must be treated as a public health issue where the public, patients, caregivers and decision-makers are educated about suffering at the end of life and how effective quality hospice palliative care can be in relieving suffering and enhancing the quality of life for the last stages of life. Strategic public education can be a very effective force to move the public, healthcare providers, and policy makers into providing quality care at the end of life.

Key learning points

- Public education is important in hospice palliative care around advocacy, education of decision makers, awareness of hospice palliative care in the general population, and education of patients and informal caregivers.

- As healthcare systems become more complex with multiple options for care there is a need for patients to be aware of how to access care and how to navigate the healthcare system.

- The WHO's Ottawa charter of 1986 defined health promotion as 'the process of enabling people to increase control over, and improve their health'.

- Educating healthcare decision makers is essential and is achieved by understanding the healthcare system and knowing what the public expects from the healthcare system and backing that up with appropriate research and data.

- Public education campaigns targeting the public may contain public awareness messages, media engagement, and targeted brochures and pamphlets and other materials.

- Models of excellence (HIV/AIDS movement) should be considered in creating public education campaigns.

- Outcomes in public education are hard to measure as considerable diligence and experience is required to achieve accurate measurement with outcomes that will be sensitive or specific enough to detect a difference.

Challenges of research in palliative medicine

IRENE J HIGGINSON

INTRODUCTION

All research, whatever the field, faces scientific, practical, and ethical challenges. Palliative medicine is no exception.[1,2] Indeed the challenges in palliative medicine are often greater than those experienced in other fields of medical research because of the nature and complexity of the problems faced by patients and their families, the services they receive, the settings of care and way that patients' conditions can change dramatically in a short period of time. There is often a web of challenges that the investigator has to face. As much as possible, problems should be anticipated and prepared for in advance to minimize their effects. But this is not always possible, and sometimes problems must be dealt with as they arise. Often it requires great courage, skill and hard work to manage obstacles that can occur during the course of a study and to minimize the effect these have on the quality of the findings. Many of the challenges described here apply equally to clinical audits, quality assurance, and total quality management projects.[3] An audit where the design is not appropriate, or a quality assurance review that collects information from a biased sample of people, suffers from the same weaknesses and limitations as a research study with these problems.[4] The wealth of studies already conducted in palliative care and the evidence base to date demonstrate that successful research and audit are possible.[5,6]

SCIENTIFIC CHALLENGES

Scientific challenges are the most predictable difficulties to be faced in any study and should be planned for in advance. Careful piloting of the methods can test possible solutions,

and this may uncover further challenges that need to be planned for. A pilot will often consist of a small investigation, or series of investigations, to test specific components of study design and analysis. This may include, for example, testing the methods of recruitment to see how many patients can be recruited, testing the questionnaires to see how long they take and which are acceptable for patients, or the range of scores to calculate sample size.

Setting the aims and objectives and/or hypothesis or research question

All research is driven by a question or idea that the investigator wants to answer or better understand. Focusing one's ideas on what is to be explored, and what can be investigated in a study is an important step, requiring knowledge of clinical concerns, literature review (see Chapter 25), and self-discipline. It is better to decide to answer a question or explore an issue that can be achieved realistically within the resources and timescale available than to attempt to answer a whole multitude of questions that are very broad and cannot be covered within the scope of the study. Time spent refining the aims and objectives and then considering if these can be answered by the right study design is a fundamental step in any study (see also Chapter 22). In a study following a grounded theory method (in qualitative research) the process varies from that above, but guidance is available.[7]

Study design

Choosing the most appropriate design for a study's aims and objectives is then one of the most important decisions that any researcher can make.[8] Always the aims and research

questions should lead the design. For example, there is no point attempting to test the efficacy of a new drug treatment by conducting a survey of patients' views of the drug. Such a survey may give interesting information about acceptability, side effects, actual use, and patient views, but it will not give information about efficacy (i.e. if the drug works better than the current best practice in controlled conditions). Chapter 22 outlines the different research designs and options for the researcher.

Certain study designs are problematic in palliative care, and perhaps the most often discussed is the randomized controlled trial (RCT). Some RCTs have experienced such severe problems that the trial failed to produce any results.[9] Nowadays RCTS, especially crossover trials for drug treatments in palliative care, are more often used,[10,11] although there can be difficulties with recruitment, attrition, and measurement (see below). However, trials of nondrug interventions often face additional difficulties in maintaining a difference between intervention and control, and because they are difficult to blind can have problems of contamination and disappointment (if patients feel they are not receiving a service they wish to receive).[12–14] There is a growing body of literature showing that, although the RCT is often regarded as the gold standard method in evaluative research, alternative quasi-experimental and observational methods can yield just as much, and sometimes more, useful results.[8,15,16] Some successful RCTs have been conducted, for example of communication skills training,[17] a nurse clinic for breathlessness,[18] community palliative care teams,[19,20] and a broader range of trial methods have been developed including cluster randomized trials,[21,22] wait list control groups (only possible among patients with longer life expectancy) and N of 1 trials.[23] Studying the designs of others, including those researching outside palliative care, and their successes and failings, can often provide useful guides.[24]

Increasingly mixed method study designs (combining quantitative and qualitative methods) are being used in health services and clinical research. These methods have much to offer to palliative care. The quantitative approaches can count numbers affected and provide external validity, whereas the qualitative methods can help to understand the more intangible aspects of symptoms, feelings, or treatment effects, and provide internal validity.[25–31]

Selection and recruitment

Many studies in palliative care, whatever the design, can have problems with patient selection and recruitment. Selection (or sampling) bias occurs when the group of patients selected for or included in the study is different from the total population of interest. For example, one may wish to study the management of pain in patients toward the end of life, but the way that one is able to recruit patients means that patients in the last week of life are excluded – because they could not participate in interviews, or for some other reason. There are many reasons why selection or sampling bias may occur, some of the common types and their effects are shown in Table 20.1. Chapter 21 considers the patient population in greater depth and the issues and problems of recruitment, including among disadvantaged groups.

Further, recruiting patients who are often quite ill, or carers who are distressed and/or bereaved can be difficult.[32] Many research studies assessing the efficacy of drug treatments have automatically excluded older people (even those over 65 years), and those with multiple pathologies, because of the difficulties of recruiting individuals who are ill. In palliative care, excluding people in these categories would remove almost the entire sample, leading to terrible selection bias (see Table 20.1). However, recruiting ill or frail people into research studies requires skill, time, and energy. It involves winning the hearts of professionals who may refer patients to the study, and interviewing patients and families in a way that makes them feel prepared to take part and continue to be involved. Jordhøy et al. and others have written useful guidance on methods of improving recruitment,[1,33] including ensuring staff awareness, and ensuring regular updates and feedback (see Chapter 25 for useful tips, and Chapter 21 for more information on selecting the patient population). In palliative care interviewers must be sensitive and flexible when attempting to recruit patients. There may need to be three or four visits to patients to secure one interview (because patients are ill, factors change, and patients may prefer the interviewer to come back at different time). In one recent study we conduced at King's College London among patients with advanced cancer, in one instance more than 10 contacts were required to secure a complete interview, despite the patient wishing to be involved in the study. That said, many patients in palliative care do wish to be involved in research, and to tell their story, particularly if they feel it may help others in their situation in the future.

A common challenge in palliative care is establishing suitable criteria for recruitment to the study. If prognosis is used, then past experience suggests that patients may be referred too late for the study. In one instance, when patients with a prognosis of less than 1 year were to be referred for the study, 1 in 4 patients had died before the interviewer could recruit them.[12] Teno has suggested the criteria of 'not being surprised if the patient had died within one year', which is likely to be more successful, but may not work in some cultures (J Teno, personal communication, 2004). Prognostication is difficult but a range of estimated survival is more likely to be correct than any absolute assessment.[34] Further work is improving our prognostic assessments by providing information on other relevant factors.[35] Other recruitment criteria, such as the nature of problems or functional assessment, or a combination of these, may also be needed[1,36] (see Chapters 21 and 25). Careful piloting may shed light on the most effective strategies and methods for recruiting research subjects, and the information and updates needed for staff and subjects.

Table 20.1 *Common biases (i.e. systematic rather than random errors) that can be encountered in palliative care research*[a]

Type of bias	Definition
Sampling bias	The inclusion of subjects that distorts the nature of those who would have been chosen by chance
Selection bias	The selection of subjects that distorts the nature of those who would have been chosen by chance, for example selection by nurses or doctors or patients suitable for interview. This can occur in many ways, but selection of any sample is likely to result in sample bias, especially in palliative care where patients may become too ill to contact, or may not be in contact with particular services from which patients are selected (e.g. clinic, hospital, primary care doctor), or may be excluded because staff feel they are too ill for interview
Nonresponse bias	The biasing of the sample due to the nature of those who do not respond being different from that of those who do respond, For example, relatives who are most distressed may (or may not) respond to a questionnaire
Attrition/dropout bias	The biasing of the sample due to subjects being lost to follow-up because they choose not to be involved in the study, or become too ill for interview, move away, or die. Some attrition bias is inevitable in palliative care
Missing data bias	The biasing of the responses due to some subjects not responding to some questions. For example, if the most distressed patients do not answer questions about depression. There is in effect a nonresponse by some of the sample to some of the questions
Measurement bias	The collection of data or measurements that distorts the nature of the data collected from its true state
Recall bias	The biasing of data collected because of inaccurate or varied recall, perhaps for some events more than others, or because of varied time (e.g. 1 year vs. 6 weeks) or events
Poor measurement tools, validity/reliability	The use of measurement tools that introduce bias because they are not valid or reliable in certain situations, or among certain cultures
Digit preference bias	The use of measurement tools that introduce bias because respondents choose particular digits in their answers. For example, on a scale of 1–100 most people tend to use numbers that end in 0 (10, 20, etc)
Observer/researcher's bias	The systematic error introduced by an expectation or belief on the part of the observer or researcher (this can be quite unconscious and is most common when researchers are not blinded to situations, although it can occur even then)
Subject bias	The systematic error introduced by an expectation or belief on the part of the research subject (this can be quite unconscious, and is most common when subjects are not blinded to situations, although it can occur even then)
Hawthorne effect	The change in behavior made by people (e.g. staff or patients) when they know they are being studied. The effect was first noticed in the Hawthorne plant of Western Electric. Production increased not as a consequence of actual changes in working conditions introduced by the plant's management but because management demonstrated interest in such improvements
Reporting bias	The reporting and publication of research findings in a way which distorts the dissemination of findings toward more positive or negative findings
Publication bias	The publication or nonpublication of research findings, depending on the nature and direction of the results. In general positive studies are more often published than negative ones
Language bias	The publication of research findings in a particular language, depending on the nature and direction of the results. Research findings in some languages, particularly English, are more accessible
Funding bias	The reporting of research findings, depending on how the results accord with the aspirations of the funding body. Further there may be considerable hidden bias in the nature of research supported, whereby certain investigations are not funded
Selective outcome reporting bias	The selective reporting of some outcomes but not others, depending on the nature and direction of the research findings. For example, positive findings are reported but a lot of negatives ones are not
Time lag reporting bias	The delayed (or rapid) publication of research findings, depending on the nature and direction of the results
Developed country bias	The publication of findings, depending on whether the authors were based in developed or in developing countries

[a]Main categories of bias are shown in italics, subcategories/causes of each type of bias are shown above. Note that over 100 different types of biases are known, but three main categories – sampling, measurement, and reporting – include most types.

Measurement, interviews, and data collection

The insurmountable challenge in palliative care research is to find measures that detect relevant changes and yet are suitable for very ill populations. This creates tension between attempting to capture detail by using long-standardized measures or conducting qualitative interviews and having short interviews with short measures and/or short qualitative interviews. In the end the researcher must balance the amount of information that can realistically, reliably, and validly be collected with the ideal needed. Often the plan of analysis is helpful here, as well as referring back to the aim, objectives, and/or hypothesis of the research. The analysis plan helps to clarify how the data will be used, and this in turn clarifies what needs to be collected.

There are now many hundreds of quality-of-life instruments and a range of palliative outcome scales that have been developed or validated specifically for palliative care. Chapter 23 provides more details of individual scales and outcome measurement. In addition, there are several books on quality-of-life assessment and reviews of the measures.[37–43] Therefore, there is every opportunity for the researcher and clinician to use validated and tested scales. Only if a thorough systematic review reveals that no suitable (or partially) suitable scale is available, should the researcher embark on developing a new scale.

Less frequently qualitative researchers publish their topic guides, which are generally developed for specific lines of inquiry. However such publication is useful, for conducting open qualitative interviews is a highly skilled activity. Listening to the tapes of, or reading or typing the transcripts of highly skilled qualitative interviews is very instructive.

In general interviews should be kept as short as possible, and in some instances the researcher should order the questions or scales so as to collect the more important information first. Missing data for some questions among some patients will be inevitable, and researchers should minimize this for the primary outcomes of their study. When patients become tired or do not wish to continue interview, the data collection should be terminated because collection will become unreliable if patients cannot concentrate. It may be necessary to complete the interview at a later date if the person is willing.

Missing data and attrition

Missing data in palliative care studies are inevitable. Data may be missing for individual questions (for example if the patient did not wish to answer a question or scale) or for individual subjects (for example in a longitudinal study, a patient may miss a follow-up interview because they are away or because of illness, or they may be lost to follow-up because they become too ill to participate in the study, or they die). The most important thing is to understand the reason for the missing data and in which subjects this

occurs. Any missing data may bias the results (see Table 20.1). Therefore missing data should never be ignored. In general missing data should be classified and explored in three categories:

- *Data missing completely at random.* There is no discernable pattern to the missing data with any variable in the data set.
- *Data missing at random,* There is no relation between the missingness of data with the outcome variables of interest, but there is a relation with one of the other variables which does not appear to be related to the exposure or outcome variable. For example in an evaluation of palliative day care, we found missingness was associated with whether patients had smoked or not, although there was no relation with pain, symptoms, quality of life, hope, diagnosis, or any clinical variable.
- *Data missing not at random.* The missingness of the data is associated with an important variable in the study, e.g. diagnosis, or importantly, with one of the outcome variables, e.g. quality of life.

The field of research into missing data and its effects is growing rapidly. New techniques are being developed (e.g. imputation and modeling) to handle missing data.[1,44,45] The old notion of just ignoring missing data is now rarely acceptable, unless there are minimal missing data. Any analysis conducted with missing data excluded from the analysis is in effect assuming that those subjects with missing data will give the same results as those with complete data. Thus there is an implicit imputation, even if the researcher has not formally carried this out. And even if it is missing completely at random, missing data will reduce the sample size, and may mean that the study becomes underpowered. Missing data should always be reported and understood. In palliative care the pattern of missing information can often say much about the sample and the subjects. If modeling or imputations are undertaken, then often several imputations are advisable, followed by a sensitivity analysis, to determine the effects of different approaches.

CLINICAL, ORGANIZATIONAL, AND PRACTICAL CHALLENGES

Challenges in this area can occur in all forms. There may be concerns among colleagues or reluctance to refer patients for studies in palliative care on the part of both specialists outside palliative care and those in the field. This may be because of concerns about the nature of the questions or a belief that palliative care equates with end-of-life care, and so patients should only be included in studies when they are very close to death. Interviews may have to be organized around clinical treatments. Patients may not clearly distinguish between new services or interventions and the

research interview if both are introduced at the same time. The Hawthorne effect (see Table 20.1) is likely for a wide range of reasons.

In addition, there are many practical challenges to consider in a palliative care research project. One may need to travel to patients' homes to conduct interviews, and the nature of a home may make it difficult to ensure that patients and carers can be interviewed separately. Sometimes the only way to achieve separate patient and carer interviews is to have two interviewers, and even in some homes this is not possible. Travel time and costs must be accounted for.

During the course of any study things will change. New treatments or services may be introduced which may require a change in the recruitment or inclusion criteria. Staff in the clinical service will change, which may mean there is a need to educate the new staff. Even researchers on a study may leave because of being offered a post elsewhere, finding the work not as interesting as they thought, or they may fall ill. A common problem in palliative care research is if the researcher suffers a bereavement in the family and so begins to find interviewing difficult (see below). Senior investigators and research teams are often crucial here; they have seen this problem before and there may be several individuals who can help out with the study or who can at least speak with the funding body and others to let them know what is happening.

The potential effects of interviews on those conducting them should also be considered in terms of safely and emotional effects. When interviewing patients in the community the safety of interviews, especially in more deprived and dangerous areas, should be considered. Community clinical services may provide useful information. Using mobile phones, keeping lists of places/people to be visited, agreeing associates who will check whereabouts, and in difficult circumstances joint interviewing can be helpful. Conducting interviews, transcribing and even analyzing data (including collected by post) can also be potentially distressing for researchers, particularly those who do not have clinical experience to make them aware of services that might be available for others. Often a system of support – even if mutual within a department – is helpful. At times of particular stress, e.g. following a bereavement, for clinical staff it may be appropriate that the person should not conduct the interviews.

A project advisory committee (PAC) can also be helpful. The PAC usually comprises relevant clinical investigators, and depending on the scale of the project it may be small (two or three individuals) or for complex projects it may be large (involving several centers, representatives of the funding body, external experts, and users/patients). The PAC may be established by the funding body or by the investigators. It meets regularly and oversees the progress of the project, and provides a forum to discuss challenges as they arise, monitor research ethics, governance, and progress, and considers the relevance of findings to patients, policy, and practice.

A final practical challenge is obtaining funding for the study. Many funding bodies do not see palliative care as a priority, and many scientific assessors on grant awarding bodies are not aware of the specific outcome measures and methods needed. In Canada a specific palliative care program has been established within the national research boards and has international expert assessors. This is a good model for other countries, as only with specific programs dedicated to a field can the best studies be supported.

ANIMAL MODELS: ISSUES IN TRANSLATING FINDINGS TO PEOPLE

Often work with animal models involves the artificial inducement of the problem under study in the animals (e.g. the cancer is induced in the animal). Then the researchers measure parameters that they believe are sufficiently close to or reflect those of interest in humans. The animals are killed at a point when they are thought to be suffering. There are many challenges in animal model studies. Specific guidance exists in many countries regarding the welfare of animals, but it is beyond the scope of this chapter. Research using animal models requires a model sufficiently close to the situation experienced in humans to be developed in the animals. For example, to study hypertension, types of rat that develop high blood pressure have been bred. To study problems in cancer, the cancer is often artificially induced. One of the apparent problems is being able, in animals, to induce problems sufficiently similar to those faced by humans and to find ways to measure them. Caution is therefore needed when extrapolating from animal studies to human beings.

ETHICAL ISSUES AND DEALING WITH INSTITUTIONAL REVIEW BOARDS

The ethical challenges in palliative care research are wide ranging, and for this reason Chapter 24 deals with this subject in detail. Common ethical issues that can arise occur at the point of consent (ensuring that full information is given, and the time taken for consent in the interview), during the interview, when researchers may uncover problems that they feel they need to act on, and dealing with distressed individuals. Nevertheless, it is arguably unethical to make decisions for patients about whether or not they should be given the option of being involved in research if they wish. Institutional review boards (IRBs) or ethics committees will need to approve the research (and in many instances the audit) to be undertaken, and will required detailed project information. They will cover not only research among patients but also staff surveys and any action that is not part of routine good clinical practice. Allowing sufficient time during a study for the review is essential. Ethical committees and IRBs vary in their

approach and are often not familiar with palliative care and survey research, and so may initially be reluctant to pass a study. Often considerable persistence and explanation is needed, although often their suggestions and advice improve the study. If in doubt about whether the study requires IRB approval it is sensible to take advice from the chair of the committee. Chapter 24 provides further guidance.

INVOLVING USERS IN RESEARCH

There is a growing view, on the part of many patients, families, caregivers, and research investigators that the involvement of patients and families/relevant others in research is helpful and good practice. Some charities that support research have user forums that help to decide on research priorities, questions, and the review of potential grants. For example, at King's College London, a study we have been conducting, funded by the Multiple Sclerosis Society (UK), was reviewed by users as well as scientific experts and is being monitored by a PAC involving users, scientific experts, and clinicians. A user chairs our PAC.

However, there can be particular challenges in involving users in palliative care research and audit – patients are often quite ill, may need special facilities, and cannot be recruited in all circumstances. Increasingly it is recognized that users involved in appraising research need some development or training, so that they can understand some of the concepts involved. This, and the course of a research study over 1–3 years, takes time. But it is completely unrealistic to expect palliative care patients to be involved for this period of time. Involving users who are not palliative care patients, for example involving cured cancer patients, can be problematic, because these users – although very familiar with some of the problems in care – have not experienced the specific issues faced by palliative care patients. Other proxies, such as bereaved relatives, or representatives from relevant patient bodies and in some instances relevant clinicians, may overcome this to some extent, but bring other challenges. However, the ways to involve users in palliative care needs more development and testing. Small and Rhodes' guide provides a good introduction.[46]

REPORTING THE RESULTS

Many challenges can arise in the final stage in a research project – reporting the results (see Table 20.1 and Chapter 25). It can be difficult to write-up the paper fully within the word limit required by many journals, and there is often a time lag between completing the study, analyzing the data and finally getting the paper out. However, dissemination is an important part of all research, different audiences should be considered, and a dissemination strategy should be developed in the original protocol.

CONCLUSION

There are many challenges in conducting research in palliative care, which mean that research in palliative care needs skills, training, effort, and links to those with expertise in dealing with such issues. Some of the challenges are similar to those in other fields (especially for example psychiatry and health services research), whereas other challenges are unique (for example the problem of attrition, issues of involving users). A growing number of units are becoming skilled and experienced in conducting research in palliative care, and have sufficient expertise and infrastructure to begin supporting others in their research training. In the future, bringing researchers, clinicians and users together – through collaboratives, rotations,[47] and ideally institutes devoted to palliative care – will help improve the infrastructure for researchers, especially new investigators. Successfully completed studies are rewarding for investigators and more importantly for patients and families. Research can begin to discover better and more effective, efficient, and humane ways of providing care and treatments to benefit patients and families.[48–50] But failed studies are demotivating for investigators and take valuable time away from patients, families, and clinical staff.[51,52] Good research in palliative care can overcome many of the challenges, although there is a need to find better ways to deal with some of the problems of recruitment, attrition, outcome measurement, and missing data.

Key learning points

- Research in palliative care faces a complex web of scientific, practical, organizational and clinical challenges.

- Many of these challenges are common to those faced in other fields, but some (e.g. attrition and missing data) are especially likely in palliative care.

- Scientific challenges include setting aims and objectives, study design, outcome measures, recruitment, follow-up, attrition, and dealing with missing data.

- Practical and other challenges include selling the project to others, interviewing patients in various settings and different contexts, managing changes in treatments and/or services and/or staff, ethical issues, and involving users.

- Many challenges can be avoided or their effects minimized by careful planning and piloting, developing a PAG and working in or with units that possess relevant palliative care research expertise and skills.

- Research is important to palliative care, to develop the knowledge and discover improved treatments and care.

The patient population: who are the subjects in palliative medicine research?

JENNIFER KAPO, DAVID CASARETT

INTRODUCTION

Although the volume of published research in palliative medicine has increased substantially in the past 20 years, there is still a need for high-quality, randomized trials to provide evidence for many palliative care interventions.[1–5] However, researchers face many barriers including the difficulty of defining precise outcomes, and the ethical issues that pertain to studying dying patients with the resultant scrutiny by institutional review boards.[6] These other challenges will be discussed in depth in Chapters 24 and 25. This chapter focuses on the additional challenge of defining the population to be studied, and will consider three key questions related to the palliative care population in research:

- Which patients should be included in palliative medicine research?
- What are the challenges of recruitment and retention of subjects in this population?
- What groups are currently underrepresented in palliative research, and how can these disparities be overcome?

WHICH PATIENTS SHOULD BE INCLUDED IN PALLIATIVE RESEARCH?

Researchers and clinicians appear to be in the process of redefining what characterizes a 'palliative care patient'. In the early stages of the field's development, attention was focused

primarily on patients near the end of life and their families. More recently, however, there has been a shift in the definition of palliative medicine from care only for the imminently dying to a larger population. Typically, palliative care now encompasses the care of persons who have chronic medical illnesses with physical, spiritual, and psychological symptoms in need of palliation, but who are not necessarily terminally ill.[7] Indeed, the most recent World Health Organization definition emphasizes palliative care's focus on improving quality of life rather than its focus on a particular patient population.

Therefore, there is reason to avoid definitions of the palliative care research population that are prognosis based. For instance, recruitment strategies that rely on prognostic inclusion criteria may exclude a group of healthier patients whose inclusion would have improved the generalizability of the study's results. In addition, investigators who use prognosis to define study eligibility must overcome substantial inaccuracies in the predictions even using the best available models as tools.[8*,9*] Finally, physicians are not only reluctant to make prognostic estimates, but also tend to overestimate life expectancy.[10*,11*] They may therefore be hesitant to refer their patients to palliative studies with a prognostic inclusion criterion.[12]

Instead, investigators might rely on a symptom or cluster of symptoms to identify the study population. This approach is particularly appropriate for randomized, controlled trials that aim to demonstrate the efficacy of an intervention. However, depending on the prevalence of the symptom, accrual may be very slow.[3,13,14*] Finally, a population defined in these terms may be heterogeneous, particularly if the

symptom is commonly found in different disease states. For example, pain is associated with diverse conditions including cancer, osteoarthritis, and end-stage renal disease. Although one might logically include several of these conditions in a single study, the resulting heterogeneity may make analysis difficult.

Investigators may also define the study population using a single diagnosis. Although this may the best approach for studying many outcomes such as dyspnea related specifically to chronic obstructive pulmonary disease (COPD), focusing on one disease state may lead to limiting information applicable to other disease states. For example, although only a minority of all deaths in the USA are due to cancer, the majority of the existing palliative medicine research focuses on the care of patients with cancer. Cancer tends to follow an illness trajectory that is often more predictable than that of other diagnoses,[15*] and a substantial symptom burden is common at the end of life.[16–19] Although in some cases the results of studies that focus on one condition may be applicable to other conditions, this need not be the case. For instance, although the phenomenological experience of dyspnea may be similar for patients with cancer and patients with COPD, the mechanisms that produce dyspnea in these populations may be very different.

Another strategy for defining the palliative care population for research might rely on functional status. This approach is worth considering, first, because it is known that functional impairment may be closely linked to other symptoms such as fatigue, pain, and depression.[18,20–22] Therefore, investigators who rely on functional impairment as an inclusion criterion are likely to identify patients with a high prevalence of palliative care needs. Although this is a heterogeneous population, as a group they may have substantial disability and may benefit considerably from palliative interventions. Second, functional status can be assessed readily and with minimal clinical data. Thus eligibility criteria that are based on functional status offer a relatively straightforward way to identify potential study participants. However, not all patients at the end of life have functional impairment and frailty. In fact, many patients retain high levels of function until the last days of life.[15*] Therefore, focusing on functional status alone will both include patients with a good prognosis and will also exclude a significant number of patients who are near the end of life.

As detailed above, there are disadvantages and advantages to all of the strategies described. Different approaches have particular value when evaluating specific questions. For example randomized controlled trials generally require highly specific inclusion criteria such as symptom severity, functional status, and prognosis. However, a study designed to assess home care needs could use a more broad set of inclusion criteria, perhaps based on functional needs. Studies that use qualitative methods, for which precisely defined sample characteristics may not be essential, can often sample a broader and more heterogeneous population using more general inclusion criteria.

OTHER PALLIATIVE CARE POPULATIONS: FORMAL AND INFORMAL CAREGIVERS

Although the focus of palliative care research is typically on the patient, patients are surrounded by others who play a substantial role in their care. Therefore, it is also reasonable to consider these caregivers as potential subjects of palliative care research. For instance, a growing body of evidence points to the unique and significant stresses with associated morbidity that can be associated with caring for a loved one at the end of life.[23–29*] While the effects of caregiving are clear, their scope and reach are not, and it may be difficult to determine how to define a 'caregiver' for eligibility purposes (see Chapter 108). Similarly, the formal caregivers who comprise the interdisciplinary team (physicians, nurses, social workers, aids, chaplains, etc.) also need to be included as a part of the population to be studied. The team's decisions and actions are paramount to the delivery of quality palliative care. In addition, a wealth of information may be gained by studying the attitudes, beliefs, and practices of the providers who provide 'up-stream' care and eventually refer their patients for palliative care, or who wish to provide this care themselves.

Finally, both formal and informal caregivers experience grief and loss after a patient's death. These responses have been studied both for formal and informal caregivers, and it is clear that the effects of a patient's death can be both multifaceted and longlasting. Therefore, in defining the population that is relevant to palliative care research, both formal and informal caregivers should continue to be the focus of research even after the patient's death.[30–32]

CHALLENGES OF RECRUITMENT AND RETENTION

Recruitment for palliative care research may be limited both by patient and physician-specific barriers.[33] For instance, numerous patient characteristics impede research recruitment, including poor performance status, intense emotional strain, and uncontrolled symptoms. Together, these factors limit patients' ability to answer questions and to undergo repeated tests or examinations that are often required in research participation.[2,14] Patients may also have cognitive impairment that makes it difficult to communicate, which may impair their ability to provide adequate informed consent, to contribute valid and reliable self-reports, or both.

In addition, even among those patients who are eligible and approached to participate, a substantial proportion may decline to enroll for personal ('Not the right time', 'I need more time to think about it') and family-related reasons. In several studies this rate is reported to exceed 50 percent.[3*,34*] Finally, once patients are enrolled, dropout rates due to deteriorating health status, noncompliance with the treatment regimen, and death are high.[14,34] It is not uncommon for less than half of those enrolled to finish a trial.[7,8*,14]

Accrual to studies may also be delayed if healthcare providers are hesitant to refer their patients. Several researchers have documented their experiences and the challenges they face with recruiting patients.[3,33,35,36] Physicians may have trouble identifying patients who have poor prognosis,[10*] and they may be reluctant to express the possibility of a poor prognosis with a patient and/or their family for fear of causing psychological distress and harm.[11*,34] Physicians may be uncomfortable with the proposed research agenda, and fail to see the benefits of the study. For instance, some providers, such as home hospice clinicians, may have very strong preferences about valuable research and important research questions.[37*] An investigator whose research does not fit with these priorities faces additional challenges of recruitment. In addition, many providers have concerns that a patient referred to a palliative care study may not receive the highest quality care available. Patients and their families may be reluctant to enroll for similar reasons.[34*] Finally, providers may be concerned that asking their patients to participate in palliative medicine research is intrusive, particularly when patients are experiencing physical or emotional distress, or are near the end of life.[31,32]

IMPROVING RECRUITMENT AND RETENTION

Despite these perceived harms of enrolling in palliative medicine research, there is evidence to suggest that patients recognize several advantages of enrolling in trials, and that they may in fact derive benefit from research involvement, even at the end of life.[13,38–41*] For instance, patients may wish to enroll in research studies to benefit from close monitoring and attention provided by the research team. Others may hope for clinical benefit, even if none is expected. Patients also report humanistic benefits such as wanting to help others and wishing to 'give something back' to society, and to leave a legacy. Others report enrolling in trials as an expression of gratitude for the staff that provided care to them throughout the illness course.[34,39]

In order to improve enrollment and retention of subjects, several strategies have been proposed. One method is to capitalize on the potential benefits of study enrollment alluded to above. However, there is the possibility of creating an undue inducement to enroll if the patient feels that they need to enroll in a study to gain a treatment or evaluation to which they would not otherwise have access. Strategies to improve enrollment in trials have been the subject of several reviews and empirical studies.[33*,34,42,43*]

To improve recruitment, relationships must be forged with the referring doctors to build trust and enthusiasm for the study. One researcher suggests writing personal letters to care providers to engage them in the study and ask them to be a part of an advisory committee for the project.[42] Given the daunting challenges of recruitment, some trials may require specialized training of a person or persons who are responsible for the recruitment process and are therefore committed to the success of the project. The numbers of patients enrolled can be increased by the efforts of a dedicated recruiter who is stationed in primary care providers' offices, and by advertising with flyers and public service announcements.[44] In addition, more specific recruitment interventions for subgroups of patients may be useful as well and are described below.

Preventing dropout and loss to follow-up is often more difficult in this population. However, three broad recommendations show promise. First, clinic visits for data collection should be limited in number and duration. Techniques of remote data collection are promising and, if widely adopted, have the potential to dramatically decrease the burdens associated with palliative research participation. Second, assessments and instruments used should be minimally burdensome and invasive. Last, if there is a high attrition rate during data collection the patients' and caregivers' opinions regarding the study should be elicited to determine if minor changes to the study protocol will keep patients from withdrawing from the study.

UNDERREPRESENTED POPULATIONS IN PALLIATIVE MEDICINE RESEARCH

As discussed in the preceding section, there are considerable challenges to the recruitment and retention of palliative care research subjects. Although this is true of the population taken as a whole, it is important to consider groups of patients who may be underrepresented in palliative medicine research. For example, there is a growing body of evidence that suggests that ethic minorities, in particular African Americans, as well as older patients have been underrepresented in research studies.[45–51] As a consequence, data from many clinical trials are extrapolated, often inappropriately, for application to older adults and those from ethnic minorities.[12,52–54]

Individuals from different countries and ethnic backgrounds have different preferences and needs for end-of-life care. Focusing only on Western, predominantly white patients will result in research conclusions which lack generalizability to all populations. Currently, there is a small, but growing body of research that is examining cultural differences in regards to attitudes, preferences, and care needs of those from different cultures at the end of life. However, there is an enormous need for further work in this area. For example, there is extensive evidence that African American patients are less willing to forgo life-sustaining treatment compared with white patients.[35,55–60*] Researchers from the UK have studied the differences in end-of-life preferences between native born white and black Caribbean patients. These studies suggest significant differences in the characteristics of informal caregivers, preferred location of death, acceptance of euthanasia, and reported symptom related distress; however,

the authors conclude that there is a need for larger studies to fully describe these differences.[61–63] Hawaiian researchers have studied cancer evaluation and treatment strategies preferred by Native Hawaiians compared to Japanese, Filipino, Chinese, and white patients.[64–66] Failing to enroll patients from different ethnic and cultural groups will result in invalid conclusions in studies that have similar outcomes.

Research programs can improve the enrollment and retention of ethnic minority patients in studies if the researchers are aware of the knowledge gained from previous work that examines end-of-life care preferences of those from different ethic groups. For example, one researcher advocates that it might be best to address mistrust at the time of enrollment and/or follow-up by asking the patient directly, 'Is it difficult to trust a physician who is not (of the same background as you)'.[67] Another strategy includes stating explicitly that the team will work together with the patient and family to accomplish common goals.[68] In order to communicate effectively during recruitment and data collection, it may be particularly helpful to hire ethnically and culturally diverse research staff.[67]

CASE STUDY: EXAMPLE OF RECRUITING OLDER ADULTS IN PALLIATIVE CARE RESEARCH

Older adults are one important population that has traditionally been underrepresented in clinical research, including palliative care research. The most significant evidence of underrepresentation comes from oncology trials, which often exclude older adults despite the fact that most people with advanced cancer are elderly.[12,48*,49,53] As a result, clinicians who make treatment decisions need to rely on data that are extrapolated from studies of younger patients who may have better biological and physiological function, less comorbid diseases, and less polypharmacy.[52,54,69] Palliative care research, and particularly palliative care research that focuses on patients with cancer, may be following the same pattern, making this population a useful case study in the challenges of recruitment and potential solutions.

Perhaps the most significant barriers to including older adults in palliative care research are eligibility criteria that exclude patients with comorbid conditions. More generally, studies may exclude patients with hearing impairment, cognitive impairment, or those with functional impairment. As all of these are more common in older adults, these criteria create a de facto exclusion of this group.

Barriers to recruiting and retaining older adults in palliative care research may also come from providers. For instance, referring physicians may refuse to enroll older patients because they may perceive them to be too sick to participate, have too many comorbidities, or likely to benefit more from conventional therapies. They may also feel that the enrollment process is too time consuming, both for the patient and for themselves.[18*,50*] In fact, these sorts of barriers are not unique to recruitment of older patients, and are a magnified version of providers' reluctance to recruit patients who are near the end of life and perceived to be vulnerable.

Finally, patients and families may also be reluctant to enroll in research.[18,49–51,70] Common reasons not to enroll include: underlying comorbidities, concerns for potential toxicities, lack of social support, and excessive time for enrollment.[51] Several researchers note that older persons are particularly concerned with the added costs of treatment related to research protocols, including the treatment of adverse effects and the cost of travel to the evaluation appointments.[18,51] In addition, patients fear that the research will be inconvenient and take excessive time away from family and friends.[49] Again, these barriers are not unique to the recruitment of older adults. Concerns about risks and toxicity are common, and may be magnified in populations that harbor mistrust of the medical establishment.

Given these potential challenges to enrollment, several practical strategies have been proposed to improve enrollment of older adults. These strategies are a useful case study both because the challenges are not unique and because they require solutions that are multidimensional. Broadly, efforts to enhance recruitment of older adults, and indeed all underrepresented patient populations, can be grouped in three main categories: study-specific issues; provider-specific issues; and patient and family-specific issues. Each of these is discussed briefly below.

First, study-specific barriers to enrollment should be addressed in the earliest phases of a study's design. Inclusion criteria that are as broad as possible are ideal, and efforts should be undertaken to avoid study design features that may constitute a particularly significant barrier for some groups. Of course, broad inclusion criteria create other design challenges. For instance, by including older, more frail subjects, a prospective study may need to anticipate higher dropout rates. In addition, a study sample that is more heterogeneous may make it more difficult to detect main effects in an interventional trial. However, these and other difficulties should not by themselves prevent investigators from including a diverse patient population, but instead require careful attention and trade-offs in the early phases of study design.

Second, in order to address physician concerns regarding patients' comorbidities, researchers might design protocols that specifically target underrepresented populations (e.g. older adults, ethnic minorities, rural populations). Researchers need to find meaningful ways to communicate the importance of studying this group with the referring care providers. Involving the referring physicians as consultants during the design of the study may result in modifications of the protocol that will increase its appeal to the collaborators. In addition, training an efficient research recruiter with expertise in communication with older adults will limit burdens on the referring physician's time and efforts, and

therefore increase their willingness to refer patients for enrollment in studies.[49]

Third, in order to address patient and family-specific barriers to study recruitment and enrollment, several over-lapping strategies may be useful. For instance, one approach is to use an interdisciplinary research team including nurses, physicians, social workers, pharmacists and chaplains who can evaluate and care for the needs of study participants. This approach has been used successfully to increase recruitment and retention of older adults in clinical research[49,70] and offers promise for other underrepresented populations as well.

Others suggest designating a portion of the study budget to provide transportation to and from the study site, or providing interventions within the older person's home.[18] A portion of the budget should also be available to use to purchase the supplies needed to treat adverse effects that are the result of a study intervention. Given the importance that the family and caregivers frequently have in the care of older patients, the research staff may benefit from involving them in the study process. Finally, the time spent completing the study intervention should be kept to the minimum needed to be complete.[50]

CONCLUSION

Researchers are faced with many challenges in the identification, recruitment, enrollment, and retention of the population to be included in palliative medicine research. However, there is a growing body of evidence elucidating these challenges and defining targets for intervention to improve the quality of research and ultimately the care we provide to vulnerable and potentially under-served patients at the end of life. Further research is needed to determine the best interventions to improve the quality of recruitment and retention of patients, particularly those from different cultural and ethnic groups and older patients.

Key learning points

- Different approaches may have particular value when evaluating specific questions.

- Recruitment and retention of palliative care research subjects is subject to both patient and physician-specific barriers.

- Despite the challenges, there are several well-written guidelines to guide researchers.

- Ethnic minorities have traditionally been underrepresented in palliative care research.

- An understanding of the cultural differences in regards to the attitudes, preferences, and care needs of patients may help researchers design appropriate trials.

- Older persons are also underrepresented in palliative care research.

- Older persons may be excluded from enrollment due to medical comorbidities, concerns for toxicity, and declining functional status.

- Strategies that include education for the referring clinicians and the participation of a trained research coordinator with expertise in palliative medicine may increase the number of older patients enrolled in palliative medicine trials.

Study designs in palliative medicine

MASSIMO COSTANTINI

The question being asked determines the appropriate research architecture, strategy, and tactics to be used – not tradition, authority, experts, paradigms, or schools of thought.

Sackett and Wennberg (1997)[1]

INTRODUCTION

The objectives of this chapter are to define, discuss, and compare study designs commonly used for quantitative research in palliative care. Quantitative research uses the epidemiological approach to define and shape all the aspects of a study, including its design.

Epidemiology is the study of disease and health in human populations.[2] In palliative medicine we focus on at least two populations of interest: people at the end of their lives and their families. For both populations, 'the disease' is a multidimensional problem involving suffering, dignity, care needs, and quality of life.[3] Within these specific areas of interest, the general aims of epidemiological research in palliative medicine are:

- *to describe* needs and problems of people at the end of their lives and their families in terms of frequency, risk factors (frequency within groups), and trends
- *to explain* the causal relationships between the developing of a particular outcome and the presence of a study factor or exposure. The outcome in palliative medicine is one or more components of the multidimensional concept of quality of life, or other issues that, directly or indirectly, can help to better know and improve the quality of care. The study factors

(the exposure) are the potential determinants of the outcome. These include characteristics of the subject, of the disease, or of the environment

- *to assess the effectiveness of interventions* aimed at modifying the distribution of the problems in the population of interest by prevention of new occurrences, effective treatment of existing cases, or, in general terms, by improving quality of life of affected persons.

High-quality research is required to achieve these aims because of the unique challenges posed by studies focused on terminally ill patients. The choice of appropriate study design is probably the most important factor for the quality of a study. A study design can be defined as the strategy adopted to describe a problem (in descriptive designs), or to test hypotheses and evaluate strengths of associations (in analytical and experimental designs). Each study design has a particular methodology and can investigate particular aims (Table 22.1).

Epidemiological research makes use of observational, quasi-experimental and experimental studies. In observational studies there is no artificial manipulation of the study factors, and events and associations are described and analyzed as they naturally occur. Whenever there is an artificial manipulation of the study factor, the study is (i) experimental if the study factor is randomly allocated to study subjects, and (ii) quasi-experimental if the study factor is allocated without randomization.[2]

Any attempt to rank study designs according to their inherent value makes little sense, since it is the main objective that defines the most appropriate design for a specific study (see Table 22.1).[1] This chapter seeks to help the researcher to identify the most appropriate study design for answering a specific question.

Table 22.1 *Types and general aims of the principal study designs*

Study design	Method used	General aim
Cross-sectional	Observational	Descriptive – analytic
Retrospective cohort study	Observational	Analytic – descriptive
Prospective cohort study	Observational	Analytic – descriptive
Case–control	Observational	Analytic
Quasi-experimental	Experimental without randomization	Analytic
Experimental	Experimental with randomization	Analytic

STUDY DESIGNS

In all study designs, the investigator must be concerned with avoiding any effect or inference that tends to produce results which depart systematically from true values. In other words, the researcher should avoid any kind of bias at any stage of the study, from study design to publication of the results. More than 100 biases have been described.[4] A conceptually appealing classification identifies two general classes of systematic error. The first, selection bias, includes any error that arises in the process of identifying the study population. The second, information bias, refers to any error in the measurement of information on exposure or outcome.

Observational studies

There are three basic designs for observational studies: cross-sectional, case–control and cohort studies. The differences between them are related to the sampling frame and the time frame.

In a **cross-sectional study** subjects are selected from the target population at a particular point in time, regardless of their exposure and disease, and the associations among variables are evaluated.[2] This type of study can be conducted at a specific point in time (e.g. of pain at a specific date), at a fixed point during the course of events (e.g. of pain at hospice admission), or in a specific time window (e.g. of pain during the last month of life).

In a **case–control study** samples of subjects with (cases) and without (controls) a condition are identified, and the groups compared with respect to prior exposure to one or more study factors.[2] The validity of this design depends on the ability to draw valid samples of cases and controls from the target population. In palliative care, it is difficult to identify the whole population of palliative patients, and to appropriately sample cases and controls (for example, patients with and without a symptom). As a consequence, this design, seldom used in palliative care research, will not be discussed in this chapter.

In a **cohort study** (also called longitudinal study) samples of subjects with and without specific characteristics of exposure are followed forward in time from exposure to outcome, and the outcome in persons exposed to the study factor (exposed) is compared with the outcome in persons not exposed to the study factor (unexposed).[2] A cohort study can be done 'prospectively', where the study population is identified at the time the study starts, and then followed over a certain period to assess the outcome; or 'retrospectively', where the study population of exposed and unexposed is identified in the past and the occurrence of the outcome is evaluated in the period elapsed from the time when exposure was assessed to the present.

The choice of a retrospective or prospective design is based essentially on logistic and scientific considerations. Retrospective studies require much less time and resources, because all events have already occurred when the study is initiated. In palliative care, retrospective cohort studies are difficult to perform because information on exposure or outcomes is usually not available retrospectively. In at least two situations this design is possible and potentially useful. The first one refers to palliative care services that routinely assess quality of life using validated tools such the Palliative Outcome Scale as part of quality management programs.[5] In these cases, the 'historical database' of the service can be used to implement retrospective cohort studies. The second situation is for studies assessing 'hard outcomes', such as place of death, easy retrievable for all patients, also retrospectively. At least two limitations should be taken into account. First, data were collected for purposes other than research and their quality can be variable and is sometimes poor.[6] Second, as all information on potential confounders is not routinely collected, the results of the study need to be interpreted cautiously.

Experimental and quasi–experimental designs

In experimental and quasi-experimental designs an intervention is deliberately introduced to observe its effects (the artificial manipulation of the study factor). The general aim of these designs is to study the efficacy (or the effectiveness) of the intervention. Random allocation of the intervention between groups of patients discriminates experimental (with randomization) from quasi-experimental (without randomization) studies.[2] All quasi-experimental and experimental studies are, by definition, prospective.

QUASI–EXPERIMENTAL DESIGNS

A variety of quasi-experimental designs have been proposed: some are not very reliable, others, more sophisticated, allow in some situation a strong causal inference.[7] The validity of the study design depends on the degree of control that the researcher has over several elements of the study design such as the assignment of the patients to different treatments, the measurement of the outcomes, the choice of comparison groups, or the application and the scheduling of the treatment.[7]

In the classic non-equivalent groups design, the two (or more) groups are identified from convenience (patients of different services, hospitals, health districts) or according to their voluntary behavior. The researcher can also compare the subjects of the experimental group with subjects who received a different intervention for the same condition at a different time, generally an earlier period (so called historical controls). In these studies, the control group is selected to be as similar as possible to the intervention groups for all characteristics but the intervention. Matching or stratifying for relevant characteristics, or adjusting for baseline values of the outcomes can increase the comparability between groups.

These designs can prove severely biased when the subjects themselves determine the intervention they receive. People who choose a new therapy or to be followed by an experimental service are likely to be different for many characteristics related to the outcome of interest. Designs less amenable to selection bias are those in which the two groups are selected for factors not related to their preference for the intervention.

EXPERIMENTAL DESIGNS

In experimental studies the population of units selected for the study is split into two (or more) groups using randomization. This procedure ensures that chance alone determines the groups to which each unit is assigned. Each group is assigned to a different intervention, and outcomes in the groups are compared to infer the relative effects of the intervention(s).

Randomization implies that the probability of receiving each of the possible interventions under study is the same for each unit being entered into the study. Notably, this probability does not need to be the same for all interventions being compared. For instance, the researcher may decide to randomly assign 25 percent of the patients to the experimental intervention and 75 percent of the patient to the control (usually the standard intervention), for various reasons (convenience, costs, organizational problems, etc.). This approach is correct as long as these probabilities are the same for all subjects being entered into the study. Randomization is a powerful tool that, if appropriately used, protects the study by the risk of selection bias. Note that randomization does not guarantee that the two groups are identical, even in large samples. However, it does guarantee that the distribution of known and unknown characteristics in the two groups is determined by chance alone.

At least three experimental designs are used in palliative care research: the parallel group design, the crossover design, and the cluster randomization design. In the **parallel design** patients are randomly allocated to receive the intervention(s) of interest (the experimental group) and the best available treatment (the control group). Only if no effective treatment for the condition under study is available, the control group should receive either a placebo or no treatment.[8] In the **crossover trial** patients are given various treatments in sequence, with the aim of studying differences between these treatments.[9] In a randomized crossover trial patients are randomly allocated to different sequences of treatments. In the simplest design (AB/BA design), half of the patients are randomly allocated to receive treatment A followed by B, and half to receive the treatment B followed by A. In **cluster randomization**, the randomization unit is represented by groups of individuals (for instance, all patients of a given health district).[10] This means that all the individuals belonging to that group will receive the same treatment, and that different groups, at random, will receive different treatments.

STUDY AIMS

Descriptive studies

Descriptive studies describe 'patterns of problems occurrence' in relation to variables such as person, place, and time. In palliative care they have been used to describe needs and problems encountered by patients and their families during the advanced and terminal phase of disease.[11]

Two basic designs are used: **cross-sectional** and **longitudinal** studies. The first design, regarded as primarily descriptive, provides a snapshot of the health experience of a population at a given time. The simplest design is relatively inexpensive and quick as compared to longitudinal studies. If well designed, the results from the study sample can be generalized to the population of interest. Moreover, it provides estimates of the prevalence of all factors measured. Studies describing the proportion of patients with severe pain among hospitalized patients,[12] or the prevalence of severe communication problems among patients followed by palliative care services,[13] are classic descriptive studies. The cross-sectional design is not well suited to study rare problems. It has an inherent bias (usually referred to as length biased sampling), since it overrepresents subjects who have the problem for a long duration of time.

Longitudinal studies represent the best way to describe the natural history of a disease in terms of outcomes relevant to palliative care. The main advantage of a longitudinal design is that the individual development of the outcomes of interest over time can be studied. This approach is easy when

the outcome variable is an irreversible endpoint. In palliative care most outcomes should be measured in the same individual on different occasions, and viewed in a dynamic prospective over time. To this purpose, a longitudinal design is the best choice, although statistical analysis of its results can be complex.[14]

Apart from the statistical problems, in longitudinal studies researchers deal with a number of methodological issues related to the validity of the results of their descriptive study. A descriptive study is valid in as much as it is able to describe what it intends to in the population from which the sample is drawn. Selection and information bias can compromise the ability of a study to provide information generalizable to the population of interest.[2]

Information bias is a particularly sensitive issue in palliative care, as it is difficult to measure without distortion the 'subjective point of view' of patients experiencing progressive functional and cognitive decline. As far as selection bias is concerned, there is a theoretical and practical difficulty in identifying the population of terminally ill patients in a specific geographical area. At least theoretically, patients with cancer can be identified when they enter the terminal phase of disease and assessed when they are still alive. For most patients dying from noncancer diseases, there is uncertainty about the course of disease, and even theoretically, it is impossible to avoid any selection bias. Also for patients with cancer, it is difficult to plan an unbiased population-based study (either cross-sectional or longitudinal) as these patients are followed by a number of health agencies in all possible different settings of care.

Retrospective studies have tried to overcome these problems using the 'after death' approach, where information is collected after the death of the patient from the non-professional person who attended the patient during the last period of life. This cross-sectional design (but similar in some characteristics to a retrospective cohort design) has been used in a number of influential studies[15–18] to estimate the multidimensional problems experienced by patients during their last period of life. The strength of this design lies in the possibility to evaluate a representative sample of patients with advanced and terminal disease, as the sample is built after deaths have occurred. So far, the most reliable estimates of patients needs during their last year of life derive from the 'after death surveys' conducted in UK between 1969 and 1995.[11] For example, according to these studies, it is possible to estimate that 84 percent of patients with cancer in the last year of life experience pain that requires treatment.[11]

This approach overcomes many of the problems of the studies performed directly on the patients, as it has been possible to generalize the results to the whole population of terminally ill patients. This approach has at least two weaknesses. First, in death certificates, the cause is often unreliable, especially for older patients, or incomplete, especially for noncancer deaths.[19] Second, the assessment of the outcomes from bereaved carers, usually several months after a patient's death, may result in a large distortion of the results.[20]

Analytical observational studies

Analytical studies are epidemiological investigations in which the association between a dependent variable (the outcome of interest) and one or more independent variables is evaluated, and possible cause–effect relations are assessed. Although some implicit or explicit type of comparison exists in all study designs, analytical studies are primarily planned for determining if the frequency of an outcome is different for people exposed to a study factor (exposed) from the frequency of the outcome in those not exposed to the factor (unexposed).

The presence of an association does not imply that the relation between variables is one of cause and effect. We can speak of causal association only when an induced change in the quantity of the study factor results in a corresponding change in the quantity of the outcome. In theory, causality can be definitely demonstrated only through appropriately designed experiments. As a consequence, in observational studies, assessing whether the observed association (or the lack of one) represents a cause–effect relation, is a matter of determining the likelihood that alternative explanations could account for the observed results. In this process, at least three explanations should be considered:

- the observed association could be due to the play of chance
- the association could be the result of a systematic error in the selection of the study subjects (selection bias) or in the assessment of exposure and/or the outcome (information bias)
- the association could be due to the effect of an extraneous factor associated with the study factor that independently affects the risk of outcome (confounding).

It is not possible to summarize in this chapter the long and often sophisticated discussions on the nature of causation and on the methods for identifying causal effects. On this topic, the Bradford–Hill criteria are very popular, and seem to provide a road map through a complicated territory[21,22] (Table 22.2). Although erroneously referred to as 'causal criteria', they simply offer a systematic approach, neither necessary nor sufficient, to infer causation from a statistical association observed in epidemiological data.

The same designs used for a descriptive purpose (cross-sectional and longitudinal) can be used to analyze associations between outcome(s) and possible causative factors. Since in cross-sectional studies, problems and their determinants are collected simultaneously, it is possible to assess a number of associations among them. Using such a design with an analytical intent is often at risk of bias because it is difficult to determine the temporal sequence of the association (if the determinant preceded or resulted from the problem). Cross-sectional designs can be considered for testing hypotheses of association when the determinants are fixed, such as gender, or unalterable over time, or to

Table 22.2   *Bradford–Hill criteria*

Strength	Strong association
Consistency	Repeated observations in different populations under different circumstances
Specificity	The cause leads to a single effect
Temporality	The cause precedes the effect in time
Biologic gradient	Monotonic (unidirectional) dose–response curve
Plausibility	Biological plausibility of the hypothesis
Coherence	The association does not conflict with what is known of the disease
Experimental evidence	Evidence from laboratory experiments on animals or from humans experiments
Analogy	Analogy with similar situations

Table 22.3   *Strengths and weaknesses of cohort (longitudinal) studies*

Strengths	**Weaknesses**
The best way to study the natural history of a disease and its determinants	Expensive and time consuming
Clear temporal sequence of exposure and outcome	Inefficient for rare outcomes
Possible to evaluate multiple outcomes arising from a single exposure	Selection bias is unavoidable
Efficient for studying rare exposures	
It is possible to estimate incidence and to calculate relative risk	

generate hypotheses of association that will be tested with longitudinal designs.

A well-designed and well-conducted longitudinal study allows a valid inference about risk factors influencing the outcome(s) of interest. A number of variants of the basic design can be used, sometimes difficult to design and analyze.[2] The most important weakness remains the unavoidable presence of a systematic distortion in the estimate of effect resulting from the manner in which subjects are selected for the study population (selection bias) (Table 22.3).

Studies to assess the effectiveness of an intervention

A fundamental objective of epidemiology in the area of palliative medicine is to produce knowledge that might be or is useful to prevent and control a patient's and family's problems during the terminal phase of disease.

Although the randomized clinical trial represents the gold standard for the assessment of the effectiveness of an intervention, observational and quasi-experimental designs can provide, with different degrees of feasibility, validity, and generalizability, useful information for establishing if (and to what extent) an intervention is effective both in clinical and in health services research. The feasibility of a trial depends on its acceptance by all the subjects involved into the research. Clinical staff may be not persuaded about the utility of subjecting very sick and dependent patients to any more experimentation. Patients are not interested in experiments, and randomization is often seen with suspect.[23] As a consequence, the trial could not be accepted, or recruitment could be too slow.

Two criteria are used to assess the quality of a trial: internal and external validity. The internal validity implies

an accurate measurement of the effect apart from random errors, but all studies, including randomized ones, are subject to some type of bias. The procedure used to allocate subjects to the different treatments is the major source of bias. In all nonrandomized studies some selection bias is unavoidable, but in observational studies, and in poorly designed quasi-experimental studies where little or no control is possible on allocation procedures, the risk of selection bias is high. For example, in a retrospective study designed to determine whether a palliative home care team modified hospital utilization of patients with cancer in the last 6 months before death, the difference between the two groups (followed and not followed by the service) were significantly different, and the results suggested that the provision of home care reduced days in hospital.[24] Although the two groups were similar for most characteristics of the patients, we must consider that a selection bias could have affected the validity of the results. More specifically, there may have been differences between the groups, for example in the preference for place of care, which would independently affect hospitalization.

Another major source of bias in palliative care studies derives from the patients effectively analyzed for the outcome. In randomized clinical trials the principle of 'intention to treat' is recommended to preserve the internal validity. This approach should be extended, whenever possible, to all effectiveness studies. According to the 'intention to treat' principle, all randomized (or registered) patients should be included in the analyses of results, independent of their effective eligibility, of the received treatment, of the adherence and compliance to the treatments, and of the compliance to the assessments procedures. In palliative care research the attrition rate is usually high and the contamination by exposure (especially in health services research) frequent. Although the problem is common to all study designs, in

Table 22.4 *Differences between explanatory and pragmatic trials*

Explanatory design (the aim is efficacy)	Pragmatic design (the aim is effectiveness)
Selected patients	Patients as similar as possible to the common clinical practice
Sophisticated study protocol	Very simple study protocol
Intensive follow-up	Follow-up as in clinical practice
Multiple and complex endpoints	Simple endpoint (reflecting the benefit to the patient)
High-quality centers	Generic centers
Minimal sample size	Large sample size

nonrandomized studies it is often, mistakenly, considered less important.

External validity refers to the generalizability and applicability of study results. In this regard, an important distinction is that between the efficacy and the effectiveness of an intervention, because it defines the general aim of the study.[25] Efficacy is the extent to which a specific intervention produces a beneficial result under ideal conditions. Effectiveness assesses the same beneficial effect in the field, estimating if it does what it is intended to do for a defined population. The studies require different study designs: explanatory for assessing the efficacy, and pragmatic to assess the effectiveness of an intervention (Table 22.4).

Explanatory studies are aimed at providing the proof of principle that the intervention works (or does not work) under the most favorable conditions. As a consequence the study design is focused on detecting the maximum potential benefit (only trained and skilled centers, highly selected patients, intensive assessment of the outcomes). In these studies the internal validity must be carefully preserved. On the other hand, pragmatic studies are interested at assessing the effectiveness of the intervention in a scenario as similar as possible to everyday practice. As a consequence, patients and centers are not selected, the intervention and follow-up procedures not well codified, but the study reflects the common mistakes typical of every medical practice. In this perspective, the intention to treat approach in the analysis of the results of a study is crucial also to evaluate the true effectiveness of the intervention under study.

In clinical research, explanatory randomized studies (both the crossover and the classic parallel design) on selected patients should be considered as the first option to assess the efficacy of a new intervention. Problems in recruitment could be overcome by implementing collaborative networks of high-quality palliative care units. For these studies the internal validity is crucial, and, also if the planned sample size is not attained, they can be combined with other studies in a systematic review.

When the clinical question becomes more pragmatic, and refers to the ability of the intervention to work in clinical everyday practice, the best design is often a quasi-experimental or an observational study. Note that negative results from a pragmatic trial in the absence of evidence from explicative trials, may lead to the false conclusion that the treatment is not effective at all, and, as a consequence, to discard potentially useful practices.

For health services research the problem is more complicated. Most of the questions are intrinsically pragmatic, and pure randomized explanatory trials are very difficult to conceive. It is difficult to randomize selected series of patients, avoiding any contamination between the groups. To assess the effect of a service, a number of outcomes with their valid, reliable and sensitive tools should be available, and the best timing of the assessments clearly defined. Moreover, new activities are difficult to standardize, so that it is often difficult to be certain that the effect (or the lack of effect) is not due to the intrinsic quality of that specific team.

As a consequence, in the assessment of new services, one might consider the use of a cluster-randomized design, which recent studies report favorably as an alternative method for establishing evidence of effectiveness.[26] A second option is to consider a well-designed quasi-experimental trial, in which the researcher maintains the highest possible control over the elements of the study design, including, of course, the allocation of the subjects to different interventions.

CONCLUSIONS AND FUTURE PRIORITIES

In this chapter, the various study designs commonly used in palliative care research were reviewed and discussed in terms of feasibility, validity, and potential biases. Further methodological research is much needed in palliative care research and particularly in three critical areas:

- the validity of the 'after death' designs and their ability to produce an accurate portrait of the care provided to dying patients, recently questioned in a paper[27]
- advantages and disadvantages of quasi-experimental designs in palliative care research to assess the effectiveness of an intervention, and the identification of the study designs that can provide a high level of internal validity
- the differences between explanatory and pragmatic trials, and their relative role in palliative care research.

Key learning points

- As the design of a study is the strategy of answering a clinical or epidemiological question, it is the question that determines the appropriate study design.

- In studies regarded as primarily descriptive, selection and information bias (in different degrees according to the study design) can compromise the ability of the study to provide information generalizable to the population of interest.

- In analytical observational studies, the architecture of the study design should allow the researcher to assess if the observed associations represent a cause–effect relation, or if alternative explanations could account for the observed results (chance, bias, and confounding).

- Studies aimed at assessing the efficacy or the effectiveness of an intervention require different study designs: explanatory for assessing the efficacy, and pragmatic to assess the effectiveness.

- In clinical research, explanatory randomized studies should be the first option to assess the efficacy of a new intervention, followed by more pragmatic quasi-experimental or observational designs aimed at assessing the beneficial effect on the field.

- For health service research, the questions are intrinsically pragmatic, and pure explanatory trials difficult to conceive. Cluster randomized trials or quasi-experimental designs (with a high control over the elements of the study design) should be considered as the first option for the assessment of a new service.

- The perfect study design for answering a specific question is not always feasible, and often the choice will be based on a compromise between feasibility, validity, and generalizability.

Outcomes measurement in palliative care research

JOAN M TENO

WHY MEASURE OUTCOMES?

Key to achieving excellence in palliative medicine is a process of self-reflection that measures the end results of care. To not know the outcomes of care is simply not an acceptable medical practice. Without knowledge of the outcomes of care, the quality of care will not be improved. Excellent quality of care is only achieved through a process of ongoing research that examines the outcomes of palliative care programs and medical treatments, audits that help to shape quality improvement efforts to change medical practice, and publicly reported quality indicators. Auditing the quality of care is not just applicable to industrial nations. Rather, program evaluation is important in developing nations with limited resources.[1] While outcomes measures that examine new medications or other treatments are essential for the development of the evidence base of palliative medicine, the focus on this chapter will be on the use of measurement in health services research, quality improvement, and publicly reported quality indicators.

An outcome measure examines the 'end results' of care. The 'end results' are the impact of medical care on the dying person and/or family. For the seriously ill and aged, it is important for the measurement of the outcomes of care to acknowledge the important role of informal caregivers, usually close family members, and that medical care must attend to both the needs of seriously ill persons and those of their family. This view is ratified in the World Health Organization[2] definition of palliative medicine as achieving the best possible quality of life for dying patients *and* their families. Outcomes measures are the ultimate judge of the quality of care. Achieving those outcomes is based on ensuring that processes of care are in place to achieve the desired outcomes. A process measure examines what health providers 'do' for dying persons and their family. Often, process measures can be proxy for outcome measures that can only be examined years later (e.g. the treatment of hypertension and prevention of strokes). Ultimately, the quality of care is based on the outcomes of care. However, a focus on achieving quality of care is to ensure that correct processes of care are undertaken for the right patient.

The natural reaction of staff to outcome measurement is fear that the results will be misinterpreted that they are providing inadequate care. Often, that is hardly the case. Outcome measurement should not be used to 'punish' staff. The vast majority of people come to work every day to do the best possible job within the constraints of current healthcare systems. It is important that the use of outcome measurement is not used to blame staff. Rather, outcomes are the result of complex interactions. It is important that the people assessing the quality of care approach the examinations of outcomes from this perspective. For example, a local hospice found that 80 percent of decedents were dying in the hospital as opposed to at home. One interpretation of these results is the staff are not doing their job in providing adequate supportive care that allows a person to die at home. In this particular example, a further exploration of semi-structured interviews with the staff about the barriers to people dying at home revealed that all home deaths were being treated by the local authorities as potential homicide. Families had learned to avoid the embarrassment of having their loved ones' death be treated as a homicide investigation by insisting that the dying person was transferred to an acute care hospital. The solution is not blaming the staff but making changes to the system of care (e.g. developing

an inpatient hospice unit, working with the police to change how expected home deaths are treated, etc.) to ensure that dying persons and their family are receiving medical care consistent with their needs and expectation. This is an important lesson. Achieving excellence in end-of-life care requires a critical examination of the systems and processes of care alongside the outcomes.

WHAT IS QUALITY OF CARE FOR SERIOUSLY ILL AND DYING PERSONS?

Having a serious illness that raises the possibility of mortality is unique and sentinels time of life, unlike any other time period. Consider the following two clinical cases and the implications for measuring the quality of care:

- A 45-year-old man presents with acute anterior wall myocardial infarction. One proposed measure of quality of care by the Center for Medicaid and Medicare Services, the branch of the US government that oversees healthcare services, is whether he is discharged with an aspirin.[3]
- For a person of the same age and gender with stage IV lung cancer, the development of quality indicators that examine both the outcomes and process of care is much more difficult. Not all persons will want active treatment. The vast majority of 45 year olds without a contraindication to aspirin would want to take it given the evidence of its efficacy. Seriously ill persons with lung cancer are faced with important trade-offs where their preferences are important for measuring the outcomes of care.[4]

The importance of patient preferences is reflected in the Institute of Medicine's proposed definition of quality of care as 'the degree in which health services for individuals and populations increase the likelihood of the *desired* health outcome and are consistent with current professional knowledge'[5]. Over the past century, the majority of deaths have been from chronic, progressive illnesses, often involving a decision that weighs the quality versus quantity of life. Despite the early stage of development of quality of measure, there is an evolving consensus regarding what are the key domains to examine the quality of care for seriously ill and/or dying persons (Table 23.1).

To date, various sources of evidence have been used to formulate definitions of quality of medical care for the seriously ill and dying. Professional bodies that rely on expert opinion, such as the National Hospice and Palliative Care Organization[8] or the Canadian Palliative Care Organization have proposed key domains and processes of care that define quality of palliative and/or hospice care. Newer proposed definitions of the quality of care have involved the input of consumers.[10,11] While there is agreement on many key domains, dying persons and their families provide a unique perspective that should be accounted for in definitions of quality of care. Based on experts and focus groups with dying persons and family members, Teno and colleagues have developed a model of quality medical care entitled patient-focused, family centered medical care (see Table 23.1).[10] Under this model, high-quality medical care is achieved when healthcare providers:

- provide the desired physical comfort and emotional support
- promote shared decision making, including advance care planning for future period of impaired decision-making capacity
- treat the dying person with dignity and respect
- attend to the needs of the family for information and skills in providing care for the dying person and support the family at a time prior to and after the patient's death
- coordinate care across settings of healthcare given the increasing fragmentation of the healthcare of the dying.

Over the past decade, a consensus has been emerging regarding what are the key domains to examine both the processes and outcomes of care. In the future, a linking of outcome and process measures to authoritative professional standards, such as the National Consensus Project in the USA,[12] will be critical to the evolution of measurement of quality of care for the seriously ill and dying.

WHAT ARE THE SOURCES OF INFORMATION TO JUDGE THE OUTCOMES OF CARE?

A key step in measuring the outcomes of care is the decision on what is the source of information to judge the outcomes of care. Each source has both advantages and limitations. Often, an audit will need to draw from multiple sources of information to provide a more comprehensive view of care of the seriously ill and dying. Among the available sources of information on the outcomes of the quality of care are:

- the medical record, e.g. one could examine whether patients in pain receive medications for pain
- administrative data, e.g. site of death based on death certificate data
- staff reports of the outcomes of care, e.g. pain noted on the minimum data set (MDS)
- interviews with dying persons and/or their families conducted prior to and after the patient's death
- independent assessment of the quality of care performed by experts.

Each involved trade-offs of strengths, limitations, and financial costs.

The medical record is a legal record that reflects healthcare providers' documentation of the patient's condition

Table 23.1 *Comparison of domains of experts, patients, family members, healthcare providers, and the combined model*

Expert opinion			Consumer opinion			Combined model
Emanuel and Emanuel[6]	IOM[7]	NHO Pathway[8]	Patients with HIV, renal failure on dialysis, and nursing home residents[9]	Patients, families, and healthcare providers	Bereaved family members[10]	New proposed conceptual model of patient–focused, family–centered medical care[10]
Physical symptoms	Overall quality of life	Safe and comfortable dying	Receiving adequate pain and symptom management	Pain and symptom management	Providing desired physical comfort	Provide desired level of physical comfort and emotional support
Psychological and cognitive symptoms	Physical wellbeing and functioning	Self-determined life closure	Avoiding inappropriate prolongation of the dying	Clear decision making	Achieving control over healthcare decisions and everyday decisions	Promote shared decision making
Social relationships and support	Psychosocial wellbeing and functioning	Effective grieving	Achieving sense of control	Preparation for death		Focus on the individual. This includes closure, respect, and patient dignity
Economic demands and care giving demands	Family wellbeing and perceptions		Relieving burdens	Completion	Burden of advocating for quality medical care	Attend to the needs of the family for information, increasing their confidence in helping with patient care and providing emotional support prior to and after the patient's death
Hopes and expectations			Strengthening relationships	Contributing to others	Educating on what to expect, and increasing confidence in providing care	Coordination and continuity of care
Spiritual and existential beliefs				Affirmation of the whole person	Emotional support prior to and after the patient's death	Informing and educating

IOM, Institute of Medicine; NHO, National Hospice Organization; HIV, human immunedeficiency virus.
Based on Teno *et al.*[10]

and treatment decisions. The absence of documentation of a process of care in a chart audit of medical record does provide valuable information, given the legal standard that if it is not documented, it was not done. However, the medical record does reflect that bias of a healthcare provider. For example, the documentation that discharged medications were reviewed with the patient and family may not indicate that the patient and family understood how properly to take the medications after discharge from the hospital.

Administrative data can range from information used for the purpose of billing to death certificate data. Similarly, these data sources reflect the perspective of the healthcare providers. However, these data are often available at minimal costs and can provide important overall descriptive information for program planning. For example, aggregate death certificate data can provide important information on the site of death that can allow for examining changes in the location of death with time as well as differences among subpopulations such as leading cause of death, age groups, or ethnicity. This information, however, does not provide definitive information on the quality of care. It is important for tracking changes, and information on site of death can provide both hospice and palliative care programs with important information to strategize on where to provide services. For example, the state of Rhode Island, USA, went from twenty-fifth to second in the nation for nursing homes as the site of death.[13] This in itself may not indicate poor quality of care, but provides important information for healthcare providers regarding the importance of developing programs in nursing homes on care of the dying.

In the USA, all nursing homes are required to complete the Resident Assessment Instrument for every nursing home resident on admission, quarterly, and with significant changes in health status. Although the intent of this assessment is

care planning, it represents an important source of information to examine some of the key domains. However, the important limitation similar to the other sources of data is ascertainment bias (e.g. pain is underreported when compared to an expert assessor of pain). Given the important role of patient preferences, surveys of dying persons and/or family provide an important source of information about the quality of care. There are important limitations of the typical satisfaction survey item that asks the respondent to rank a particular aspect of care on a scale from 'excellent' to 'poor'. The distribution is often skewed given the reluctance of respondents to use 'fair' or 'poor'. In addition, research has found that a respondent will rate that care is excellent despite reporting severe pain, reflecting the lowered expectations that the respondents have for the level of pain control that can be achieved among the dying. A third limitation is that the typical rating question does not provide information to guide improvement. Knowing that 85 percent of bereaved families rated an aspect of care as 'very good' does not provide information that allows the healthcare provider to improve. However, knowing that one in four people did not understand how to take their pain medications provides a target for improvement that has face validity. Such information can provide information that raises awareness of the opportunity to improve.

WHAT TOOL SHOULD BE USED?

Key to selecting a measurement tool is to first clearly state the goals of measurement. Table 23.2 notes that the audience, focus of measurement, evidence base to justify the use of the measure, and psychometric properties vary based on the intended use of an outcome measure. A measure as part of an audit for a quality improvement intended audience is the teamworking on improving the quality of care, and the focus of measurement is to provide information that will help select the target for improvement, raise awareness of the opportunity to improve, and monitor whether the quality improvement effort is achieving its stated goals. A measure for public reporting (or accountability) is held to higher standards given the focus is to provide consumers and payers with information to select healthcare providers.[15] It is important that the chosen measure is under the control of that healthcare institution and the psychometric properties have been validated across multiple settings of care.

The selection or development of the measurement tool should receive careful consideration. Too often, researchers and persons conducting an audit ignore the critical steps of ensuring the reliability and validity of the chosen or developed measures. Reliability examines the reproducibility of the measure. Two different nurses using the same chart abstraction tool getting different results would indicate a concern with the reliability of the tool. Achieving reliability is a key step, but not sufficient evidence of the validity of a measurement tool. A measurement tool is valid if there is evidence that it measures the constructs that it purports to measure. Essentially, you are asking 'Is the tool measuring the "truth"?'. Often, there is not a 'gold standard' to judge the validity of the measurement tool. In that situation, the measurement tool should present evidence of the content or face validity, construct, and potentially criterion validity if a 'gold standard' exists.

The content validity essentially asks whether the measurement tool is examining the right constructs. To meet the goal of content validity there should be evidence that the development of the measurement tool was based on a systematic review of the literature, involved experts in the field, and that theoretical model informed the selection of items

Table 23.2 *Purpose of outcome measurements*

	Purpose of measure		
	Research	Improvement	Accountability
Main audience	Science community	Quality improvement team and clinical staff	Payers; public
Focus of measurement	Knowledge	Understand care process	Comparison
Confidentiality	Very high	Very high	Purpose is to compare groups
Evidence base to justify use of the measure	Builds off existing evidence to generate new knowledge	Important	Extremely important in that proposed domain ought to be under control of that institution
Importance of psychometric properties	Extremely important to that research effort	Important within that setting	Valid and responsive across multiple settings

This table was adapted from Solberg *et al.*[15] and modified from *Journal of Pain and Symptom Management*, **17,** Teno JM, Byock I, Field MJ. Research agenda for developing measures to examine quality of care and quality of life of patients diagnosed with life-limiting illness. White paper from the Conference on Excellent Care at the End of Life through fast-tracking Audit, Standards, and Teamwork (EXCELFAST), September 28–30, 1997. 75–82, Copyright (1999) with permission from The US Cancer Pain Relief Committee.

to include in the outcome measure. Construct validity tests whether known relationships hold with the measurement tool. For example, a survey that examines patient perceptions of the process of care regarding pain management should have at least a moderate correlation with the respondents' overall satisfaction with pain management. Criterion validity examines whether the measure is associated with an accepted 'gold standard' or predicts future outcomes.

Over the past decade, there have been increasing numbers of measures to examine key outcome measures for the seriously ill or dying. Previously, a structured literature review was conducted by the staff at the Center to Improve Care of the Dying and Center for Gerontology and Health Care Research (see www.chcr.brown.edu/pcoc/toolkit.htm[16]) and updated by Lorenz and colleagues[17] for the National Institutes of Health conference on the State of the Science of End of Life Care in December 2004. Each key domain has several potential outcome measures with the majority of measures having psychometric properties reported. However, there are still two important areas for research. First, the responsiveness of measures is often not documented. Responsiveness examines the degree to which an intervention or historical event results in change in the outcome measure. For example, a change in policy regulation that limits access to opioids would be expected to result in different reports of bereaved family members regarding unmet needs for pain medications. Second, many of the instruments have been developed and validated in a population of English-speaking people only. Future research needs to examine whether the same constructs hold in different cultures and, when appropriate, have the instrument translated into other languages.

A common mistake in measurement is the attempt to examine every possible outcome. Rigorous data collection on a small number of items is far superior to any effort that collects a lot of items in a manner where there are concerns about the accuracy of the data collection. This can result in time consuming data collection and raises important concerns in terms of respondent burden, especially when one is interviewing seriously ill or dying persons. Parsimony is important. Winnowing should be based on the goals of measurement and the realization that examining multiple outcomes raises the possibility that one outcome will statistically significantly be based on chance alone. While time is one aspect of individual respondent burden, a second concern is the number of subjects on which data collection occurs. For the purpose of a quality improvement effort, a small number of cases collected from a random sample can provide enough data to guide efforts to select targets for and monitor the rate of improvement. The sample size for research or accountability should be based on the effect size that is required to be able to measure the level of statistical significance, and the probability that you want to be able to find that difference. Statistical software packages such nQuery Advisor 4.0 (Statistical Solutions, USA) allow for estimation of the sample size with these three parameters.

WHOSE OUTCOMES ARE MEASURED?

A key specification of any proposed outcome measure is choosing a numerator (e.g. the number of people with a moderate or excruciating level of pain) and denominator (e.g. all people who are not comatose). At face value, this can seem quite simplistic. However, the difficulty is determining who should be counted among the 'dying' or the denominator. This decision has important implications. Numerous studies have reported the limitation of physicians in prognostication[18] and that prognostic guidelines can be overly specific, but not sensitive.[19] Thus, careful consideration must be given to the specification of the sample. For the dying person, the last month of life often involves transitions in care and flare of symptoms such as pain, dyspnea, etc. Often, a dying person is not able to give interviews during the last month of life. One solution is the mortality follow-back survey that uses death certificates to determine the denominator and contact the next-of-kin. This represents an efficient data collection strategy with important, acknowledged limitations.[20] With this strategy, the denominator is clearly defined. However, family members more accurately report on factual information and their interactions with healthcare providers. Those observations are valuable. Families are less accurate in reports of symptoms and other subjective patient outcomes.[21] This limitation needs to be acknowledged, but one should not ignore the perceptions of bereaved family members. Dame Cicely Saunders, the founder of the modern hospice movement, eloquently stated, 'How people die remains in the memories of those who live on.'[22]

WHAT TO DO WITH CONFLICTING OUTCOME MEASURES?

Often a research effort involves examining multiple sources of data to evaluate an intervention, such as the palliative care team or to conduct an audit of the quality of care that a hospice delivers. Sometimes the results are in conflict. In my experience, this is more likely in an audit or quality improvement effort. For example, an audit of nursing home pain management may use the MDS (i.e. an assessment form completed by nursing home staff), chart review (e.g. whether a complete pain assessment was done on admission to the nursing home), and interviews with cognitively intact nursing home residents regarding their observations of staff efforts in their pain management. Often, these results are in apparent conflict. For example, a nursing home could have a 10 percent prevalence of moderate pain, with the chart review indicating that only 30 percent of residents had a complete pain assessment done on admission and 45 percent of the nursing home residents reporting that they had to wait too long for pain medications. The low prevalence of moderate pain seems in conflict with the

other two results. However, this discrepancy is most likely explained by ascertainment bias, in that staff of the nursing home complete the MDS pain items and often, they under-report the pain. The other two indicators provide tangible opportunities for improvement. The goal should be that 100 percent of the people should have a complete pain assessment on admission with as low as possible number of nursing home residents reporting they have to wait too long for pain medication.

CONCLUSION

Knowledge and use of outcome measure is an important tool for healthcare providers with an interest in palliative and hospice medicine. Both process and outcome measures can provide important information to guide efforts to improve quality of care. Outcome measures are key to generating new scientific knowledge of the efficacy of medical treatments and interventions. Key steps to selection of a measure tool is to be clear on the goals of measures including the proposed definition of the quality of care, the proposed source of data, and consideration of the bias and perspective of the source of data. The choice of measurement tools should be based on knowledge of the reliability and validity of the measure. The mistake of collecting information about every possible outcome should be avoided. Rather, a focused data collection effort on a small number of subjects can provide valuable information for quality improvement efforts.

Key learning points

- Assessment of processes and outcomes is an important and essential part of examining the quality of palliative care in all settings.

- Consumer preferences are an important aspect of examining the quality of end-of-life care.

- Valid and reliable measures are needed whatever the purpose.

- Strengths and limitations of various sources of information need to be considered in the selection of measures and interpretation of results.

- Different purposes of measurement mean that different measures may need to be used.

- It is unwise and usually impractical to try to measure everything. Rather, a small amount of information collected on a random sample of subjects can guide quality improvement efforts.

Ethics in palliative care research

JONATHAN KOFFMAN, FLISS MURTAGH

INTRODUCTION

Palliative care has at its core not only the discipline of rigorous symptom control but also the need for patient-centered communication, holistic care of the patients and their families, the consideration of advance directives including patient preferences for place of care and death, and respect for spiritual and religious beliefs of patients and families.[1] Palliative care as a specialty remains unique in its contribution to patient and family care, but the fundamental ethical principles underpinning the conduct of medical research are identical to those in primary, secondary, and tertiary care. Where or how the research takes place should not affect the standards laid down in national and international guidelines such as the Declaration of Helsinki and the Belmont Report (as discussed later). However, the application of these guidelines, and their underlying principles, may have specific implications for particular types of research carried out in palliative care, and for the health and social care professionals involved. Given that palliative care is a relatively new specialty, the volume of research conducted is increasing. This includes exploration of disease groups and symptoms associated with advanced disease that are potentially amenable to palliative care intervention,[2–5] the context in which care is provided,[6–8] cost-effectiveness of service provision,[9] and provider effects, including how care is delivered and received by an increasingly diverse society.[10,11] The impact of the proliferation of 'evidence-based guidelines' for managing advanced disease is also an all-pervading concern.[12] These areas, among others, were the subject of a recent National Institutes of Health State-of-the-Science Conference in end-of-life care.[13]

One of the most useful issues raised by the State-of-the-Science Conference summary statement were the ethical concerns associated with palliative and end-of-life research.[13] Expansion of research in palliative care requires more than merely transposing traditional clinical trials, methods of health services research, or epidemiological methodologies into the specialty. New methods and research approaches need to be developed and refined to explore the complex clinical, psychosocial, and service and policy-related situations seen in palliative care. There has been some discussion of the theoretical and practical problems of research in palliative care and approaches to developing high-quality rigorous research[14–16] but less discussion of the ethical

---

Box 24.1 Key terms

- *Research* is defined as any form of disciplined inquiry that aims to contribute to a body of knowledge or theory

- *Research ethics* refers to the moral principles guiding research, from its inception through to completion and publication of results and beyond

- *Human participants* (or subjects) are defined as including living human beings, human beings who have recently died (cadavers, human remains and body parts), embryos and fetuses, human tissue and body fluids, and human data and records (such as, but not restricted to medical, genetic, financial, personnel, criminal, or administrative records and test results including scholastic achievements)

issues raised. Research in palliative care may raise different ethical questions to other specialties, including the nature of the study design, issues of consent, the balance of benefits versus the risks of involvement in research, what is considered a potential harm, and the importance of confidentiality. In this chapter we apply the historical perspective of ethics in relation to medical research to palliative care, appraise international codes that guide ethical frameworks in research, describe a practical approach to research ethics, and discuss important ethical challenges when undertaking palliative care research. Box 24.1 defines some key terms.

A HISTORICAL PERSPECTIVE ON RESEARCH ETHICS

There are historical reasons why the regulation of clinical and health research involving patients differs from the regulation of normal clinical practice. The horrific medical experiments conducted by a number of doctors under the Nazi regime led to the first internationally agreed guidelines on research involving people, the Nuremberg Code of 1947.[17] This consisted of 10 principles that were finally incorporated into the Declaration of Helsinki produced by the World Medical Association in 1964, an international body set up soon after the Second World War to represent doctors, and funded by national medical associations. The Declaration has been revised no less than five times since 1964, the last being in 2000, and a further note of clarification was added in 2002[18] (see Box 24.2).

Box 24.2 Extracts from the Declaration of Helsinki (2002) with particular considerations in palliative research (our italics)

1 The World Medical Association has developed the Declaration of Helsinki as a statement of ethical principles to provide guidance to physicians and other participants in medical research involving human subjects. Medical research involving human subjects includes research on identifiable human material or identifiable data.

5 In medical research on human subjects, considerations related to the well-being of the human subject should take precedence over the interests of science and society.

7 In current medical practice and in medical research, most prophylactic, diagnostic and therapeutic procedures involve *risks and burdens.*

---

10 It is the duty of the physician in medical research to protect the life, health, privacy, and dignity of the human subject.

13 The design and performance of each experimental procedure involving human subjects should be clearly formulated in an experimental protocol. This protocol should be submitted for *consideration, comment, guidance,* and where appropriate, *approval to a specially appointed ethical review committee, which must be independent of the investigator, the sponsor, or any other kind of undue influence.*

15 Medical research involving human subjects should be conducted only by scientifically qualified persons and under the supervision of a clinically competent medical person. *The responsibility for the human subject must always rest with a medically qualified person and never rest on the subject of the research, even though the subject has given consent.*

20 The subjects must be *volunteers and informed participants* in the research project.

29 The *benefits, risks, burdens,* and *effectiveness* of a new method should be tested against those of the best current prophylactic, diagnostic, and therapeutic methods. This does not exclude the use of placebo, or no treatment, in studies where no proven prophylactic, diagnostic, or therapeutic method exists.

30 At the conclusion of the study, every patient entered into the study should be assured of access to the *best proven prophylactic, diagnostic, and therapeutic methods identified by the study.*

Source: World Medical Association[18]

The Declaration has been significant in its influence in setting ethical standards for medical and human research.[19] However the latest version has not been without its critics. In particular, disagreement has focused on clauses 29 and 30 (see Box 24.2) and concern has been voiced about the potential exploitation of research subjects in developing countries.[20] These clauses have also been criticized for being too crude and absolute, and that they may even be damaging to the very research subjects they are intended to protect by unintentionally limiting research in those countries.[21] This has serious implications for palliative care research, and particularly for research that takes place in developing countries. The reasons for this include increasing evidence that double standards are frequently adopted in the quality of clinical trials that could never pass ethical muster in the sponsoring country.[22]

The current version of the Declaration has also been criticized for its overly expansive remit. It now includes all forms of medical research.[23] It has, for example, changed its

designation from 'recommendations for doctors', to that of 'ethical principles for everybody involved in research'. Medical research in general, and palliative care research in particular, are frequently an interdisciplinary exercise, and there are times when research is either inadequately conceptualized or not addressed at all in the Declaration of Helsinki. The focus of the Declaration was originally, and still is, the *conduct of human experiments*: the frequent use of the term 'experimentation' in the current version of the Declaration is just one manifestation of this. Doll states that the Declaration only really applies to 'research in which patients are required to take drugs or have invasive procedures' (a relatively small part of palliative research) but that 'even here, however, some of the principles show a lack of understanding of what their effects would be if rigidly applied'.[23]

RESEARCH ETHICS COMMITTEES

The Declaration of Helsinki stipulates that any research involving any human subjects should be reviewed by a properly constituted research ethics committee (REC) or institutional review board (IRB). As a result, many countries throughout the world now have strict regulations governing the formation and procedure of such bodies. The Netherlands, Belgium, and the USA have specific legislation in this area.[24–26] Until recently, the UK adhered to a regulatory system controlled by government, but not by legislation.[27] Following implementation of the EU Clinical Trials Directive in 2004, UK research ethics committees now have a basis in law. Their accountability is also clearly defined: they are answerable to strategic health authorities in England and to the Central Office of Research Ethics Committees (COREC).

Both RECs and IRBs are responsible for ensuring that they act independently within their institutions. They must be free from bias and undue influence from the institution in which they are located, from the researchers whose proposals they consider and from the personal or financial interests of their members.[28] This independence is founded on its membership, on strict rules regarding conflict of interests and on regular monitoring of and accountability for decisions made. The membership of an REC or IRB must ensure that it has the range of expertise and the breadth of experience necessary to provide competent and rigorous review of the research proposals submitted to it, and to do so from a position that is independent of both the researchers and the institution in which it is located. They should be multidisciplinary and consist of both men and women, as well as reflecting other aspects of diversity within society.[29] There must also be members who have broad experience of and expertise in the areas of research regularly reviewed and who have the confidence and esteem of the research community. This can be problematic with palliative care research given the limited number of ethics committee

members who have experience of such research. End-of-life care is typically characterized by a focus on symptom control with minimum interference and intervention. Many RECs and IRBs are reluctant to approve studies in this group of patients. It has been suggested that this might be so because of misconception that research studies may detract from the ethos of care, that studies are unlikely to be supported by previous good research in the field, and because of the perceived vulnerability of research participants. In addition, even when studies are approved, extensive gate-keeping by health professionals may create future barriers to recruitment.[30]

For all their good, RECS and IRBs are not without their critics. It has been stated that they are risk averse,[31] and that they concentrate disproportionately on the information about a study that will be given to potential participants.[32] This includes the manner in which consent is recorded (the expectation is usually a signed consent form for each participant) and the justification and special procedures required for studies involving children, or mentally incompetent or otherwise vulnerable adults. However, given the emphasis on the production of information sheets for clinical trials or other research, there are still some participants who do not fully understand the information they have been given as part of the procedure to obtain consent for their participation.[33,34] As with research involving children or other vulnerable patients,[35,36] the closer scrutiny of research involving patients with advanced disease may necessitate that palliative care researchers need to invest more time, effort, and ingenuity in developing consent procedures to gain approval for their studies.[37] This may bring benefits in the protection of patients, and it may also result in fewer evaluated interventions and services for these groups.

A PRACTICAL APPROACH TO RESEARCH ETHICS

Three broad areas of ethical concern outlined by Foster[38] have been identified in relation to research:

- Duty of care to research participants
- Respect for the rights and autonomy of research participants
- The scientific validity of the research (without which no research can be ethically justified).

These areas approximate to different moral and philosophical traditions. Duty of care derives from duty-based deontological thinking, which acknowledges that there are rules of conduct which ought to be followed, not because of the ends that are likely to be achieved, but by the nature of those involved and their inherent responsibilities. Respect for rights derives from rights-based deontological traditions, which recognize the right of each person to self-determination and autonomy. Emphasis on the scientific validity of research

Table 24.1 *Ethical principles guiding medical research*

Ethical principles derived from Beauchamp and Childress[39] and Gillon[40]	Ethical principles derived from the Belmont Report[41]
Respect for autonomy: This implies self-rule, but is probably better described as deliberated self-rule, a special attribute of all moral agents. If we have autonomy we can make our own decisions on the basis of deliberation. In healthcare, respecting people's autonomy has many *prima facie* implications. It requires consulting people and obtaining their agreement before we do things to them	**Respect for persons**: Incorporates at least two ethical convictions: first, that individuals should be treated as autonomous agents, and second, that persons with diminished autonomy are entitled to protection
Beneficence: Whenever healthcare professionals try to help others they inevitably risk harming them. Those who are committed to helping others must therefore consider the principles of beneficence and aim at producing net benefit over harm	**Beneficence**: Persons are treated in an ethical manner not only by respecting their decisions and protecting them from harm, but also by making efforts to secure their wellbeing. Such treatment falls under the principle of beneficence
Nonmaleficence: An obligation not to inflict harm intentionally, that is distinct from that of beneficence – an obligation to help others. In codes of medical practice the principle of nonmaleficence (*primum non nocere*) has been a fundamental tenet	**Justice**: Who ought to receive the benefits of research and bear its burdens? This is a question of justice, in the sense of 'fairness in distribution' or 'what is deserved'. An injustice occurs when some benefit to which a person is entitled is denied without good reason or when some burden is imposed unduly. Another way of conceiving the principle of justice is that equals ought to be treated equally
Justice: This is often regarded as being synonymous with fairness and can be summarized as the moral obligation to act on the basis of fair adjudication between competing claims	
Scope: There may be agreement about substantive moral commitments and *prima facie* moral obligations of respect for autonomy, beneficence, nonmaleficence, and justice. Yet there still may be disagreement about their scope of application, that is, about to whom do we owe these moral obligations	

draws on goal-based moral theory (consequentialism) which judges the moral worth according to predicted or actual outcomes. These different but complementary philosophical approaches have been used by Claire Foster to derive a framework for the consideration of research ethics,[38] and this can be a useful way to review any specific research project. Dilemmas or tensions which arise usually occur because of conflict between these different moral approaches; in palliative research it is particularly important to recognize the reasons why conflict arises, the moral arguments in support of each approach, and then aim to achieve an acceptable balance between these different ethical demands.

These three broad areas of ethical concern can more simply be viewed as based on key ethical principles[39,40] and each principle should be applied in the context of any one research study (Table 24.1). But ethical considerations should be wider than just the single research study or group of studies. Allocation of research resources, cost-effectiveness (of both research and the interventions evaluated), population benefit (and harm), and overall public health must all be considered, and here the concepts of justice and equity become important. The experience of individual research participants and the conduct of the researchers themselves are also important considerations, which introduce concepts of fidelity, trust, and truthfulness.

THE SPECIFIC ETHICAL CHALLENGES IN PALLIATIVE CARE RESEARCH

There has been extensive debate about whether research in palliative care raises ethical challenges unique to the specialty.[30,42] Particular ethical challenges in palliative research include research-related distress and the perceived vulnerability of participants; research burden for ill patients; consent and capacity issues; ensuring confidentiality and anonymity; and the methodological challenge of producing high-quality research, including the contribution of the randomized controlled trial (RCT).

Research-related distress and vulnerability of research participants

In Foster's ethical framework,[38] it is duty of care which requires that distress and vulnerability are given careful ethical consideration. It is often perceived that interviews, surveys, or questionnaires about end-of-life care may be distressing to those interviewed, whether patients or their unpaid informal caregivers. Indeed, patients with advanced disease often experience many distressing symptoms and are

frequently fatigued, frail, depressed, and heavily dependent on others.[43–46] Questions therefore need to be raised regarding whether it is ethical to engage these patients in research at a time when they may wish to make use of their remaining time with their family and friends. Given that many of these patients will not stand to benefit directly from the research they are involved in it could be argued that it is unreasonable and unethical for them to offer their remaining time,[47] as well as a host of concerns that research in palliative care should be wary of including those patients with disease who are particularly vulnerable as they represent a captive audience.[48] Some have even suggested that research involving dying patients is, because of this vulnerability, ethically unacceptable.[49] Few would currently accept that position, and a contrary argument, that it is unethical *not* to undertake palliative research because this diminishes the ability to provide patients with a high standard of evidence-based care, is much more widely accepted. There is no doubt, however, that it is sensible to pay additional attention to the rights of palliative patients who take part in research, and the ways in which those rights will be protected, in the same way that other vulnerable groups such as the elderly or cognitively impaired are considered. This approach has been adopted in a number of countries, with, for example, the Office of Human Research Protections in the USA classifying terminally ill patients as a 'special class' for research purposes.[50] Incorporating the 'user voice' is another way to endeavor to protect the rights of vulnerable research participants, and to ensure that the patient perspective influences research goals.[51]

It has also been suggested that those patients who are cared for within inpatient hospice settings may believe that refusing to participate in a study may result in their discharge. Some patients may be experiencing severe pain and rely on healthcare professionals to administer pain relief in addition to tending to intimate care needs. It has therefore been suggested that this entirely appropriate reliance on healthcare professionals means that it is unethical to ask patients to participate in research because they may well feel coerced into doing so, or may be unwilling to give an honest appraisal of the care they have received.[52] Other evidence does not support this; on the contrary many patients and their informal caregivers are very willing to participate in research.[53–55] The reasons that may account for this include altruism, defined as a desire to increase a third party's welfare.[56] Other important interrelated factors may involve gaining a sense of purpose from participation, and finding the overall experience of being involved in research cathartic and helpful.[55,57]

Although post-bereavement research has been shown to carry a small risk of distress, this has been shown to be much less than expected, and this distress was often outweighed by the benefits of open discussion.[58] Seamark *et al.* have also demonstrated low levels of distress in post-bereavement interviews.[59]

Research burden: balancing risk against benefit

The risks and benefits of research in palliative care are often hard to assess comprehensively because of the limited preexisting evidence. The frequent heterogeneity of study populations also makes weighing up risk and benefit difficult. In general, palliative research participants are likely to be at greater overall risk, because of their advanced disease and the nature of end-of-life care.

As previously mentioned, RECS and IRBs have tended to be reluctant to permit palliative patients to be burdened, and professionals may 'gate-keep' to protect patients from research because of perceptions about their frailty and distress,[54] which concur with the perception of this research group as vulnerable, as discussed above.

Consent and capacity

Informed consent and the patients' capacity to consent are prerequisites if any research in palliative care is going to be conducted. Until recently, however, there has been little consideration or practical advice for palliative care research regarding the methodological challenges of informed consent.[60] There are reasons why consent deserves additional consideration in palliative care research. Patients involved in these studies are drawn from a population with a high prevalence of characteristics that make informed consent challenging, with those who enroll in palliative care studies often being seriously ill. These issues are important given that research ethics committees scrutinize the consent process very closely, particularly when a study involves patients near the end of life.

In order for consent to be valid, it must be informed, voluntary, and given by a research participant with full decision-making capacity. Research consent procedures need to be planned carefully, with detailed consideration of the expected prevalence of impaired capacity, and how capacity should be assessed. An important question is how extensive and detailed assessment of decision-making capacity should be. This depends to a large extent on the level of impairment of capacity expected within a study population, whether participants with impaired capacity will be included in or excluded from the research, and the risks and benefits associated with the research – higher risk demanding correspondingly greater effort to protect the rights of participants.[60] Palliative care patients often have high levels of cognitive impairment and hence potentially impaired capacity,[61] so exclusion from research is self-defeating. If a formal assessment of capacity is required (only likely in those studies associated with greater risk), then a number of tools have been developed, or modified,[62] to guide the decision-making process about which patients may be eligible for inclusion in a study (see Box 24.3).

Box 24.3 The MacArthur Competency Assessment Tool modified for clinical research (MacCAT–CR)

The MacCAT-CR consists of a series of scripted interview questions, divided into four sections that relate to four domains of decision-making capacity. The MacCAT-CR is scored on a scale of 0–2. Incorrect and correct responses are scored as 0 and 2, respectively. Responses that are difficult to interpret are scored as 1.

Understanding (total possible score = 26)
The subject understands:

- the purpose of the study is to test the effectiveness of a case-management intervention (2)

- the study lasts 1 year (2)

- the study requires two additional procedures (two questions) (4)

- the effectiveness of the intervention is unknown (2)

- not all subjects will receive the intervention (2)

- subjects who do not receive the intervention must complete surveys and undergo health evaluations (2)

- the intervention will be assigned at random (2)

- how the study results will benefit future patients (2)

- how subjects in the study may benefit (2)

- the study imposes two additional burdens (two questions) (4)

- subjects can refuse to participate or can withdraw from the study without penalty (2)

Appreciation (total possible score = 6)
The subject appreciates that he or she:

- would not be asked to be in the study solely for his or her personal benefit (2)

- would not be assigned to receive the intervention or not based on his or her needs (2)

- can refuse to participate or can withdraw from the study without penalty (2)

Reasoning (total possible score = 8)
The subject is able to:

- describe two reasonable consequences of participating in the study (2)

- compare the merits of participating versus not participating (2)

- give two examples of the impact of participating on his or her everyday life (2)

- express a choice that is consistent with the consequences that he or she has described (2)

Choice (total possible score = 2)

- The subject is able to express a choice about whether or not to enroll (2)

Reproduced with permission from Grisso et al.[62]

When a research subject does not have capacity, as is common in the last days or weeks of life, then several considerations are important.[63] First, ethical consideration of the research risks and benefits must be reevaluated in the context of lack of capacity; how much risk is the individual participant exposed to by participating, and is the overall likely benefit of the research substantial? Second, the precise role of a proxy, such as a relative, in the consent process must be considered. Third, incapacity is variable and not always total: a participant may be able to give consent at some level, and it is important to include this within the consent process. Lastly, alternative consent procedures might be necessary, especially in the final days of life, such as the advanced consent suggested by Rees and Hardy.[37]

Confidentiality and anonymity

Most clinical or health research involves collecting patient data, which should always be kept confidential and anonymous. Palliative care research is no exception. A researcher could be found negligent if reasonable precautions were not taken to ensure that all the information gained during a study was not stored in a secure manner or if the identity of a research subject was compromised. Further, information resulting from a part of a study should not be shared with a third party unless there is explicit consent of the research subject. This requirement is underpinned by the ethical principle of autonomy. In quantitative studies these obligations are more straightforward, with the use of unique identifying codes in place of names. In qualitative research, however, the data collection process requires more prolonged face-to-face contact, and makes researcher–participant anonymity more challenging. Pseudonyms can be used in place of actual names in written reports and publications. Participant confidentiality can be further protected through the omission of identifying of key contextual details and circumstances. However, the reality of small sample sizes and the detailed descriptions which accompanies this information may be recognizable to some readers familiar with the setting.

Ethical challenges among disadvantaged patient or population groups

Ill health, chronic diseases, high levels of comorbidity, polypharmacy, cognitive impairment, and fatigue frequently challenge or prevent an individual's ability to consent and then participate in palliative care research. However, there are other patient and population-related factors that may operate in isolation or in combination to further complicate this situation. These include very old patients, those with learning disabilities, and those from black and minority ethnic communities, to name just a few. It has been suggested that because of these difficulties these groups may be excluded from research or may be particularly vulnerable.[64–68]

Older people represent a heterogeneous group where competency and capacity vary considerably. Indeed many will have no problems with consent and will be able to participate in research. At a purely practical level, however, others may be excluded as a result of their inability to consent due to poor vision or as a result of hearing problems.[69] The type of research older people are invited to engage with also needs to be considered. It has been suggested that frail older people, who would probably not be competent for inclusion in a pharmaceutical trial because they may have difficulties understanding the extent of their involvement and possible implications for their health, may, however, still be eligible to participate in research if it involved noninvasive, semi-structured interviews, to discuss their experiences of advanced disease or service use.[70]

In the past, individuals with learning disabilities were sometimes chosen as research participants precisely because they were less capable of understanding what was being done to them and were less likely to object.[71] There are many different kinds and degrees of learning disability, and many patients, depending on the extent of the disability, will be able to consent on their own behalf. Ensuring that the consent is indeed informed may be more difficult and require special skills in conveying the relevant information, but it should be attempted wherever at all possible. Even if patients can give consent, it is always advisable for it to be witnessed by a relative.

To date, there has been very little published research about engaging patients from black and minority ethnic communities and refugees in palliative care research.[66] Since these population groups have traditionally been socially excluded from mainstream health services research they have been referred to as 'invisible' or 'elusive' populations. Their notable absence and unheard voices in research therefore reflects their position on the periphery of society.[72] Where they are identified and recruited, research considerations include those described above. Heterogeneity will be evident and naturally many will be able to consent. Those persons who do not possess adequate language skills either may be excluded from the research or may have to rely upon family members or advocates to translate for them. Given the many sensitivities associated with palliative care researchers need to be aware that confidentiality may become compromised, or in order to prevent this, the respondent, the family member, or advocate, may distort realities to protect privacy.

Methodological challenges and the use of RCTs

The type of research methodology employed during palliative care research poses interesting ethical questions. While quantitative studies often place considerable time and energy demands on dying patients, participation in qualitative studies, which frequently explore issues in considerable detail, may create an emotional burden for patients and their families.[73] Qualitative interactions often become highly personal and interpersonal, and in that context, may be even more intrusive than with quantitative approaches.[74] The researcher comes to know the interviewees in a more intimate manner. Interviews that raise issues such as terminal illness, suffering, and loss may bring research participants' feelings to the fore, feelings that may have been previously largely suppressed. These undisclosed problems may then be exposed with serious consequences. Johnson and Plant[75] and others[57] have reported that, in their interviews with cancer patients, participants sometime reported they were emotionally troubled as a result of reminders of their diagnosis, experienced upset feelings in response to talking about their illness, and began to question if their condition might be more serious than they had assumed.

Randomized controlled trials raise particular issues in palliative research. Traditionally, the RCT has been viewed as the gold standard for conducting clinical research.[76] Proponents of RCTs argue that where there is uncertainty, randomization minimizes the risks of exposure to unevaluated hazards. Although in select situations RCTs have been successfully employed in palliative care research, for example examining the management of pain,[77] breathlessness,[78] and the enhancement of advanced directives,[79] they are not without their problems[15] or ethical challenges.[80] Randomization can partially involve relinquishing individualized care and for some patients, the forgoing of potential benefits to new treatment or care. McWhinney and colleagues endeavored to minimize the potential of the latter[81] during an evaluation of a palliative care home support team based in an inpatient unit. Patients in the study group received a service immediately, whereas those in the control group received the service a month later. The two groups were then compared after a period of one month using measurement of symptoms levels and patients' quality of life. The trial however failed. The reasons advanced for this included high rates of attrition due to death, and low compliance rates due to very sick and weak patients. Knowing this, health professionals too may have been reluctant to cooperate with the study, discouraging recruitment.

CONCLUSION

The ethical issues in palliative care research need to be understood in the context of the historical background of research ethics, and the national and international frameworks which already exist to inform ethical standards in research. Having said this, both impose some constraints on present day palliative research, having been developed primarily for research in different contexts. Imaginative and intelligent ways to refine existing research methodologies, develop new ones, and to work with the vulnerabilities of palliative research participants need to be found. There are ways to respect patient autonomy, minimize harm, and reduce research burden. But these are not always easy to find, nor encouraged within existing structures for ethical review.

Key learning points

- Historically, research among human subjects was not governed by guiding ethical principles. This had catastrophic consequences.

- International guidelines, notably the Declaration of Helsinki, relating to health research now advocate ethical review, and RECs and IRBs are an almost worldwide phenomena.

- In many countries, RECs and IRBs now have a basis in law, their accountability is clearly defined and their performance regularly audited.

- Ethical regulation of medical research on humans provides essential reassurance that the risk of harm has been minimized for all participants.

- Palliative care research raises unique methodological and therefore ethical challenges. These include research-related distress and the perceived vulnerability of participants; research burden for ill patients; consent and capacity issues; ensuring confidentiality and anonymity; and the methodological challenge of producing high-quality research, including the contribution of the RCT.

Practical tips for successful research in palliative care

EDUARDO BRUERA, ELLEN A PACE

INTRODUCTION

Palliative medicine emerged in the UK during the 1960s as a response to the unmet needs of terminally ill patients and their families. The development of this movement in the UK has been addressed in Chapter 1, and Chapters 2–7 have addressed the successful development of palliative medicine as a global discipline.

In most regions of the world palliative care did not emerge as a result of mainstream academia, rather it emerged as a number of 'bottom up' approaches on the fringes of the existing healthcare movement. This relative isolation allowed palliative clinical programs to successfully interact with their communities and to develop the basic principles of the disciplines. However, this isolation also made it difficult for palliative medicine groups to interact with academic groups including methodologists, biostatisticians, clinical trialists, epidemiologists, and other groups that are readily available to other content areas of healthcare.

Palliative medicine programs have a strong clinical commitment and limited access to protected time for research and research training.[1–3] For this reason our book has committed a considerable amount of space to chapters on the specific challenges of research, the patient population, the different research designs, outcomes, ethics in research, and the process of audit and quality improvement.

The purpose of this chapter is to discuss some practical issues that are not always available in methodology textbooks, but that are crucial to the success of research projects in palliative care. Most of the tips included in this book are the result of difficulties encountered by our and other research teams in the process of establishing a research program.

THE SETTING FOR PALLIATIVE CARE RESEARCH

Choosing the appropriate setting is of great importance and one of the main reasons why research projects fail. Box 25.1 summarizes what is important about the setting where research will take place.

Box 25.1 Understanding the research setting

- Clinical characteristics of patients
- Socioeconomic characteristics of patients and families
- Type of care provided
- Staffing arrangements
- Length of stay and/or frequency of patient follow-up

Appropriate understanding of the patient population requires not only the basic diagnosis and demographics but also many practical issues such as the level of literacy. (Several studies in the developing world could not be performed

because they required patients to complete questionnaires they were not able to read. See also Chapter 21.) The inclusion of minorities may be difficult in some areas of the USA unless Spanish versions of questionnaires are available. The average length of stay of patients in the specific setting or average number of patient visits to outpatient settings is an important consideration to ensure that the study can be completed in time. In the case of studies on patients and families it is important to know how many patients are accompanied by a relative and in how many cases the relative lives with the patient. The percentage of patients unable to attend a scheduled outpatient visit ranges from 20 percent to 50 percent in most outpatient care settings and thus can have major impact on missing data for clinical studies. The ability for patients to communicate on the telephone for follow-up may be useful in recovering some of this missing information. The availability of rooms where interviews can be conducted and discussing arrangements for the research team in the inpatient or outpatient areas needs to be appropriately planned prior to study initiation. Otherwise it may be impossible to keep a patient in an examining room for assessments or consent, and there may not be staff available for notification when a patient becomes eligible for a study.

The types of treatment are of great importance. In many clinical trials there are criteria for eligibility including certain treatments. Appropriate understanding of these criteria will assist in determining how feasible a certain study will be. For example, in two clinical trials in patients with dyspnea, patient accrual was extremely difficult because although dyspnea is a frequent symptom in palliative care settings, the clinical trials required patients to be able to complete self-assessment questionnaires with excellent cognitive status and comply with complex research designs.[4,5] As a consequence, a large number of patients were identified but only a small number were able to actually enter the clinical trials. A clinical trial comparing methadone versus morphine as first-line opioid for cancer pain required simple assessments by patients with a common pain problem. However, the main difficulty in admitting and maintaining patients on this study was the requirement for very frequent follow-up assessments during the first week of treatment. Many of the centers were not able to conduct frequent assessments in the patients' home or admit the patients for a 1-week period.[6]

The idea for a study on the use of methylphenidate 'as needed' for the management of cancer-related fatigue emerged from the comments of a colleague who had observed excellent response of patients to this modality of administration.[7] The idea for a clinical trial of donepezil on the management of sedation and fatigue emerged from a letter to the editor submitted by a clinician who had observed improvement among patients receiving opioids when treated with donepezil.[8,9] A randomized controlled trial comparing methylphenidate 'as needed' with placebo emerged from the result of the pilot study by the same group.[10] These three examples emphasize the importance of publishing letters to the editor, based on observations or pilot projects. This is

one of the ways in which colleagues can pick up important ideas from findings and translate them into useful research projects.

The research idea

In palliative care research ideas may emerge from a clinical observation, comments by colleagues, papers published in different journals, or previous research conducted by a group. Clinical research is most successful when it is investigator driven because investigators who are highly committed to a certain domain will be much more motivated to spend a considerable amount of extra time in pursuing this research in addition to other clinical and educational responsibilities.

One of the most difficult processes is that of turning a research idea into a well formulated hypothesis. Being able to frame the general idea into a very specific question is extremely important because this will frame the whole methodology of the project. It is important for researchers to have a conversation with a mentor at an early stage in the development of this early hypothesis. This will help them to immediately identify how feasible the whole project may be.

LITERATURE SEARCH

It is very important to read good-quality material but it is not necessary to read all material on a given subject. The literature search should consist of a number of recent high-quality reviews of the area as well as a number of recent original papers on the subject under study. This quick review of the literature will rapidly demonstrate if the investigator's hypothesis has already been appropriately studied or if it would be justifiable to proceed with further research on the subject. If there have been only one or two brief reports or letters to the editor with a small number of cases, this suggests that there is probably strong justification for the study. If the investigator finds no reference at all it is important to consider whether they are researching the correct literature on this subject.

The literature search has three main purposes:

- to provide an indepth understanding of the content area in which the investigator is planning to conduct research
- to be able to understand the methodology employed by other researchers
- to understand the main outcomes studied by previous researchers.

As much as possible the investigators should attempt to take advantage of previous knowledge and methodologies. This will save a great amount of time and also will increase the likelihood of publication of their findings since they can provide literature support for having followed a certain methodology.

The literature search is not only useful for justifying the project and applying to a research committee and/or granting agency, but it can also *per se* become a major publication and be extremely helpful to other readers. For example, the literature search concerning survival estimation used for the design of a clinical trial was also very useful when published as a systematic review.[11,12]

DEFINING THE RIGHT OUTCOMES

In palliative care outcomes are mostly subjective (i.e. symptom intensity, satisfaction with communication by patients and/or families, perceptions of quality of communication, etc.; see Chapter 23 for a full assessment of measures). These outcomes are much more likely to be subject to bias and therefore the nature of these outcomes will have major impact on the methodology used by the investigator.

In the study of a specific problem such as cachexia there may be a combination of outcomes highly unlikely to be influenced by patient or investigator bias (such as body weight and other nutritional findings), other outcomes that may have an intermediate risk of bias (such as daily energy intake), and a third group of outcomes that is highly subject to bias (such as anorexia, fatigue, etc.). Similar statements could be made for other physical and psychosocial symptoms. The timing for modification of variables may also differ dramatically (for example anorexia or fatigue can be modified by an intervention in hours whereas body weight may require weeks).

It is important to use a methodological approach that will best address the most important question and to try to keep it very simple as the likelihood of the completion of the study will be directly linked with the simplicity of the design. One of the most common mistakes is to attempt to address too many outcomes or one main outcome that is beyond the reach of the research team. In the case of cancer cachexia a clinical trial of megestrol acetate showed significant improvement in body weight but was of limited clinical relevance as the main outcome was to successfully reverse cachexia.[13] On the other hand, when clinical trials were conducted using a very simple subjective outcome such as appetite the same drug was found to be effective.[14,15]

ORGANIZING THE TEAM

The principal investigator will need to put together a research team. Box 25.2 summarizes the main members of the research team. The methodology expert will need to be an individual who may or may not work in the palliative care area but who is highly experienced in the use of the methodology for this research project, for example an expert in surveys, clinical trials, qualitative studies, etc. This individual will have a major role in helping the team choose the different

tools, the overall design, and refining the outcomes the principal investigator is currently considering.

Box 25.2 The research team

- Principal investigator
- Content expert
- Methodology expert
- Biostatistician
- Clinical expert
- Administrative expert

The statistician should be approached early during the process of consideration of a study. Even if the outcomes are likely to be mostly descriptive the statistician may have a crucial role in assisting the team in the best use of the existing data. The role of the statistician will become more prominent as the study becomes more complex. One of the most important roles of the statistician is to assist the investigators in calculating the sample size required. It may become clear early in the study that the number of patients required is too large for the setting where the investigator is planning to conduct the research. This will require the investigator to find a number of additional sites where data collection can take place. It is very important that this process takes place early in the research project so that so the individuals responsible for the other sites can become part of the research team during the process of defining the study.

The principal investigator may certainly be a content expert. It is always useful to have at least one more additional expert in the content under study. These experts are usually also familiar with many methodological issues and they can make suggestions based on their personal experience and the connections they have with other content experts. For example, in a study on cachexia a content expert may be aware of research being conducted by a colleague somewhere else and may be helpful in directly contacting this investigator for specific information about the rationale for a certain study or outcome.

Clinician experts include nurses, pharmacists, and other clinical colleagues. These individuals are essential for the success of any clinical study including trials, surveys, or qualitative studies. These individuals will be able to address many practical issues that are crucial for the success of the study. Clinical trials may be more apt to fail if patients receiving placebo have to make multiple hospital visits; if patients are required to take an excessive number of tablets; if questionnaires are too long and difficult to explain; and if there are a number of practical aspects regarding the setting of care that the principal investigator and other experts did not completely understand.

It is important for the investigators to remember that the current access to global communication by low-cost telephones and internet allows teams to function quite well and in real time from multiple locations. It is important to understand if the local requirement of the institutional review board (IRB) puts some limitations on the participation by distance co-investigators. Two important items need to be discussed very early in the process of planning the research:

- *Authorship*. This expectations of the different team members regarding authorship is an important issue to discuss in an open and friendly way. It may be possible to designate expected first authors and senior authors for presentation, publication of the main paper, as well as other secondary publications that may result from the study. A frank discussion regarding the different roles of the investigators will help prevent misunderstandings and unnecessary stress on the participants. This is the responsibility of the principal investigator.
- *Financial issues.* It is important to be open about any resources that may be obtained for conducting the study and how this will be distributed among the different participants. If an application is being made to a research granting agency or an industry sponsor all details regarding the financial arrangements need to be disclosed before the application is submitted. This will maintain the friendly and open environment throughout the project and will ensure collaboration for future projects.

It is important for the principal investigator to put together a successful research team and to understand that it is his or her ultimate responsibility to write the proposal.

Palliative care is a content area and researchers working in this area will need to use a variety of methodologies to better understand their areas of work. It is impossible for an investigator to become an expert on the methodology and biostatistics of all the different approaches. However, it should be expected that the principal investigator would have a basic understanding of methodologies and biostatistics to be able to appropriately communicate with these experts and be a resource for all areas of content.

WRITING THE PROTOCOL

The protocol should be written down in all cases, including case series and retrospective reviews. The process of writing the protocol will help the research team clarify ideas, to make sure that all aspects of the process are well outlined, and will clearly show the team if they are attempting to address too many issues. In general it is much more effective to address one aspect well rather than many aspects with a lower level of evidence. By its nature palliative care research takes place with patients and families who are facing multiple problems and therefore the likelihood of our interventions may be at

best only partially successful. Complex and lengthy studies have a high chance of failure.

ADMINISTRATION OF THE STUDY

One of the main challenges is to obtain appropriate approval by the IRB. This may require the research team to make several modifications in their design, questionnaires, and consent forms. Understanding how the IRB operates, their main areas of expertise, and the wording they prefer to see in the research protocols and consent forms can prevent many problems. It is important that at least one member of the research team is familiar with the operation of the IRB and is able to provide advice about the way the protocol and consent forms should be written. In case of doubt it can be helpful to consult the chair of the IRB about specific aspects of the study before a full submission.

Once the study has been approved the investigators should meet regularly to see if there are any problems with the actual conduct of the study. Some of the most common problems include lack of patient accrual related to some of the eligibility criteria, missing data because of an excessively ambitious assessment method, patients who are unable to stay on in the study because of clinical and social issues, or unexpected side effects or distress by patients and families in the case of discussion of questionnaires (see Chapter 20). It is important to make very early adjustments in the criteria for eligibility or methods since each adjustment needs to be submitted to the IRB for consideration and this will take a considerable amount of time (see Chapters 20 and 24). It is also important to accept when studies can just not be completed so they can be completely rewritten in a more appropriate way.

PREPARATION OF THE MANUSCRIPT

Although the input of the whole research team is vital at this stage, the principal investigator should write the initial draft of the manuscript. This will provide the necessary leadership for all the other experts to contribute. It is essential to write concise manuscripts summarizing the main aspects of the study. If there is other information it could be prepared as additional reports for presentation at scientific meetings or as additional publications.

During the past 10 years there has been a major improvement in the number of peer-reviewed palliative medicine journals and in the number of scientific meetings where palliative medicine research can be presented. It is important to submit for publication all studies whether the results were encouraging or disappointing since this information can be invaluable to other researchers who are planning to conduct similar research. One should be flexible while responding to the comments from the reviewers and take advantage of these reviews as a way of improving the manuscript even if the

journal has decided to reject the manuscript. Consideration to the reviewer's comments will result in a better manuscript to be submitted to the next journal.

Young investigators frequently feel disheartened by devastating comments from reviewers. Journal editors should take appropriate steps to protect authors from vicious comments by reviewers protected by anonymity. Investigators should never decide to discard the manuscript without consulting with an experienced mentor who may help put some of the comments from the reviewer in perspective. It is important to remember that 100 percent of the manuscripts that are not resubmitted will not get published. Resubmission will result in a higher success rate for publication if the investigator adequately addresses the reviewer's comments in the resubmission letter to the journal.

APPLYING FOR FUNDING

In many cases the only way a research project can be conducted is after the research team applies for funding. This is time consuming and slow but unfortunately there is no other way to conduct successful research than establishing a research team and completing grant applications. The methodology expert, biostatistician, and content expert will usually have considerable experience in grant writing and will be able to advise the investigator along the way. Most of the time it is most useful for the investigator to hold individual meetings with each of the members of the team rather than lengthy meetings involving the whole team assembled together. It is important to understand that each of the experts has limited time and that the investigator should use this time in the way that is most conducive to writing a successful application.

In most cases having some pilot data (see Chapter 20 regarding the importance of conducting a pilot study) will be essential for writing a grant application. This short pilot study may need to be conducted with no access to funding. A number of organizations/universities provide bridge money for conducting brief pilot studies that will lead to major grant applications. These granting committees usually require simple design outlines. The investigator may obtain considerable information about availability of philanthropical or bridge funding from the local research office of their university. It is important to arrange for a formal visit and consultation with the research director.

CONCLUSIONS

Palliative medicine is a young specialty. A large number of aspects of this discipline are not well understood. Almost all clinicians are capable of making a meaningful contribution by publishing their observations, case series, retrospective studies, and other more sophisticated research designs.

Perhaps the most important tip for an investigator is to put together a research team that can collaborate in a friendly and effective manner. This will ensure that not only is the research project successful but that the whole experience is highly enjoyable for all members of the research team.

Key learning points

- Choosing the appropriate setting for palliative care research is of great importance and is one of the main reasons why research projects fail.

- Clinical research is most successful when it is investigator driven.

- A thorough literature search is essential to complete prior to starting a research project to take advantage of previous knowledge and methodologies.

- In palliative care research the outcomes are mostly subjective (i.e. symptom intensity, etc.), and thus it is essential for the investigator to use a methodological approach that will address the most important question and keep the design of the study simple.

- Authorship and financial issues should be discussed early in the process of planning the research project.

- The research team should be able to collaborate in a friendly and effective manner to ensure the success of the research project

Audit and quality improvement in palliative care research

HSIEN-YEANG SEOW, SARAH MYERS, JOANNE LYNN

INTRODUCTION

High-quality care can mean better outcomes,[1] enhanced efficiency and patient safety,[2,3] and reduced disparities.[4,5] Traditionally, methods to improve quality of care have used formal research to guide reform. Formal research is key to identifying more effective pharmaceuticals or procedures but less effective in rapidly changing clinical practice. In discerning how to deliver optimal care to a specific patient population without incurring unacceptable costs, quality improvement can be superior.

WHAT IS AUDIT AND QUALITY IMPROVEMENT?

Quality improvement (QI) is an empirical, goal-oriented method of improving the performance of a system.[6] Not a new concept by any means, QI as applied to healthcare dates back to the Crimean War in 1854, when Florence Nightingale began keeping statistical records to reform the hospital and sanitary administration within the British army.[7] In recent years, QI has become pervasive within the healthcare system. QI allows clinicians to assess whether they are doing the right thing, with the right patients, at the right time – and if not, to make needed changes quickly.[8] Quality improvement models provide clinical teams with a structure for identifying areas ripe for improvement, strategies for identifying process improvements to test on a small scale, and tools for measuring progress toward reaching established goals. Generally, QI requires stating an aim, measuring success, and testing possible improvements.

Effective QI is an ongoing cycle that encourages ongoing organizational learning.[8–13] Quality improvement teams ideally begin by addressing discrete, narrow problems, but then expand their efforts in size and scope, moving from time-limited, focused tests of change to broad implementation of changes that their own data have proved to be effective.

Audit – a term most often used in Britain – is 'a continuous process whereby healthcare professionals review patient care against agreed standards and make changes, where necessary, to meet those standards'.[14] In essence, audit is similar to QI. One key difference is that the process is formalized and centralized by a governmental body, the National Health Service, and thus is a core function of the healthcare system. In the USA, private healthcare organizations embark upon and carry out QI efforts on their own initiative for the most part, in response to consumer or professional demand, outside standards, or business considerations. In the past several years, however, more and more healthcare organizations have been required to participate in QI by payers or by their accrediting bodies. Audit and QI can apply to any size population from the quality of care for a few patients daily[15] (often called clinical QI or audit initiatives) to implementing guidelines across a nation.[16]

AUDIT AND QUALITY IMPROVEMENT IN PALLIATIVE CARE

Palliative care 'aims to relieve suffering and improve quality of life for patients with advanced illness, and their families.'[17] Only recently have some healthcare organizations

begun to incorporate formal and informal palliative care programs and services. In many nations, distinct palliative care programs are relatively new in the healthcare system, with palliative care services having previously been part of primary care, geriatrics, and hospice. This nascent field – with a dearth of well-established standards and guidelines – presents tremendous opportunities for QI. The opportunities reach all aspects of palliative care, including advance care planning, symptom management, and continuity and coordination of care.

A case study using one QI model

The following case study describes a team's application of QI.

A hospital serves a substantial number of oncology patients through their clinical trials program. Although their remission rate is high, there are generally around 60 deaths per year in the hospital. Nurses are frustrated because so many of these patients' families say that they would have preferred to die at home. Seeing an opportunity for improvement, a few colleagues express an interest in improving this outcome. Together, they analyze the potential causes of unwanted inhospital deaths and determine that (1) no-one is sure that staff are soliciting information about patients' preferred site of death, and (2) staff are uncomfortable with discussing this with patients who are pursuing aggressive cancer treatment.

First, the team develops a measurable aim: 'Within two months, we will have documented site-of-death preference for 100 percent of acute leukemia patients within 24 hours of admission'. They start small by targeting only one segment of the oncology patient population. However, by setting an aim of 100 percent within 2 months, they alert their colleagues they want to change current clinical practice quickly. To achieve this, they test several different methods:

- including a question regarding preferred site of death on the admission form

- instituting a social worker visit within the first 24 hours of admission, during which site of death would be one topic of discussion

- providing pamphlets regarding advance care planning in all patient rooms.

To learn from their efforts, a nurse will review the chart of two patients in the target population each week to look for documentation of site of death preference, and the team will review the results. Over the next 2 months, the team test out their ideas with a small number of new patients. They quickly realize that the direct question asked on the admission

form is well received and leads to an increase of documented preferences in the medical record. They also learn that staff are still avoiding talks about preferred site of death. Based on these results, they continue the intervention, add role-playing about preferred site of death conversations for staff, and start expanding both to all new admissions. They also continue to review charts to track their effectiveness.

Within 2 months, 100 percent of acute leukemia patients have a site of death preference noted in their chart within 24 hours of admission. Having achieved this process-oriented aim, the team sets an aim related to the actual outcome – increasing the number of patients for whom death occurs at their preferred site. Over the next several months, they set about testing changes and learning from their results.

In summary, the team identified a problem, stated an aim, tested ways to achieve their aim, measured their progress, and learned from their trials to modify current hospital practice and expand their efforts.

EXAMPLES FROM AROUND THE GLOBE

Quality improvement is applied to palliative care on large scale (e.g. national guidelines and care standards)[18–21] and small scale (e.g. clinical QI and audit initiatives).[15,22] The former is generally the purview of regulatory and oversight bodies and healthcare payors, both private and public. The latter often arises at the organizational level. A review of the experience of several countries and regions seeking to improve palliative care reveals a range of approaches in each domain. Below we highlight some examples of such approaches from around the globe though we do not imply that these examples are superior to those not addressed here.

National guidelines and care standards

Many countries have begun using national guidelines and policies to improve palliative care, often in the form of accreditation. A global study for the World Health Organization (WHO) in 2000 identified 36 nationwide healthcare accreditation programs.[23] Starting with the Joint Commission of the Accreditation of Healthcare Organizations (JCAHO) in the USA in 1951, the number of programs around the world has doubled every 5 years since 1990.[24] JCAHO in the USA accredits healthcare organizations in compliance with their quality standards. In 2000 JCAHO added pain management standards that address assessment and management of pain, education around effective pain management to patients and families, and continuous organizational improvement.[25,26] In 2004 JCAHO explicitly made advanced directives (addressing the patient's wishes related to end-of-life decisions) a part of the patient rights standards that hospitals and other

healthcare organizations must adhere to.[27] Presently, nearly 16 000 healthcare providers – from small, rural clinics to expansive, complex healthcare networks – use JCAHO standards to improve their quality performance and how they provide care.[28]

Large-scale QI efforts have also been implemented in developing countries. The WHO is working with five African countries to improve the quality of life for patients with cancer and human immunodeficiency virus (HIV)/acquired immune deficiency syndrome (AIDS) by developing palliative care programs with a community health approach.[29] Key to this collaboration program is its emphasis on developing palliative care services and standards and attempting to integrate them into existing health systems and national strategic plans for health and social services. For instance, the WHO has defined a minimum standard of care for HIV patients with cancer in Africa.[30] The initial phase of the project identified improved care for dying patients using palliative care as a national concern. Using data to guide reforms, the project collected information concerning target countries' health systems performance and also assessed needs and gaps in patient care.

The first phase of the project found that terminally ill patients in the target countries had these key needs: relief of pain, accessible and affordable drugs, and financial support.[31] Suggested strategies to address these needs include: incorporating drugs in palliative care packages, focusing on home-based palliative care, and establishing national policies to support availability of analgesics. The second phase of the project calls for a 'stepwise approach to fill in the gaps, so that existing resources/initiatives are optimized', and specific pilot projects that use a 'methodology of problem solving and team learning'.[29] A survey of end-of-life programs in Africa already shows some successes in palliative care program development.[32] Of the programs surveyed, 85 percent reported government endorsement of their program, 94 percent had written goals and objectives, 90 percent had measurement indicators, 79 percent had guidelines for good practice in place, and 86 percent reported monitoring critical elements such as patient care and outcomes, patient and carer need, or place of death preferences.

Canada also established national initiatives and policies focused on creating care standards to improve end-of-life and palliative care. In June 2000, a Canadian Senate subcommittee produced a national end-of-life strategy.[33] The subcommittee noted as integral to ensuring integration of quality end-of-life care within the healthcare system specialized training for end-of-life interdisciplinary teams, increased research, and ongoing development of guidelines. The subcommittee recommended that the federal government, in collaboration with the provinces, develop a national strategy for end-of-life care, implement it within 5 years, and prepare an annual progress report. Additionally, the Canadian Hospice Palliative Care Association addressed national care standards in hospice and palliative care in 2002,

when it published the results of a 10-year consensus-building process to develop a national model to guide hospice and palliative care across the country.[34]

Clinical QI and audit initiatives

In contrast with the national projects described above, many QI and audit initiatives have been implemented at the healthcare system and organization level. There are also many examples of individuals and grouped audit initiatives and it is impossible to review them all. A large variety of individual topic based audits have led to improvements in practice for the management of individual symptoms, discharge planning, coordination, and education.[35–42] There has been the incorporation of outcome measures into clinical practice[35,43–45] (see also Chapter 23) and the use of these measures, e.g. the Palliative Outcome Scale, to help to audit care.

In nonspecialist palliative care settings, Dr Keri Thomas and the Macmillan Cancer Trust have developed the 'gold standards framework', which is 'a practice-based system to improve the organization and quality of palliative care services for patients who are at home in their last year of life'.[46] This framework gives providers seven 'gold standards' for care of patients: communication, coordination, control of symptoms, continuity out-of-hours, continued learning, carer support, and care in the dying phase. A key goal was to improve generalist palliative care to better dovetail with specialist palliative care, thereby enhancing continuity and coordination. The framework was implemented using QI models, and began with 12 family doctor practices.[47] Unpublished results suggested that between December 2001 and August 2002, indicators related to coordination had improved and there was an increase in the number of deaths taking place in the place preferred by patients.[48,49] A more detailed evaluation is underway.

Another example of local collaborative QI efforts with a national impact comes from the USA, where the RAND Palliative Care Policy Center has partnered with over 200 healthcare provider organizations through QI collaboratives.[15,50] A collaborative consists of multiple healthcare organizations working together for up to 2 years to improve a specific clinical or operational area, under the guidance of a panel of national experts. Following the collaborative model, teams quickly learn from one another, promising ideas are easily disseminated among teams, and in turn these teams spread proved interventions within their respective organizations. Past collaboratives have made significant improvements in various palliative care areas such as pain, advanced care planning, and dyspnea around the country.

Other local QI efforts have led to wide dissemination of knowledge, tools, and resources. The Beth Israel Medical Center Division of Palliative Care and Pain Medicine in the USA developed a free online manual and toolkit based on its own QI learning.[51] The online manual includes tools

such as an interdisciplinary plan of care and a documentation tool for daily assessments and interventions so that goals such as reducing unnecessary interventions and minimizing symptom distress can be achieved.

FUTURE OF QUALITY IMPROVEMENT

Despite documentation of some successes resulting from QI applied to palliative care, there is substantial room for continued improvement. Recent WHO Europe reports state that challenges in palliative care remain in integrating with health services; educating health professionals, policy makers and the public; implementing improvements; and prioritizing palliative care research.[52,53] Moreover, a qualitative study of palliative care in a developed (Scotland) and developing (Kenya) country demonstrate that dying patients in developing countries still lack access to analgesics, medical support, equipment and facilities, basic necessities, and relief from great physical suffering, whereas patients in developing countries on the whole do not.[54] The study also shows however, that despite the availability of resources in the UK, people still have major areas of unmet needs.

The inertia of accepting current practice is difficult to overcome, and there are still insufficient forces driving continuous improvement, and barriers that need to be overcome.[43–45] Outlined below is a vision of the future of QI, building the case for its use as a widely adopted – and indeed sometimes required – method for change.

Building obligation and opportunities

All of those involved in the healthcare system – from the policy maker to each clinician – needs to honor the obligation to provide the best quality of care. That obligation involves not accepting substandard care and making small improvements in everyday clinical practice based on evidence. Financial incentives, such as performance linked to payment or accreditation can help foster this obligation to improve quality of care.[55,56] Moreover, we need to better develop opportunities to utilize QI in everyday practice. For example, healthcare contracts should mandate audit and evaluation, a plan to implement research findings,[57–60] and forethought about the scalability, replicability, and spread of the intervention.[61] Quality improvement should be a part of the education of any healthcare provider.

Monitoring quality and responding

Quality must be continually monitored on a large scale, such as through tracking adherence to national quality standards. By doing so, the national standards generate a feedback loop for quickly assessing which ideas are successful, which ones are not, and which require a mid-course

correction.[19] Integrating technology into the monitoring process, so that the information is timely, meaningful and actionable will be important. Furthermore, quality standards will help countries learn from each other through international comparisons,[62] alleviate the variation that exists among settings and geography,[63] fill in the missing gaps in knowledge as to which interventions are most effective in which settings, and help highlight the various factors for success.[64,65]

Publicizing benchmarks and supporting QI efforts

We need not only monitor quality but also to publicize the results. Standards that are simple and transparent will help get the public involved as an important advocate for change. Recognizing the exceptional facilities and revoking accreditation for those that fail to meet standards could be key to validating the efforts. Lastly, we must provide support to QI through knowledge and finance, nurture struggling facilities, and commit to teaching the QI process, so that an environment exists that allows good ideas to succeed and spread.

Not long ago, discovering the latest drug or publishing the newest procedure in the professional literature was seen as sufficient to change clinical practice. No-one believes that now. Deliberate, planned improvement activities are proving effective at changing practice. In order to build a care system that we can rely on and will serve us well at the end of life, we need to quickly acquire the skills that will allow us to learn from our current clinical practices, to improve upon it, and to disseminate the information broadly. Audit and QI can help us achieve that.

Key learning points

- Traditional methods to improve quality of care use formal research to guide reform, however, these methods are less effective for introducing rapid change in clinical practice.

- Quality improvement allows clinicians to assess whether they are doing the right thing, with the right patients, at the right time – and if not, to make needed changes quickly. Effective QI is an ongoing cycle that encourages ongoing organizational learning.

- Audit is similar to QI, the key difference being that in audit the process is formalized and centralized by a governmental body.

- All aspects of palliative care, including advance care planning, symptom management, and continuity and coordination of care, present tremendous opportunities for QI.

- Many countries have begun using national guidelines and policies to improve palliative care, often in the form of

accreditation, e.g. JCAHO in the USA and the WHO's QI program in Africa involving a community health approach.

- An example of QI at the local health system level is the 'gold standards framework' approach in the UK. The gold standards arose from general practitioner (family doctor) practices trying to improve care for those in the dying phase and has since spread to hundreds of practices.

- Quality improvement has a growing role in improving palliative care. The future effectiveness of QI depends on several factors including building obligation and opportunities for QI; monitoring quality and responding; and publicizing benchmarks and supporting QI efforts.

Standards of care

FRANK D FERRIS

WHY STANDARDS OF CARE?

With the successful implementation of modern medicine and public health, patients and their families are living for much longer with one or more life-threatening illnesses and multiple issues that can cause them suffering and adversely impact the quality of their lives. Today more than ever before there is an urgent need for palliative care, including hospice care, around the world. This is particularly true when access to therapies to treat the disease process and/or resources are limited.

To this end, patients and families are hoping that palliative care will 'relieve their suffering and improve the quality of their lives whether they are living with an advanced life-threatening illness, or are bereaved'.[1,2] They are hoping for a consistent approach to palliative care wherever they receive their care so they can maintain their health and the activities that bring them meaning and value for as long as possible.[3] They want to choose from therapeutic options appropriate for their context and goals of care.[4] They want help to navigate the healthcare system. They do not want to have multiple repeat assessments, mixed messages or fragmented care from many different healthcare providers who do not function as a team.[5,6] This is particularly true for older people, who may not have the energy, stamina, or friends or family members available to help them.

At the same time, clinicians want to know how to provide palliative care in a way that will produce the best results for their patients and families without adverse events, and may even prolong their lives. Administrators, policy makers, regulators, and funders want to know how to best integrate palliative care into their existing healthcare system in a manner that is ethical, legal, fundable, and provides a consistent

experience for patients, families, healthcare organizations and systems, and ultimately, for their society within the available resources. They also want to ensure that the correct medications and therapies are available when and where the patient needs them, and that they are delivered safely, with the least risk of adverse events.

Today, there is increasing interest and value to develop standards of care for palliative care that provide clear definition and elaboration of:

- the practice of palliative care (a model to guide patient and family care) and the organizational structures and functions needed to provide it (a model to guide organizational development)
- the activities that are part of the process of providing palliative care (preferred practice guidelines)
- the data and documentation that clinicians should routinely collect (outcome measures)
- what palliative care realistically hopes to achieve, i.e. its goals or targets (standards of practice)
- strategies to review these outcomes so that the patient's, family's and society's experience will improve over time (performance improvement).

If growth in the number of palliative care programs occurs rapidly without widely accepted standards of care, there is a risk that clinicians and organizations will start services that address only some of the issues that patients and families face. Clinical practice may vary considerably with little or no sense of the impact of the care provided. Healthcare funders and policy makers may develop limited funding and service delivery models and regulations, which are barriers to good palliative care delivery, e.g. limit access to opioids.

INDUSTRY ANALOGY

Industry has long known that standardized approaches to facilitate consistency in products and services are invaluable. When a company wants to make an automobile, there are fixed expectations on the part of a consumer for what a car will do. Once a design is established, it is easy to reproduce the product.

Industry has refined the process of mass-producing a high-quality product. The industry uses an interactive process that includes regularly updated:

- needs assessments to find out what the customer wants/needs (both opinion and data driven)
- definition of the organizational strategic and business plan
- definition of the principal activities and the products the company will produce (through consensus, refined based on evidence); the goal is a high-quality product that is overall consistent, yet customized to the individual hopes, expectations, and needs of each individual customer
- measurement of their outcomes of process and products (fruits of their labor), e.g. through statistics, changes, resources used, risks
- review of their outcomes to improve their products and the process to create them.

Comparison between industry and palliative care

The development of plans of care for individual patients and families follows a similar process. Clinicians first identify each patient's and family's issues, expectations and goals of care using standardized approaches to functional inquiry, communication, and decision-making. Once their treatment priorities have been clarified, the interdisciplinary team plans and delivers the agreed-to medications, therapies, and care in the manner that has the greatest potential for benefit, and the least risk of adverse events based on best practice and treatment guidelines. Each visit, the team reassesses the patient's and family's status, issues, expectations, goals, treatment priorities, understanding, and satisfaction with the plan and treatments and revises them whenever necessary.

The most significant difference between palliative care and a manufactured product occurs in the outcome – the patient/customer satisfaction. A manufactured product is just what it appears to be. The manufacturer and customer can both examine it and determine whether it is satisfactory or not. The quality is easily measured. In addition, manufacturers compete in markets where consumers have access to information and choices, and can compare price and value across companies. Customers make choices based on subjective and objective evaluation of the product. If they make a bad choice, they tell their friends, sell the product, and buy something different.

Care, on the other hand, can be defined in one way by the health professionals who deliver it, and assessed quite differently by the patient/family who receives it. It is the perception of what is received, and not the care plan or vision of the health professionals, which determines patient/family satisfaction. If the patient or family does not like the care they are receiving, they may be able to change providers, but it might not be easy.

Paradigm shift

We are all familiar with the process of deciding what is in the best interests of the patient/family, deciding on a plan of care, implementing it, and assessing how well we have followed through with our plan. However, to deliver care effectively and improve patient/family satisfaction requires a dramatic re-focusing of our understanding, *a paradigm shift*. We must move away from autonomously making decisions and evaluating the quality of service we deliver, to a position where it is the satisfaction of the patient/family with the outcomes of the care they receive that determines success or failure.[7]

TYPES OF STANDARDS

Clinicians, administrators of healthcare organizations, funders, policy makers, regulators, and accreditors are all interested to know how palliative care will be delivered. As a result of their different perspectives (see Fig. 27.1), many different types of standards have been developed relative to the practice of palliative care. Examples are listed in Appendix 27.1. A regularly updated listing is available online (http://standards.cpsonline.info).

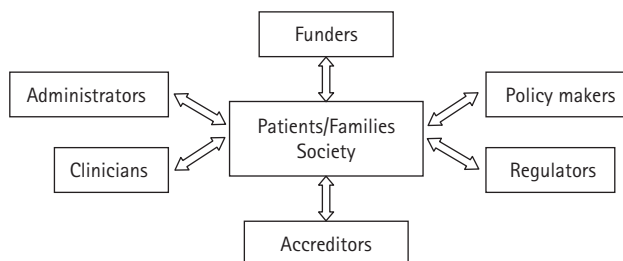
Well developed **organizational standards of practice** are of greatest importance to guide a consistent patient/family experience. Each healthcare organization should be developing standards of practice specific to the culture, environment, funding, and service delivery models in


Figure 27.1   *Perspectives on palliative care practice. Redrawn with permission from Canadian Hospice Palliative Care Association, 2005.*

which it works. These standards describe the structure for their palliative care service(s), the issues they address, the process for providing care, the outcomes they measure, and their performance improvement strategies.

STANDARDS OF PROFESSIONAL CONDUCT

Individual disciplines on the interdisciplinary palliative care team may also develop standards of professional conduct that govern the professional behavior of their members. They often focus on maintaining the integrity of the profession. They address how a professional acts and define core competencies for the discipline.

MINIMUM STANDARDS

Policy makers and funders often define minimum standards that must be met before an organization can use the label 'palliative care service' and/or receive funding. As an example, the Medicare Hospice Conditions of Participation in the USA specify the minimum standards of practice for hospice organizations to be eligible to be reimbursed under the Medicare Hospice Benefit.[8]

LAWS

Policy makers and regulators may create laws to ensure that minimal standards of practice are enforceable, e.g. opioid control legislation specific to each country.

ACCREDITATION STANDARDS

Accreditation organizations focus on developing accreditation standards that can be used to examine and compare the activities and outcomes of many different healthcare organizations providing palliative care services. (As an example, the Canadian Council on Healthcare Services accreditation is currently developing modules to examine the delivery of palliative care services in acute and long-term care facilities, cancer clinics and home care programs across Canada.)

Central role of organizational standards of practice

Historically, most organizations that were part of the early grassroots hospice and palliative care movement were developed by people with passion and good will. There was minimal literature to guide consistent practice; each organization developed its own approaches to palliative care delivery; components of palliative care were frequently been left out, leaving gaps in the services available within a given geographical region; organizational standards of practice were frequently not been developed. As a result, patients and families experienced considerable variability in the services available to them, and the care they received.

Today, for there to be consistency in the palliative care experienced by patients and families, across an organization,

or across a geographical region, there needs to be a shared understanding by clinicians, administrators, and volunteers of the standards, preferred practice guidelines, data collection, and documentation strategies that the organization or the region has decided on. Ideally, each healthcare organization will develop its own standards of practice as it first evolves. Then, on a routine cyclic basis, it will review all of its standards to assess what is current and working well, and what is not working and needs modification, e.g. yearly.

If an organization's standards of practice are well known and understood by all staff, they will influence the language everyone uses, the values and principles guiding their activities, the issues they address, their approach to care planning and delivery, their management of resources, the data they collect, the documentation they keep, and the outcomes they achieve. Once the standards of practice have been subjected to review and updating, they will also stand up to external scrutiny when outsiders compare one organization with another, e.g. during accreditation.

DEVELOPING ORGANIZATIONAL STANDARDS OF PRACTICE

Whom to involve

Any process to improve the quality of palliative care being provided by an organization must engage everyone who will be involved in the process, i.e. clinicians, administrators, volunteers, and selected patients and families. When stakeholders are not involved in the development process, there may be little or no improvement in quality as people who don't know the content can't be expected to work with it. It is not advisable to delegate the process to a committee that then tells the rest of the organization how to improve their practice. Committee-based processes to develop standards of practice rarely change behaviors or patient/family experience as 'knowledge alone is insufficient for change'.[9]

Decision-making process

For there to be consistent high-quality palliative care, every individual in the organization will need to know, accept and agree to work with all elements of the final standards of practice that are pertinent to their day-to-day activities. Most people like to participate and have a say in developing any product. Ultimately, people who agree with a plan are much more likely to adhere to it, whereas people who don't agree with a plan, or don't have a chance to participate in building it, are much more likely to 'battle' the plan.

A carefully constructed consensus-based process based on a Delphi technique[10] is an ideal strategy to ensure that everyone has a working knowledge of the content and a chance to discuss and express their opinion about each issue. Groups need time to form, storm, and norm before

they perform effectively.[11] A consensus-building process will encourage everyone to join at least one workgroup to work through the content. Ideally, the decision-making process will stimulate discussion among all stakeholders and increase their awareness of all aspects of palliative care practice and organizational development.

When constructing a consensus-building process, start by establishing (i) a quantitative and qualitative strategy to collect reviewers opinions of each of the major elements of the proposed model; (ii) the degree of agreement that will constitute consensus on numerical data (typically 70–80 percent); and (iii) the minimum number of contrary comments that will trigger modification of the content. Then, ensure that everyone who will participate agrees in advance to (i) share their opinions honestly and openly, (ii) listen to others, and (iii) work with the final product, even though they may not agree with all aspects of it. Also ensure that there is agreement on the values and principles guiding discussions and committee processes, e.g. honest, empathic, motived, professional, respectful, trustworthy.

To facilitate the process for each issue for which content is needed:

1   Constitute a small workgroup to draft content based on a review of the chosen model, e.g. the Canadian Hospice Palliative Care Association (CHPCA) model, existing literature, and committee opinion
2   Disseminate the draft to all organizational stakeholders and educate them about the content
3   Invite stakeholders to review and comment on the draft within a specified timeframe
4   Modify the draft based on the feedback
5   Ask stakeholders if they can agree to accept and work with the content; if not, make any necessary modifications and ask them again
6   Once consensus is reached, publish and disseminate the final content.

What approach

There are two possible approaches to developing organizational standards of practice:

● Develop independently: Each organization develops the process and content from scratch without using an existing model[1,2] to guide the process or provide content to review.
● Develop based on a model: Each organization uses a widely accepted model standard of care to (i) guide the process to develop its own standards of practice and (ii) provide content to review and adapt to the culture, environment, funding and service delivery models in which the organization works, rather than developing it from scratch.

The latter approach is faster and more efficient. If several organizations within a given geographical region base their process on the same model, there is much greater potential for consistency in practice and the experience for patients, families, organizations, and society across the region.

Based on what model

Already there are a number of widely accepted model standards of care that can be used by an organization to guide it through the process of developing standards of practice. The CHPCA's *Model to Guide Hospice Palliative Care: Based on National Principles and Norms of Practice* is one such widely accepted model.[1,2]

The CHPCA Model took 9 years to develop through three iterative consensus-building cycles based on a Delphi technique.[10] Hundreds of participants from across Canada representing thousands of stakeholders from their organizations reviewed the successive draft documents, participated in workshops, and provided their opinions. By 2001 there was >90 percent agreement on virtually all of more than 100 items (exceeding the goal of >75 percent agreement) and the model was published in both English and French in 2002. Already it has been endorsed by all 11 provincial hospice palliative care associations, the College of Family Physicians of Canada (http://www.cfpc.ca), the Royal College of Physicians and Surgeons of Canada (http://rcpsc.medical.org/), the Canadian Nurses Association (http://www.cna-nurses.ca/cna/), the Quality End-of-Life Care Coalition of Canada (http://www.chpca.net/quality_end-of-life_care_coalition_of_canada.htm), and the Canadian Strategy on Palliative and End of Life Care as the basis for a variety of national efforts in education, research, public awareness, and service delivery (see http://www.hc-sc.gc.ca/hcs-sss/pubs/caresoins/2005-strateg-palliat/index_e.html#4). The Canadian Medical Association (http://www.cma.ca) has supported it.

The model will be used in this chapter to illustrate the process, and its impact is detailed in Appendix 27.2. Other model standards of care are listed in Appendix 27.1. A regularly updated listing is available online (http://standards.cpsonline.info).

Clarify the framework

Once a model has been chosen, clarify the framework contained within the model so that all of the components are clear. Figure 27.2 presents the framework that is the basis for the CHPCA Model. It builds from the bottom up, and starts by specifying all of the components of standards of practice that are defined during the strategic planning process, including:

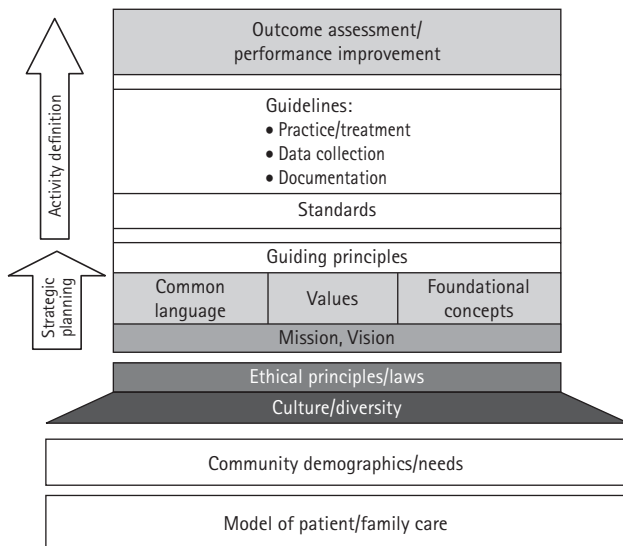
● the mission/vision of the organization
● definitions of the common language/terminology it uses
● values, foundational concepts and principles guiding its activities.


Figure 27.2 *Components of organizational standards of practice. Redrawn with permission from Canadian Hospice Palliative Care Association, 2002.*

It then specifies the components that are detailed for each principal activity and each issue the organization will address, including:

- standards that the organization is hoping to achieve
- practice and treatment guidelines
- data collection and documentation guidelines
- outcomes to measure
- performance improvement strategies.

Developmental steps

Once the participants have been selected, the process clarified, and a model to guide the process chosen, the following sequential steps are recommended as a strategy to build the standards of practice.

STEP 1: REVIEW THE ORGANIZATION'S STRATEGIC PLAN

Start by reviewing the organization's strategic plan.

Organizational focus

From the outset, remind all participants that the organization focuses on changing the experience of patients and families, not simply on providing care. To consider this perspective effectively, the CHPCA Model provides a model to guide patient and family care to help participants develop a shared understanding of the patient and family experience, the definition of palliative care, and the process for providing care to them.[1,2]

- Modern illness experience: Today, in the face of any illness process, most patients and families experience multiple issues that are the manifestations of the underlying

disease process(es) or aging (e.g. symptoms, functional and psychosocial changes), and the predicaments of how to adjust and continue living life to the fullest given these new circumstances (see Fig. 27.3).[12–18] If not treated properly, many of these issues can cause considerable suffering, reduce the quality of their lives and have an adverse impact on their future.[19] Patients and families come to the healthcare system seeking help to address the issues that are bothering them.

- Definition of palliative care: To address these issues, the CHPCA Model states that 'palliative care aims to prevent and relieve suffering and promote quality of life'.[1,2] In 2002, the World Health Organization endorsed a more elaborate definition of palliative care:[20]

   Palliative care is an approach that improves the quality of life of patients and their families facing the problem associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual.

- Process of providing palliative care: Over time, clinicians build a therapeutic relationship with patients and families through a series of sequential encounters (see Fig. 27.4). During each encounter, clinicians follow six essential steps to provide palliative care (see Fig. 27.5).

Environment in which the organization functions

For participants to consider all perspectives related to their organization, it will be important for them to understand the environment in which they provide care, including:

- the demographics of the population
- who the customers and stakeholders are
- what their unmet needs are
- the ethical principles that will be the foundation for their activities including autonomy, beneficence, nonmaleficence, justice, confidentiality, truth-telling and discrimination[21–24]
- the laws and regulations governing care in their jurisdiction.

Definition of the organization

After reviewing the strategic plan, participants should understand the organization's:

- Mission: A short statement of the organization's purpose, e.g. what it is, what it does, and in which geographical region. For example: 'The (named) program provides palliative care services and education to all patients and families within (named geographical region or health care district)'.
- Vision: A short statement of the organization's aspirations; what it hopes to become and achieve. For example: 'The (named) program will be the leading palliative care program providing clinical services to all

Disease management

Primary diagnosis, prognosis, evidence

Secondary diagnoses (e.g. dementia, psychiatric diagnoses, substance use, trauma)

Comorbidities (e.g. delirium, seizures, organ failure)

Adverse events (e.g. side effects, toxicity)

Allergies

Physical

Pain and other symptoms[a]

Level of consciousness, cognition

Function, safety, aids:

  Motor (e.g. mobility, swallowing, excretion)
  Senses (e.g. hearing, sight, smell, taste, touch)
  Physiological (e.g. breathing, circulation)
  Sexual

Fluids, nutrition

Wounds

Habits (e.g. alcohol, smoking)

Psychological

Personality, strengths, behavior, motivation

Depression, anxiety

Emotions (e.g. anger, distress, hopelessness, loneliness)

Fears (e.g. abandonment, burden, death)

Control, dignity, independence

Conflict, guilt, stress, coping responses

Self-image, self-esteem

Loss, grief

Loss

Grief (e.g. acute, chronic, anticipatory)

Bereavement planning

Mourning

Patient and family

Characteristics

Demographics (e.g. age, gender, race, contact information)

Culture (e.g. ethnicity, language, cuisine)

Personal values, beliefs, practices, strengths

Developmental state, education, literacy

Disabilities

Social

Cultural values, beliefs, practices

Relationships, roles with family, friends, community

Isolation, abandonment, reconciliation

Safe, comforting environment

Privacy, intimacy

Routines, rituals, recreation, vocation

Financial resources, expenses

Legal (e.g. powers of attorney for business, for healthcare, advance directives, last will/testament, beneficiaries)

Family caregiver protection

Guardianship, custody issues

End-of-life care/ death management

Life closure (e.g. completing business, closing relationships, saying goodbye)

Gift giving (e.g. things, money, organs, thoughts)

Legacy creation

Preparation for expected death

Anticipation and management of physiological changes in the last hours of life

Rites, rituals

Pronouncement, certification

Perideath care of family, handling of the body

Funerals, memorial services, celebrations

Practical

Activities of daily living, i.e. for personal care = ambulation, bathing, toileting, feeding, dressing and transfers; for household activities = cooking, cleaning, laundry, banking, shopping

Caregiving

Dependants, pets

Telephone access, transportation

Spiritual

Meaning, value

Existential, transcendental

Values, beliefs, practices, affiliations

Spiritual advisors, rites, rituals

Symbols, icons

[a] Other common symptoms include, but are not limited to:
Cardio–respiratory – breathlessness, cough, edema, hiccups, apnea, agonal breathing patterns
Gastrointestinal – nausea, vomiting, constipation, obstipation, bowel obstruction, diarrhea, bloating, dysphagia, dyspepsia
Oral conditions – dry mouth, mucositis
Skin conditions – dry skin, nodules, pruritus, rashes
General – agitation, anorexia, cachexia, fatigue, weakness, bleeding, drowsiness, effusions (pleural, peritoneal), fever/chills, incontinence, insomnia, lymphedema, myoclonus, odor, prolapse, sweats, syncope, vertigo

patients and families within (named geographical region or healthcare district) and a leader in palliative care education and research'.

- Common language: Definitions of the terminology commonly used by staff. A detailed lexicon is available in the CHPCA Model.
- Values: The fundamental beliefs on which organizational activities are based. Examples from the CHPCA Model include:[2] (p. 19)
  - The intrinsic value of each person as an autonomous and unique individual.
  - Value of life, the natural process of death, and the fact that both provide opportunities for personal growth and self-actualization.
  - The need to address the suffering, expectations, needs, hopes and fears of patients and families.
  - Care is provided only when the patient and/or family are prepared to accept it.
  - Care is guided by quality of life as defined by the individual.

  - Caregivers enter into a therapeutic relationship with patients and families based on dignity and integrity.
  - A unified response to suffering strengthens communities.
- Foundational concepts: Concepts that underlie all activities. All healthcare organizations are built on: effective group dynamics/leadership; effective communication based on a common language; and effective strategies that aim to change the experience of patients, families, caregivers, and the communities in which they provide care.
- Guiding principles: The fundamental truths guiding all of the organization's activities. Principles frequently used by palliative care programs include patient/family focused, high quality, safe and effective, accessible, adequately resources, collaborative, knowledge based, advocacy based, research based, etc.
- Principal activities that the organization engages in: In addition to patient/family care, palliative care organizations often engage in education, research

and advocacy. They all need an administrative infrastructure to support their activities.

- Specific issues: Specific issues the organization addresses in each principal activity. For patient and family care this might include pain control, spiritual management, legacy creation, and the management of the symptoms during the last hours of life. For education, this might include orientation for staff, continuing education for community clinicians, volunteer training, and an introduction to palliative care for medical and nursing students.

STEP 2: DEVELOP CONTENT FOR THE STANDARDS OF PRACTICE

No organization will be able to develop all of the content for its standards of practice at one time. It will likely take months to years to develop all of the necessary standards, guidelines, and outcome measurement tools. Start by developing and prioritizing the list of issues that the organization will address in each area of activity. For the purposes of planning and developing standards of practice, the interrelationship of the therapeutic process with the issues faced by the patient can be illustrated as a simple table 'The Square of Care' (Fig. 27.6). As organizations implement their services, the table can be filled in to illustrate the specific issues for which standards, guidelines, and outcomes measurements have been developed. The gaps will indicate where work is still needed.

On the basis of preestablished priorities, workgroups can then develop standards, guidelines, and outcome measures for each issue the organization will address:

- Standards: These are criteria established for the measurement of quality, value, or extent.[25,26] They present the organization's process and outcome goals related to a particular issue. In a widely accepted model, e.g. the CHPCA Model, norms present the 'usual' or 'average' practice across many different organizations (see Fig. 27.7). They are less specific than the standards which each individual organization will

define based on their local environment, and funding and service delivery capabilities. Norms are also different from minimum or regulatory standards (which typically describe the 'floor' or minimum that is acceptable, e.g. the Medicare Hospice Benefit Conditions of Participation in the USA[27]). Many existing standards detail process. Only recently have there been attempts to look at outcome standards. An example of how standards can be developed from norms is presented in Appendix 27.3.

- Guidelines: These are systematically developed statements to assist decision making about appropriate strategies to manage specific circumstances.[25,28] Ideally, guidelines include details of the process to be followed, the data to be collected, and how to document the activity. Many organizations will want to develop two types of guideline: (i) practice guidelines that detail the essential steps to assess and manage a particular issues, e.g. pain; and (ii) treatment guidelines that detail the indications, steps for delivering a specific medication or therapy, e.g. morphine, and potential risks, e.g. drug interactions and adverse effects. Some organizations

will choose to develop specific disease management pathways, with or without standing orders. For sensitive issues, i.e. infection control, many organizations will develop very specific policies and procedures to guide care. For examples see Appendix 27.1.

- Outcome measures: These are the measurable end results or consequences of a specific action or essential step in a process, including effectiveness, resource utilization, risk, compliance and satisfaction. These can be simple measures to compare the change in a variable from day to day, e.g. the severity of a patient's pain today compared with yesterday. They can also be complex measures that capture overall performance of the organization related to a given issue, e.g. the percentage of patients with a pain severity score <5/10, 48 hours after admission to the program. For examples see Appendix 27.1.

STEP 3: IMPLEMENT THE STANDARDS OF PRACTICE

As each part of the model is developed and accepted by the staff, disseminate it throughout the organization. Modify staff orientation and continuing education activities to include the changes. Ask staff to practice to the new standards and guidelines, and measure their outcomes.

STEP 4: DEVELOP A PERFORMANCE IMPROVEMENT STRATEGY

Concurrently, every palliative care organization will want to choose specific outcomes to measure and review on a regular basis. Then, based on the results, specific strategies to improve staff's performance related to problematic activities can be implemented. The Plan-Do-Study-Act cycle is an excellent model to guide performance improvement strategies.[29,30] The document *Improving the Quality of Pain Management Through Measurement and Action* by the Joint Commission on the Accreditation of Healthcare Organizations is a wonderful example of a performance improvement strategy.[25]

SUMMARY

Standards of care are increasingly important for everyone involved in palliative care. By defining its principal activities, standards, practice and treatment guidelines and outcome measures, and developing a performance improvement strategy, a palliative care organization will set the stage to ensure that it changes the experience of patients and their families.

Although it is possible for individual organizations to define themselves independently, a regionally, nationally, or internationally accepted consensus-based 'model standard of care' can: expedite the process for all stakeholders; ensure that the standards of care live from day to day; increase the possibility of consistency of the experience for patients and families regardless of the setting or the organization from which they receive care; and minimize risks of liability of adverse events. A number of models, standards and guidelines already exist to guide the development of sound approaches to the delivery of palliative care. At present, most are based on consensus opinion. With time, as the evidence supporting palliative care practice grows so will the strength of our service delivery models.

After all, isn't it true that: 'The standards of practice we create and the people we train will look after us when it's our turn to receive care. If it was your turn tomorrow, would you get the care you hoped for?'[31]

Key learning points

- There is a growing need for widely accepted standards of care to ensure that patients and families receive consistent, high-quality palliative care wherever they receive their care.

- It is the experience of the patient and family, and their satisfaction with the outcomes of the palliative care they received that matters, not how the care was delivered.

- There are many different types of standard, of which the most important is organizational standards of practice.

- Every organization needs to develop its own organizational standards of practice specific to the culture, environment, funding, and service delivery models in which it operates.

- When developing organizational standards of practice, involve everyone in the process who will participate directly or indirectly with providing care using an iterative consensus-building process

- Rather than building standards of practice from scratch, use a widely accepted model standard of care as a template to guide the process and provide content for participants to consider, e.g. the CHPCA *Model to Guide Hospice Palliative Care*.

- Start by reviewing the organization's strategic plan and the environment in which the organization operates.

- Once the principal functions and issues the organization addresses are clear, for each issue develop content sequentially, including process and outcome standards, practice and treatment guidelines, data collection and documentation guidelines, and outcomes to measure.

- As content becomes available for each issue, disseminate and implement it across the organization.

- Concurrently, review the measured outcome and develop a performance improvement strategy.

APPENDIX 27.1: SELECTED RESOURCES

Several regional and national organizations have already developed models, standards, and guidelines. These can be used to increase awareness of the importance of palliative care and guide the development of organizational standards of practice that guide palliative care practitioners and organizations. A regularly updated listing is available online (http://standards.cpsonline.info).

APPENDIX 27.2: IMPACT OF A WIDELY ACCEPTED MODEL

By providing 'one message, one voice', the CHPCA *Model to Guide Hospice Palliative Care* has already had significant impact since its publication in 2002, including:

- **Companion standards of care** have been developed by
  - Canadian Nurses Association to develop standards for nurses working in hospice palliative care and a process to certify them[32]
  - Hospice Association of Ontario to build standards for both volunteer hospice visiting services and community residential hospices,[33]
  - Canadian Network of Palliative Care for Children (CNPCC) to develop norms of practice for pediatric hospice palliative care (see http://cnpcc.ca/pages/documents.htm).
- **Patient/family care:** In 2003–04, the new Canada Health Accord included money to provide universal access to home-based care across Canada.[34] As part of this strategy, the Ontario Ministry of Health is increasing home-based palliative care across the province based on the CHPCA *Model*.[35] In 2005, Cancer Care Ontario made palliative care one of its four strategic thrusts. Implementation will be based on the CHPCA *Model*. Multiple palliative care programs and services are in the process of building their standards of practice based on the CHPCA *Model*.
- **Accreditation:** The Canadian Council on Health Services Accreditation is using it to develop accreditation standards for all healthcare agencies across the country, including acute and long-term care facilities, cancer clinics, homecare programs and hospice palliative care programs (see http://www.cchsa.ca).
- **Education:** The Educating Future Physicians in Palliative and End-of-Life Care Project is developing competencies for both undergraduate and graduate medical trainees (see http://www.efppec.ca). EPEC-O, the Education on Palliative and End-of-life Care for Oncology Project, is structured based on it (see http://www.epec.net).

- **Research:** The Canadian Institutes for Healthcare Research (CIHR) used it to guide palliative care research proposals (see http://www.cihr-irsc.gc.ca/e/22757.html).

APPENDIX 27.3: DEVELOPING STANDARDS FROM NORMS

Norms present the 'usual' or 'average' practice across many different organizations (see Fig. 27.7). They are less specific than the standards which each individual organization will define based on their local environment, and funding and service delivery capabilities. In the example in Table 27.1, norms for care delivery (on the left) become much specific standards for the delivery of pain management (on the right).

Table 27.1

Norm 5.13 from the CHPCA Model	Standards for pain delivery
All therapeutic interventions are delivered in a safe and timely manner that:	All pain management is delivered in a safe and timely manner:
is consistent with the organization's standards of practice and policies and procedures	90 percent of care plans follow the network's policies and procedures
optimizes their potential for benefit	The incidence of medication interactions and adverse events is <1 percent
minimizes the potential for medication interactions, adverse effects or burden	90 percent of patients and families express their acceptance of the therapies offered to manage their pain
is consistent with manufacturer's/supplier's instructions	50 percent of patients have pain <5/10 within 48 hours of admission
is acceptable to the patient and family	

The adoption of palliative care. The engineering of organizational change

WINFORD E HOLLAND

INTRODUCTION

Imagine that you have just been named to the faculty of a distinguished medical institution. Further imagine that you have been asked by the director of the institution to 'help us implement palliative care in our institution'. What would you do? How would you do it? With whom would you work? Whom might you avoid? What mis-steps would you want to avoid?

Hopefully many of the readers of this book will be asked exactly that question: 'Can you help us implement palliative care?' The goal of this chapter is to offer a framework for thinking about such an implementation as well as some practical tools that might be used to make such an implementation possible in a relatively short period of time.

ELEMENTS OF THE FRAMEWORK

Although most of us spend our time inside a large organization, we usually do not spend much time thinking about the organization. What is an organization? What is it made of? What do we mean when we talk about 'changing the organization'? When we say that we want to implement palliative care in an organization, what does that mean?

The following three subject areas can form a framework for envisioning and then changing an organization and how it operates:

1 *The organization as a mechanical system.* A large organization can be thought of as a mechanical system made up of concrete 'moving parts' – parts that can be altered to cause the organization to function in a different way, like delivering a new service such as palliative care to the institution's clients. As a metaphor, organizations can be thought of as 'theatre companies' performing in continuous 'plays'.

2 *The diffusion of innovation within a social organization.* Innovations – ideas that are new to an organization – diffuse through an institution in a patterned way over time, with some organization members far more inclined to adopt an innovation like palliative care than others.

3 *The role of leadership in creating change in an organization.* Leaders cause things to happen in an organization. Leaders take direct actions on the moving parts of an organization; they influence organization members to enable the organization to make changes like implementing palliative care on an institutional basis.

The following sections of this chapter will explore in more detail these three key framework ideas, providing both understanding as well as action steps that can be used to implement, or 'engineer', an innovation into an institution in an effective and efficient way. The last section of the chapter will 'pull it all together' to illustrate how the actions can be used for real-world implementation of palliative care.

THE ORGANIZATION AS MECHANICAL SYSTEM

Implementing a change … like the introduction of palliative care … requires us to know something about what an

organization is from a structural or system point of view – the mechanics of organizations. In today's world of work, we must be able to do two things at the same time – to *use* the organization to get today's business done and *change* the organization so that we can be ready to do tomorrow's business.

Organizations as ongoing theatrical performances

We see an organization as an ongoing play, where organization members are cast and crew in a satisfying performance for clients/patients. Use of the scenario of changing plays from *Romeo and Juliet* to *My Fair Lady* as an example of what happens in organizational change is a helpful framework for managers and employees to easily grasp the changes involved in moving a theater company from one performance to another – from learning new scripts to changing costumes and sets, all the way to the full dress rehearsal before opening.

Once this theater metaphor is learned, our students of change management can use it to understand why many changes they have seen go awry! More importantly, it becomes easy to understand the *single most important concept* in organizational change – that organizations are structured, mechanical systems with concrete moving parts that must work and change together. Translating the theater metaphor to organizations, students can see the four primary structural elements:

- Vision – like the play's storyline and script
- Work processes – like the roles in the play
- Plant/equipment/tools – like costumes and sets
- Performance agreements – like contracts for actors

Although it is easy to comprehend the 'work process–role' and the 'plant/equipment/tools–props' connections, it does take some stretch to see that the 'agreements for performance', like actor contracts, are an attribute of the organization and not the 'employees–actors' themselves. In our experience, the most difficult part of organizational change for many companies is understanding that change is designed to alter the roles that people play in the organization, not to alter people themselves. Failure to grasp the idea that *change hinges on altering roles* and subsequent performance agreements that we make with employees is the most common downfall of organizational change.

For an organization to change, all four mechanical attributes of the organization (Fig. 28.1) must change – in concert – or there will be no change. Vision alteration, work process alterations, plant/equipment/tools alterations as well as performance agreement changes are all done in a social setting. All the alterations have to be done by people who are involved and committed to (i) making the alterations and (ii) working in the new organization after the alterations are made. Managing the people dynamics can
Figure 28.1   *Mechanical attributes of organizations.*

be challenging, but it is doable as long as leaders of the change understand the mechanical things that must be done to achieve organizational change.

The five requirements for engineering change

As discussed, the way any organization works at a given point in time is the direct and inescapable result of the configuration of the firm's Vision, work processes, physical plant, and performance system (agreements with employees and their competence to perform to those agreements). Just as in a mechanical system, the way the organization operates cannot change without a change in its key components.

Calling these needed alterations 'requirements' allows us to see change as a true engineering challenge. These four alterations, along with the development/communication of action plans, make up what we call the 'Five requirements for engineering change'. The critical part of organizational change is the unglamorous, detail-oriented, hard work of engineering.

REQUIREMENT 1: ENGINEERING AND COMMUNICATING THE CHANGE VISION

The first requirement of organizational change is to engineer a Vision of the organization's desired future that will be valid, complete, feasible, resourceable, and engaging. In this case, the detailed vision would include palliative care. Once detailed, the Vision should be tested with members of the organization to ensure that it is an understandable picture of the desired future. To ensure that the organization is positioned to really hear and digest the Vision, we construct a 'Case for Change' that describes in some detail the potential consequences of keeping the organization exactly the way it is now.

An institution bent on implementing palliative care would be able to describe a time in the near future when such care was an integral part of the organization's services,

providing a real alternative to end-of-life care in an intensive-care facility. In addition, reasons for implementing palliative care, including benefits to patients, families, as well as institutional economics, should be clearly detailed.

Once the change Vision and the Case for palliative care are complete, the next step is to communicate with all organization members multiple times using multiple media. In today's world that means the institution's website as well as its internal communication programs. Palliative care brochures, signage, and even slogans, pins, and badges, could complement the face-to-face communication of the Vision.

Technically this communication requirement is not complete until all management levels have worked through the Vision and Case for Change and translated them into action terms for their level and function, as well as for their individual associates. The final step in this requirement is to test each employee's understanding of the translation of the palliative care Vision for his or her job. Without this test, leaders of the change can hardly know if they are ready to move on to the next requirements of altering the mechanical components of the organization.

Failure to translate the Vision and Case for Change would be like the director of a theater company who does not individualize the new play for each member of the cast and crew. Imagine trying to stage a new play without specific role assignments for each actor!

REQUIREMENTS 2–4: ENGINEERING THE ORGANIZATION'S MECHANICAL COMPONENTS

Requirements 2–4 call for the physical alteration of the institution's work processes, its physical plant/equipment/tools (PET), and the employee performance system. The first step in this alteration process is to inventory the organization's current components – work processes, PET, and performance agreements with employees – to identify those elements that will not be in sync with the palliative care Vision of the future organization. Once identified, each of the elements must be physically altered and tested. It is these alterations of the existing components, along with the addition of new work processes (e.g. billing procedures for palliative care), physical plant (e.g. dedicated palliative care beds), and performance agreements (e.g. job descriptions for personnel servicing palliative care beds) that will become the 'stuff' of the changed organization that will include palliative care.

Development and negotiation of new performance agreements for all affected managers and employees is critical at this point to ensure they are signed up for palliative care in the institution. Organizations and theater companies alike deal with the reality that some employees, or actors, will *not* elect to sign up for the change. Completing these alterations is akin to the work that must get done in the theater company to ensure that the new play is translated into individual roles and scripts for the newly assigned cast, that the new costumes and sets have been constructed, and that the actors have been put under formal contract and rehearsed for the new play.

The final step in each of these three requirements is to systematically dismantle or remove those elements that will not be a part of the new organization's structure. Old work processes, procedures, tools, and equipment will need to be removed from the workplace to ensure they will not be used again. This dismantling includes the often forgotten step of directly and formally cancelling any agreements with managers and employees for performance in the old organization. For example, we might want to verbally and in writing cancel the institutional procedure that assigns end-of-life patients to this intensive care unit or to that designated wing.

We want to cancel the agreements that our employee had for doing work the old way (without palliative care) now that they have already been signed up for doing work the new way (with palliative care as a mainstream service). This final dismantling is akin to the director removing all vestiges of the last play (old scripts, costumes, and props) to ensure that they will not be inadvertently used in the new production. Included in this dismantling step is the cancellation of any cast contracts that would have tied them to the old play.

REQUIREMENT 5: ENGINEERING ACTION PLANS FOR CHANGE WORK

Even though employees are clear on the Vision that is to be implemented, they need day-by-day or week-by-week action plans to guide them through the many steps of organizational change. Employees need an action plan that tells them 'What to do on Monday morning...' to go forward with the coordinated implementation of the new Vision.

These action plans must be a part of a critical path project management plan and master schedule that lays out all the engineering work to be done for the organizational change to embrace palliative care. Critical to the action planning requirement is the translation of action plans on a weekly or monthly basis for all involved managers and employees so that they are clear on their roles in (i) transitioning to the new organization and (ii) playing new or altered roles in that new organization. Failure to keep action plans updated and communicated would be like the director who does not lay out and communicate detailed plans and schedules for reading the new roles, signing contracts, fitting new costumes, or rigging new props.

The engineering challenge in this action planning requirement is to ensure that all of the required modifications to Vision, work processes, physical plant, and performance agreements have been done in a thorough, comprehensive manner. Although it may be a technical challenge to keep track of all of the needed alterations, particularly if the organization is large, it is technically not difficult to find out exactly where the organization is in organizational change.

Implementation planning is first and foremost a case of deciding exactly and precisely *what* alterations will be required in each of the components and then *how* the required alterations are to be made. The physical change piece is all about making the required alterations and ensuring that they were done … and done right.

Knowing where we are in engineering change to include palliative care is a matter of auditing the status of required alterations and dealing with the reality of what we find:

- Either work processes have been altered to include palliative care or they have not. New procedures that allow people to bill for palliative care have been written and distributed or they have not. The old processes and their supporting procedures have been dismantled/destroyed or they have not.
- Either new tools (beds devoted to palliative care) are assigned and working or they are not. Either the guidelines for operating the new palliative care suite have been written and distributed or they have not.
- And either the performance contract for each and every doctor, nurse, and administrator impacted by the introduction of palliative care has been altered and negotiated with them or it has not. Either each and every manager and employee has been trained on the new palliative care admission processes and new suite or they have not … and so on.

So ends this section of the framework that deals with the organization as a mechanical system, a system that can be literally engineered from one configuration to another. But organizations vary in their susceptibility to engineering, as explained in the next section.

THE DIFFUSION OF INNOVATION

The mechanical approach to leading an organization change like the introduction of palliative care is simple and straightforward to describe, but there are organizational situations in which it is an oversimplification. In professional organizations where there is a high degree of individual autonomy, another framework element has much to offer.

A major social study area for the past few decades has been the 'diffusion of innovation' – the way and rate something new to an individual or organization gets adopted by the members of the organization. The basic idea is that an innovation spreads rather slowly across a social system, like a healthcare institution, by traveling from member to member. Key elements of the diffusion theory include:

- *The innovation.* An idea or practice (like palliative care) that is perceived as new by individuals or the institution.
- *Communication channels.* The means by which messages about the innovation get from one individual to another (formal and informal communication
Figure 28.2   *Categories of adopters of innovations.*

between departments and members of the medical community).
- *Time.* The relative time an innovation takes to be adopted by an individual or group.
- *Social system.* A set of interrelated units (departments) that are engaged in accomplishing a common goal (providing healthcare to patients – the institutional goal).

In studying the diffusion process, researchers have been able to consistently identify individuals who have different rates of adoption. The by now classic categories of adopters are (Fig. 28.2):

- Innovators
- Early adopters
- Early majority
- Late majority
- Laggards

Several characteristics dominant in each category have been identified (Box 28.1).

Box 28.1 Characteristics of adopters by category

Innovators

- Venturesome; desire for the rash, the daring, and the risky
- Control of substantial financial resources to absorb possible loss from an unprofitable innovation
- Ability to understand and apply complex technical knowledge
- Ability to cope with a high degree of uncertainty about an innovation

Early adopters

- Integrated part of the local social system
- Greatest degree of opinion leadership in most systems

- Serve as role model for other members or society
- Respected by peers
- Successful

Early majority

- Interact frequently with peers
- Seldom hold positions of opinion leadership
- Deliberate before adopting a new idea
- Constitute a third of the members of a system

Late majority

- Pressure from peers
- Economic necessity
- Skeptical
- Cautious
- Constitute a third of the members of a system

Laggards

- Possess no opinion leadership
- Isolates
- Point of reference in the past
- Suspicious of innovations
- Innovation-decision process is lengthy
- Resources are limited

The practical significance of these categories has not been lost on the advertising and sales communities who routinely take advantage of innovator categories. Change leaders can also take advantage of the research by treating different populations within their institutions differently.

For example, when an innovation like palliative care is first introduced into a department or institution, health-care professionals produce an 'adoption reaction'. Thinking simply, about a third of the community is likely to have an open, even positive reaction, while another third might have a very closed or even negative reaction. A middle third might be observable as those professionals who lean no way or the other, as if waiting for the next act. In fact, this middle third is likely to be doing just that … waiting to see how the introduction goes.

From the point of view of the change leader(s), working with the three communities takes very different levels of energy and produces varying degrees of results:

- First third (innovators and early adopters) – working with them is simple, straightforward, and positive.

Reasonable suggestions about palliative care and its adoption are heard, evaluated, and frequently acted on.
- Second third (majority adopters) – working with them is frequently frustrating since they are less into 'listening, trying, and evaluating ideas' than they are into 'watching the success' (or lack of success) of the first third.
- Third third (late majority and laggards) – working with this group is usually argumentative, frequently unfriendly, and sometimes downright nasty and unpleasant.

Change leaders assigned and/or committed to the implementation of palliative care have the choice of the populations they address. Diffusion of innovation research would suggest the tactic of working with the first third to gain as much implementation success as possible … and then allowing those in the first third do the job of influencing others through their own work and social channels.

LEADERSHIP IN ORGANIZATIONAL CHANGE

Organizational change does not happen without leadership … and lots of it! We have not seen success in change when the organization's leadership, at all levels, was unwilling to take responsibility for setting a direction or was lacking the courage and commitment needed to carry out that direction. Decisive leadership at the highest level of the organization is essential for successful change. The leader who is unable or unwilling to pick a new future for the organization, give that future some detail, and then steer toward that future is destined to keep the organization right where it is. The bottom line is simple: organizational change takes leadership … from both the boss and his or her collaborators (Fig. 28.3). The final word, however, is that the boss must be the one who brings the energy and excitement to organizational change along with the personal leadership to get his or her collaborators on board.
Figure 28.3 *Change leadership acts on the mechanical attributes of organizations.*

Three critical sources of leadership must be engaged for successful organizational change: the Chief Executive, key managers at the department level, and healthcare professionals. Each leadership source has a primary mission to accomplish in an organizational change to implement palliative care. The Chief Executive is the 'Chief Change Officer' for the organization. Period. No one else in the organization has the authority and stroke to make change happen. No one else has the legal responsibility for the enterprise. No one else can be held accountable for the performance of the organization before, during, and after organizational change. The primary Change Mission for the Chief Executive in organizational change is defining the future for the organization.

The Chief Executive's primary change mission is to develop (or select) the desired future for the organization and express it as the Vision that includes palliative care, just like the director's job is to select a script that will result in a successful play. In addition, the executive must resource with dollars and personal commitment the palliative care Vision as it is being implemented. The need to continuously resource the change initiative is because a change like the movement to palliative care is difficult, frustrating, and tiresome. It is critical for the Chief Executive to be personally visible and available while the organization is implementing the palliative care Vision.

The Chief Executive must also develop his/her own altered executive role as it will need to be played for palliative care to become a reality. Actions speak louder than words, but we are talking about something more than that. What the Chief Executive does on a day-to-day, week-to-week, and month-to-month basis must routinely include the Vision of palliative care if that Vision is to become a reality.

The Cadre of Management serves as the organization's source of energy and initiative for altering work processes, altering the physical plant, and altering the performance system to include palliative care. In this cadre will likely be the organization's departmental palliative care leader(s) who have taken on primary responsibility for day-to-day operations as well as guiding the implementation effort.

The organization's Cadre of managers is directly and personally responsible for completing the changes needed to get palliative care into operation. The Cadre's job is the 'Chief Change Communicator and Director' for their part of the institution. Their primary change mission is threefold:

- relentlessly communicate the palliative care Vision
- guide organizational healthcare professionals as they complete the organization's move to palliative including professional education and training
- develop their own altered management and professional roles as they will need to be played for palliative care to be a reality,

The healthcare professionals in the organization will do the majority of the Change Engineering needed to alter the organization's mechanical attributes. It is the workers who will physically do the detailed alternations needed in work processes and physical plant and develop the new organizational roles that enable palliative care. The primary change mission of the involved professionals must, however, be focused on the alteration and development of their own roles and skills needed for their success as a part of the palliative care Vision.

PULLING IT ALL TOGETHER … A PALLIATIVE CARE SUCCESS STORY

Take for example, the introduction of palliative care at MD Anderson Cancer Center (MDACC) in Houston. The Chief Executive made the decision to move toward palliative care and hired a leading physician to come to Anderson and 'run the show'. Upon arrival, the newly appointed Palliative Care Department Head encountered stiff resistance and many logistical obstacles that were almost impossible to overcome. At the end of the first 18 months, progress in gaining acceptance of palliative care was very slow, and the third-third population of resisters had made themselves heard. The situation was uncomfortable enough for the Department Head to say 'that he felt like he had parachuted in behind enemy lines'.

In an effort to move the ball, MDACC retained the services of a change consultant to work directly with the Department Head and his palliative care team of department member physicians and administrators. The steps taken included the following:

- Instruction of and consultation with the palliative care team in the change concepts that are described in this paper. The Department Head stated that the consultations and training has 'opened a window into the world of organizations' that allowed to better see and understand the actions that he and his team needed to take.
- Decision of the palliative care team to 'ignore the third-third detractors' and to find and work with 'first-third' professionals only (i.e. working only with those who were relatively positive and eager to look at palliative care as a treatment alternative).
- Formation of a Palliative Care Steering Team made up of volunteer senior physicians/faculty members (all of whom were first-third).
- Arranging an early meeting/workshop of the Steering Committee to hear directly from the MDACC Chief Executive. The Chief Executive explained to the steering team his reason for moving the institution toward palliative, his reasons for selecting the Department Head and his vision of palliative care as a legitimate and important treatment modality for the institution.
- These key, friendly members helped establish a vision, mission, and strategic plan of action and not only provided extremely useful feedback but by the same process they were sold.

Table 28.1 *The Impact of Palliative Care Services on overall hospital mortality in a comprehensive cancer care center*

	1999	2000	2001	2002	2003	2004
Consultations prior to inpatient death Under services other than PCS	8	17	54	106	112	95
Inpatient death under primary care of the Palliative Care Service (PCS)	NA	NA	NA	54	123	169
Total number of patients accessing palliative care before death	8	17	54	160	235	264
Percent of patients accessing palliative care before death	1% (8/583)	3% (17/657)	8% (54/671)	24% (160/657)	35% (235/689)	35% (264/764)
Total number of palliative care inpatient visits (death and discharges)	800	1006	3396	5476	6489	6689

- This strategic plan was later moved upwards in the administration to convince senior management, and a process of continuous monitoring of the level of adoption of palliative care was established.
- The palliative care team and Steering Team worked directly with administrative officers of the institution to ensure that processes were in place to handle business and scheduling aspects of palliative care.
- With a palliative vision and strategic in place, the Department was able to launch communication and public relations programs, clinical education sessions, as well as consultations inside and outside MDACC. The focus on these programs initially focused on the first-third. As a result of positive acceptance by the first-third, members of the second-third began to sign up … and before long the first two-thirds were chiding members of the third-third as 'being behind the times'.
- The result of this was the large growth in referrals to the palliative care program that have succeeded in fully establishing it as a viable clinical and financial program. Note the rapid rate of palliative care consultations in Table 28.1.

The palliative care initiative has continued to increase in use and popularity with consultations continuing to increase and number and cost of deaths in internal care continue to decline. Blending the messages from the three framework elements is essential to effective change. The essential message of this chapter, therefore, is for leaders to:

- take strong, aggressive, visible action with/through the 'first-third' managers and professionals
- alter the mechanical attributes of the organization that will enact palliative care
- take leadership in healthcare organizations where individuals have high autonomy.

In summary, key to the success of the effective and efficient introduction of palliative care will be the continuing partnership between the committed chief executive and leaders in the management cadre. Dedicated action in the engineering framework described in this chapter … along with huge doses of 'blood, sweat, and tears'… should lead to another palliative care success story.

Key learning points

- The introduction of palliative care can be looked at as a mechanical problem that can be engineered … many moving parts must be identified and changed.

- Individuals have different rates of change acceptance … plan to work with the most eager supports of palliative care first.

- Changing an organization's way of operating requires aggressive, visible, hands-on leadership. The boss must want and support palliative care.

- Get the physical assets needed for palliative care in place early on so that the organization can see tangible organizational commitment.

- Involvement of professionals must be done at every step of the way. Involve them now to have them own palliative care later.

Cost avoidance and other financial outcomes for palliative care programs

J BRIAN CASSEL, THOMAS J SMITH

INTRODUCTION

Of all the imperatives and outcomes for palliative medicine and palliative care programs, one would hope that financial issues would rank as among the least important. Surely the other motivations for palliative care, and effects thereof – humanitarian, moral, ethical, clinical, to name a few – should be more important than costs and reimbursement. Be that as it may, financial questions are crucial for the success of palliative care, regardless of the country, system of healthcare, institutional values, and personal commitments of those involved.

Most physicians, nurses, and others who seek to begin or expand palliative care within a hospital or health system know that it will be necessary to make an accurate and compelling financial case for doing so. Clinical revenue is rarely sufficient to support the whole multidisciplinary team,[1] so palliative care teams have made their financial arguments around the notion of cost avoidance.

What do we know, given that the field is relatively new and rapidly growing? The literature to date provides two conflicting conclusions about the financial impact of palliative care. One is that palliative care has little or no impact on medical costs; 'palliative care appears to have roughly zero net effect on patient medical costs …' is how the outcome of a cost benefit analysis is described.[2] In contrast, we know from our own experience[3,4] and the success of other programs that palliative care programs are making a compelling financial case based on cost-avoidance, convincing their institutions to invest significant resources. For instance, based on their internal studies of pilot projects,[5] Kaiser

Permanente is now investing over US$2 million dollars to roll-out a home-based palliative care program for its entire southern California region (David Brumley, personal communication, 18 February 2005). Cost-avoidance data are integral to justify investments in hospital-based programs.[6]

The mixed conclusions result from different definitions of what is 'palliative care'. Boni-Saenz et al.[2] lump together hospice and palliative care, and their 'no savings' conclusion is based largely on the mixed evaluations of hospice costs in recent years, which now question the long-held assumption that hospice saves significant utilization and total costs. In contrast, our analyses of the financial impact of palliative care focus on an acute palliative care program that is not synonymous with hospice care.

Looking at how this hospice cost debate is playing out, one can surmise that the hospice movement in America today has become inexorably tied to the Medicare hospice benefit (and its inherent cost-avoidance foundation). Witness the cautionary statements issued by a hospice advocacy group, National Hospice and Palliative Care Organization (NHPCO), such as 'retrospective studies can be difficult to analyze and findings must be kept in perspective'[7] about a very strong study[8] which had indicated that hospice adds to healthcare costs for noncancer patients of all ages. NHPCO's own study[9] found no cost difference related to hospice enrollment for 12 out of 16 disease groups it studied ($P < 0.05$ with no correction for multiple tests). Of the four disease groups for which hospice use was related to cost differences, there was such a large increase in costs for stroke patients (US$12 331 per patient)

that in equal numbers they would largely cancel out the savings found for the three disease groups that demonstrated cost savings: liver cancer, pancreatic cancer, and congestive heart failure (US$14 936 combined per patient).

Clearly, both studies call into question the assumption that the Medicare hospice benefit saves Medicare money in the long run. Like many observers we believe that the hospice movement in the USA has painted itself into a cost-avoidance corner. We would caution the field to avoid basing the rationale for palliative care solely on a cost-avoidance foundation. Rather, one should fully exploit existing data to understand when and how palliative care does avoid utilization and direct costs, and to honestly admit when it does not. After all, the main goal is better patient care, and cost-avoidance is just one means of convincing administrative leaders to invest resources toward that end.

UNDERSTANDING THE RELATION BETWEEN PALLIATIVE CARE PROCESSES AND FINANCIAL OUTCOMES

Palliative care rests on two philosophical foundations: (i) zero-tolerance of suffering, which provides the basis for its focus on symptom assessment and management; and (ii) an acceptance of death and the dying process, which results in the comfort care alternative to relentless high-tech interventions aimed at extending life at any cost.

Thus palliative care programs show two *personae*: one that is concerned with preventing and ameliorating symptom distress for all patients at any point in their disease course; and another that is primarily focused on questioning, clarifying, and challenging the assumed life-extending goals of care at certain critical points in the disease process. A good multidisciplinary palliative care team will have expertise in both aspects and be recognized by other professionals throughout the institution for both strengths.

We contend that almost all cost savings will follow from the goal-setting aspect of palliative care, although better symptom management may prevent some emergency visits and inpatient admissions. See Table 29.1 for our summary of the relation between clinical and financial aspects of palliative care.

RELATIVE TO WHAT?

From a program evaluation perspective, the question of palliative care finances should be framed in terms of 'relative to what exists otherwise'. But dying patients and others

Table 29.1 *Palliative care program features that have possible financial outcomes*

Feature of palliative care program	Possible financial impact
Pain and symptom specialists alleviate and prevent suffering; best possible management of all symptoms	Within acute admission, small impact on individual length of stay and perhaps on likelihood of quick re-admission is possible. If achieved over longer period of time in home setting, may prevent emergency visits and inpatient admissions significantly
Team members clarify and possibly change goals of care when intensive care and procedures are not producing a marked improvement in patient disposition	If impact on goals of care is significant (e.g., moving patients from critical to acute care, or reducing orders for ancillary services such as diagnostics and drugs), then financial impact may be large. Financial impact will be negligible if the clinical impact is negligible
Presence of palliative care unit gives patient, families, and providers an attractive alternative kind of end-of-life care	May prevent escalation from acute to intensive care unit (ICU) level care. May encourage transfers from ICU to comfort care. If ICU beds are scarce, this may allow ICU beds to be used by other patients who are more likely to benefit from them – traumas, surgeries, etc.
Presence of, or quick access to, palliative care team in emergency department (ED); ED team may call palliative care for consult when patients present with late-stage disease for whom symptom management and comfort care is most appropriate	This prevents such patients from going to ICUs or other units and receiving procedures or testing from which they would probably not benefit. It is easier for palliative care to be included in goals of care at the time of admission, than for the palliative care team to facilitate a change of goals at some point during the admission
Multidisciplinary team that prevents and ameliorates physical, emotional, psychosocial, and spiritual distress	Patients and families who are highly satisfied with care are probably more likely to refer their friends, return when they themselves are sick, and perhaps donate money or volunteer their time
Palliative care team refers more patients, earlier, to hospice	May improve the length of stay in hospice, which may help hospice program to operate at higher margins. However, some evidence indicates that expanding use of hospice with some disease types may result in lower margins

who would benefit from palliative care may comprise 5 percent or less of most departments' admissions. With responsibility for them diffused across all providers, disciplines and cost centers, most hospital or health system administrators will have little understanding of the nature of their care and the costs and reimbursement thereof; the palliative-appropriate population is almost entirely 'under the radar' for administrative and clinical leaders in most institutions. One of the critical differences that palliative care programs make, clinically, is to halt that diffusion of responsibility, and to provide accountability for the nature and cost of the care of such patients. See Table 29.2 for a further analysis of the diffusion of responsibility, as well as the concept of diffusion of innovation. Both have implications for the financial aspects of palliative care.

One of the first steps, then, in planning for and evaluating palliative care programs is to assess the status quo before the team begins to change bedside practices, clinician education, and institutional culture. A series of leading questions are provided in Box 29.1 for such an assessment.

Delving into the baseline or status quo data on this issue is important not only for eventual program evaluation, but also for program development: it may help the nascent palliative care team better understand what they could change; and it may help administrators understand this unknown patient

---

Box 29.1 Ten questions to ask about patients dying in your institution before palliative care team begins

1 How many patients die in system each year?

2 What was their first location, department, admitting service, registration source?

3 What was their end location, department, discharging service, length of stay (LOS)?

4 What were all the locations and departments in between?

5 What were the diagnosis-related groups (DRGs), primary disease groups, and acuity?

6 What were the patients' demographics and history of utilization prior to last admission?

7 What was the quality of care?

8 If ICUs and intensive procedures were used, at what point during admission?

9 What were the costs of care – the total, pattern per day, kinds of cost drivers?

10 Were there any opportunities where a palliative care team could have made a difference?

Table 29.2   *Two 'Diffusions' relevant to palliative care and financial outcomes*

	Diffusion of responsibility	Diffusion of innovation
Source	Latane and Darley, 1968[10]	Rogers, 1995[11]
Concept	Knowing that others are available to take action reduces the likelihood that any given individual will take action Problems remain unaddressed	Getting a good idea disseminated and adopted throughout a group is often harder than one thinks it should be. As the innovation is increasingly adopted, the baseline for evaluating impact moves and changes as well
Relevance	It is difficult to manage symptoms and clarify or change goals of care, and these tasks do not belong to any one specialty. Palliative care specialists may break the cycle of denial and inattention by taking responsibility, by refusing to pass the buck, by not assuming someone else will have the difficult conversations and tackle the intractable symptoms	One method of diffusing innovation is to get the new behavior adopted by opinion leaders such as chief residents. Palliative care teams have learned (sometimes the hard way) to ignore those physicians who would reject the innovations of palliative care, and to focus instead on those who are likely to be early adopters and who would also be persuasive change agents for their peers
Implications for financial aspects of program development and evaluation	Prior to the palliative care team's existence, no one in the institution has a good idea of the extent of suffering, futile intensive care, the cost of care for dying patients, etc. Thus palliative care teams must first generate the baseline data about the problem, both to garner support and to establish goals and benchmarks. Demonstrating the need for the program, and its effects, are equally important aspects of ongoing program development and evaluation	A goal of most palliative care teams is to educate other clinicians about symptom assessment and management, and goal clarification. Some take this one step further, and aim for institutional culture change. As these innovations become adopted and diffused throughout an organization, the baseline moves – the natural 'comparison groups' against whom we can measure the quality and cost of the palliative care patients are also improved. If the culture change is thorough and complete then it is difficult to say that patients treated by a palliative care team will look markedly different than those treated elsewhere. We can only hope.

population, and current costs. Conducting and sharing financial analyses on the target population – complex and dying patients (however defined in a given setting), may itself be an educational intervention for administrators and department chairs, whose attention may be drawn to that population for the very first time.

Before continuing with our examination of approaches to assessing palliative care, we should address the natural question: since palliative care is not concerned only with dying patients (and indeed some programs may studiously avoid focusing on death and dying), why focus so much analysis on patients who did die? Much palliative care research uses dying patients in analyses to provide an adequate comparison group, because they have the complexity of care (symptoms, psychosocial, family needs, goal clarification, etc.) that are typical of patients who would benefit from palliative care. And philosophically, if the palliative care team does not take responsibility for dying patients, who will? For these reasons, many studies of palliative care use patients who died as the population.

EVALUATING FINANCES OF PALLIATIVE CARE PROGRAMS

Informally, we would say that palliative care programs cannot be evaluated as 'silos' – evoking the image of a lone structure separate from others. Traditionally most business analyses in healthcare treat each department and program as a financial silo that must produce sufficient revenues to cover the costs of its treatments. In contrast, we contend that palliative care programs will have two populations of patients: those admitted directly to the palliative care units or services, and those transferred to palliative care from intensive upstream services such as neuroscience, oncology, and cardiology.

A 'silo' analysis is indeed appropriate for the former set of patients, at least as a start: care begins and ends under the control of the palliative care team, and all reimbursement for the case is attributable to the program itself. For patients transferred to palliative care at some point usually late in the admission, the question is, what cost differential does the palliative care program achieve for each day the patient is under its care, rather than standard care? What would have happened with those patients had the palliative program not existed? Because the goals and nature of the care on the palliative care unit (PCU) are dramatically different from those elsewhere in the hospital, the costs are generally much lower.

The lesson is deceptively simple. Palliative programs get at least half of their patients from upstream services, and have an institutional impact via cost avoidance rather than a local impact via revenue generation. At the heart of this issue is clarifying or changing goals of care so that patients who are not responding to curative or life-extending care (e.g. in intensive care units (ICUs)) are offered care that

focuses mostly or entirely on palliation, comfort and perhaps life closure.

INSIDE THE COST–AVOIDANCE CLAIMS OF PALLIATIVE CARE PROGRAMS

The most critical questions – and perhaps those least understood – about finances are those pertaining to cost avoidance, which is a result of comfort care goals, and that is what we will focus on in this section. We have organized this section by a series of questions.

1 Do palliative care interventions change the nature of the care provided, such that it is less intense, and therefore less costly?
   – Critical or intensive care is the site of a great deal of expensive, high-tech care for patients, some of whom do not benefit from this level of care. At the point when the care team and family recognize that comfort care would be more appropriate and beneficial for a given patient and family, the palliative care intervention can facilitate a profound change in the goals of care and thus the cost as well. In the inpatient setting, simply moving the patient from intensive to acute care can reduce the cost per day by hundreds of dollars. A typical pattern is shown in Figure 29.1, where we have disaggregated our patient population into those patients who were at high cost care, and compared them with patients whose care was already low cost.
   – However, one must not assume that just because a palliative care consult or other intervention has been done, that the care goals have been dramatically changed. As with any program evaluation, one must determine in each instance the nature, strength and penetration of the intervention (process evaluation), before assessing its impact (outcome evaluation).
2 What other financial implications are there for moving patients out of intensive care units, when they are no longer benefiting from that kind of care?
   – Most hospitals' bottlenecks occur in the ICU, and increased throughput at that critical juncture can allow for increased surgical admissions and fewer diversions. Surgeries are usually the most profitable treatment for hospitals to conduct, so anything that increases the hospital's ability to keep patients moving through its operating rooms is going to be beneficial to the bottom line. If a patient dies in the ICU after a 30-day stay, but the team knew on day 15 that the ICU was doing more harm than good for the patient and family from then on, how many other patients would have benefited from that ICU bed in the last 15 days? Does a Level 1 trauma center on diversion due to a full ICU serve its purpose, or might more patients benefit both from trauma care or transplantation of donated organs if there was no diversion?

Figure 29.1 at top with its caption to the right:

Last five days prior to death
Figure 29.2   *Cost-avoidance analysis of days in palliative and nonpalliative settings. Cost per day, PCU versus acute medical-surgical cancer unit, last 5 days before death, at Virginia Commonwealth University (VCU) Medical Center. N = 133 patients, 65+ years old, cancer as primary diagnosis this admission, LOS at least 5 days, admission ended in death, in 2001–02. For the most part this is a between-groups analysis, although some patients (21 percent) transferred from non-PCU services to PCU during these last five days; the analysis is conducted at the 'day' level with each day coded as to location.*

3   What about patients who are already being treated in standard medical-surgical acute beds, and not in ICUs? Do palliative care programs still show an impact on ancillaries for such patients?

– This question was answered by the special study we did for the *Wall Street Journal*.[4] In that study we looked at the costs per day for patients who were 65+ years old, with a primary diagnosis of cancer, who died in the hospital, after an admission of at least 5 days. We used only the last 5 days prior to death so that it was the same time-frame for all patients. PCU patients' pharmacy costs were US$511 during those 5 days, compared with US$2267 for non-PCU patients; lab costs were US$56 versus US$1134; and radiology US$29 versus US$615. Supplies and other treatment costs showed similar differences. There was little difference in the room costs, as they were almost all in acute medical-surgical beds.

– Figure 29.2 shows the day-to-day pattern of costs for these ancillaries prior to death, not previously published. The costs spike for several categories on the last 2 days before death.

4   What about patients admitted directly into the PCU, rather than being transferred from another unit elsewhere in the hospital?

– Palliative care isn't just about changing an established goal of care, it is also about being in the right place to determine the course of care from the point of admission forward. Over the years, our palliative care program has established a closer and closer connection with the emergency department, where so many patients arrive for admission, and where the goals and level of care are determined on day 1. A palliative care consult can have a tremendous impact in that location by helping the emergency staff consider palliative care alternatives to intense,

high-tech, life-extending or curative care. We believe that taking over control of care for appropriate patients right at the point of admission will be much easier for programs that have a dedicated unit, to which such patients can be sent, rather than a consult service only. At Virginia Commonwealth University (VCU), our direct admits to the PCU are profitable, as well as being at least one-half as costly per day as care in other units. These direct admissions have increased from just 32 cases in 2001 to 85 in 2004.

5 In typical hospitals, many patients who start to die are transferred from acute med-surg beds to ICUs, where the ensuing death takes place. Do hospitals with palliative care programs show less of that pattern?

– This would be a natural consequence, though not necessarily articulated as a goal, for mature palliative care programs, and is similar to the question of direct admissions at the point of the ED. As a palliative care team begins to have an impact on the culture of its institution, do clinicians begin to recognize *ahead of time* when using the ICU would be futile? Do they begin to accept that an ICU is not necessarily the place to achieve the best care, and a good death? We do not have data on clinicians' attitudes at VCU regarding this, but we do have data on 'escalation of acuity' that speak to this trend.

– In 2 years the number of adult cancer patients whose care trajectory went from acute to ICU, followed by death in the ICU, dropped from 27 to 12. Combined with fewer patients remaining in ICUs to die once they started there, our hospital has seen fewer such patients (adult cancer patients who die in the hospital) using the ICU at all during their final admission – from 40 percent in 1999 to 30 percent in 2003. There were no other interventions during this time that would explain this difference in care. This is the opposite of the trend toward higher intensity deaths in the USA documented by Barnato et al.[12]

6 Do home-based palliative care programs also show a reduced utilization and therefore cost?

– As mentioned in the introduction, the Tri-Central (California) Kaiser Permanente program has shown just that (for cancer and chronic obstructive pulmonary disease but not statistically significant for congestive heart failure).[5]

7 How are quality of care, the use of palliative care services, and cost of care all related?

– Few studies have been conducted to date that tie all of these pieces together. One intriguing study, however, was the benchmarking study conducted by the University Healthcare Consortium (UHC) using about 40 chart reviews each from 35 member institutions, for a total of 1596 cases. Most (90 percent) of these cases did not actually receive palliative care services but based on their selection criteria (certain DRGs, prior admissions, and LOS for target admission), were likely to be of the kind of complex, later-stage, typically high-symptom load patients for whom palliative care is thought to be most helpful. This study demonstrated three things: although care for most patients was sub-par, it was better for the 10 percent who received palliative care services; that the higher the quality, the lower the cost and LOS; and palliative care services were correlated with lower cost.[13] Thus, cost and quality are inversely correlated for all patients, and for those receiving palliative care, palliative care is correlated with higher quality and lower cost. About one-half of the difference in cost can be accounted for by the shorter LOS, while the remainder was due either to lower intensity or less use of ancillary services.

CONCLUSIONS AND FUTURE DIRECTIONS

Unlike biomedicine, health care finances are usually not measured in terms of confidence intervals and *P* values; business decisions are usually not made on the basis of experiments with patients randomly assigned to treatment conditions. Indeed, most internal assessments of program successes and failures are not documented and published. For these reasons, much of the data we have seen to date on palliative care financial outcomes, especially cost avoidance, range from anecdotal to correlational; most are based on nonscientifically designed data analyses.

The field would benefit from more research designs that assess inputs and outputs at a patient level or population level (rather than at an admission level) such as that employed by Brumley et al.[5] Also, we need prospective and longitudinal studies that can determine at which point for which patients palliative care is presented as an option and actually implemented. These kinds of research designs are especially important as the maturing movement of palliative care begins to address care from diagnosis forward, and not just a few hours or days before death.

We also look forward to multicenter studies that can assess whether consultative services have the same kind and degree of clinical and financial impact (or for the same kinds of patients) as dedicated units. Or, whether other aspects of program design are important, such as the degree of clinical control that the palliative care team has after their initial consultation. In such studies, we hope that the financial outcomes would be studied with as much rigor and interest as clinical effects.

Another research approach that will become more important in the next 5–10 years is whether incentives and disincentives provided by payors (e.g. extra payments for better symptom management) have an impact on the field of palliative care.

Key learning points

- The imperatives for palliative care include financial issues, but the main goal is better patient care.

- The evidence for cost avoidance in hospice is mixed.

- The evidence for cost avoidance in acute palliative care is sufficient for investment.

- The financial outcomes of palliative care programs are not limited to cost avoidance.

Organization and support of the interdisciplinary team

KAREN MACMILLAN, BETTE EMERY, LOUISE KASHUBA

INTRODUCTION

Palliative care encompasses the physical, psychosocial, and spiritual dimensions of the patient and family. The expertise of various healthcare professionals is necessary to manage their complex needs.[1–18] In this chapter the interdisciplinary team will be explored. Team composition, communication and collaboration strategies, and support and leadership for interdisciplinary teams will be outlined. Areas of required research will be identified. Interdisciplinary teams can provide care and support in all settings, however the focus will be on specialized palliative care units.

To discuss the organization and support requirements for professionals, terms need to be defined to foster a common understanding. Multiprofessional teams have existed since the early 1900s in the interests of achieving efficiency by reducing cost and minimizing interventions.[14] Multiprofessional teams are either multidisciplinary or interdisciplinary. There is a notable distinction between multidisciplinary and interdisciplinary teams.[4,14,17,19,20] Multidisciplinary teams consist of independent healthcare professionals who conduct independent assessments, planning, and provision of care with little communication or coordination with other team members. In a multidisciplinary team the physician traditionally prescribes the involvement of the other team members. Interdisciplinary teams, in contrast, function as collaborative units working together to establish common goals of care. Automatic referral is assumed for each team member; the professional, along with the rest of the interdisciplinary team, determines the focus of intervention. In order to provide care, the interdisciplinary team uses skills of communication, problem solving, and goal setting to enhance the collaborative nature of interaction between team members.

INTERDISCIPLINARY TEAM: COMPOSITION

There are many publications on the value of interdisciplinary teams in palliative care, however, there is a paucity of research to support this belief.[5,21–23] Although palliative patients and their families report satisfaction with the interdisciplinary approach,[24–28] there is an absence of substantive research to fully describe the benefits.[5,21–23,29] Systematic literature reviews, meta-analysis and meta-regression of published research on the effectiveness and impact of palliative care teams and models of care have been inconclusive.[5,21–23,30] Inherent problems with all of these studies exist because of the vulnerability of the terminally ill patients being studied and the lack of comprehensive outcome measures. Nevertheless, even with the poor quality of the studies, there is evidence that palliative care teams have a positive effect on patient symptoms, length of stay, patient/family satisfaction, and costs.[6,8,9,11,22,24–28,31–44,53]

Interdisciplinary teams can ensure comprehensive coordinated care. This requires time and financial resources in order to be successful.[14,45–48] Some question the costs associated with multiple disciplines and caution about the effectiveness and efficiency of too large a team.[48] Yet others have demonstrated that developments of comprehensive interdisciplinary palliative care programs/teams are cost effective in a variety of settings.[8,11,30,49] Again, there is limited research exploring team composition or team size based on patient caseloads.

Members of the interdisciplinary team may include:[3,6,8,12,16,17,50,53]

- Art therapists
- Dieticians
- Holistic health practitioners
- Music therapists
- Nurses
- Occupational therapists
- Pastoral/spiritual care
- Pharmacists
- Physicians
- Physiotherapists
- Psychiatrists
- Psychologists
- Recreation therapists
- Respiratory therapists
- Social workers
- Volunteers

Although all of these disciplines can add value to the patient and family experience, if resources are limited, choices must be made as to which disciplines will be part of the team. Many sources suggest a palliative care physician and a nurse as core members, with other team members added as determined by needs and resources.[9,31,38–40,51,52] The needs of the patient and family ultimately dictate which healthcare professionals are involved in their care. It is equally important that composition of the team reflects the needs of the patient group seen by the service. For example, a service that provides care for a large number of end-stage respiratory diseases might consider having a respiratory therapist as a permanent team member. Alternatively, if disciplines are not represented on the palliative care team, there needs to be a provision to consult them. Tracking the frequency of these referrals can support planning for team composition as programs expand and change.

INTERDISCIPLINARY COMMUNICATION AND COLLABORATION

Communication and collaboration are key aspects of any interdisciplinary team.[1,4,14,17,46,47,54] Each profession's education has unique vocabulary, similar problem solving strategies, and similar world views.[4] Members of each specialty and discipline have a theoretical basis through which they interpret and address issues that arise in their work.[4,55] Team members must excel at their competencies, be secure in their own disciplines, and be able to uphold their ideas.[20] Successful contributing members of an interdisciplinary team require skills beyond those typically acquired in their discipline-specific programs.

Roles within an interdisciplinary team are less well defined than traditional roles of healthcare workers in other settings. As roles often blur, it is important that

team members feel secure, thus avoiding being undermined by these overlapping roles.[12] Role blurring can be problematic if it is not well understood and can lead to under or overutilization of team members. These situations can lead to resentment, burnout and team conflict. Poor communication is one of the major factors preventing effective interdisciplinary teamwork.[4] Exercises which clarify roles, professional competencies, perceptions, and expectations are valuable.[46]

Setting aside traditional roles is required to engage in creative dialog with each other. Each professional reviews the documentation completed by other team members, to clarify information, questions, and concerns prior to entering the patient's room. Patients should not have to repeatedly tell their stories if the team is effectively sharing information. This demonstrates courtesy and respect, as well as conserving the patient's energy. The use of discipline-specific language is discouraged, as plain language is important to enhance understanding and communication. It is recommended that all disciplines document in the same area of the health record. Documentation, including physician orders, must be supported by rationale to enhance understanding by all team members. Avoiding abbreviations enhances communications in documentation.

Team members need to respect, value, understand, and trust each other's contributions.[17,56,57] Effective conflict resolution will foster team growth and maturation. Methods to reach consensus, resolve conflict, and effectively communicate are essential. While allowing for individual differences, bridges are built by striving to understand others' perspectives and ways of doing things. Formal staff debriefing is helpful when case circumstances are particularly traumatic or there have been multiple deaths in a short period of time. If care did not go well, a clinical postmortem can identify ways to improve in the future.

Care planning is ongoing; formally with interdisciplinary team conferencing, and more informally between meetings as the need arises. Weekly team conferences enhance coordination of care with assessment, planning, and evaluation of patient care. This is an appropriate time for team members to identify individual responsibilities related to tasks and interventions.

Family conferences assist in directing care by updating medical information, formulating goals and planning discharge. Not all members of the interdisciplinary team participate in a family conference as having all of the professionals involved may overwhelm the patient and family. The goals of the family conference and the patient will dictate which team members attend. To ensure a comprehensive picture, it is helpful to elicit pertinent input about the patient's level of functioning from team members not attending the conference. When there is conflict a family conference may help to problem solve and/or support behavioral changes. Both team and family conferences may serve as a forum to exchange ideas, share information, set goals, develop care plans, and solve problems.

SUPPORT FOR THE INTERDISCIPLINARY TEAM

Individual team members and the interdisciplinary team require support to ensure the success of the team.[58] Team members must be clinically competent in their discipline and be committed to improving their practice through ongoing education. There needs to be recognition that each member will be at a different stage in his or her professional and personal development. Team members are encouraged to be involved in discipline-specific professional development activities such as participating in special interest groups, courses and reading professional journals.[54] Completing an oral presentation for educational rounds provides the team member a forum to present subjects relevant to their discipline and to other disciplines. These represent only a few of the many possibilities for professionals working in palliative care. The intense nature of work in palliative care, as with most high-demand specialty areas, requires diverse opportunities to reflect, grow, and find balance.[58] Support is necessary at the group level as well as at the individual level coming from within the group itself as well as from administration.

Support requirements of an interdisciplinary team are greater than a sum of the needs of the individuals. Within the work environment, the development of supportive, collaborative relationships is fundamental.[4,47,59] Factors for coping are planned orientation, ongoing education, administrative support, and an environment conducive to team building.[60]

Planning a comprehensive orientation for new staff extends beyond the organization's corporate orientation. The new team member must understand the roles of each discipline. When possible, a new team member overlaps with the team member they will replace. Time spent job shadowing prior to being independent allows scheduled time with a professional to answer questions and support the individual. Well-established teams can be daunting; therefore strategies to integrate a new team member need to be considered. Assigning a mentor may help. Those in remote areas need mentors to call for consultation and support. New programs should consider partnering with successful programs, as this can provide them with a wealth of knowledge and support.

Keeping abreast of developments in a cutting edge field can be challenging. A variety of palliative care texts, websites, professional peer-reviewed journals and subscriptions to listserves are available as resources for information for professionals. Journal clubs and weekly rounds are a structured means of advancing knowledge. By sharing an article or presentation the individual professional has the opportunity to discuss ideas with their colleagues to glean their perspective. Workshops and conferences are also educational but may be cost prohibitive. Distant learning or video conferencing may be more economical. Often availability of resources is not the problem; the limiting factor is time.

Commitment from administration for time and education opportunities as well as acknowledgment of interdisciplinary and individual projects contributes to the success of the team.[2,46,59,61] Adequate space for meetings and individual offices or workspaces in close proximity to one another can enhance teamwork and collaboration.[62] Space in offices that allow for counseling patients and their families may be required for team members such as the chaplain and social worker.

LEADING INTERDISCIPLINARY TEAMS

Program management is an ideal structure, given the unique composition and needs of the palliative care interdisciplinary team. This is a management structure in which groups of professionals with skills and expertise care for a specific population of patients. Co-leaders may be necessary for managing the team. It is common that the leaders are a nurse and physician; although any discipline with management expertise, education and skill could fill the nurse leader's role. The structure usually has physicians reporting to the physician leader and other disciplines reporting to the other co-leader (program manager).[63] The physician leader engages the palliative physicians to ensure their accountability and responsibility as team members. The program manager has the same responsibilities with all other disciplines. The program manager is also responsible for management activities such as budget, finance, hiring, operations, and administration of the program. The co-leaders provide vision and direction for future planning, as well as drive and support change. Since team members report to the program manager, there needs to be a mechanism for managing professional issues that is specific to each discipline.[63,64] Support and guidance may be necessary from a professional peer as well as the program manager.

Clearly defined and established mission, purpose, standards of care, values and goals to guide and support the interdisciplinary team are foundational concepts.[2,62,65] The involvement of team members in articulating these concepts is essential as this supports team development and future strategic planning. Strategic plans should be agreed upon by team members and revisited on a yearly basis. Consumer satisfaction surveys, outcome measurements and program evaluations may also shape the program's future directions.[34] Outcome measures chosen must reflect the goals of the program.

Commitment and ongoing support by senior administration is key to successful program management models of care delivery.[66] The leaders need to be clear on the direction of the program and be able to make decisions in order to achieve the team's agreed upon goals. The primary focus of the leaders is to serve the needs of the team, empower them in delivering care and advancing knowledge and skill in palliative care.[67,68]

One of the greatest barriers to an integrated team approach to end-of-life care is the structure of healthcare financing.[15] Physicians traditionally bill the healthcare system or the insurance company directly, whereas the program

manager budgets for the other disciplines within the inter-disciplinary team.[15] System reimbursements for physicians ought to address the importance of spending adequate time with the patient and family, the need for family meetings and team meetings, as well as the appropriate utilization of costly interventions in terminal care. The cost of the palliative care interdisciplinary team must be justified to senior administration. A database to collect information that quantifies time and tasks performed by each discipline in providing care to patients assists this process. Team members must understand the significance of collecting and recording these data. This not only substantiates costs in the current program but also aids in projecting future resource requirements. Once the financial offsets are considered, the interdisciplinary approach to palliative care is a cost effective program.[24,30,37,40,42] Leaders of palliative care interdisciplinary teams must be prepared to face the aforementioned administrative challenges by developing a strategic plan based on evidence and data analysis. Ensuring that the administrative needs of the program are addressed ultimately leads to a better functioning team that can more effectively provide care to the patient.

FUTURE DIRECTIONS IN RESEARCH

There are many unanswered questions related to interdisciplinary teams in palliative care.[4,12,23,69] Examples of possible research questions include:

- What outcomes need to be measured?
- Do interdisciplinary teams provide more holistic and effective care?
- How is palliative care best delivered?
- How are interdisciplinary teams best organized?
- Which disciplines are essential to a palliative care team?
- What size and composition of interdisciplinary teams are most cost effective?
- What environments and practice settings benefit from having an interdisciplinary team?
- Are members of interdisciplinary teams more satisfied with their work?

CONCLUSION

Successful teams value and support their members, have a commitment to improve communication, resolve disagreements, and provide services. Support for individuals within the team to pursue professional and personal growth is encouraged. A coordinated effort by administration and leadership is required to meet these needs. The key factors for the success of the palliative care interdisciplinary team are vision, leadership and coordinated delivery of care, respectful interactions, professional development, and competence.

Key learning points

- The composition of the interdisciplinary team in palliative care is determined by the unique needs of the patient population being served.

- Effective role blurring is essential for the coordinated delivery of care.

- Concentrated efforts to hone communication and collaboration skills are needed to facilitate team growth.

- Commitment at all levels of leadership is required for the interdisciplinary teams in palliative care to succeed.

Population-based needs assessment for patient and family care

IRENE J HIGGINSON, CHARLES F VON GUNTEN

INTRODUCTION

As palliative care services develop all across the globe, those planning and funding services for populations of people will seek to ensure that services are developed in a way to meet the needs of patients and families. This is a group of the population which is often least able to make their needs known – as Hinton said, 'the dissatisfied dead cannot noise abroad their concerns'. So it is often left to patient groups and professionals to advocate for them. Policy makers and planners responsible for the healthcare services to a population have to make decisions that involve a range of health services. One way to help to plan services is to undertake a population-based needs assessment. Thus, to negotiate with planning officers, governments and funders, and to develop services, those working in palliative medicine have to develop a good understanding of needs assessment.[1] This chapter explains the concepts of needs and shows various methods of needs assessment. It highlights some of the pitfalls and factors that should be considered in the different approaches. Needs assessment in this context takes as its starting point a community that requires palliative care, rather than individual patients. It is concerned with how many people need what types of service, and where and when. The assessment of an individual patient can occasionally be described as a needs assessment,[2] but this is a component of assessment for direct clinical care planning and is not considered here.

WHAT IS NEED?

Contributions to the definitions of need come from the fields of sociology, epidemiology, health economics, public health as well as from clinicians. Bradshaw outlined a 'taxonomy of social need'. This distinguished between:[3]

- felt need (what people want)
- expressed need (felt need turned into action)
- normative need (as defined by experts or professionals)
- comparative need (arising where similar populations receive different service levels).

Raised within these distinctions are the questions of:

- Who determines need (professional, politician, or public)?
- What are the influences of education and media in raising awareness about health problems?
- What are the cultural effects on need?

Social and cultural factors have an enormous impact on levels of morbidity and on health and the expression of health need.

CONCEPTS OF NEED, SUPPLY, AND DEMAND IN HEALTHCARE

The above definitions of need do not take account of whether there is an effective remedy or treatment (i.e. supply) that
Figure 31.1   *Relationship between need, supply, and demand. Need = ability to benefit from healthcare.*
Figure 31.2   *Ideal relationship between need, supply, and demand.*

can be provided for the problem experienced by the patient. Any assessment of the health needs of a community must take this into account. Thus needs assessment includes both the health problem (whether felt, expressed, normative, comparative, or a combination of these) and an effective humane and accessible remedy or treatment for this problem.[4] The remedy can include prevention, treatment, rehabilitation, and palliation. The modern epidemiological approaches to needs assessment take account of both health need and effective treatment.[5]

Demand in healthcare is a function of expressed need, although economists would define it as: 'What people would be willing to pay for in a market or might wish to use in a system of free health care'.[5] Demand, therefore, is influenced by the nature of information available to patients and to communities, the social and educational backgrounds, the media and the influence of doctors and nurses. Furthermore, for any patient or family, interpretation of information would be affected by the severity of his or her illness and his or her concern about that illness. The supply of health services has been influenced by historical patterns, political pressures, pressures from healthcare professionals, from the public, the media, and from patients.

Stevens and Raftery have argued that need for healthcare should be defined as: 'the population's ability to benefit from health care'.[5] They argue that need, supply and demand partly overlap but also differ. Figure 31.1 demonstrates the differences and overlap, and shows seven different potential situations.[5] In the central area, need is both demanded and supplied. However, there may be supply where there is no need, there may be care demanded but not needed, and there may be demand and supply without need. The aim of a needs assessment in this context is to bring the circles to overlap more closely (as in Fig. 31.2), so that need is demanded and supplied. However, this Stevens and Raftery hypothesis has one major flaw. It makes a rather simplistic assumption that need, demand, and supply are of equal size, and that reorganization of healthcare is a matter of lining up the need, demand, and supply. But in reality this is not likely to be the case. As part of the MSc in palliative care at King's College
Figure 31.3   *Are the areas of need, supply, and demand of equal size? One hypothesis.*

London, students from different countries report how they feel need, demand, and supply are related and sized in their countries. Figure 31.3 shows one hypothesis, where supply is smaller than demand and need.

ALTERNATIVE APPROACHES TO NEEDS ASSESSMENT

Three main approaches to needs assessment have been developed. These can be used independently or in combination.

Comparative needs assessment

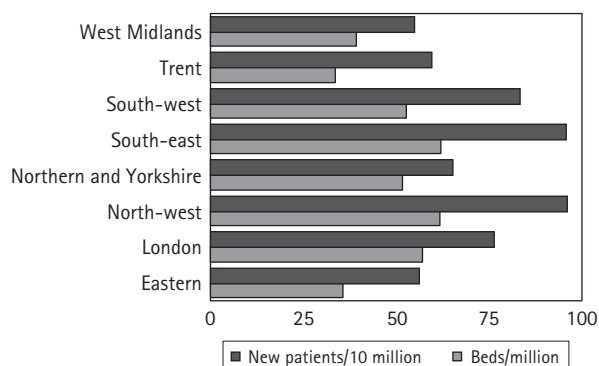
A comparative needs assessment contrasts the services received by a population in one area with those elsewhere. Thus if one area has, for example, 40 hospice beds per million population it might be seen as less well provided than an


Figure 31.4   *An example of comparative needs assessment – comparing beds available. Beds per million population, new patients per 10 million population: health regions in England (2000). Redrawn with permission from Higginson,* Palliative Care for Londoners, *2001.[37]*
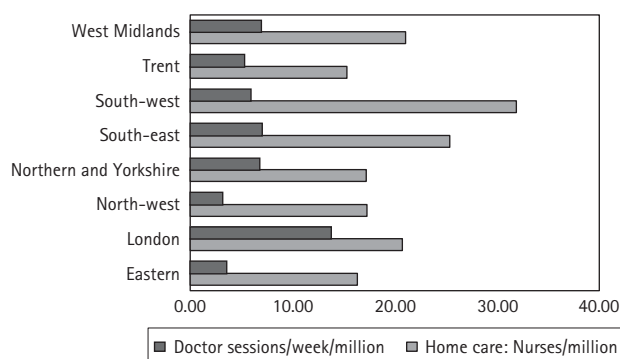

Figure 31.5   *An example of comparative needs assessment – comparing nurse and doctor sessions available. Home care nurses and doctor session per million population, England 2000. Redrawn with permission from Higginson,* Palliative Care for Londoners, *2001.[37]*

area with say 70 beds per million population. Figures 31.4 and 31.5 show examples of such a comparative assessment. However, such an assessment is clearly limited, as it does not take account of differences between the populations, nor of which model of care (more beds or more home nursing) is most effective for the population.

Corporate approach to needs assessment

The corporate approach to needs assessment is based on the demands, wishes, and alternative perspectives of interested parties including professionals, politicians, patients, and the public. A variety of interview schedules and tools in many areas of healthcare have been developed to aid this approach.[6] This approach commonly involves surveys of professionals,[7–9] and may also survey the public, patients,[10] or a combination of views (for example professionals and public).[11] Perhaps the most comprehensive instrument is that developed by Currow *et al.*, who surveyed 3027 randomly selected South Australians in 2000 on the need for,

uptake rate of, and satisfaction with specialist palliative care services. One in three people surveyed (n = 1069) indicated that someone 'close to them' had died of a terminal illness in the preceding 5 years. Of those who identified that a palliative service had not been used (38 percent, n = 403), reasons cited included family/friends provided the care (34 percent, n = 136) and the service was not wanted (21 percent, n = 86). Respondents with higher income and those with cancer were more likely to report that a specialist palliative care service had been used.[12] Currow *et al.*'s approach utilized the views of proxies, i.e. not directly the patients but bereaved carers or others. The corporate approach has the potential advantage of gauging the patient's (or their family's) perspectives and capturing expressed need. However, surveying only professionals captures only normative need. And there is the added problem that expressed need is determined by individual's understanding of services, which is dependent on the provision of information about palliative care. Such information can be highly varied both within and between countries, and should be considered when interpreting a corporate needs assessment.

Needs assessment reviews based on epidemiological data

The third approach to needs assessment is the epidemiologically based assessment. Epidemiological data have been applied in healthcare planning for many years.[4,13] Data on the incidence (the number of new cases arising in a given period) and prevalence (the total number of cases existing at one time) of diseases, and demographic information on population structure and likely changes, were used by healthcare planners to determine the extent and impact of health problems. Epidemiological studies are also concerned with the quality of measurements, including the validity and reliability of tests. Population comparisons are usually more clearly made using rates rather than crude numbers, often giving age- and sex-specific rates or standardized according to the national population.

The epidemiological approach to needs assessment[7] combines elements of epidemiology and health economics and is a triangulation of three components:

● incidence and/or prevalence
● health service effectiveness and cost-effectiveness
● information and views about existing services.
  Information allows funders and planners to determine the direction they wish to pursue in the future (see Fig. 31.6).

Because any needs assessment will usually make incremental rather than dramatic changes to existing services and because there is little information on effectiveness and prevalence, it is usually recommended that this approach is combined with the more simple comparative and corporate

approaches described above. The main components of the epidemiologically based approach to needs assessment are shown in Table 31.1.

EPIDEMIOLOGICALLY BASED NEEDS ASSESSMENT FOR PALLIATIVE AND TERMINAL CARE

In an attempt to provide assistance for those planning and funding palliative care services, an epidemiologically based
Figure 31.6 *The three main components of the 'epidemiologically based' approach.*

needs assessment for palliative (and end of life) care was produced in the UK.[14] This provided standard definitions of palliative and end-of-life/terminal care and used national and local data on the incidence and prevalence of cancer, other diseases and likely symptoms to estimate the numbers of patients and families needing palliative care. The absolute numbers of patients dying from cancer and other diseases likely to have a palliative period are available from government statistical departments in many countries. Applying the prevalence of symptoms to this population gives estimates of the range of problems and the size of population needing care.

The protocol suggests that a standard population size is used, for example 1 million people. Within such a population, if the age and gender mix is similar to that of a developed country, there are approximately 2800 cancer deaths per year and 6900 other deaths, some of which may have a period of advancing progressive disease, when palliative care would be appropriate. Table 31.2 shows the number of deaths within a population during 1 year for the most common causes, and Tables 31.3 and 31.4 show the likely prevalence of problems for patients with cancer or patients with progressive nonmalignant diseases.

These prevalence data can then be contrasted with the numbers who are receiving different services in an area. For example, a needs assessment for the London region showed

Table 31.1 *Components of the epidemiological approach to needs assessment[5,14,37]*

Component	Description
Statement of the context of the problem	The problem in its context including labels attached to the disease or service, e.g. international classification of disease codes, healthcare resource groups. The context should relate the disease to the services it impinges upon
Subcategories	A division of the health problem into categories which are of value to purchasing, planning or providing healthcare. Often this is based on severity or type of problem presenting. Conventional, medical subcategories sometimes do not help
Prevalence and incidence	Prevalence and incidence data including that available for the subcategories described and/or need for treatment. It considers variations by age, sex, region, socioeconomic and ethnic status
Services available	Description of existing services defining the components, including the structures and processes as clearly as possible
Effectiveness and cost-effectiveness of services	The efficacy (benefits achieved under study – usually ideal conditions), effectiveness (the benefit achieved in the real world) and efficiency (output or outcome of healthcare per unit of money expended). Efficacy is considered first and the quality of the evidence is graded according to the strength of design of the studies. This is followed by a statement of the strength of recommendation to support or reject the use of the service or procedure based on the strength of the evidence
Models of care and local assessment	Alternative models of providing services to meet patients needs. For example, one model might be orientated towards prevention, one towards treatment and a third model towards education of existing staff. An appraisal of the models and their application in different social, geographical and healthcare settings is included Here local assessment of individual wishes or local data on the preferences/wishes of patients and families can be used. It may help to decide between the amounts of different models provided
Outcomes, targets, information and research	Outcome measures or targets which might prove useful in practice to monitor services plus other information and research needs

that in the over 7 million population there were 15 780 deaths from cancer each year, and of these it is estimated that 13 260 have pain; 12 200 patients received hospital support each year, and 11 700 home palliative care, suggesting that there may be reasonable but incomplete coverage (see Fig. 31.7). However, the proportion of noncancer patients with symptoms and who received services was much smaller (see Figs 31.7 and 31.8), suggesting a need to develop services for these groups of patients.

Current levels of use of specialist palliative care services can also be used to estimate need. However, this is really a comparative evaluation, and is really only as good as the

Table 31.2   *Number of deaths in the population during 1 year for the most common causes[14]*

Cause of death	Men	Women	Total
Neoplasms	1460	1340	2800
Circulatory system	2430	2620	5050
Respiratory system	600	630	1230
Chronic liver and cirrhosis	30	30	60
Nervous system and sense organs	90	90	180
Senile and presenile organic conditions	20	20	40
Endocrine, nutritional, metabolic, immunity	190	120	310
Total of these diseases	**4820**	**4850**	**9670**
Total deaths from all causes	**5360**	**5640**	**11 000**

Note: total population = 1 million, estimate for developed country.
Note: deaths in those aged under 28 days excluded.

Table 31.3   *Cancer patients: prevalence of problems (per 1 000 000 population, developed country context)[14]*

Symptom	% with symptom in last year of life[a]	Estimated number in each year
Pain	84	2357

Depression	38	1065
Loss of appetite	71	1992
Constipation	47	1318
Bedsores	28	785
Loss of bladder control	37	1038
Loss of bowel control	25	701
Unpleasant smell	19	533
Severe family anxiety/worries	33	930
Severe patient anxiety/worries	25	700
Total deaths from cancer		2805

[a] Symptoms as per Cartwright[15] and Seale[16] studies, based on a random sample of deaths and using the reports of bereaved carers.
[b] Anxiety as per Field *et al.*,[17] Bennett and Corcoran,[18] Higginson *et al.*,[19] Addington Hall *et al.*[20]
Note: Patients usually have several symptoms.

Table 31.4   *Patients with progressive nonmalignant disease: prevalence of problems (per 1 000 000 population, developed country context)*

Symptom	% with symptom in last year of life[a]	Estimated number in each year
Pain	67	4599
Trouble with breathing	49	3363
Vomiting or feeling sick	27	1853
Sleeplessness	36	2471
Mental confusion	38	2608
Depression	36	2471
Loss of appetite	38	2608
Constipation	32	2196
Bedsores	14	961
Loss of bladder control	33	2265
Loss of bowel control	22	1510
Unpleasant smell	13	892
Severe family anxiety/worries[b]	33	2200
Severe patient anxiety/worries	25	1600
Total deaths from other causes, excluding accidents, injury, and suicide, and causes very unlikely to have a palliative period		6864

[a] As per Cartwright[15] and Seale[16] studies, based on a random sample of deaths and using the reports of bereaved carers.
[b] Anxiety as per Field *et al.*,[17] Bennett and Corcoran,[18] Higginson *et al.*,[19] Addington Hall *et al.*[20]
Note: Patients usually have several symptoms.
Figure 31.7   *Example 1 from* Palliative Care for Londoners, *2001. Estimated yearly numbers of cancer deaths, cancer deaths with pain, and patients with cancer who receive different services in the London region. Redrawn with permission from Higginson,* Palliative Care for Londoners, *2001.*[37]

estimated current levels of use. Such an approach maintains the status quo, although it may allow for comparison between areas. There are no really good estimates of 'correct' levels of use of palliative care. Estimates of the proportion of patients with cancer who need palliative care ranges from 15 percent to 80 percent, and are generally not based on good evidence. There are no comparative studies to show the effectiveness of provision at different levels, although there are good studies demonstrating the benefits of palliative care on symptom management and patient satisfaction, suggesting that most patients with cancer benefit.[21,22] The Australian survey discussed above suggested that less that 10 percent (86/1069) of people would not want palliative care services.[12]

INCORPORATING THE EVIDENCE BASE AND OTHER VIEWS

In addition to the data on prevalence of symptoms, an epidemiologically based needs assessment includes data on the effectiveness of different models of palliative care. Rather than attempt new systematic literature reviews, a variety of high quality systematic reviews and meta-analyses are available.[23–33] These show that specialist palliative care has
Figure 31.8 *Example 2 from* Palliative Care for Londoners, *2001. Estimated yearly numbers of noncancer deaths, noncancer deaths with pain, and noncancer patients who receive different services in the London region. Redrawn with permission from Higginson, Palliative Care for Londoners, 2001.[37]*

benefits, particularly in terms of pain and symptom control and patient and carer satisfaction.[34,35] However, most evidence exists for specialist home care, and for inpatient palliative care, either with specialist beds in a freestanding unit or hospice, and/or advisory hospital teams, seeing patients on all wards (see Table 31.5).[23] Other components of palliative care, including day care, outpatient services and hospice at home have not yet been well evaluated. This evidence has now been used in several countries to plan for services and some evidence sources are available on the internet for free download for any groups wishing to use them.[23,32] However, much of the evidence is drawn from developing countries and the evidence base in African and developing countries is (for reasons clear in the chapters about those countries) not yet developed.[36]

Gaps identified between the epidemiological information on need and the services currently provided can then be appraised against the evidence and any comparative or corporate data. The gaps may also suggest lines of inquiry in a survey of patient, carer or professional views, e.g. would they prefer more home care, hospital support or inpatient care developed? This then suggests options for the future development of palliative care services.

LIMITATIONS OF NEEDS ASSESSMENT

Although the approach provides a useful model for examining health needs, it is based on assumptions that limit its conclusions:

- The overlapping circles of need, demand and supply shown in Fig 31.1 imply that if only need, demand, and supply can be lined up, then need and demand will be satisfied by supply. If demand and need are larger than supply, they cannot be met completely, even if improved alignment is of value. A needs assessment, where the supply of palliative care is limited, will lead to a demand for more resources, and health planners may not be prepared for this.
- The data available to undertake the needs assessment are often limited. Epidemiological studies have often been more concerned with the etiology of diseases than the scope for benefit or need for services. For this

Table 31.5 *Summary of evidence of the effectiveness of specialist palliative care services[22,3,24,25,28,34]*

Specialist palliative care service	Studies	Findings: compared with conventional care
Inpatient	1 RCT, >5 comparative, versus conventional care	Equal or improved symptoms, improved satisfaction
Multidisciplinary home care team	4 RCTs, >15 comparative, versus conventional care	Longer time at home, equal or improved symptoms, improved satisfaction
Multidisciplinary hospital team	1 RCT, >10 comparative observational studies	Symptoms and problems improve during care (as for home care and inpatient)

RCT, randomized controlled trial.

reason most of the epidemiological data are reliant on estimates from death registrations and estimates of the prevalence of symptoms in selected populations. Death registrations may not be available and can be inaccurate, especially among older people, where there may also be multiple causes of death. Such data do not take account of the trajectory of illness and the time period that services are needed for. Thus those undertaking the needs assessment must take these limitations into account when presenting the data.

- Effectiveness and cost-effectiveness studies may be carried out in communities different from that where the service is concerned. For example in palliative care, the well-designed randomized controlled trials were carried out in the USA and not the UK. Thus methods of needs assessment are needed for developing contexts, and require some further development.

- Effectiveness and cost-effectiveness are main components in an epidemiological approach. However, humanity, equity, acceptability, appropriateness, and accessibility are also essential in determining the quality of the service. However, it could be argued that without efficacy and effectiveness these are of no value (one would not want a humane service which had no effectiveness or was even harmful). Nevertheless, these are important components of care and, given that effectiveness data are often limited, excluding such components weakens the approach. A corporate assessment is often useful in exploring aspects of appropriateness, acceptability, and humanity, whereas a comparative assessment may throw light on accessibility. These approaches can be combined with the epidemiologically based needs assessment.

- The needs assessment approach was originally developed for disease-oriented single interventions, such as cataract surgery. Applying the model of needs assessment to care groups such as elderly people and, to some extent, to palliative care is more complex. There are multiple possible interventions and multiple possible needs within these populations. This limitation is evidenced by the aspects covered in the early needs assessments: diabetes mellitus, renal disease, coronary heart disease, cancer of the lung, colorectal cancer, hip replacement, hernia repair, prostatectomy, etc. More recently, however, needs assessments have addressed mental illness, dementia, learning difficulties, community child health services, and palliative care. However, the needs assessment in these contexts will tend to highlight a number of possible options, rather than, for example, the number of patients who require a particular operation.

CONCLUSIONS AND FUTURE ISSUES

The epidemiologically based needs assessment approach to planning palliative care services has emerged in the past decade. It has three main components: incidence and/or prevalence of a disease or condition; effectiveness and cost effectiveness of services; and review of existing services. It can be combined with corporate and comparative approaches to needs assessment. This information is combined and culminates in recommendations for particular procedures or interventions based on standard criteria for the quality of evidence and an appraisal of alternative models of care.

Because the approach is time-consuming and subject to limitations, some guidance is available, especially on the effectiveness of models of care and on incidence and prevalence guidance. However, there is a need to further develop approaches to needs assessment in developing countries and those where there is little palliative care. Ideally a template is needed, which can be applied to different settings. Presentation of the data to local groups (statutory and voluntary and at public meetings) can help to facilitate discussion about where services should develop in the future.

Key learning points

- There are four main elements of need: felt need, expressed need, normative need, and comparative need.

- Need, supply, and demand for services may not overlap.

- There are three common approaches to needs assessment, all of which have been used in palliative care.

- A comparative needs assessment determines need by a comparison of supply between areas.

- A corporate needs assessment determines needs by taking views from local stakeholders.

- Both of these approaches can tend to confirm the status quo, rather than identify groups who are missing out on care more fundamentally.

- An epidemiological approach to needs assessment examines the incidence and prevalence of problems, the effectiveness of services and the services available and views on these.

- The epidemiological approach can be combined with the comparative and corporate approaches.

The palliative care consult team

ALEXIE CINTRON, DIANE E MEIER

INTRODUCTION

Larger numbers of patients treated in hospitals are not imminently dying but are living with chronic and debilitating illnesses. In addition, virtually all persons with serious illness spend at least some time in a hospital, usually on multiple occasions, in the course of their disease or condition.[1] Unfortunately, hospital care of these patients is often characterized by untreated physical symptoms, poor communication between providers and patients, treatment decisions in conflict with prior stated preferences, treatments that may be more burdensome than beneficial, and poor care transition management. These patients need expert symptom management, communication and decision-making support, and care coordination. By addressing these needs, the palliative care consultation team (PCCT) aims to improve hospital care for patients living with serious illness.

In the USA, national initiatives have called for improved pain and symptom management and for psychologic, social, and spiritual support for patients and families living with serious illness.[2–10] Hospital-based palliative care programs of widely varying structures and composition have grown rapidly in number in recent years.[11–13] In a survey of 100 teaching hospitals in the USA published in 2001, researchers found that 26 percent of respondents had either a PCCT or a palliative care unit, and 7 percent had both.[12] Another survey of hospitals in the USA showed that 30 percent of respondents had a hospital-based palliative care service and another 20 percent had plans to establish one.[13] Although specialist-level palliative care is delivered through a range of clinical models, the predominant delivery model in the USA (outside of hospice) is the inpatient PCCT.[13,14] In this chapter, we describe the organization, operation, and outcomes assessment of the hospital-based

PCCT. We also discuss the design and implementation of a successful hospital-based PCCT.

STRUCTURE OF THE PALLIATIVE CARE CONSULTATION TEAM

As described in the recently released National Consensus Project's *Clinical Practice Guidelines for Quality Palliative Care*,[4] palliative care is optimally delivered through an interdisciplinary team consisting of appropriately trained and credentialed physicians, nurses, and social workers with support and contributions from chaplains, rehabilitative experts, psychiatrists, and other professionals as indicated. However, individual institutions have adopted different models to provide palliative care in a manner that is feasible and sustainable according to the particular needs of these institutions. The PCCT is generally structured in one of two ways: the solo practitioner model or the full team model.

Solo practitioner model

In a solo practitioner model, the PCCT consists of a physician or advanced nurse practitioner (ANP) who provides an initial assessment of the patient's needs and communicates this assessment directly with the attending physician, the nursing staff, and the social work staff. The practitioner may or may not write patient orders. The physician or ANP then refers patients to needed services, discusses needs in conference, and communicates with clinicians. In addition, the practitioner assists patients and their families with clarification of goals of care, care plans, and advance directives. Finally, the palliative care physician or ANP develops protocols for patient care in

conjunction with treatment teams and educates staff about palliative care and treatment protocols.

The solo palliative care practitioner must have access to and sufficient time allotted from social work, nursing, physical therapy, occupational therapy, and pharmacy to respond to referrals, all of which should be monitored for time requirements. The practitioner must spend time providing psychosocial support and symptom management to the patient, coordinating services, and teaching family and staff. The literature does not define the patient volume that the practitioner is able to handle, but reports from established programs suggest that a maximum comfortable caseload would consist of four new cases per day and an average daily census of 15 patients.

The advantages of the solo practitioner consultation model of palliative care are lower start-up costs and financial risk, opportunity to develop a program based on the existing patient population, lower threat to medical staff, and the ability to build on existing programs and services and use them whenever possible. The major disadvantage to this model is that the program and the care of highly complex cases rest on one discipline and one individual's shoulders. The patient volume can be quickly limited by workload.

Full team model

The full team model for the palliative care consultative service consists of a physician, an ANP or nurse, and a social worker. Everyone on the team is responsible for assessing and following patients referred by an attending physician. The team then provides advice to the primary physician based on the assessment and follow-up. Alternatively, the team may assume all or part of the care of the patient including writing patient orders. The team refers the patient to needed services, discharges the patient to appropriate settings, discusses needs in conference, and communicates with all care providers. For this model to be successful, the team must work in unison to coordinate the plan of care and to provide appropriate services.

As with the solo practitioner model, the team model should have access to and time allotted from social work, nursing, physical and occupational therapy, and pharmacy services. In contrast with the solo practitioner model, the patient volume threshold for the team model varies depending on whether patients are transferred to the team for complete management. Consequently, the team model may reach a larger number of patients compared to the solo practitioner model.

The team model has several advantages over the solo practitioner model. More providers on the team means more disciplines and more expertise are available to the patient and the hospital community and an ability to reach a large number of nurses and physicians through bedside and nursing station teaching and role modeling. The PCCT can also provide support and teaching to medical staff learning to implement new skills and knowledge. The major disadvantage of the team approach to the PCCT is the added costs for a team with limited, or no, additional revenue beyond the physician's billing.

OPERATION OF THE PALLIATIVE CARE CONSULT SERVICE

The role of the PCCT is to assess the physical, psychologic, social, spiritual, and cultural needs of patients with advanced, life-threatening illness. The team then advises the consulting provider on how to address these needs. Why do primary providers request a palliative care consultation? What is the PCCT's approach?

Reasons for palliative care consultation

Studies characterizing the reasons for palliative care consults among different hospital settings have demonstrated that pain management and other symptom management were the predominant reasons for consultation, usually accounting for about 70–80 percent of palliative care consultations.[13,15–17] Other reasons for consultation included discharge planning,[13,15,17] organization of care,[16] establishing goals of care,[13] and end-of-life discussions.[15] The PCCT also provides psychosocial, spiritual, and bereavement support.[7,18–23] Finally, the PCCT provides help with care coordination and continuity.[18,24,25] While more than one reason for consultation was identified per patient in most consults,[15–17] after investigation, the number of problems subsequently identified by the PCCT tended to be higher than those initially reported by the primary care provider.[16]

The consultation process

Palliative care consults must be ordered by a physician, but nurses, or social workers may initiate a consult if approved by the attending physician.[26] The PCCT can also get involved in a case if the patient or the family request to be seen.[5] Once the consult has been ordered, the first task is to elicit the specific reasons for consultation from the primary care team.

The approach to the patient then begins with a comprehensive assessment of the patient and family including physical and psychological symptoms, as well as social, spiritual, and cultural aspects of care. Validated assessment instruments should be used whenever possible. The assessment is followed by the evaluation and management of symptoms.

Once the patient is comfortable, a discussion of realistic goals and overall goals of care can be held. The PCCT should elicit the patient's understanding of the disease and its treatment as well as the patient's opinion about what constitutes an acceptable quality of life. During this process, the PCCT can assist the primary care provider to communicate

bad news and discuss the benefits and burdens of various treatments. Once goals of care are established, decision making regarding treatment options and advance directives can be pursued. At this time, the team should also encourage the patient to designate a healthcare proxy or durable power of attorney for healthcare to ensure continuity of decision making if and when the patient loses decisional capacity.

The team's approach to the family begins with identification of the patient's primary care giver and/or healthcare agent. With the patient's permission, the team can then elicit the family's understanding of the disease and its treatment and provide the primary caregiver and family with support and education about the patient's distress and symptom management, practical needs, and plans for the future. The PCCT typically coordinates a family meeting to discuss goals of care and further plans for care. An appropriate plan of care and discharge plan should take into account family support systems including their physical, emotional, and financial resources and should be consistent with the established goals of care.

Throughout this process, the PCCT maintains a close working relationship with the primary care team. This begins with good communication regarding the assessment and recommendations made, paying particular attention to the original reasons for the consultation. An attempt should be made to establish personal contact with the primary service rather than rely on communication by notes in the medical chart.[27] While the primary care service generally decides whether or not to implement the consult team's recommendations, the PCCT can seek to obtain permission from the primary service to implement certain interventions promptly to avoid unnecessary delay and suffering.[27] The consult team should encourage participation from the primary service at family meetings (especially important in teaching hospitals) and should educate staff regarding particular aspects of the patient's management and care plan.

Interaction with and engagement of nursing and support staff is key to the success of the palliative care consult. The consult team should, therefore, encourage participation from nursing and support staff in the formulation of the patient's care plan, educate the nursing and support staff about palliative care management issues specific to the patient, and provide the staff with bedside support regarding difficult patient situations and treatment decisions.

This consultation process is time consuming. One study reported that the median time spent in consultation was 60 minutes by the palliative care fellow and 30 minutes by the palliative care attending physician.[15] Another study reported that an initial consult of over 2 hours was common.[28] Moreover, the total time spent in consultation and follow-up – including review of the medical record, interviewing and examining the patient, meeting with the family and having discussions with the attending physician, nursing, social work, and other members of the primary care team – often exceeds 5 hours.[28] The process can therefore take several visits over several days. Most of the time spent during consultation is occupied by eliciting and giving information and providing counseling.[27,29]

IMPACT OF PALLIATIVE CARE CONSULT TEAMS

Few studies have specifically examined the impact of PCCTs on patient care. Among these studies, some have found that a PCCT makes an average of three to four recommendations per patient to consulting physicians.[17,27] Of these recommendations, over 90 percent are implemented.[27,28] This statistic is impressive in the light of the paucity of evidence demonstrating the impact of PCCT structures and processes on patient-related outcomes.

Various studies have shown that inpatient palliative care teams improve patient symptoms, particularly pain.[30*,31*] However, these studies have been small and observational. A pilot study conducted at Mount Sinai Medical Center in New York compared pain ratings for 463 cancer patients followed by the PCCT to 653 cancer patients not receiving palliative care. Palliative care patients were significantly more likely to be discharged from the hospital with no or mild pain (96 percent of patients) compared with cancer patients not receiving palliative care (84 percent of patients, $P < 0.001$). Similarly, compared with patients receiving palliative care, usual care patients were significantly more likely to be discharged from the hospital with moderate to severe nausea (14 vs. 2 percent, $P < 0.001$) and moderate to severe constipation (46 vs. 3 percent, $P < 0.001$) (R Sean Morrison, personal communication, June 12, 2004).

Other studies have examined the impact of PCCTs on establishment of goals of care. One such study demonstrated that goals of care were identified in about 85 percent of patients seen.[15] The most commonly cited goals of care were: improved symptom control, return home, receipt of hospice care, no further hospital admissions, and a comfortable death.[15] Another study showed that the PCCT conducted discussions with patients/families about prognosis and goals of care in about 94 percent of cases. After these discussions, there was a modification of the understanding of prognosis and goals of care in 87 percent of cases.[27*] PCCTs have also been effective in increasing discussion of advance directives, including discussion about a Do Not Resuscitate (DNR) order[15*,27*] and designation of a healthcare proxy.[27*] Some studies have associated palliative care consultation with reductions in resource utilization, hospital costs, and hospital and length of stay in the intensive care unit.[32*,33,34]

Regarding the impact of PCCTs on communication with patients and families about heir care, researchers at Mount Sinai Medical Center have surveyed relatives of patients who died in the hospital and received palliative care consultation (n = 14) or usual care (n = 13) (unpublished data, R Sean Morrison, personal communication (June 12, 2004). As compared with relatives of usual care patients, palliative

care patients' relatives were more likely to report being informed about the patients' condition (64 vs. 46 percent), receiving the right amount of support (79 vs. 69 percent), and that a physician or nurse talked to them about how they might feel after their relative's death (91 vs. 62 percent). Another study showed that relatives of patients receiving palliative care consultation were more likely to report that doctors listened to them (100 vs. 86 percent), received the right amount of information regarding the patients' condition (100 vs. 85 percent), and were informed as to how the patients' pain would be managed (100 vs. 60 percent) compared with families of patients not receiving palliative care.[27]*

In summary, studies to date point to the benefits of palliative care services on patient care. Yet, while the number of hospital-based PCCTs have increased dramatically over the last two decades, most of what we know about the effectiveness of such programs comes from small studies of palliative care provided in individual hospital units, free-standing hospices, and at home. Most of these studies were observational and inadequately powered to detect clinically significant differences in outcomes such as the management of pain and other symptoms, analgesic prescribing, and service utilization. Systematic reviews[35–38]*** have summarized these studies and suggest modest benefits for patients with life-limiting illness and their families from palliative care compared to usual medical care, but the effect of palliative care on family outcomes of satisfaction and anxiety was not significant.[35]*** Clearly, further studies are necessary to demonstrate the clinical outcomes of palliative care programs and to delineate the key program structures and processes required to achieve them.

BARRIERS TO CONSULTATION AND UTILIZATION OF SERVICES

Perhaps the lack of empirical evidence supporting the use of PCCTs has led to their underutilization. Even when palliative care services are used, there is evidence that many referrals tend to occur late in the course of the patient's illness or hospital stay.[15] Another barrier to consultation in palliative care is the limited acceptance of the concept of palliative care consultation. This lack of acceptance has been attributed in part to cultural attitudes of inpatient hospitals, which focus on curative treatment and may view palliative care as tantamount to 'giving up' on this mission. This attitude is fueled in turn by confusion around the distinction between palliative care (medical care focused on relief of suffering offered simultaneously with all other appropriate therapies) and hospice care (care limited by statute to the terminally ill who are willing to give up life-prolonging treatments).[39] Even more compelling is the belief that requesting a palliative care consult signals a point in the course of the patient's illness when there is no more 'hope'. Primary physicians are therefore likely to request a consult only after the patient has

decided to forego further curative therapy rather than earlier in the course of serious, life-threatening illness when the patient could be experiencing significant symptom burden and social, psychologic, or spiritual distress.

Palliative care consultation has also been seen as threatening to some physicians who feel that many of the PCCT's recommendations overlap with care that, in theory, every physician should be able to provide for a patient.[26–28] Educating every physician in the basics of palliative medicine has been a goal of the Education on Palliative and End-of-life Care (EPEC) project, which has been sponsored by the American Medical Association and the Robert Wood Johnson Foundation.[6] However, at this time, physicians with special interest and training in palliative care possess attitudes, knowledge, and skills not yet shared by most physicians[26,27] and are equipped to handle the very time-consuming and complex interventions required by hospitalized patients with serious, life-threatening illness.[27,28] The reality is that the typical busy physician simply does not have time to devote the hours necessary in this high-intensity subset of their patients.

DESIGNING THE IDEAL PALLIATIVE CARE CONSULT SERVICE

The following segment provides some recommendations for structuring and running a PCCT. These recommendations are not meant to be exhaustive, but simply a starting point. The material for this section was obtained from the website (www.capc.org) for the Center to Advance Palliative Care (CAPC).[5] Further details on how to establish a successful, lasting, hospital-based palliative care program can be found in *A Guide to Building a Hospital-Based Palliative Care Program* published by CAPC.[40]

The design of a successful palliative care program tries to reflect the unique mission, needs, and constraints of the hospital it serves. The program design should address the type and volume of patients that will be served, how they will be referred, and the type of program and palliative care team that will care for them. The initial design may require modification once implementation begins, and it will likely require further adjustment as the program grows and evolves. A strong palliative care program adjusts to accommodate shifts in hospital priorities and patient needs. Such flexibility and responsiveness are required for programs to retain their base of support and to remain successful over time.

Administrative structure

The decision about how to administratively structure a program generally depends on how the program was initiated. For instance, if a clinical leader has spearheaded the palliative care initiative, the program usually is placed within the clinical specialty of that leader. There is no 'right' administrative home. Successful programs have been located in a

range of settings including: oncology departments, geriatrics departments, intensive care units, scattered inpatient beds throughout a hospital, and in outpatient clinics. When deciding on the optimal administrative structure, the planning team should consider how best to support the program and respond to unintended consequences of the decision.

Program model

Just as there is no one solution as to the best program location, there is no single palliative care program model that works for all hospitals. Nevertheless, the program model must fit the needs and resources of the institution. Selecting the appropriate model may depend on hospital size, patient load, physician practice patterns and culture, bed availability, and other circumstances. For example, a physician-led team may work more effectively in a private practice or academic culture while a nurse-led team may be ideal in a more institutional or collaborative culture. The availability of trained palliative care staff often guides the choice between starting the program with a solo practitioner versus a full team. As more staff trained in palliative care become available and the demand for services from the PCCT increase in the institution, the program can transition from a solo practice to a full team model.

Referral and support sources

When designing a PCCT, planners should make a list of the best potential sources of referrals, clinician supporters, and targeted departments. To achieve this, the program should consider the following questions:

- What target populations does the program intend to serve?
- What clinical departments of the hospital have the greatest need for palliative care services?
- Where do most patients die within the hospital and service areas?
- Which departments of the hospital have palliative care supporters or clinicians who are likely to refer to a palliative care program?
- In what areas is palliative care strategically matched to departmental initiatives?

In addition, the program should consider creating a database of internal and external stakeholders such as managers, community health leaders, donors, and grateful families. These individuals should be updated on the progress of establishing a program, as they can be tapped for support and resources once the program is established.

Core clinical components and staffing requirements

Ideally, a PCCT should be an interdisciplinary team consisting of at least a physician, a nurse, and a social worker with appropriate training and education in palliative care. Other team members may include clergy, rehabilitation professionals, psychologists, and psychiatrists. The team should have skills and training in: complex medical evaluation, pain and symptom management, professional-to-patient communication, addressing difficult decisions about the goals of care, sophisticated discharge planning, and providing bereavement support. Due to fiscal constraints, this may be difficult to achieve. Therefore, many programs pursue a shared arrangement with the hospital's social work and pastoral care departments to provide the necessary services.

The team should provide a coordinated assessment and services adhering as closely as possible to accepted guidelines of care and/or accepted practice standards. In the USA, the National Consensus Project for Quality Palliative Care has identified eight domains as the framework for its clinical practice guidelines.[4] These domains include:

- Structure and processes of care
- Physical aspects of care
- Psychological and psychiatric aspects of care
- Social support
- Spiritual, religious, and existential aspects of care
- Cultural considerations
- Care of the imminently dying patient
- Ethics and the law

Proper adherence to these guidelines requires that members of the team have special training and/or work experience in palliative medicine, hospice, or nursing home settings, as well as familiarity with the demands and standards of the acute hospital culture.

Equally important is the team's ability to work well and communicate effectively with each other and with other healthcare professionals. Effective palliative care teams understand that the referring physician is their client. While their work directly benefits the patient, they understand that they must show a benefit to the clinicians treating that patient if they want to obtain future support and referrals. The PCCT supports and supplements other physicians' care of their most complex and seriously ill patients. Consultation educates clinicians about the benefits of palliative care, generates visibility and awareness of the program, and builds support for the services it provides.

Key learning points

- The role of the PCCT is to assess the physical, psychologic, social, spiritual, and cultural needs of patients with advanced illness. The team then advises the consulting provider on how best to address these needs, often operationalizing their recommendations upon the referring physician's request.

- The major reasons for palliative care consultation are to relieve pain and other symptoms, to establish communication about goals of care and provide support for complex decision

making, to provide psychosocial, spiritual, and bereavement support, and to provide care coordination and continuity.

- A major barrier to palliative care consultation is the belief that recommendations made by the PCCT may overlap with care that every physician should be able to provide for a patient. However, at this time, physicians with special training in palliative care possess the time, attitudes, knowledge, and skills not yet shared by nor available to most physicians and are therefore better equipped to handle the very time-consuming and complex interventions required by hospitalized patients with advanced illness.

- Most of what we know about the effectiveness of palliative care programs comes from small, preliminary studies that suggest modest benefits of palliative care, particularly in alleviating pain and other symptoms. Further studies are necessary to demonstrate the clinical outcomes of palliative care consultation and to delineate the key program structures and processes required to achieve them.

- While the ideal PCCT should have an interdisciplinary team of physician, nurse, and social worker with appropriate training and education in palliative care, the design of a successful PCCT fully reflects the unique mission, needs, and constraints of the hospital it serves and adjusts to accommodate shifts in hospital priorities and patient needs.

Models of palliative care delivery

BADI EL OSTA, EDUARDO BRUERA

INTRODUCTION

Palliative care delivery has changed considerably during the past 30 years. During the second half of the past century in North America, care of the terminally ill patients moved from the home, where most patients state that they would prefer to die,[1] to the hospital, where medical technology shifted the focus to prolonging life and avoiding death.

After a brief presentation of the different settings of palliative care delivery discussed elsewhere in this book, this chapter will attempt to provide an integrated vision for palliative care programs capable of delivering high rates of access and seamless care to patients in the palliative stage of their illness and to their families.

PATIENT AND FAMILY NEEDS

Palliative care is appropriate at every stage of the disease whether or not the patient is seeking curative treatment. By introducing palliative care earlier in the disease process, it becomes possible for healthcare professionals to detect subtle shifts that take place and help patients and their families to adapt to the disease progression, redefine goals of care, and reframe hope. Therefore, understanding patient and family needs and expectations is important for the patient's care. The lack of addressing their needs and expectations adequately leads to further distress and conflicts between patients, family members, and healthcare workers.[2]

Patients who are terminally ill may develop a number of devastating physical and psychological symptoms[3] that necessitate the need for access to a multidisciplinary palliative

Table 33.1 *Frequency of symptom distress and poor prognostic indicators in palliative care patients admitted to a TPCU, hospices, and acute care hospitals*

Symptom	TPCU	Acute care	Hospices
Pain (%)	75	48	57
Fatigue (%)	90	70	82
Nausea (%)	37	20	24
Depression (%)	59	43	45
Anxiety (%)	67	49	51
Drowsiness (%)	72	64	74
Appetite (%)	76	82	74
Wellbeing (%)	80	71	65
Shortness of breath (%)	50	32	38
Overall (%)	67	55	57

care service to achieve better symptom control, and psychosocial and spiritual support until death (Table 33.1). Patients need to have good symptom control for improved quality of life.[4] Among the symptoms at the end of life, fatigue has been reported to be the most common[3,4] and pain, depression, and anxiety to be the most distressing for patients with advanced cancer.[3]

Patients also expect to be treated with dignity and respect and not as a 'disease' and appreciate physicians who listen to them and allow them to express their personal concerns and feelings.[5] Most patients expect truth telling from their physician in an honest, timely, and sensitive manner as well as continuity of care and ability to participate in their plan of care, especially when more than one option is available.[3]

They need interdisciplinary help while coping with the physical, financial, psychosocial, and spiritual impact of their disease. Finally, most terminally ill patients prefer to live the remainder of their life as fully as possible, rather than marking time waiting to die.[5]

Helping families to meet their needs will also lead to an improvement in the patient's care. Informational needs have been identified as the most important among other needs.[6] Given et al.[7] identified three types of need for family members of a dying person: need for information regarding the disease; need for assistance with how to structure care activities; and continued guidance to alleviate stressors, burden, and associated depression. Families should be provided with clear information about physical care and comfort measures, what to expect and how to manage symptoms as the disease progresses, treatments and their side effects, patient's emotional response, and community resources. Families need assistance in monitoring and reporting symptoms, nutritional considerations, transportation, coordination of care, financial concerns, and in coping with escalation of care as the patient's disease status worsens, without forgetting their psychosocial needs as well as the respite care.

In conclusion, the interdisciplinary approach to patient and family needs leads to improvement in the patient's care and avoidance of a vicious circle of severe burnout and conflicts between the patient, the family, and the medical team. Effective communication secures the trusting partnership and help to ease their burden.[4]

INTERDISCIPLINARY CARE

Palliative care has been successful in borrowing ideas and techniques from other disciplines in healthcare, to meet the patients' and families' needs during the trajectory of their terminal illness. The timely referral to each discipline allows its members to carry out baseline assessment, monitor changes, and apply appropriate interventions that meet the physical, psychosocial, and spiritual needs of the patients and their families. The main disciplines involved in palliative care are: occupational therapy, physical therapy, music therapy, speech therapy, nutrition, pharmacy, clinical psychology (counseling), social work, and chaplaincy.[8]

In some settings (e.g. acute care hospitals), these disciplines are readily available. Therefore, outpatient facilities, inpatient hospices, acute palliative care units, and day hospitals should ideally be placed geographically within acute care facilities that already have these healthcare professionals available. If outpatient centers, inpatient hospices, and day hospitals operate elsewhere, it may be necessary to make the appropriate transportation arrangements to allow the different disciplines to see the patients in case these facilities don't have their own interdisciplinary team.

Interdisciplinary care may be difficult, if not impossible, to conduct at home or in a nursing home because of the cost of transportation of all the different disciplines to the patient's location. However, the possibility of video interactive techniques for the access to social worker, counselor, pastoral care, and other members of the interdisciplinary team may be a promising way to stay in touch with the patients and their families. These techniques have been used in psychiatry for various purposes.[9,10] Studies need to be done in palliative care telemedicine to assess cost effectiveness of these techniques as well as patients' and families' satisfaction. The best level of palliative care delivery consists of having multiple disciplines involved in each setting to provide care that meet the needs of patients and families. The subsequent sections of this chapter discuss the different settings of palliative care and their integration into a seamless network that every patient can access.

DIFFERENT SETTINGS FOR PALLIATIVE CARE DELIVERY

The home

Although most patients die in hospital or a nursing home, surveys indicate that more than 70 percent of people would prefer to die at home.[11] Despite the existence of different models internationally, palliative home care provides a patient the possibility of a quality of life and death at home, if that is the preferred place to spend his or her last days. This setting has its own advantages and limitations, and can be challenging as well as rewarding for the patient and the family. Wenk has discussed these issues in depth in Chapter 34.

At home, most patients have more autonomy, privacy, freedom, and feel safer than anywhere else.[12] The family can potentially anticipate the loss, have a better bereavement and familiarize with death by learning that death is a normal stage of life.[12] Care at home at the end of life can also reduce the cost of care: it prevents unnecessary admissions to acute hospital and skilled nursing facilities and avoids unnecessary use of the emergency department by having nurses (backed up by a palliative care specialist) on-call 24 hours per day, 7 days per week to provide a rapid response to changes in symptoms in the last days of life.[13] On the other hand, care at home may be difficult or impossible if the patient does not wish so; lives alone or far away; cannot afford the care expenses; needs higher skilled care; if the family is physically or emotionally tired, cannot deal with uncontrolled symptom or cannot provide the patient with 24-hour care; or if the home does not meet the minimal comfort needs.[14] When providing palliative home care, the team should be able to get early referrals, have access to an inpatient hospice unit for possible direct admission, provide medications and home equipment for the patient, be able to assess and control symptoms using universal tools, and document visits and phone calls on the patient's chart.

The responsible caregiver is the member of the family who is in better condition (health, relation, proximity and available time) to carry out and coordinate the care.[15] The education of the responsible caregiver must be done progressively, with simple verbal, written, audio- and/or video-taped instructions about how to administer medications, evaluate symptoms, diet, hydration, hygiene and evacuation, position and dressing changes, organize family tasks, and recognize death. To prevent frequent hospitalization, the responsible caregiver needs support with the guarantee of the best possible symptom control, the availability of the team, and access to easy admissions 24/7, establishing a caring plan and a schedule of activities, anticipating the changes that can occur in the patient's condition, and reducing doubts and uncertainty, and providing material resources.

Usually a month of care should include approximately two medical visits per week, two nursing visits per week, two psychology/counseling interviews for the patient and two for the family per month, and provision of oral and parenteral opioids analgesic. When the patient's condition is stable, medical and nursing visits can occur once weekly; in the terminal phase, one or more visits are needed per day. However, available services can vary dramatically in different areas of the world, particularly regarding access to medical care.

Volunteer collaboration increases both team activity and interaction with the community.[16] After their selection and training, volunteers can help in evaluating patients at home or on the phone, educate the responsible caregiver, offer practical support (housekeeping, transport, etc.), and be company for the patient and family.

The home hospice service enables patients to live at home in the last days of life. The demand for such services is expected to increase in the future because of the aging population.[17] This rapidly growing concept can be a source of ethical dilemmas.[18] It is very important to have a complete discussion with the patient and family regarding the choices and wishes of where to receive end-of-life care and get into an agreement within some principles with the possibility of changing choices at any time:[19] patients and families should be aware that palliative home care does not medicalize or technicalize the dying process, and it should not intrude on the privacy of their home or disturb the family life.[1]

Finally, it is unclear whether palliative home care produces savings by reduction of the expenses of both fragmented care and the use of high-tech interventions; however, in many cases the burden of cost shifts from the healthcare system to the caregiver.[12] Because nonprofessional caregiving is crucial to effective end-of-life care for patients who wish to die at home, early recognition of family distress, validation of their role, and effective communication by physicians may ease their burden and avoid physical illness, emotional distress, financial hardship, and early mortality in the caregivers.[20] If palliative home care is promoted and implemented, resources should be minimized for medications and maximized for responsible caregiver funding.

Palliative care outpatient centers

Patients with advanced cancer often develop devastating physical, psychosocial, and existential distress[21–25] associated with the disease or its treatment.[21,23,24] These symptoms cannot be controlled appropriately[22] in a standard setting based on a physician/nurse team with a waiting area and small private examining rooms, which do not allow interactions between different discipline members. Therefore, the multidisciplinary symptom control and palliative care (MD) clinics were developed to unify different disciplines in a team that combines their assessments and formulates a plan of care[21,22] that meet patients' and families' needs in the same visit and at the same place. The MD clinic helps patients and their families to avoid the distress generated by the visits of several offices located in different areas of a tertiary hospital, and by the waiting time before each appointment in order to receive a multidisciplinary assessment and management.

In their retrospective study, Strasser et al.[21] compared the assessment of 138 consecutive patients with advanced cancer referred to the MD clinic and 77 patients referred to a traditional pain and symptom management clinic. The two groups were similar in tumor type, demographics, and symptom burden. Patients of both clinics were evaluated using the same tools: Edmonton Symptom Assessment Scale[26] (ESAS), CAGE questionnaire,[27] and Mini-Mental State Questionnaire[28] (MMSQ). In addition to a physician and a nurse, the patient was assessed by a social worker, physical and occupational therapist, pharmacist, clinical nutritionist, pastoral care worker and a psychiatric nurse practitioner. The MD clinic has no waiting area and patients had their own private rooms with a full-sized bed and bathroom. After the patient's evaluation, the multidisciplinary team discussed the assessment, interventions, and recommendations in a team conference. The patient as well as his or her oncologist and primary care physician received a handwritten and audio-taped[29] form of the team conference. A follow-up visit was scheduled within 1–2 weeks after initial assessment[21] and monthly thereafter; otherwise, follow-ups were provided per patient or family needs at the MD clinic[21] or over the phone.[22] Patients from the MD clinic received a total of 1066 nonphysician recommendations (median 4 per patient, range 0–37) in a 5-hour assessment. Among 83 patients interviewed after the MD clinic visit, satisfaction was rated as excellent in the following areas: caring team members, adequate assessment, treatment plan, useful recommendations, and time spent. In contrast, the duration of the pain and symptom management clinic assessment, done only by a physician and a nurse, was 30–45 minutes. No nonphysician recommendations were given; instead, eight patients were referred to specialists in psychiatry, three to rehabilitation, and three to social work.[21]

In conclusion, the interventions of a interdisciplinary half-day symptom control and palliative care clinic can

result in reduction of the physical and psychosocial distress of patients with advanced cancer,[21,22] large numbers of physician and nonphysician specific care recommendations,[21] and high levels of patient satisfaction.[21,22]

There are some specific characteristics of successful outpatient palliative care delivery:

- *'Just in time access'*. Patients need to access these consult programs without lengthy appointments or waiting times. It is important to encourage a 'drop-in' approach.
- *Physical facilities.* The rooms need to have enough space for a full-sized bed since palliative care patients are frequently severely symptomatic and cannot tolerate long period on examining tables. These rooms also need enough space for families to be able to sit comfortably with the patient. Privacy is important for the different discussions that take place.
- *Availability of team members.* A successful outpatient palliative care program requires rapid access to the different disciplines. Physicians and nurses are generally ineffective in identifying problems that require interdisciplinary interventions.[22] Therefore, palliative care patients and families should ideally be provided access to as many disciplines as possible during the course of an initial outpatient consultation. Further follow-up may not be required by all disciplines.

Day care hospitals

Day care hospitals were originally developed for the geriatric population[30] in response to a lack of continuity of care between acute hospitalization and long-term placement[31] and with a concept to lower the cost of care.[32–37] Later on, day hospitals extended to other specialties[38] including palliative care.

Day care hospitals vary in funding, facilities, and staff.[39] They are mainly funded by the private sector.[39–54] A third are attached to inpatient units, another third are attached to inpatient units with home care teams, and the last third are attached to a home care team alone or are freestanding.[39,46] Palliative care day hospitals (PCDH) are usually open 3–5 days a week and are mainly led and managed by nurses.[39,46,47] The day hospital staff is specialized in palliative care and includes physicians, bedside and clinical nurses, psychologists, social workers, physical and occupational therapists, chiropodists, dieticians, chaplains, managers, aromatherapists, hairdressers, and volunteers. A mixture of hospital bedrooms with private washrooms, clinic-type rooms, interview rooms, treatment rooms, and specific rooms with special research equipment is ideal. Sufficient space for patients and family members should be provided such as a waiting room, a kitchen, a private meeting room, etc. A unified, well-planned central working area for the staff increases efficiency of communication and should not replace separate offices to allow team members to perform their charting and telephone communications.

It is essential to plan a lounge area within the day hospital setting for the staff to rest while remaining accessible to patients and family needs during their resting time.

A PCDH provides palliative care assessment and management to patients with severe symptoms, existential distress, difficult family situation, regardless of their prognosis. It assumes a consult role for patients who are not in terminal phase of their illness, and a treating physician role with terminal patients with complex palliative care issues. It also provides family meetings, advanced care planning including clarification of code status, emergency consults within 48 hours, and specialized services to special populations (i.e. patients with lymphedema, wound care, methadone clinic, etc.). A PCDH coordinates referrals to other palliative care services and allows access to other disciplines available in a tertiary care hospital such as anesthesiologists, surgeons, oncologists, radiooncologists, skin care nurses, etc. PCDH should improve links between specialized services of the hospital, promote links with home care services and hospices through adequate referral, respond to home 'crisis' by giving support to home-based palliative care teams and by coordinating admissions to the day hospital or the inpatient unit to prevent terminally ill patients visits to the emergency room, provide phone consultations to physicians and nurses in the community regarding complex issues, and develop protocols of care with community services. The day hospital setting has been discussed in depth by Gagnon in Chapter 35.

Fifteen papers reported data from 12 observational studies of day care, 11 from the UK[41–54] and one from the USA,[40] and provided some information on the structure, process and outcomes of day care. Many qualitative studies found that most patients were highly satisfied and valued the social contact[41,44,48,50–53] and the opportunity to take part in activities that day care provided. Caregivers opinions was sought in one study:[53] the majority found care 'excellent' or 'good' and were 'greatly helped' by their day off. However, further studies are needed to provide conclusive evidence of improved symptom control, mainly pain,[41,43,44,53] and quality of life in PCDH as well evidence-based standards of care.[39]

The three settings discussed above, home care programs, outpatient centers, and day hospitals are part of the palliative care services available to patients who are still staying at home. In these settings, bus rounds[55,56] may be a useful mechanism for unifying criteria and sharing strategies for patient care as well as promoting continuing patient-based education in palliative care for physicians, nurses, and medical students in the community. They have been shown to be highly satisfactory from participants' perspective[56] with low overall cost.[55]

Consult teams in acute care facilities

Consult teams in acute care facilities act as a bridge between the 'palliative' and 'active' models[57,58] of care by providing access to palliative care services at a time when the patient is still receiving active treatment.

In a retrospective study, Jenkins et al.[57] reviewed the charts of 100 consecutive cancer patients who had been referred to a palliative care consult team within a tertiary acute care hospital during a 6-month period. The palliative care consult team consisted of a physician and a nurse trained in palliative care and available on a full-time basis. Demographic characteristics, including reason for admission and disease status upon admission, length of stay, length of time from consult to discharge, admission location, and code status on admission and discharge were recorded. Symptom acuity, cognitive status, and risk for substance abuse were evaluated respectively using the ESAS,[26] CAGE[27] questionnaire, and MMSQ.[28] Medications before and after the consult were compared to the recommended medications; compliance of the primary team with the consult team recommendations was assessed. Five patients were not palliative at the time of the consult. Only 46/95 (48 percent) were known to have untreatable cancer at the time of their admission. The CAGE questionnaire for alcoholism and the MMSQ were abnormal in 19/78 (24 percent) and 40/91 (44 percent), respectively. The most intense symptoms, as measured by the 100 mm scales of the ESAS were fatigue (72 ± 24), appetite (60 ± 32), and well-being (50 ± 29). Eighty-nine of the 95 patients were living at home prior to admission and 34/95 (36 percent) were able to return home. The median length of time between consultation and discharge was 6 days[57] (5 days in a recent study carried out by O'Mahony et al.[59]). Twenty patients died during hospitalization, 23 were transferred to a palliative care unit, and the remaining 18 were discharged to another hospital or long-term care facility. Two-thirds of the patients were on dimenhydrinate as anti-emetic by their primary team, 4 percent of the patients had neuroleptics ordered before the consult compared to 19 percent for whom neuroleptics were recommended, 22 percent of the patients were not prescribed opioids, and 54 percent were prescribed opioids on an as needed basis. The patient's physician complied with the palliative care consult team's recommendations in 122/137 cases (89 percent).

Hospitalization of terminally ill patients is a pivotal time in their disease course. In this study,[57] 52 percent learned that they were in the palliative phase during this hospitalization. The consult team was able to rapidly assess and treat patients, verify a terminal diagnosis and ensure that medical options have been exhausted. By providing alternative palliative care resources and placements options, the consult team helped in reducing the number of patients admitted to the hospital for social reasons,[57] hospital charges,[59] length of stay,[57,59] and inter-unit transfers.[59] Using the cited tools above,[26–28] the consult team was able to help the primary team in detecting missed delirium in about half of the patients, assessing and managing cancer pain as well opioid side effects, and other symptoms related to the cancer more effectively. The high rate of adherence to the consult team's recommendations[57,59] suggests that the primary team was able to incorporate palliative care approaches into the management of acute patients.

Higher adherence rate (>90 percent) was reported in a recent study carried out by O'Mahony et al. after evaluating data regarding 592 consecutive patients seen by their palliative care consult team during a 16-month period.[59]

Palliative care units

A tertiary palliative care unit (TPCU) is a distinct type of palliative care unit, designated for terminally ill patients who require intensive involvement of a specialist interdisciplinary team able to manage their complex problems. von Gunten defined it as an academic medical center where specialist knowledge for the most complex cases is practiced, researched and taught.[60]

Given the physical, psychosocial, and spiritual nature of the TPCU patient population complexity, the ideal location for such unit is in an acute care hospital that offers a full range of diagnostic and interventional procedures, support services, specialty and subspecialty consultation. The TPCU staffing includes palliative care specialists, nurse practitioners, registered nurses, research nurses, licensed practical nurses, nursing attendants, a chaplain, a social worker, a physical therapist, an occupational therapist, a pharmacist, a clinical dietician, a palliative care counselor, a clerk, and volunteers. The optimal unit size for staffing efficiency is 16–24 beds and the minimum size is 10–12 beds.[96] Watanabe and Macmillan have discussed in depth this setting in Chapter 37.

One example of TPCU is the Edmonton Regional Palliative Care Program (ERPCP) PCU in Canada.[62] The ERPCP is a publicly funded program that provides a comprehensive range of palliative care services, including home care and specialist consultation in the community, long-term care, hospices, ambulatory care and acute care settings. Its TPCU is located in an acute care teaching hospital and has 14 beds. Amenities include a patient smoking room, a family lounge, a kitchenette, a quiet room, and a conference room. Family members may stay overnight if they wish, and pets are allowed. Referrals are screened after direct patient's assessment by the palliative care consultants. Such patients are referred for acute symptom control, emotional and family distress, difficult discharge planning, and rehabilitation. As discussed in Chapter 37, the TPCU is intended to be a short-term place of care, until symptoms have stabilized sufficiently to allow discharge of the patient to another palliative care setting: the expected length of stay is less than 2 weeks. The goal of admission and its temporary nature should be discussed with the patients and their families. Most patients are asked to agree electively to a 'do-not-resuscitate' status prior to admission. Discussing 'do-not-resuscitate' status is a valuable opportunity to clarify the patient and family's understanding of the illness, prognosis, as well as goals of care.[63] The tools used daily for assessment are: ESAS,[26] CAGE questionnaire,[27] MMSQ,[28] Edmonton Staging System (ESS) for cancer pain,[64]

Edmonton Labeled Visual Information System[65] (ELVIS), Edmonton Functional Assessment Tool[66] (EFAT), Palliative Performance Score (PPS),[67] and constipation score.[68] A family conference coordinated by the social worker and attended by the team, the patient, family members, and friends whom the patient wishes to involve is often advisable to clarify goals and establish plans of care and further discharge to a more appropriate palliative care setting that will satisfy their needs. Patients have the option not to be present at the family conference.

For those patients who are discharged home, clear and timely communication with community healthcare providers (e.g. primary care physician, home care manager, pharmacist) is critical. Transfer to a hospice may pose a difficult transition for the patients and their families because of their need to adjust to a new environment and staff, and most importantly because they may view hospice as a lower level of care and feel a sense of abandonment.[69] These concerns may be alleviated by explaining to them that the fact that the patient does not require treatment in a TPCU is a positive outcome and that the option of coming back is possible if the symptoms exacerbate and the patient decides so.

The TPCU provides an excellent environment for research in which all the interdisciplinary team's medical members are expected to participate. Since patients are under direct care of the medical team, the process of screening and recruiting them for studies becomes easier. The TPCU of the Edmonton Regional Palliative Care Program receives undergraduate and postgraduate medical trainees from the University of Alberta on a regular basis. Clinical teaching is enhanced by journal club,[70] held three mornings a week, during which time relevant articles to palliative care are presented and discussed. Other educational activities include tests taken before and after the residents PCU rotation,[67] seminars, weekly grand rounds, and presentations from other specialists sharing their expertise as applied directly or indirectly to palliative care.

Inpatient hospices

Hospice is a model designed to provide care at the end of life. The goal of hospice is to palliate the suffering at the end of life by addressing the emotional, social, physical, and spiritual needs of patients and their families. The in-patient hospice care is the highest level of care within a hospice program. It is designated to control physical suffering and support family and patients when such care is not manageable at home. Described in depth by Keen in Chapter 36, the majority of inpatient hospices are staffed by at least one full-time physician trained in palliative medicine, nurses, physiotherapists, occupational therapists, social workers, chaplains, and offer bereavement support services. In addition to providing inpatient end-stage care, patients are admitted for symptom control, rehabilitation, and sometimes respite care.

Statistically, five independent factors were found to predict inpatient hospice care: pain in the last year of life, constipation, breast cancer, being under 85 year of age, and being dependent on others for help with activities of daily living for between 1 and 6 months before death.[71] Hinton demonstrated a higher rate of admission among patients receiving palliative home care over those who were living alone or with unfit relatives and those with breast cancer.[72] One study of data relating to cancer deaths showed that patients accessing palliative care services were significantly younger and had longer survival times from diagnosis.[73] An analysis of place of death of cancer patients demonstrated an increased likelihood of dying in a hospice if they lived close by.[74]

In the USA, cancer diagnosis accounted for 46 percent of hospice admissions during 2004 and noncancer diseases accounted for 64 percent: end-stage heart disease and dementia have been shown to be the two most common terminal illnesses.[75] Medicare, through Part A, limits in-patient hospice care reimbursement (US$491.19/day in 2000).[76] The length of stay per hospice admission was 4–5 days and the median length of stay in 2004 was 22 days.[75] In the UK, the average length of stay in inpatient hospice was 13.5 days[77] compared to Canada where the average of stay was 44 days and the median length of stay was 22 days.[78] The principal problems triggering admission were mainly anorexia, weakness, and drowsiness.[3]

There is little good quality research measuring the contribution that inpatient hospice care makes to patient care. However, the studies at St Christopher's Hospice comparing hospice and hospital care from the viewpoint of the surviving spouse found a consistent impression of a better social and psychological environment within the hospice compared to the hospital.[79,80]

Consult teams in nursing homes

More than 25 percent of Americans die in a nursing home.[81] Considerable evidence indicates that nursing home residents do not receive optimal end-of-life care,[82,83] their pain is undertreated,[84] and they are often transferred to an acute care setting to receive aggressive rather than palliative treatment in the last weeks of life.[85,86] Therefore, families express dissatisfaction with the end-of-life care that their loved ones receive in nursing homes.[87] Hospice care may improve the quality of end-of-life care for nursing home residents, but it is underused by this population, in part because physicians are not aware of their patients' preferences.[82]

Casarett et al. carried out a randomized controlled trial of 205 nursing home residents and their surrogate decision makers in three US nursing homes to determine whether it is possible to increase hospice utilization and improve the quality of end-of-life care by identifying residents whose goals and preferences are consistent with hospice care.[82] A structured interview identified nursing home residents

whose goals for care, treatment preferences, and palliative care needs made them appropriate for hospice care. Of the 205 residents, 107 were randomly assigned to receive the intervention, and 98 received usual care. Intervention residents were more likely than usual care residents to enroll in hospice within 30 days (21/107 [20 percent] vs. 1/98 [1 percent]; $P < 0.001$ [Fisher exact test]) and to enroll in hospice during the follow-up period (27/207 [25 percent] vs. 6/98 [6 percent]; $P < 0.001$). Intervention residents had fewer acute care admissions (mean: 0.28 vs. 0.49; $P = 0.04$ [Wilcoxon rank sum test]) and spent fewer days in an acute care setting (mean: 1.2 vs. 3.0; $P = 0.03$ [Wilcoxon rank sum test]). Families of intervention residents rated the resident's care more highly than did families of usual care residents (mean on a scale of 1–5: 4.1 vs. 2.5; $P = 0.04$ [Wilcoxon rank sum test]).

In conclusion, by increasing early access to hospice care in a nursing home setting by a simple and prompt communication intervention, pain will be better controlled, the use of inappropriate medications as well as physical restraints and acute hospital admissions will decrease, and family satisfaction with end-of-life care will increase.[82]

INTEGRATION OF CARE

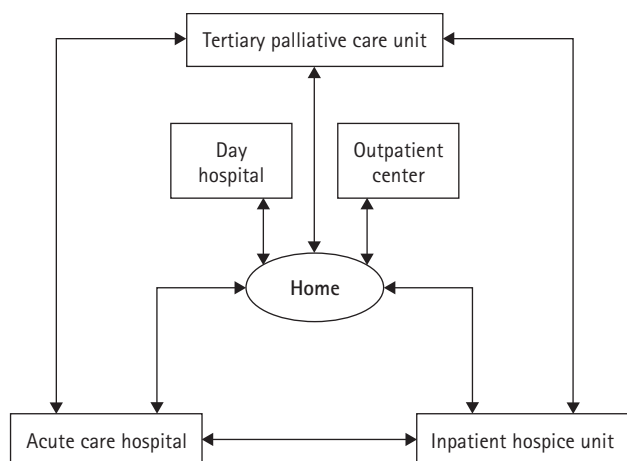
Figure 33.1 summarizes the different components of palliative care delivery. The most important aspect of this model is the different arrows connecting the different settings of care. The flow of patients needs to be seamless and this is facilitated by using compatible assessment tools, similar treatment and counseling protocols, and frequent communication among the different teams, video-conferencing, regular teaching rounds, or bus rounds. However, the different settings do not need to have a unified ownership or administrative structure to be able to meet the goal of seamless patient and family care.


Figure 33.1   *Home as the center of palliative care delivery.*

During the past several decades, terminally ill patients were increasingly dying in acute care setting.[88–90] With the recent changes in healthcare, there is greater emphasis on providing care at home and supporting families to enable more home deaths.[90,91] Since home death may not be simple, practical or desirable in every family situation,[90–94] there is a need for an objective way to assess the viability of a home death in each family situation. Cantwell *et al.*[14] formulated a tool called the Home Death Assessment Tool (HDAT) as a result of a cohort study conducted to describe the relative role of predictors of home death in palliative care patients with advanced cancer. They created a simple questionnaire of five questions to assess the viability of a home death: patient and caregivers' desire for a home death, physician's support for a home death, presence of more than one caregiver, patient's environment, and sufficient financial resources. Ninety questionnaires were administered by home care coordinators and a follow-up questionnaire was administered to record the place of death. Of the 73 patients, 34 (47 percent) died at home and 39 (53 percent) died in a hospital or a hospice. Logistic regression identified a desire for home death by both the patient and the caregiver as the main predictive factor for a home death. The presence of more than one caregiver was also predictive of home death. The financial resources, in a private healthcare system, can determine also the feasibility of death at home. However, physician's support for a home death and patient's environment were not significant predictors of home death in Cantwell's study.

In that study, HDAT was highly specific in identifying patients who were not going to die at home but was not sensitive in identifying those who would die at home. It was used to guide the care coordinator in planning a home death and to increase the understanding among patient, family, and professional caregivers of what is required for a successful palliative care delivery at home.[14] If there are fewer than three positive answers, the home care coordinator should explore a different setting as a care plan.

Home death is not universal and has its limitations. Decreased support, symptom distress, and inability of the palliative home care and caregivers to meet the patients' needs make peaceful death at home impossible. Also, patients and caregivers can change their minds about their desire for a home death as their circumstances change.[16,94,95] In these cases, the patient has to be moved to a higher skilled setting. The role of day hospital team in this case is very important: it assures support for the palliative home care team and responds to home crisis within 48 hours, provides optimal care if possible, or helps coordinating a patient's disposition to the appropriate setting (specialized clinics, TPCUs, acute care hospitals, inpatient hospice units).

There are no systematic reviews of the effectiveness of palliative day care and no randomized controlled trials comparing this care with other settings.[39] There are no studies of referral into day care or the cost of this care.[39] Planned to provide a leadership role in promoting links between a tertiary care hospital and community services, the

day care hospital should be for patients with terminal illness who are still receiving active treatment and for patients in their terminal phase who need rapid access to palliative care. Inpatient care can be delivered, in decreasing order of patient and family distress, at the TPCU, by consult teams in acute care hospitals, and in hospices. In a review of admission data for all patients discharged from the ERPCP from November 1, 1997 to October 31, 1998, patients with high symptom distress, positive screening for alcoholism, and poor prognostic indicators of cancer pain (ESS[64] > 0/5) were referred to TPCU, while those with lower level of distress, negative screening for alcoholism, and better prognostic indicators (ESS = 0) were treated in acute care hospitals, hospices, and the community.[3] The availability of a palliative care consult team allows patients access to palliative care at an early stage of their illness, when they are still receiving active treatment and when they are still candidates for cardiopulmonary resuscitation.[57] It has reduced significantly hospital charges[59] as well as length of stay,[57,59] inter-unit transfers,[59] and admissions for social reasons.[57]

In the USA, admissions to inpatient hospice are limited to a median of approximately 5 days. This length of stay is related to the need to deliver 80 percent of hospice care at home. Since the median length of inpatient hospice stay in the USA during 2004 was 22 days,[75] the median inpatient hospice stay per admission is approximately 5 days (20 percent of the yearly total stay). This duration is relatively shorter than in Canada or UK where its average is 44[78] and 13.5,[77] days respectively. Therefore admission to hospice in the USA may not be able to meet the patients' and families' needs, and referrals to higher skilled-setting would be the appropriate choice so patients can spend more time at home after discharge from a TPCU for example, and avoid recurrent admissions to inpatient hospice.

In the outpatient setting, the multidisciplinary symptom control and palliative care (MD) clinic allows a better integration of care between a cancer center and community-based physicians and nurses. It also allows patients access to multiple disciplines that are not available outside tertiary centers.[22] Home is considered the center of palliative care delivery since most patients and their families prefer to stay at home as long as possible,[1] and during all the early stages of the illness patients receive all their care while residing at home. From home, patient can be moved to an acute care hospital (e.g. patient develops hematemesis), admitted to a tertiary palliative care unit (e.g. control of severe symptoms or psychosocial distress), or even to an inpatient hospice unit in case the responsible caregiver becomes ill or needs a respite. Of note, patients can also be transferred from one setting to another within this model based on their needs as well as their family needs (e.g. after controlling an acute exacerbation of a right arm pain in a tertiary palliative care unit, a patient can be moved to an inpatient hospice unit while waiting for the caregiver to recover from a severe flu; the same or a different patient can be transferred from an inpatient hospice unit to an acute care hospital after a hip

fracture secondary to a fall from the bed; again, the same or a different patient can be transferred from a surgery floor to a tertiary palliative care unit if they develop a delirium that the surgeon cannot manage appropriately). In any of these settings, the discharge plan would be directed, if practical and desirable, toward returning the patient home to spend the last days surrounded by loved ones.

The two main issues in deciding the setting of care are the level of distress and available support. The patient's distress may be physical, psychosocial, or spiritual and can be measured with the ESAS, the MMSQ,[28] the McGill Quality of Life Questionnaire[96] (MQOL), the EFAT,[66] the PPS,[67] the constipation score,[68] and others. The level of support can be determined by the structure and function of the family, financial status, medical insurance, and overall physical condition of the home. If there's worsening of the physical and the psychosocial distress, the patient has to be transferred to an acute care hospital where he or she will have access to many disciplines (e.g. consult teams or tertiary palliative care unit). Once the distress is controlled, the patient can be moved to the community or home if he or she has good social and financial support. Otherwise, a transfer to an inpatient hospice unit would be more appropriate. If the distress could not be alleviated or the support could not be provided, the patient would not be able to return home and might die in an acute care hospital or in the inpatient hospice unit (Fig. 33.2).

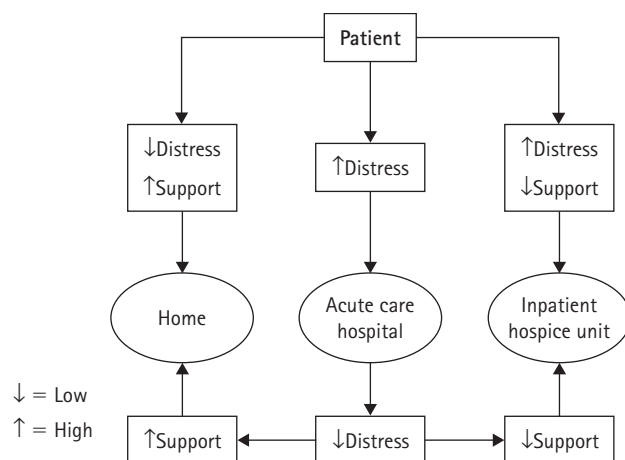
In summary palliative care services should match the needs of patients and families. These services can be provided in an inpatient or outpatient setting. The inpatient care can be delivered in TPCUs, in acute care hospitals, and in the inpatient hospice units. The outpatient care can be delivered at home, in day hospitals, in nursing homes, or in MD clinics. No single palliative care program needs to have all these components. These settings can be owned by one institution or can have different owners to integrate palliative care delivery. Most importantly, every palliative care patient should be able to have access to any of these settings in a seamless way


Figure 33.2 *Matching palliative care services to patient and family care needs.*

appropriate to their needs. To achieve a seamless network for delivery of care, palliative care programs should have the following resources: agreement between different settings, bus rounds, common assessment tools, common treatment guidelines, and regular communication (audio-visual: patient care and education).

CONCLUSION

In more than 30 years since the inception of the modern hospice movement, a number of clinical programs have emerged. These programs have demonstrated their value in a number of specific patient populations. One of the greater challenges has been to make it possible for patients in different regions of the world to access the system that is most appropriate to their needs (i.e. home care and day care hospitals versus inpatient hospices or inpatient acute care facilities). In addition, a setting that is appropriate for a patient at a particular time, i.e. the patient is comfortable at home with home care, may be inappropriate when there is complete family burnout or severe aggravation of symptoms distress.

One of the greatest challenges is to have a seamless care so that patients at any given time are able to receive palliative care in the setting that is most appropriate to their needs. There has been significant progress in recognizing that the different settings described in this chapter are complementary rather than competitive. There is still considerable need for research on the best way to integrate these different programs into a seamless network.

Key learning points

- Palliative care services should match the needs of patients and families.

- The interdisciplinary approach to patient and family needs leads to improvement in the patient's care and avoidance of a vicious circle of severe burnout and conflicts between the patient, the family, and the medical team.

- A multidisciplinary symptom control and palliative care clinic allows patients and their families to avoid the distress generated by the visits of several departments located in different areas of a tertiary hospital, and by the waiting time before each appointment to receive a multidisciplinary assessment and management.

- The inpatient care can be delivered in TPCUs, in acute care hospitals, and in the inpatient hospice units.

- The outpatient care can be delivered at home, in day hospitals, in nursing homes, or in MD clinics.

- Integration of the different settings into a seamless network is necessary for patients to be able to have access to any of these settings as appropriate for their needs.

Palliative home care

ROBERTO WENK

INTRODUCTION

Most seriously sick patients prefer to stay at home during their final days; 50–80 percent elect to receive treatment and to die in their homes.[1] They prefer their homes to the unknown environment of a healthcare institution. However, there is a majority who die in the institution where they have been receiving care or treatment.[2]

Palliative care provides a way to change this situation. Its objective is to obtain the best possible quality of life for patients with incurable advanced illnesses, and for their families.[3] With palliative home care (PHC) all patients have the possibility to receive good quality care and die in their homes if that is the place where they would prefer to spend their last days. A growing number of patients are preferring PHC, and this is a great challenge because it is largely dependent upon the patients and their families, the health system, and the health professionals.[4]

This chapter analyzes different aspects of PHC based on the experience of the palliative care teams of the Pograma Argentino de Medicina Paliativa-Fundación FEMEBA (PAMP): CCP San Nicolas, UCP Sommer, and UCP Tornú. The methods described here may be similar to those present in other developing countries.

PALLIATIVE HOME CARE

Palliative home care is an option for patients who wish to be cared for at home and has three essential requirements: needs which can be met at home, a home where care can be provided, and a family to collaborate. Patients, families, professionals, and the public need to know about this option, its availability, and its limits; and they must also be aware that it can be challenging as well as rewarding for the patient and the family.

Advantages

The following factors regarding PHC are related to the fact that it enhances the patient's and family's independence and psychological wellbeing: the home is a place of familiarity and comfort without institutional regulations.[5]

- *Autonomy*. Patients stay with the family and plan their activity, rest, and diet. They can carry out some tasks at home and thus maintain their role.
- *Privacy*. Patients are not exposed to intrusive, at times unnecessary and not desired, medical activities. Nor are they exposed to the suffering of other patients.
- *Protection*. Patients are less exposed to therapeutic procedures, which are at times futile in incurable advanced diseases (intensive care, parenteral nutrition, etc.).
- *Better bereavement*. The family can anticipate the loss.
- *Less discomfort with death*. The death of a relative in the place where life was shared is a way to learn that death is a normal not unusual stage of life.

Saying that a patient spent the last days at home says little about the quality of life during that time. If PHC is efficient, symptom control is similar to that offered at an institution with palliative care; and better than that offered by an institution without palliative care.[6]

Disadvantages

With the patient at home there is only a partial return of the family equilibrium; finally the equilibrium is disturbed with the physical changes in the patient and the modifications of mood and behavior. The families facing the changes suffer, experience negative emotions (anxiety, fear, guilt, anger) and crisis and may develop psychological disorders.[7] There is considerable reduction of sleeping hours and activities, and families face economic hardships due to the increase in expenses (medication, healthcare personnel fees, etc.) and reduction of income (absence from or giving up work).[8]

The following patient and family factors make PHC difficult or not possible:

- Patient wishes to be hospitalized.
- Patient lives alone, with no family willing to provide care[†].
- Family members tired, no responsible adult, physically or emotionally weak, or dysfunctional.
- Home with unmet comfort needs (kitchen, running water, indoor toilets, electricity)[†].
- Situations that generate anxiety or family discomfort (convulsions, hemorrhages, smelly tumors, fecal incontinence).
- Frequent need of medical or nursing procedures.
- Hospital far away from patient's home.

BARRIERS TO DEVELOPMENT

The multiple barriers to the implementation of PHC are basically extensions of barriers to palliative care and can be discussed under the following headings according to the source of the barrier.

Health systems

Most public or private health systems include neither home care for chronic diseases nor palliative care.[9] With this background, plans to offer palliative care to different groups of patients are lacking with some exceptions and thus there are few PHC services available. The exceptions include a few health systems, mostly private and in small cities, that include PHC because the authorities became interested as a result of the positive results of local palliative care programs.

The lack of support from health authorities for PHC is the reason why most patients with incurable, advanced diseases spend their last days (sometimes weeks and months) in public or private institutions that guarantee available physicians, medication, technical resources, and some kind of symptom control; but these as a rule also provide medical interventions, which are often futile and expensive.[10]

[†]Main cause of long hospitalizations among the patients assisted by the UCP Sommer and UCP Tornú.

It is a contentious situation based on the failure to use resources efficiently and effectively: there is no budget assigned to PHC but admissions and aggressive treatments are encouraged. By supporting PHC the health system can offer an adequate solution to both the poor quality care of dying patients and the problem of maintaining full institutions with high assistance costs.

Professionals

There is no uniformity with regard to PHC: late referrals, treatment options not discussed with the patients and the families, poor symptom control, home visits without the necessary frequency, etc. characterize the care pattern. There is no difference among healthcare professionals from different disciplines in this respect – they have all neither learned about palliative care nor learned about the concepts of symptom control. They do not have experience in home care, and have difficulties in both team working and communicating with patients, families, and other team members.[11]

The reason for this situation is that palliative care is still not accepted as discipline, and as a consequence education and reimbursement for professionals are inconsistent. It is impossible to provide good home care with unpaid or underpaid professionals with incomplete training: it is more profitable and technically easier to hospitalize a patient.

Patients and families

Poverty challenges PCH. It cannot be effectively provided to patients who live in homes without kitchens, running water, indoor toilets, electricity, etc. It is also impossible if there is no public or charity support to pay for expenses related to care: medications, equipment, personal care items, transportation costs, and sometimes food.

The lack of public awareness about treatment options delays PHC: community education about the care they may expect can encourage patients to demand PHC, a possible powerful factor for its development.[12] There is a need to document these barriers to plan appropriate actions to reduce their impact and move community acceptance of the institutional care model to the background. Health systems require reforms to increase the availability and provision of PHC.

SPECIFIC ASPECTS OF PALLIATIVE HOME CARE

Models

For a better understanding of the different models of PHC the local development of palliative care is described in this section.

Ideal palliative care requires a complete team: (i) multiprofessional and interdisciplinary to treat the social, psychologic,

physical and existential problems according to the needs of the patients and their families, and (ii) activity adapted to the changing situations of the patient with 24 × 7 activity in the office, at home, and during day care or hospitalization. Universally, and especially in developing countries, comprehensive palliative care teams are not in majority; partial palliative care is the most common model of care in the final period.[13] In Argentina, almost all palliative care teams begin their activity in similar way: a group of volunteers (physicians, trained naïve personnel, nurse, psychologist) working in an institution or in the community, without specific planning, start the activity with outpatients. Then, with resources, they progress to develop a complete team. Figure 34.1 shows the development stages of a palliative care team in Argentina.

Each stage is a model providing palliative care based on the team's available resources; in all the stages there is home care, but of different complexity and effectiveness. In stage 1 home care is in the charge of the responsible caregiver (RC); the team works from the office and over the phone and does not come to the patient's home. In the other stages the care is still in charge of the RC, but home visits and care aid are added according to the team's capacity (personnel, time, transportation, etc.). The stages (and thus the models) are not static: activity is modified continuously with the development of the team and its changing characteristics. Different combinations of characteristics (Box 34.1) determine the complexity and the results of the PHC.

Examples

A team in stage 1 – community based with institutional support – offers care to outpatients. When patients cannot come (bad physical condition, long distances to travel, no transportation) 'distance' PHC is carried out: (i) the RC provides information about the condition of the patient, (ii) a presumptive diagnostic is made, (iii) the RC receives verbal and written instructions on specific techniques and takes care of the patient at home, (iv) when the patient gets worse he or she is hospitalized and cared for by other

Box 34.1 Characteristics of teams that influence palliative home care

- Institutional support (diagnostic and therapeutic resources)

- Availability of resources for home visits (vehicles/drivers)

- Number of disciplines

- Training

- Free care or paid care

- Dedication time/availability

professionals.[14] A team in stage 2 – community based with institutional support – offers care to outpatients and performs home visits. In out of office hours (nighttime, weekends) the institution's physicians collaborate in the care (they know the patient's clinical condition: the RC is provided with a summary of the clinical record, the medications in use and therapeutic suggestions in possible crisis).

- The UCP Sommer, in stage 5, in rural areas with resources for home visits: 60 percent of the patients die at home[‡].
- The UCP Tornú, in stage 5, in Buenos Aires city, without resources for home visits: 17 percent of the patients die at home[‡].
- The CCP San Nicolas offers paid palliative care to patients with health coverage. In this model, the team (2 physicians, 2 psychologists, and 2 nurses) are permanently available and assistance is completely delivered at home; 85 percent of the patients die at home[‡] cared for by the members of the team. Some members of the team (1 physician, 1 psychologist, and

3 trained persons; volunteer work) offer free palliative care to patients without resources one morning and one afternoon for a week at the office; when the patient deteriorates and cannot come to the office, he or she is hospitalized; 50 percent of the patients die in institution[‡], cared for by other professionals.

Team development can be optimized by:

- easier access to program by early referral
- availability of institutional beds for direct admissions
- medications from a specific *vademecum*
- equipment for comfort in the patient's home
- progressive development of:
  - care standards (symptom control, bereavement)
  - assessments tools
  - PHC chart
  - information systems
  - teaching protocols for team members
  - program audit.

THE RESPONSIBLE CAREGIVER

The availability of teams and resources do not guarantee the PHC. The family (persons with biologic, legal, or social relationship with the patient) plays a central role in all the treatments.[16] If these informal caregivers, who carry out a full time job without being paid, are integrated into the team, the majority of the patients can remain in their homes until death.

Steps in integrating the family

1 Evaluation of the family's capacity to care for the patient.
   - Do they wish to do it?
   - Can they understand and follow the indications for the treatment?
   - Will they be able to continue with their work?
   - Is the financial situation and the health coverage enough for the treatment expenses?
2 Identification of the RC.
   The RC is the member of the family who is in a better position (health, relation, proximity, and available time) to carry out and coordinate the care.[17] In one study[18][¶] 81 percent of RCs were women, 54 percent were siblings, and 32 percent spouses or couples; the average age was 46 ± 15 years. In all the cases the RC was the same person throughout the treatment period.

3 Education of the RC.
   It must be done progressively, with simple verbal and written instructions about how to carry out home procedures. Key areas to cover are:
   - Administration of medications (i.e. following schedules, measuring syrups, placing suppositories, subcutaneous injections, etc.)
   - Symptom evaluation (vomiting, pain, dyspnea, cough, insomnia, constipation, and delirium) and recognition of their different aspects (Is it nausea or vomiting? How many times per day? For how long was the episode? Content?)
   - Diet and hydration
   - Control of evacuations
   - Hygiene (bath, oral cavity)
   - Changes of position, dressings
   - Organization of the family tasks
4 Recognition of the death.
   The RC has the information about the patient's physical condition and completes the necessary cycling of information for the care: he or she is the intermediary between the team and the family.
   In the study described above,[18] the RC reported little practical difficulty in carrying out the task (2.32 ± 3.5) and great satisfaction to have done it (8.9 ± 1.6) at the end of the treatment[¶].
5 Support for the RC.
   Lack of support is a frequent cause of patient hospitalization. The RC is supported by:
   - guaranteeing the maximum possible control of symptoms, the availability of the team and access to easy admission
   - establishing a caring plan and a schedule of activities
   - anticipating the changes that can occur in the patient's condition
   - reducing doubts and uncertainty about:
     - choice of the adequate therapeutic option
     - possibility of causing damage
     - medication (drugs and doses, when to increase the dose, fear of overdosing, undesirable effects)
     - meaning of new symptoms with negative impact (feeding difficulties, problems with breathing, pain, sleeping disorders, delirium, weakness, increase of dependence, mood changes) and how they will be corrected
     - operating dichotomies (personal needs versus those of the patient)
   - arranging measures to reduce the emotional load.
   The RC is part of the patient–family unit of treatment: they are clients with full-time tasks and responsibilities who need to be cared for.[19] In teams in stages 1 and 2 the RC is invited to psycho-educational meetings of 1–2 hours duration, every 2–4 weeks. In the meetings, coordinated by a psychologist, they can reflect upon issues, doubts are analyzed and resources are optimized.

[‡]If admission is possible when the patient's symptoms are not controlled at home it can be assumed that the number and length of hospitalization are smaller, and the percentage of deaths in the institution is lesser when the PHC quality is greater; these data can be used as indirect indicators of the PHC efficacy.[15]

In more developed teams the RC is assisted during the visits to the office or during hospitalization. In the above mentioned study[18] the RC reported moderate emotional difficulty (5.7 ± 3.8) in carrying out the home care[¶]. They also reported a lot of suffering during the entire treatment, with no difference between the initial (7.5 ± 2.8) and final (8.4 ± 1.8) evaluations after a mean time of 39 ± 11 days. The causes of suffering were their own emotional situation, the emotional and physical condition of the patient, and the financial problems.

6 Providing material resources.

During PHC, resources must be provided; the public hospital and community are sources of medications, hospital beds, wheelchairs, urinals, commodes, walkers, etc. If possible, financial aid should also be offered to compensate for the increase of the family expenses and the reduction in income. In general the negative impact of the home care of a patient is underreported: in spite of the bad economic situation of the family, and of the limited aid that is given, no economic damages are reported. In the reported study[18] a mean 2.2 (±1.9) RCs reported sufficient family income during the treatment and 1.8 (±2.8) reported negative economic repercussions of the home care[¶]. Although a family's capacity for adaptation to adverse situations seems unlimited, it is a fact that the home care of a patient generates significant economic deterioration.

7 Symptom control.

Symptoms are controlled according to the criteria established by the World Health Organization (WHO).[3] The important issues are:

- *Medication.* In Argentina the high cost of commercial preparations of opioids is a barrier to adequate pain treatment.[20,21] The provision of opioids without charge or at low cost can be guaranteed with compound preparations (prepared by a pharmacist according to the national pharmacopeia in an individualized prescription) or generic preparations (products for which the patent has expired and thus can be manufactured and commercialized without restrictions of trademark) of aqueous solutions of morphine (6 g/mL), oxycodone (3 mg/mL) or methadone (1 mg/mL) for oral use, or aqueous solutions of morphine or oxycodone (10 mg/mL) for subcutaneous use. The same can be done to provide

dexamethasone, metoclopramide, hyoscine, bisacodyl, haloperidol, acetaminophen (paracetamol), etc.

- *Treatment monitoring.* The semi-structured evaluation of symptoms enables different team members (volunteer, nurse) to carry out uniform and regular monitoring of the treatment. This is especially important when patients remain for variable periods of time without medical evaluation (stages 1, 2, and 3). The information is obtained from:
  - the patient, on office or home visits. The PAMP uses a form to collect date and place of consultation, clinical disorders, symptoms (ESAS),[22] cognitive disorders, hydration, bowel movements, hospitalizations, route and doses of opioids, adjuvant drugs, diagnostic and therapeutic practices.
  - the RC, on an office visit or via telephone calls. The RC reports the patient's symptoms on a form that lists 22 symptoms; for 11 the options are yes/no and for 11 information on symptom intensity is recorded with a 4-point Likert scale.
- *Regulation of the interventions* that are prescribed and carried out to avoid 'hospitalization at home'. The following can be included:
  - administration of symptomatic medication
  - psychological interventions
  - lab tests
  - thoracic/peritoneal drainage, dressings, rectal maneuvers, physical therapy, electrocardiogram (EKG), chest/abdominal X-rays
  - subcutaneous administration of drugs
  - hypodermoclysis, blood transfusions, bladder catheterization, oxygen supplement, etc.

  At the CCP San Nicolas the three most frequent therapeutic practices are subcutaneous infusion of drugs, enemas, and hypodermoclysis; the three most frequent diagnostic investigations are plain X-rays, echocardiography and EKG, and the six most frequent lab tests are complete blood count, creatinine, electrolytes, blood sugar, calcium and prothrombin time, and partial thromboplastin time.[23]
- *Psychological evaluation and assistance of the patient.* As this is not possible for all patients it is carried out:
  - when the patient comes to the office or during hospitalization
  - according to established criteria: the patient or a team member request it, risky situations, lack of adhesion to treatment, or anguish, sadness and insomnia with intensity over 6 in the 0–10 scale
  - with semistructured evaluation based on the Diagnostic and Statistical Manual (DSM)-IV axes system
  - With brief psychotherapeutic practices: analysis of problems, behavioral techniques, cognitive techniques, and relaxation techniques.

¶In the CCP San Nicolas the RCs of 50 consecutive patients were interviewed and aspects related to the caring task were evaluated: their suffering and their causes (Suffering Scale, MSKCC, NCI 1.0), the emotional and practical difficulties of the task (0–10 scale: 0 without difficulty, 10 maximum difficulty) and satisfaction with the caring task (0–10 scale: 0 dissatisfied; 10 maximum satisfaction), the sufficiency of family incomes during the home care (0–10 scale: 0 not enough for nothing, 10 permits savings), and the negative economic repercussions of the home care (0–10 scale: 0 none, 10 maximum).[19]

ECONOMIC ISSUES

It is unclear if palliative care produces savings by reduction of the expenses of both fragmented care and use of high-tech interventions; some studies do not show savings and others show up to 68 percent savings.[24] The direct cost of PHC is related to the intensity of the assistance, the number of professionals that intervene, and the use of therapeutic and diagnostic resources. PHC can produce savings by the reduction of the number and the length of the hospitalizations.[15]

The use of resources was registered in CCP San Nicolas (stage 2, exclusive home care) and UCP Tornú (during its stage 4, assistance only in office and hospitalization). Members of both teams have similar training and therapeutic approach; the patients have free access to the resources. When comparing the therapeutic and diagnostic resources used with cancer patients with similar initial clinical conditions the results showed that (i) there were no differences in the length of treatments, nor in the number of diagnostic investigations, therapeutic practices, lab tests and consultations with non-team healthcare professionals, and (ii) there were significant differences in hospitalization (proportion of patients and length of stay) and in the percentage of deaths at home (lower and higher, respectively, in CCP San Nicolas).

In our experience, PHC by a team that does not carry out diagnostic procedures or therapeutic measures without reasonable expectation of benefit and that incorporates a competent RC, requires resources similar to institutional care but can generate savings by reduction of the number and length of hospitalizations.

ASSISTANCE COSTS FOR A GIVEN TIME PERIOD

The items that generate the cost over a period of time are:

- Number of professional visits
- Diagnostic and therapeutic procedures
- Medication
- Medical supplies
- Medical equipment (i.e. wheelchairs, pneumatic mattresses, etc.)
- Operative expenses (i.e. vehicle, communication, distance to the home, secretary, office setup, etc.)

If each team member determines the utilization average of each item and knows the value of each one, it is simple to structure the assistance costs for a period of time.

The CCP San Nicolas charges the PHC by modules of assistance that have the same cost for all the patients. The items that are considered in the cost of 1 month's assistance are: 2 medical visits per week (a), 2 nursing visits per week (a), 4 psychology/counseling interviews per month (b) and provision of oral and parenteral opioids analgesic (c). The module includes regular and on-call medical and nurse home visits in a 20 km radius area, and excludes hospitalization, all the drugs except opioids analgesics, oxygen, life

support measures, palliative radiotherapy and chemotherapy, diagnostic investigations, lab tests, and medical supplies and equipment.

(a) – one per week at the beginning, with patients in stable clinical condition and controlled symptoms; one or more per day in the final period; each visit in the covered area demands 2 hours in average.
(b) – two per month for the patient and two for the family.
(c) – average daily oral dose: methadone 30 mg and three morphine 30 mg rescue doses, or their equivalent parenteral doses.

THE VOLUNTEER'S ROLE

Volunteers from different professions and social groups play an essential role in palliative care: few teams could offer quality end-of-life care without their collaboration; they increase both team activity and interaction with the community.[25] After the volunteers are convened, interviewed, selected and specifically trained to work with patients and families, they can take on different tasks in all the development stages of palliative care, but with greater importance in stages 1 and 2. The tasks which have an impact on the PHC are:

- Semi-structured evaluation of the patient, at home and by phone
- RC education
- Massages, diet, hygiene
- Practical support (transfers, housekeeping activities, purchases)
- Recreation (company, walks)

ETHICAL ASPECTS

Palliative home care is a relatively new but rapidly growing concept that redefines care; thus it can be the source of ethical dilemmas.[26] To avoid them, when making decisions the wishes, beliefs and values of patients and families must be considered within the frame of some principles.

INFORMED CHOICES

The choice of where to receive assistance at the end of life is important and worrying for patients and families. The options should be evaluated with correct and complete information, and the patient, the family and the team should agree the choice. Two tips are: adequate choices are impossible with incomplete or biased information, and it must be possible to change the choice.[27]

BENEFITS/BURDENS RATIO

Palliative care is a medical discipline that uses all available diagnostic and therapeutic practices, including high

technology. In order to justify an intervention, its expected benefits must outweigh its burdens: the selection of each intervention in each unique situation must be based on the benefit/burden analysis. Practices with bad benefit/burden ratios that do not respect the proportionality principle (i.e. mechanical ventilation, vital monitoring, dialysis, parenteral nutrition) should not be offered or included in PHC plans.[26] PHC is different from 'hospitalization at home': it must not medicalize or technologize the dying process.

PRIVACY

Palliative home care should not be an intrusion in the privacy of the home and nor should it disturb the family life; to avoid those inconveniences a balanced plan of activity should be prepared considering the needs and the operating/organizing capacity of the family.[28]

COSTS

The choice of the place of care should be made without the pressures of economic factors (the goal of the PHC is not to reduce costs but to improve the quality of life) and it is probable that there can be savings for the health system, but it should not be forgotten that it represents an economic burden for the family. If PHC is promoted and implemented resources must be provided: as a minimum to provide medication (i.e. opioids) and a maximum to assign funds to the RC; it is a fact that in most cases the burden of cost shifts from the healthcare system to the caregiver.[29]

Key learning points

- Teams must start and maintain for the longest possible time, with the best possible quality, the process of assistance at home. PHC is not a high-technology approach, but it is a sophisticated approach considering the number of factors that determine its outcomes and results. Both issues make it a challenge. But it is also a source of satisfaction: if good-quality PHC is achieved, the patient receives the best possible care.

- It is important to have a better understanding of the practice, strengths, and limitations of PHC to promote, with a strong base, this approach to care that contributes to patient and family wellbeing.

Day hospitals

BRUNO GAGNON

SETTING THE STAGE

Provision of palliative care services has been in constant evolution since the initiation of the modern hospice movement in 1960. At first, emphasis was put on inpatient beds in hospices or in hospital settings. Rapidly, homecare services, often in association with hospice settings, were developed to take palliative care expertise into the home and to allow the terminally ill to remain at home until death if at all possible and if desirable. The first Palliative Care Day Care, inspired by the experience of day care services provided to older and psychiatric patients, opened in 1975 at St Luke's hospice in Sheffield, UK, to support patients with pre-terminal cancer and chronic disease.[1] This experience was reproduced extensively in the UK and elsewhere around the world in countries such as the USA, Australia, Japan, and several European countries.[2] Situated within communities, these day centers aim at providing a link between homecare services and inpatients units[3] with special emphasis on providing support through social interaction, psychological support, and respite for caregivers, as well as offering expertise in monitoring and symptom control.[4] The efficacy of this latter role of symptom management and improvement in quality of life provided by specialist palliative day care, referring to facilities offering medical and nursing assessment of all patients, was evaluated in the UK by comparing 120 consecutive patients referred to five specialized palliative care day centers to 53 patients receiving routine palliative care services who did not attend day care.[5*] All patients were prospectively assessed through three different interviews (at baseline, at 6–8 weeks and at 12–15 weeks) using the McGill Quality of Life Questionnaire (MQOL) and the Palliative Care Outcome Scale. At baseline, the two groups differed as the day center group had a lower score in the support domain of the MQOL than the comparison group ($P = 0.065$) and this latter group had marginally more severe pain at baseline ($P = 0.053$) and more severe symptoms at the second assessment ($P = 0.025$). This study was not conclusive in demonstrating improvement of quality of life of patients attending these facilities due to some methodological issues, mainly the limitations of the quality-of-life measures in identifying the effects of palliative day care. Further studies are needed to evaluate their clinical relevance.

A survey of palliative day care centers[6*] documented that these facilities were mostly situated within the community and had criteria for admitting patients to their services. These criteria often included being terminally ill or having active and progressive disease above their need for palliative interventions. These realities may in fact limit the access to palliative care by patients in need of such care who may not be in the terminal phase of their illness and/or are still mainly cared for in the hospital setting. Palliative care should be accessible to all cancer patients[7] as there is growing evidence that proper symptom management and psychological and existential support can be contributory in cancer control.[8] An example of the benefits associated with an early palliative care approach is the recent development in the treatment of cancer-associated anorexia-cachexia syndrome as a necessary element of cancer care.[9]

The concept of the day hospital was originally developed for the geriatric population. In 1951, the first geriatric day hospital was opened at Oxford, England,[10] in response to a lack of continuum of care between acute hospitalization and long-term placement.[11] By 1995, more than 400 day hospitals were implemented in the United Kingdom.[12*] Hospital based, these facilities operate 5 days a week but

most patients visit only two to three times a week and service duration is usually up to 12 weeks.[13] These services have been defined as 'an outpatient facility where frail older patients can receive subacute or acute medical, nursing, social and/or rehabilitative services over any portion of a full day, with return visits as necessary'.[14] A systemic review of 12 controlled trials comparing day hospital care for older people to comprehensive, domiciliary, or no comprehensive care concluded that hospital day care seems to be an effective service with trends toward reduction in hospital bed use and placement in institutional care, but methodological problems with these trials limit the evaluation of the services.[15***] A recent economic evaluation of a day hospital in Canada, based on the data of 151 subjects, found that for every dollar invested in the geriatric day hospital program, the benefit for the healthcare system was Can$2.14 (95 percent confidence interval (CI) Can$1.72–2.56).[16**] By definition, a day hospital should be hospital based, however in the USA, although standard day hospitals do exist,[17,18] the Collaborative Assessment and Rehabilitation for Elders Program established a community-based center offering similar services as in a day hospital.[19] This initiative challenges the definition of the day hospital based on its location as similar services could be provided in the community.

Furthermore, during the same period, the concept of day hospital has also been developed for patients with mental illnesses. Psychiatric day hospitals usually offer services and care on a daily basis but a recent survey of five European countries found no consistent profile of structure and procedural features.[20*] For the purpose of a systematic review of the effectiveness of day care for people with severe mental disorders, day hospitals were defined as multidisciplinary day care facilities offering comprehensive psychiatric care.[21***] In these reviews, they identified nine randomized controlled trials (1568 patients). Day hospital treatment was feasible for between 23.2 percent and 37.5 percent of those admitted to inpatient care. As expected, day hospital patients spent fewer days in inpatient care and more days in day hospital than the control group, showed significantly faster improvement in mental status ($P = 0.006$) and they did not differ in readmission rates. Day hospital care was reported to be cheaper than inpatient care.

The desire to manage patients within lower cost settings led to the extension of day hospitals to other medical illnesses such as orthopedic surgery, laparoscopic surgery, stroke[22***] cancer,[23*] diabetes mellitus,[24] rheumatological diseases,[25] chronic obstructive pulmonary disease,[26] congestive heart failure,[27] and other illnesses.[28] Cost effectiveness remains the major issue for the most day hospital initiatives. For example, in stroke recovery where multiple trials have been carried out, the lack of a standardized definition of the concept of day hospital rehabilitation made it impossible to fully demonstrate effectiveness in hastening functional recovery and reducing outpatients visits among older stroke patients without additional cost.[22***] A randomized

trial comparing the effectiveness of a day hospital program to usual care, in 234 patients with congestive heart failure, demonstrated reduction in morbidity and mortality with a cost/utility ratio for the integration of the day hospital management of US$19 462 (95 percent CI US$13 904 to $34 048).[27**] Interestingly, day hospitals have also been established for the management of pain crisis related to sickle cell anemia with successful pain management and possible reduction of hospital admissions.[29*,30*]

With the desire to offer palliative care services to patients with advanced cancer but who are still receiving active oncology treatments and/or may be candidates for complex palliative care interventions necessitating the hospital setting, a palliative care day hospital (PCDH) was opened in 1998 at the Montreal General Hospital in Montreal, Canada. After 6 years of operation, we reviewed our experience using a Delphi method. Twenty-one members of our team participated in the review process: eight physicians, five nurses, two clinical nurses, two administrators, one psychologist, one pastoral person, one patient assistant, and one clerk. This chapter presents the conclusions of this review process.

MANDATES AND ROLES OF THE PALLIATIVE CARE DAY HOSPITAL

From the beginning, the PCDH was planned to provide a leadership role in promoting links between a tertiary care hospital and community services. Box 35.1 enumerates the different mandates assumed by the PCDH. Special emphasis was made to be all inclusive for patients in need of palliative care interventions during the whole disease trajectory from diagnosis to the terminal phase of their illness. At the present time, patients with a cancer diagnosis are mainly, but not exclusively, referred to the PCDH, as part of an initiative promoted in close collaboration with the oncology services. The PCDH offers services to patients who could not access such comprehensive palliative care without hospitalization due to the complexity of their clinical situation and their limited physical tolerance, and to less sick patients with difficult pain or other symptoms who then can receive, in a relaxed setting, specialized palliative care not available in the community. The PCDH rapidly evolved as a communication center between community services and tertiary hospital services. Being situated in a university teaching facility, the PCDH contributes to the development of academic excellence in palliative care through teaching and research.

Box 35.2 describes in more detail the specific roles assumed by the PCDH. The team acts as consultant to primary physicians by providing optimal palliative care assessment and specialized interventions. However, the reality of limited resources in the community, especially of physicians making home visits[31*] and the complexity of the clinical presentation warrants that the team should assume a more

Box 35.1 Mandates of the Day Hospital

- The Day Hospital provides palliative care services to patients with life-threatening illnesses, primarily cancer; due to the complexity of their symptoms and/or their psychosocial context, these patients could not be appropriately cared for without being hospitalized. Patients may still be receiving palliative chemotherapy and can be candidates for complex medical/surgical interventions to improve quality of life

- The Day Hospital provides specialized palliative care that is not available in the community or in other institutions. The goal of the Day Hospital is to improve the quality of life of patients and to support their families while allowing them to remain at home as long as possible

- The Day Hospital works as a coordination center between hospital services, including inpatient palliative care services, and community-based services such as homecare services and hospices to improve continuity of care and access to appropriate services according to patients' specific needs

- The Day Hospital, as part of the McGill Palliative Care Division, promotes academic excellence by participating in teaching and research

Box 35.2 Roles of the Palliative Care Day Hospital

Patient care

- Should provide optimal palliative care to patients with: severe symptoms, existential distress, difficult family situation, regardless of their prognosis

- Should assume a consultation role for patients who are not in terminal phase of their illness

- Should assume treating physician role with terminally ill patients only in special situations: complexity of palliative care issues and to supplement lack of resources in the community

- Should coordinate referrals to other palliative care services: pastoral, psychology, etc.

- Should organize advance care planning including clarification of code status

- Should provide emergency consultations within 48 hours

- Should coordinate special investigation and interventions to patients in the terminal phase of their illness and, in coordination with other hospital outpatient services, to patients receiving active treatment

- Should provide specialized services to special populations, for example patients with lymphedema or severe anorexia-cachexia syndrome

Coordination of services

- Should improve links between specialized services of the hospital, especially oncology services and community resources

- Should promote links with homecare services and hospices through adequate referral

- Should respond to home 'crisis' by giving support to home-based palliative care teams and by coordinating admission to the day hospital or the inpatient unit so as to prevent, if at all possible, visits to the emergency room by terminally ill patients

- Should provide phone consultations to physicians and nurses in the community regarding complex issues

- Should develop protocols of care with community services

Education

- Should educate colleagues in other disciplines within the hospital about Day Hospital mandates, resources available in the community and the process to link patients and family with community resources

- Should promote palliative care through teaching within the institution, in the community and at national and international congresses

- Should offer training sessions to physicians, nurses, social workers, and other specialized caregivers

- Should participate in teaching medical students, residents, fellows, and students of other healthcare disciplines

Research

- Should provide equivalent care to all palliative care patients including those participating in research

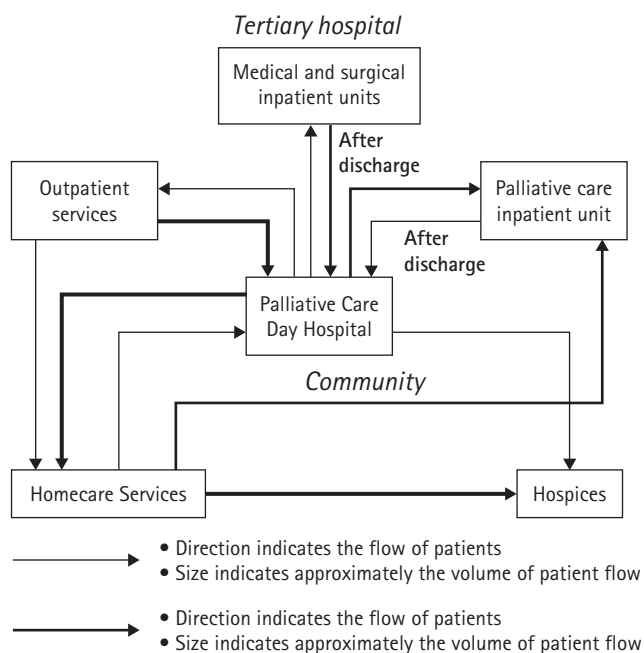
- Should collect baseline clinical and socio-demographic data for research purposes


Figure 35.1   *Links between the Palliative Care Day Hospital and other services.*

direct role in caring for this very sick population. The clinical condition of patients with advanced cancer can change drastically in a very short time and may mandate rapid interventions to adjust the plan of care. The PCDH can respond to such changes and provide support to the community by ensuring good coordination by communicating through phone calls with hospital and community services, by offering emergency visits to the day hospital and to other services within the hospital, and by coordinating admission to palliative care inpatient units. This coordination effort is an important component of the PCDH role and provides an important benefit to patients and caregivers.

Figure 35.1 illustrates the different links and the possible movement of patients between the places of care. While it was originally thought that most referrals to the PCDH would originate from community services for patients in need of specialized palliative care not available in the community, the experience demonstrated that most referrals came from other outpatient services within the hospital, such as oncology, radiooncology, and surgical clinics. Such a pattern of referrals is explained by the fact that cancer patients received care mainly through outpatient services of the hospital with minimal input from the community services until they reached the terminal phase of their illness.[31*] A possible explanation is that patients with cancer retain overall good physical function until late in the disease progression,[32,33*] and are therefore able to be cared for in outpatient clinics by cancer specialists. So, the PCDH evolved naturally into an evaluation, stabilization, and referring facility within the hospital for patients needing palliative care. Because they are located within the hospital, the PCDH team

members have access to the whole chart, previous investigations, and the technical support to rapidly assess and stabilize patients, and to provide community services with a complete palliative care evaluation and advanced care plan. However, the PCDH continues to provide valuable support to patients whose care has been assumed by community resources by providing ongoing reevaluations for complex situations and by offering specialized interventions.

The team members of the PCDH are all specialized in palliative care; they assume a leadership role in education and in research. Because the population of patients seen at the PCDH includes a spectrum of clinical conditions from early diagnosis to terminal phase of the illness within the same day, it is an ideal setting for teaching and research. Research with this population of patients is challenging due to the complexity and instability of their clinical situation. The PCDH provides a secure setting to patients with advanced disease, allowing them to contribute to the development of knowledge of palliative care by participating in research activities. Such participation offers to these patients, whose disease has often removed their social role, a sense that they are still contributing members of society.

PALLIATIVE CARE MULTIDISCIPLINARY TEAM

The basic team consists of physicians, bedside nurses, and a clinical nurse specialist in palliative care. Depending on the specific needs of individual patients, other members of the palliative care team such as the psychologist, social worker, physiotherapist, nutritionist, pharmacist, and pastoral care person will be involved in the care of the patient. Depending on the acuity of clinical situation and resources available in the community, a given patient may be evaluated the same day or at a later date by the members of the extended PCDH team or referred to services available in the community. Important elements of the team are also the unit clerk, patient attendee and the volunteers who provide an attentive ear and a helping hand during the stay of the patient in the unit. Creating an environment wherein patients can interact with staff and other patients is considered an important element of the therapeutic benefits of palliative care.[34*]

The PCDH makes it possible to access valuable highly specialized expertise available in a tertiary care hospital such as anesthesiologists, surgeons, oncologists, radiooncologists, psychiatrists, and other medical specialists, and also skincare nurses, stoma therapists, etc.

The day–to–day functioning of the Day Hospital

The daily functioning of the PCDH is based on a model of care delivered by a primary team composed of a bedside nurse and a physician. Box 35.3 presents their respective roles. As patients may be referred to the PCDH at any point

---

Box 35.3 Roles of the primary team members

Role of the Day Hospital physicians

- To take a complete history and physical including past history, cancer history, pain, and other important symptom issues

- To document diagnosis and prognosis

- To establish the priority of palliative care interventions: investigation, medication and therapeutic interventions, and referrals, in collaboration with the bedside nurse, to other team members

- To clarify the level of care and resuscitation status

- In collaboration with other team members, to establish advanced care planning: follow-up, admission, referral to hospice, etc.

- To call and to run family meetings

- To communicate information to treating physician

- To respond to phone consultations from the community related to medical issues

Role of bedside nurse

- Evaluation of the basic palliative care nursing including documentation of symptoms, performance status, cognitive testing, basic psychosocial assessment, drug profile and specific care issues such catheter, wounds, and stoma

- To establish a nursing care plan

- To teach patient and caregivers about proper use of medications, especially related to symptom management, and any other care issues

- To provide support to patients and families facing the palliative course of a disease

- To coordinate the involvement of the other team members from the PCDH or from the community

- To take an active role in the running of family meetings

- To organize and to coordinate care between the hospital and the community services to ensure continuum of care

- To assure support to community nurses

---

along their illness trajectory, the palliative care physician needs to clarify by communicating with the treating physician if necessary the exact diagnosis and prognosis to determine the level of involvement by the palliative care team and the need for follow-up. In some instances, palliative care interventions are limited in time until optimization of control of the symptoms before returning the patient to the treating physician. In most instances, the PCDH initiates care for patients receiving palliative oncology treatments and gradually assumes a growing role until assuming full care. This process involves a constant effort of communication to prevent confusion of roles and undue suffering to the patients and their caregivers. A challenging aspect of this process is the determination of level of care and resuscitation status. The treating physician has the primary responsibility in determining this important aspect of the care. In most situations, the PCDH team is called to help

patients and family to understand the meaning of a palliative care approach. By establishing a concrete advance care plan and by calling a family meeting, it is usually possible to have a smooth process that provides patients and caregivers with a sense of security and control over the situation. However, the PCDH team is at times confronted with distressed patients and family members who may not have fully understood the meaning of the information provided by the treating physicians. In these circumstances, it is useful to invite the treating physician to participate with the team in the family meeting. This approach has been extremely beneficial to this group of patients and has also revealed itself as a powerful tool to teach other specialists about the communication of bad news.

In view of better efficiency, the bedside nurse role is based on the concept of case management of the patient and family in relation with the environment. A thorough

biologic, psychologic, social, and existential evaluation of the patient is carried out by the nurse. As most patients present with complex clinical situations, the use of specific tools like the Edmonton Symptom Assessment Scale[35] (ESAS) to document symptom profile; the palliative performance scale[36] to evaluate the physical performance status; Folstein's mini-mental questionnaire[37] to screen for cognitive failure; and a locally developed semi-structured nursing interview, assure completeness of the evaluation in a timely fashion. This basic evaluation is also a therapeutic intervention which allows patients and caregivers, often for the first time, the opportunity to freely express their needs and concerns and by this very process to develop a trustful relationship with the palliative care team. It is an invaluable part of the service offered by the PCDH.

After the initial assessment has been performed by the nurse and the physician, the clinical situation of the patient is discussed to establish the plan for the day regarding further investigations, therapeutic interventions and referrals to other team members. The stay in the PCDH offers a comfortable environment to patients and family and an opportunity for observation. As the day progresses, it is not rare that hidden issues are voiced by patients and family members as they develop trust in the team members. Usually, patients are in need first of symptom control before organization of the advanced care planning. The PCDH offers access to multiple services (see Box 35.4) that allow rapid management of distressing symptoms without the need for multiple visits. After the symptoms are managed optimally, usually accomplished within one to three visits to the PCDH, patients and family caregivers, and not rarely professional caregivers from the community, are called for a family meeting. This advanced care plan includes provision of homecare services, recommendations to follow in case of difficulties with symptom management or emergency situations, and steps to follow when death occurs. Of special mention, this plan includes, in case care could not be provided at home until death, a referral to one of the hospices or to the tertiary palliative care unit for patients with complex syndromes necessitating special expertise.

During this process or after patients have been referred to either the treating oncologist if still receiving active treatments, or to the community resources for terminal care, the PCDH remains a support resource through phone calls or emergency visits. In certain situations, especially with patients in severe pain or distressing situations, or when community resources are insufficient, the PCDH assures regular follow-up until death in collaboration with the community healthcare providers.

PHYSICAL SETTING

Because the PCDH serves patients with a wide range of clinical conditions from bed bound to fully ambulated,

---

Box 35.4 Services offered at the Day Hospital

Clinical services

1   Thorough palliative care assessment

2   Diagnostic tests including radiological imaging tests

3   Coordination and administration of treatments available in tertiary hospital:

   - Blood transfusions
   - Abdominal paracentesis, thoracocentesis, etc.
   - Anesthetic interventions
   - Radiotherapy for symptom control
   - Wound and stoma care

4   Teaching to patients and family caregivers:

   - Pain medication and other care issues
   - Community services available
   - Solutions to special distressing situations like major bleeding events[38]

5   Family meeting

6   Palliative care counseling services:

   - Psychologist
   - Pastoral care
   - Nutrition
   - Physiotherapy and ergotherapy

Specialized clinics

- Lymphedema clinic
- Cancer nutrition and rehabilitation clinic
- Cancer related cognitive failure clinic
- Neuropathic cancer pain/methadone clinic

---

from specific single issues such as weight loss or lymphedema, to multiple palliative care issues, the physical settings should be variable. Our experience shows that a mixture of hospital bedrooms with private washroom, clinic type rooms, interview rooms, treatment room, and specific rooms with special research equipment, is ideal. The exact number is determined by the volume of daily visits. Sufficient space for patients and family members to relax should be provided such as a waiting room, kitchen, etc. A specific meeting room for family meetings or private discussions is essential to keep privacy. A unified, but well thought out,

well planned central working area for the staff increases efficiency of communication and should not replace separate offices to allow team members to perform their charting and telephone communication. Finally, it is essential to plan a lounge area within the day hospital setting for the staff to rest in while remaining accessible to respond to patients and family during their resting time.

INSTRUMENTAL IN ALLOWING PALLIATIVE CARE RESEARCH

The PCDH has become over the years an important setting to enable research with this fragile population. Thorough palliative care assessment and optimal symptom management assure that only patients with sufficient stable condition are offered the opportunity to participate in research protocols. Also, accessing patients and family members with palliative care needs earlier on during the illness trajectory has made it feasible to study ongoing changes in quality of life over a longer time-frame, as well as the occurrence of early cognitive failure, the value of nutritional and rehabilitation interventions when anorexia-cachexia is only beginning, new drugs for the treatment of cancer pain that require patients with longer survivals, etc. The PCDH physical setting and organization provide a supervised environment sometimes needed in specific research protocols. The establishment of specialized clinics (see Box 35.4) within the PCDH has allowed the development of expertise in specific fields of research.

THE PALLIATIVE CARE DAY HOSPITAL IN NUMBERS

In 1999, after 9 months of operation, we reviewed 154 new consecutive referrals to the PCDH over a period of 8 months.[39*] Table 35.1 gives the characteristics of the patients at the initial PCDH visit. The reduced representation of patients with breast cancer is explained by the limited number of women treated in our hospital. As expected, the majority of patients had advanced disease but we were agreeably surprised by the number of patients with regional disease in need of symptom control. While some patients were followed-up from the palliative care inpatient services, the great majority (77 percent) were new referrals to palliative care. The symptom profile as measured by the ESAS was characterized by fatigue, loss of appetite, and decreased wellbeing, for which 50 percent of patients scored their level of distress as moderate to severe (>40 on a visual analog scale from 0 mm = no symptom to 100 mm = worst symptom). Pain remained quite prevalent at 69 percent with 35 percent of these patients expressing moderate to severe pain. In fact most of these patients needed some opioid

Table 35.1 *Characteristics of patients at the initial day hospital visit (N = 154)*

adjustments: initiation (15 percent), increase (20 percent) or switch to other opioids (12 percent). Table 35.2 provides a summary of the follow-up of these patients. These 154 patients were seen 469 times. For 12 percent of patients, a same-day admission to the palliative care inpatient unit was necessary at their first visit. For the majority of patients (74 percent), one to three visits were sufficient to optimize their comfort and to arrange community-based care. However, 26 percent of patients needed four or more visits to be cared for by the PCDH team. This group of patients is composed of patients with difficult symptoms or psychosocial issues, and of patients without access to a family physician in the

Table 35.2 *Characteristics of the follow-up of the day hospital patients*

	N	Percent
Total number of day hospital visits	469	100
Number of direct admissions to the palliative care inpatient service	58	12

community. During this period, the specialized clinics (see Box 35.4) were not yet organized. With these new specialized clinics, patients with more than three visits to the PCDH should represent a higher proportion of the PCDH workload. The majority of patients were seen 2–3 months before death.

The cost of the PCDH has not been fully evaluated. In Quebec, physicians working in such settings are paid a fixed salary. The nurses and other team members are paid out of the palliative care service total budget. Transportation from home to the PCDH hospital is usually covered by the patients or their family. For patients 65 years and older, ambulance transportation is usually paid by social programs. The return transportation from the PCDH to home by ambulance or adapted transportation, if necessary, is covered by the hospital.

Is the PCDH cost effective? This remains to be determined as it has not been decided which outcomes should be used. For example, even if the majority of patients are still referred late in their illness trajectory, what is the exact value of earlier symptom management, especially through our specialized clinics? From a pure health service research perspective, the benefit of enhanced communication between the cancer center and the community-based services would need to be evaluated; the value of rapid referral back to the specialized palliative care based at the PCDH could be difficult to quantify; the continuum of care from specialized oncology services and hospital-based palliative care to homecare services would also need to be evaluated; the prevention of emergency room visits should be quantified; a reduction in the utilization of inpatient beds could lead to cost saving but should be supported by evidence of good quality of care at home, etc. Of note, the closest similar experience available has been the one of multidisciplinary symptom control clinics based at a cancer center. Two similar clinics, one in Canada and another in the USA, were partially evaluated and were found to be effective in improving symptom control and patient satisfaction.[40,41] However, cost-effectiveness was not evaluated.

CONCLUSION

Assuring access to optimal care to patients in need of palliative care remains a challenge. The creation of day hospitals within the tertiary hospitals or the cancer centers is a valuable option for patients with advanced cancer who are still receiving active care and for those in the terminal phase of their illness who need rapid access to palliative care due to their deteriorating medical condition. Such a model of care could easily be extended to other advanced, life-threatening illnesses such as chronic obstructive pulmonary disease, congestive heart failure, and neurologic degenerative diseases.

Key learning points

- Access to optimal palliative care remains limited to the very few.
- A PCDH can increase access to palliative care.
- The PCDH cares for patients earlier during their illness.
- The PCDH links the tertiary care center with the community resources.
- A basic medico-nursing team promotes efficiency and integration of care.
- The PCDH provides access to specialized palliative care techniques.
- The PCDH offers an ideal setting for end-of-life clinical research.

Inpatient hospices

JEREMY KEEN

EVOLUTION OF INPATIENT HOSPICES

The lineage of modern inpatient hospices is usually traced back to the medieval hospices that were initially 'guest-houses' (from the Latin, *hospitium*) run by religious orders for journeying pilgrims. These hospices inevitably became involved in the care of sick and dying travelers hoping for miraculous cures at the shrines to which they were heading. It is interesting to note that the words hospice, hospital, and hospitality are derived from the Latin, *hospes*, which has had different meanings as either 'guest/stranger' or 'host' at different times in history. This reflects the intimate relationship between carer and the 'cared-for' and was integral to the aspirations of the modern hospice movement.

The history of hospice evolution is punctuated by a series of remarkable individuals, mostly women, mostly with a religious conviction, who have sought to offer hospitality to the dying. Jeanne Garnier formed L'Association des Dames du Calvaire in Lyon in 1842, and opened a home for the dying the following year. The development of hospice and palliative care in Paris and New York can trace its lineage directly back to Jeanne Garnier and this first establishment in Lyon. As Superior of the Irish Sisters of Charity, Mary Aikenhead was instrumental in the opening of St Vincent's Hospital, Dublin, in 1834. Fulfilling her long-held ambition, the convent where she spent her final years became Our Lady's Hospice for the Dying in 1879. The Sisters of Charity opened St Joseph's Hospice in East London in 1905 and other hospices were to follow in Australia, Canada, and Scotland. During the period between 1879 and 1905 four other institutions opened in London specifically for the care of the 'dying poor' but did not call themselves hospices. St Luke's Home for the Dying Poor opened in 1893, was the only institution established by a doctor and its organization

of services and delivery of care was most closely linked to that developed in modern hospices. Although St Luke's employed lay nursing staff rather than those drawn from religious orders, as in the other establishments, the emphasis was still firmly on spiritual care. Dr Howard Barrett the founder of St Luke's wrote:

> It is much if we can render the last weeks and months less destitute of comfort, less tortured by pain. It is far more if through any instrumentality of ours some become humble followers of Christ.

Interested readers are directed to an excellent review of the development of hospices in the period 1878–1914.[1] The influence of St Luke's on the development of the 'modern hospice' is due in no small part to the time spent in St Luke's by Dame Cicely Saunders as a volunteer nurse. When planning St Christopher's Hospice, Dr Saunders stated:

> The name hospice, 'a resting place for travellers or pilgrims', was chosen because this will be something between a hospital and a home, with the skills of one and the hospitality, warmth, and the time of the other.

She sought to capture the hospitality of hospice but recognized that this was not enough on its own to ensure the optimal relief of suffering. Her vision for the model, upon which so many hospices in the UK and elsewhere are based, very much included aspirations toward research and the application of best evidence as an integral part of the provision of care.

After St Christopher's opened in 1967 there was a steady growth in the number of hospices opening in the UK and, internationally, a growth in the 'Hospice Movement' which has developed and adapted the philosophy of hospice care most often in a community setting rather than in institutions

called 'hospices'. Hospice care in the USA is an obvious example of a community-based service with statistics for 2003 showing that only 3.4 percent of patient days in hospice care were spent as inpatients in a hospice and only 6.1 percent of deaths in hospice care occurred in an inpatient hospice unit.[2] The philosophy of hospice care was first formally introduced into the general hospital setting by Dr Balfour Mount, who, having spent time training at St Christopher's Hospice, established a 'Palliative Care' service in Montreal in 1975.

The rate at which new hospices (for adults) opened in the UK reached a peak during the late 1980s and early 1990s (Fig. 36.1) with the majority resulting from local community enthusiasm and support rather than NHS planning.[4] The overall numbers of hospices reached a plateau in the mid-1990s. The latest statistics (2005[5]) report 220 specialist palliative care units in the UK of which 64 are totally funded by the National Health Service (NHS), and are usually situated within acute hospitals, and the remainder are independent hospices. The NHS units tend to be smaller (mean of 10.4 beds compared with 16.0 beds in independent hospices) but have very similar levels of staffing, discharge rates, and lengths of stay. The population cared for within hospices also appears to have stabilized (Box 36.1) with little obvious change over many years with approximately 95 percent of patients having a diagnosis of cancer and 96 percent being of a white ethnic background. All independent hospices in the UK now tender their services to the NHS and in so doing receive contributions approximating to one-third of their total budget. The UK government is committed to increasing its contribution to care within the independent sector but with 'strings attached' to ensure equity of access regardless of, for example, diagnosis or ethnicity.[6] This is significant for although the majority of hospices have not excluded those with diagnoses other than cancer, they equally may not have actively advertised their services for this population.

Figure 36.1 *The growth in numbers of inpatient hospices (IPUs) and hospital palliative care services in the UK (data taken from Hospice Information 2003[3]).*

Box 36.1 Inpatient hospices in the UK. Service provision 2003[3]

- Total number of adult hospices and palliative care units – 216

- Beds per million population (adults) – 51

- Beds per hospice (average)– 15

- Most common size – 10 beds

- Mean length of stay – 13.5 days

- Average discharge rate – 50 percent

In the UK the hospices have remained a focus of inpatient palliative care, research, and education. However, since the recognition of palliative medicine as a specialty by the Royal College of Physicians in 1987 and the proliferation of hospital-based services and academic departments of palliative medicine and care (see Fig. 36.1) the main focus, particularly in terms of research, has tended to shift toward the teaching hospital. This has increased awareness and acceptance of the specialty in mainstream medicine and nursing and eased the break from the perceived constraints of the hospices, by providing care for patients regardless of diagnosis and exploring 'supportive care' for patients at earlier stages of a disease process.[7,8]

Perhaps partly as a result of the recognition of palliative medicine as a specialty questions were raised as to the validity of hospices as separate institutions for the dying.[7] They were famously described as being 'too good to be true and too small to be useful'[9,10] and simply providing, to quote a general surgeon at a national meeting, 'designer deaths'. At the same time as voices outside the discipline were beginning to question hospice care, warnings were being issued from within the ranks.[11–13] Although the future of palliative and supportive care within mainstream hospital services seems to be assured, authors have continued to echo Professor David Clark's question: 'Whither the hospices?'.[14]

The development of hospices outwith the NHS, for the most part, facilitated the introduction and development of new models of care with an emphasis on an holistic approach dependent on true multidisciplinary teamworking. Features of these approaches, even the associated symbiotic 'niceness behavior' as recognized and defined by a recent study[15] are now found within mainstream medicine but, equally, increasing technology and issues of clinical governance have found their way back into the hospices. As the systems of care come closer together there is a danger that, for hospice care at least, the original concepts become lost in a drift toward medicalization and bureaucracy. However, the maintenance of independent institutions with little national governance or accountability brings

with it the danger of inequitable delivery of services, little in the way of quality control and a lack of coordination in efforts to improve the delivery of care.[16,17]

As hospices struggle with their changing role in patient care, perhaps their origins will provide a key to their further evolution. The rate of development in knowledge of symptom control has not been matched by development (or rediscovery?) of spiritual care. Now perhaps, as at no other time in history, the spiritual needs of those suffering life-limiting illnesses, with little in the way of personal religious terms of reference or the distraction of overriding physical symptoms, are becoming obvious. To use the relative freedoms of independent institutions to maintain excellence in symptom control but also to address other aspects of suffering in a novel and creative fashion may be a way forward. This may begin to ease the tensions of some of those working in hospices who feel they have become part of 'just another specialty'.[13]

WHO IS ADMITTED TO A HOSPICE?

Figures for 2001–02 show that 41 000 people in the UK were admitted to a hospice for the first time.[3] Hospices had a total of 59 000 admissions with an estimated 29 000 people dying during their inpatient stay. In England and Wales 4.3 percent of all deaths occurred in 'freestanding' hospices[18] (the Office for National Statistics is unable to separate figures for Palliative Care Units within an acute NHS hospital). Of these deaths 96 percent were certified to be due to malignancy, which demonstrates no change in the population as defined by diagnosis over the 5 years from 1998 for which statistics were accessible. The age distribution of inpatients at time of death is portrayed in Figure 36.2. Data from England and Wales in 2002 demonstrate 15.7 percent of all cancer deaths occurring in freestanding hospices compared with 22.2 percent at home and 50 percent in NHS-run institutions (hospitals and some care homes) with the age distribution shown in Figure 36.3. If deaths in NHS-run palliative care units are accounted for then figures approximate to 19 percent of cancer deaths occurring in palliative care/hospice units.[3] This represents a continuation of a trend noted by Higginson in her analysis of English data between 1985 and 1994, toward an increase in deaths in hospice and overall decline in deaths at home.[19] She added in a subsequent study that the overall proportion of deaths at home hid variations dependent upon social and geographical parameters.[20*]

Douglas in his oft quoted 'Personal View' in the *BMJ* observed, among other accusations, that the independent hospice movement was inefficient in that it provided 'deluxe' care for a favored minority.[9] A review of data generated by the Regional Study of Care of the Dying sought to address the issue of which cancer patients, dying in 1990, received inpatient hospice care.[21*] Statistically, five factors were found to independently predict hospice inpatient care: having pain in the last year of life, having constipation, being dependent
Figure 36.2　*Distribution of deaths in 2002 in independent hospices in the UK by age group. Data from Office for National Statistics.[18]*
Figure 36.3　*Distribution of deaths from cancer in the UK in 2002 by place of death and age at time of death. Data from Office for National Statistics.[18]*

on others for help with activities of daily living for between 1 and 6 months before death, having breast cancer, and being under 85 years of age. Hinton demonstrated a higher rate of admission among patients receiving palliative home care in those who were living alone or with unfit relatives and those with breast cancer.[22] Patients and relatives felt that the principal problems triggering admission were most frequently, weakness, pain or depression, and anxiety. A further study of data relating to cancer deaths in 1991 compared those who had accessed any palliative care service, including home care, with those who had not.[23*] The group accessing palliative care services were significantly younger, had longer survival times from diagnosis and tended to have been referred from certain general practices. Although it may be that general practitioner referral patterns contribute to a recognized inequity of access to palliative care across the UK,[5,24*] geographical and historical factors are likely to be

more important. An analysis of place of death of cancer patients in the North West of England demonstrated an increased likelihood of dying in a hospice if they lived close by.[25] Wood *et al.* have suggested a method of analyzing the provision of inpatient hospice care to a geographical region with particular reference to estimated level of demand, ease of accessibility in terms of 'drive-time', and levels of material deprivation.[26] In so doing the group was able to define an area within their region in which there was potential high demand, poor access, and high levels of deprivation, and which therefore merited a discussion of additional inpatient hospice provision.

A recent systematic review of access and referral to specialist palliative care found a lack of standardized criteria to guide referral.[27***] There are no national referral guidelines in the UK but most areas will have locally based guidance.[28]

The issue of the provision of hospice care for those with diagnoses other than cancer has been debated for several years now. Although many working within hospices would agree with the principle of broadening the diagnostic criteria for admission and are being encouraged to do so by the UK government there is little evidence that the hospice inpatient population is actually changing. This is likely to be a result of a perceived, and in some areas real, lack of skills and expertise among hospice staff in terms of assessing patients for admission and ongoing clinical management. There is, in addition, an ongoing perception that services will be overwhelmed by referrals. It is interesting to contrast the situation in the UK with the demographics of hospice care in the USA where only 49 percent of admissions carry a diagnosis of cancer. However, with Medicare funding only 20 days of hospice care the vast majority of patients referred are clearly in the final stages of their disease processes (35 per cent of patients die within 7 days of commencing hospice care).[2] The difficulty with prognosis in earlier stages of nonmalignant disorders has made hospices in the UK wary of potential long-term commitments and an ever-increasing rise in the number of patients 'on the books'. The introduction of NHS funding of care deemed 'palliative' in community-based care homes has focused awareness of the level of palliative care expertise that exists within these institutions. Educational initiatives are underway, some based in hospices, which not only afford support for the care homes but also allow a reverse flow of education back to the hospices in terms of the palliative care needs of the general population.[29]

WHAT DO HOSPICES PROVIDE?

The majority of hospices in the UK are staffed by at least one full time physician trained in palliative medicine, nurses, physiotherapists, occupational therapists, social workers and chaplains. Luxurious staffing levels in comparison to NHS hospitals ensure perhaps the most important aspect of care delivered to patients is the carer's time (1.88 trained nurses per hospice bed is the national average). In addition to providing inpatient end-stage care, hospices accept admissions for symptom control, rehabilitation and often, but not always, respite care. Most inpatient hospices will also provide day care and run multidisciplinary outpatient services for general palliative care needs and increasingly symptom-specific clinics for the management of, for example, lymphedema and breathlessness. In the independent hospices particularly, both inpatients and day patients may be able to access complementary therapies and in some units art and music therapy. The majority of hospices offer bereavement support services. The hospice and its staff will also act as a resource for the community providing advice and education to health workers and carers, and practical support in terms of equipment loans.

ARE HOSPICES SUCCESSFUL?

Literature supporting the care afforded by hospices is sparse certainly in terms of strictly controlled studies of sound methodology. Despite this, however, the independent hospices, in which are to be found 68 percent of available hospice beds, continue to find funds from charitable giving and operate large armies of volunteers. A survey of 2000 members of the public drawn randomly from the population in the UK asked participants to rank 12 different areas of healthcare in order of priority.[30] Interestingly, 'special care and pain relief for people who are dying' was ranked second overall to 'treatments for children with life-threatening diseases', coming above such services as hip replacements, transplant surgery, community nursing and psychiatric services. The area of care ranked as the lowest priority was care for those over 75 years of age with acute life-threatening illness.

The measurement of influence upon an individual patient's experience of hospice care is both a personal (for the hospice worker) and institutional problem. Outcomes in palliative care have often been developed to justify the service and have examined parameters that are relatively easily measured, for example, time of response to a referral, waiting times for admission, and pain and symptom control assessments. The early studies by Parkes at St Christopher's Hospice were encouraging but the methodology of retrospective carer interviews has been questioned.[31,32] Nonetheless the carers of those in the hospice were much less anxious than those with relatives in hospital and, additionally, felt part of a 'family' in the hospice. It is of interest to note the implied improvement in hospital care noted in the 10-year period between the comparative studies and the resulting relatively minor perceived difference between hospital and hospice care. This finding, in terms of the surviving spouse's perception of physical symptom control, was confirmed in a later study.[33] This is somewhat discouraging of further attempts at evaluation for a service that remains in a continuing battle for financial support. The focus for hospices has

shifted toward satisfying nationally approved standards of care that are for the most part derived from easily measurable components of service provision (e.g., QIS [NHS Quality Improvement Scotland] in Scotland). However, Needham and Newbury have recently attempted to give an evaluation of care, in an individual hospice, by assessing outcomes in terms of the achievement of individual goals set at the start of an admission by the patient, main carer, and hospice staff.[34*] Interestingly, the authors report a trend toward patients' and carers' goals of admission being more specific and functional compared with those of the staff that were more symptom or problem orientated. However, the large majority of goals evaluated from the three different perspectives were at least partially achieved in those patients discharged from hospice, with evaluations by carers and family of those dying proving difficult to obtain. More goals set by the staff were at least partially achieved than those goals set by patients or their main carers. This may reflect more realistic goal setting, optimistic assessments or possibly the relatively poor ability to identify patients' 'goals' demonstrated in an earlier study of hospice nurses.[35*] The words of Dame Cicely Saunders from over 20 years ago still need to be heeded:[36]

> No patient will thank you for much handholding or sympathetic counselling unless the things he or she perceives as the basics at that moment are attended to first.

The studies at St Christopher's Hospice comparing hospice and hospital care from the viewpoint of the surviving spouse found a consistent impression of a better social and psychological environment within the hospice compared to the hospital.[31,33*] A more recent study of patient and carer satisfaction suggested a greater influence on 'satisfaction with care' from perceived quality of life within hospice than from the presence of physical symptoms.[37*] This, as the authors observe, may reflect the general improvement over time in physical symptom control that is now occurring before admission to hospice.

If a person receiving palliative care is to be aided to 'live until he dies at his own maximum potential', again quoting Dame Cicely Saunders,[38] then this should be reflected in a wish within hospices to seek to maximize an individual's quality of life. A systematic review could find no evidence that inpatient hospices improved patient's quality of life[39***] but discussed the lack of good quality research and made suggestions of how outcomes may be assessed. However a more recent single study did suggest that quality of life improves after admission to a sample of palliative care units in Canada.[40*] However, the study quoted recognized its limitations with a mere 12 percent of admissions able to complete the study tool on admission, and only 8 percent a follow-up interview 1 week later. The study used the McGill Quality of Life Questionnaire (MQOL) and was able to show improvements in physical, psychological and existential domains. Earlier work by the same author demonstrated the importance of the 'meaningful existence' subscale of the MQOL in determining overall quality of life in palliative

care.[41] The goal of improving quality of life particularly through addressing issues surrounding the preservation of a meaningful existence such as, for example the maintenance of dignity and personhood[42,43] may become an increasing focus of research and development in care in inpatient hospices in the future.

CONCLUSIONS

The modern hospice movement and the specialty of palliative care has revolutionized the approach to the care of those living and dying with incurable illness. Inpatient hospices modeled on St Christopher's Hospice are now to be found in all parts of the world, although it is hospice as a philosophy of care, in the community or hospital, that has been developed most widely.

Inpatient hospices have proved over the centuries to be institutions that have been visionary in terms of providing for gaps in the provision of care for others. The early medieval hospices spawned hospitals and later the modern hospices which very much maintained the central ethos of providing hospitality for the stranger with the spiritual dimension of care as critical to this process. The 'modern' hospice in the UK, with independence in terms of resources and management structure, enjoyed space for the development of true holistic care and the new specialty of palliative care. The control of physical symptoms in the first phase of modern hospice development proved to be of overriding importance, and necessarily so because, just as in the care of any individual patient, one cannot address psychospiritual issues to any depth in the setting of uncontrolled physical symptoms. However, with a slowing of the rate of new developments in physical symptom control, and with the aid of comprehensive education programs, often run by the hospices, clinicians other than specialists in palliative care are able to provide a very good level of symptom control. Often initially attracted into hospice work by these early major advancements in patient care, individual staff in the UK are now having to examine their role in patient care and are dealing with new stresses. This may be particularly pertinent for practitioners who are hospice based rather than hospital-based specialists in palliative care.

A recent observational study submitted for a PhD has noted that in a freestanding hospice patients were left alone for significant amounts of time and reminds us of the power of 'being with' as a fundamental of hospice care and hospitality (E Haraldsdottir, personal communication, 2004). So, it could be asked, has care in hospices become too medicalized so that the carer's time is consumed by too many medical interventions? Have hospices, by becoming specialist palliative care units, taken on too broad a spectrum of patients so that those who are dying and 'comfortable' are not afforded as much time as others? Do we feel helpless in the light of our patients' significant emotional

and spiritual difficulties unmasked by good symptom control? In response to these sorts of questions there have been calls for 'hospice care' and 'palliative care' in the UK to proceed as distinct specialties,[44] in a somewhat similar fashion to the evolution of end-of-life care in North America.

The debate over the role and future of hospices has been ongoing since the early 1980s perhaps, in part, for reasons summed up eloquently by Torrens[45] as quoted by Small:[46]

> Early on it was clear who the villains and the heroes were, where the challenges lay, what were the pitfalls to be avoided. There was the good work and it was easy to devote one's life. . . . I think now we have passed that stage and ahead lie many diverse paths, many confusions of a subtler nature.

Now, nearly 25 years later, perhaps it is finally time for the hospices to admit their strengths and opportunities. The hospices do have the space, time and expertise to critically push forward psychological and particularly spiritual care. The acknowledgment of the existential dimension to suffering has always been fundamental to any definition of what hospices do and many authors have explored the approaches that can be taken within hospices and in palliative care. However, it is only now that, in general terms, patients have the relative freedom from physical symptoms and the hospices are perhaps mature enough to seriously explore these issues. If history is anything to go by this would only be good news for the hospitals and healthcare of tomorrow.

Key learning points

- Modern inpatient hospices evolved from institutions for the dying where spiritual care was paramount.

- There has been a phenomenal spread of the hospice movement and palliative care principally through the activity of early hospice practitioners.

- Significant developments in palliative and now supportive care are increasingly centered on the provision of care in mainstream hospitals.

- The value and role of inpatient hospice care has been questioned by the healthcare professions, but not by the lay public.

- There is little good quality research measuring the contribution inpatient hospice care makes to patient care.

- Recent research into the maintenance of personhood and dignity with an emphasis on the spiritual and psychological aspects of care may point the way to major areas of influence that inpatient hospices may have on palliative and general medical care in the future.

The palliative care unit

SHARON WATANABE, KAREN MACMILLAN

INTRODUCTION

The term 'palliative care unit' usually applies to a group of beds designated for the care of patients with terminal illness, located in an acute care hospital. Various models of palliative care units are possible, depending on local needs, resources, system characteristics and philosophies of care. Potential options in the design of a palliative care unit are listed in Table 37.1, each of which presents advantages and disadvantages.[1] Reasons for admission to a palliative care unit may include symptom control, terminal care, respite care, special treatment and investigations, and rehabilitation.[2] However, the availability of diagnostics, procedures, support services and consultants in an acute care hospital makes palliative care units particularly suited to the care of patients with problems of a complex nature.

A tertiary palliative care unit is a distinct type of palliative care unit, defined as an 'academic medical (center) where specialist knowledge for the most complex cases is practiced, researched and taught'.[1] The purpose of this chapter is to describe and discuss the role, structure, and operation of a tertiary palliative care unit, using the authors' unit in Edmonton, Canada as an example.

CONTEXT

The Tertiary Palliative Care Unit (TPCU) in Edmonton is an integral component of the Capital Health Regional Palliative Care Program.[3] This publicly funded program provides a comprehensive range of palliative care services, including home care and specialist consultation in the community,

Table 37.1 *Options in the design of palliative care units*[1]

Design element	Options
Location	Inside/outside main hospital
Admission policy	Open (any physician)/closed (specialist only)
Visiting hours	Open/limited
Source of admissions	Direct from home/in-hospital transfer only
Range of procedures, tests, therapies	Unlimited/limited
Do-not-resuscitate status	Required/not required

long-term care, ambulatory care, and acute care settings. It also supports designated units in long-term care facilities (i.e. hospices) for patients who have a life expectancy of 2 months or less.

The TPCU is located in an acute care teaching hospital. It consists of 14 private rooms in a dedicated geographical area. Amenities include a patient smoking room, a family lounge, a kitchenette, a quiet room, and a conference room. Family members may stay overnight if they wish, and pets are allowed.

PATIENT SELECTION

Admission criteria for the TPCU are listed in Box 37.1. The role of the TPCU is to provide care for the subset of patients who have the most complex problems and who

require the intensive involvement of a specialist interdisciplinary team. The problems may be in the physical, psychologic, social, or spiritual domains. Although no limitations are placed on diagnosis, the vast majority of patients have cancer as their primary illness. Unlike the hospice setting, life expectancy is not specified. However, the TPCU is intended as a temporary place of care, until symptoms have stabilized sufficiently to allow discharge to another setting. Patients are asked to agree to a 'do-not-resuscitate' status prior to admission; the pros and cons of this policy will be reviewed later in this chapter.

Box 37.1 Admission criteria for the Tertiary Palliative Care Unit, Edmonton, Canada

- Experiencing progressive disease where the focus of care is on comfort, not cure, and improving quality of life

- Requiring active care to alleviate distressing symptoms related to physical, psychosocial and spiritual needs

- Severe symptom problems for which management has not been successful in any of the other settings, and requiring intensive management

- Expected length of stay of approximately 2 weeks

- Over 18 years of age

- Accepting of do-not-resuscitate status

Referrals are screened by the palliative care consultants covering the various settings. The consultant determines, after direct assessment of the patient, whether or not a referral to the TPCU is indicated. The goals of admission to the TPCU and the temporary nature of the admission are discussed with the patient and family. The consultant is also responsible for confirming and documenting that the patient accepts a do-not-resuscitate status.

Once admission has been agreed upon, the patient's medical records are forwarded to the TPCU. The referrals are triaged to determine priority. Patients are usually scheduled for admission on weekday mornings. This allows sufficient time for a comprehensive assessment and discussion of the goals and plan of care with the patient and family. However, admissions for problems requiring urgent intervention can be accommodated 24 hours a day, 7 days a week.

STAFFING

Staffing of the TPCU is described in Table 37.2. The patients are admitted under the care of physicians who are specialists in palliative medicine, one of whom also assumes the medical

Table 37.2 *Staffing of the Tertiary Palliative Care Unit at Edmonton, Canada*

Type of staff	Full-time equivalent
Registered nurses	8.81 (2 per shift)
Licensed practical nurses	8.0 (2–4 per shift)
Nursing attendants	1.4 (1 per night shift)
Physicians	2.5
Chaplain	1.0
Social worker	1.0
Physical therapist	0.6
Occupational therapist	0.5
Dietician	0.2
Pharmacist	0.2
Clinical educator	1.0
Program manager	1.0
Unit clerks	1.7
Secretaries	1.6

administrative responsibilities. The nurses function in a team nursing model and work 8-hour shifts. The complexity of the patient population necessitates the inclusion of the chaplain, social worker, physical therapist, occupational therapist, pharmacist, and dietician as core members of the team. The program manager is charged with the organizational administrative responsibilities of the TPCU. The clinical educator arranges the admissions and supports the team's educational needs. The unit clerks, secretaries, and volunteers play an essential supporting role.

Other hospital support services, such as respiratory therapy, are frequently involved. The TPCU has a formal arrangement with an anesthesiology service at another acute care hospital for support for procedures such as spinal administration of analgesics. Patients are often referred to the regional cancer center for palliative oncological therapies. Other specialists may be accessed from within the hospital as needed.

ASSESSMENT

The tools routinely employed on the TPCU are listed in Table 37.3. Many were developed on the TPCU itself.[4–8] The tools have been adopted in all the settings of the Capital Health Regional Palliative Care Program.

The Edmonton Symptom Assessment System (ESAS) is a validated tool for measuring the intensity of common symptoms in palliative care patients.[4] Besides providing important clinical information on a daily basis, it has been successfully employed for audit purposes.[9] When patients are unable to complete the ESAS because of decreased level of consciousness, the families and nurses indicate their perceptions of patient comfort with the Edmonton Comfort Assessment Tool.[5] The Folstein Mini-Mental State Examination[10] is

Table 37.3   *Assessment tools used on the Tertiary Palliative Care Unit at Edmonton, Canada*

Tool	Domain measured	Team member responsible	Frequency
Edmonton Symptom Assessment System[5] (ESAS)	Intensity of common symptoms	Nurse	Daily
Edmonton Comfort Assessment Tool[6]	Overall patient comfort	Nurse	Daily (if patient unable to complete ESAS)
Folstein Mini–Mental State Examination[11]	Cognition	Physician	On admission and weekly
CAGE Questionnaire[13]	History of alcoholism	Physician	On admission
Edmonton Staging System for Cancer Pain[7]	Prognosis for achieving pain control	Physician	On admission
Edmonton Labeled Visual Information System[8]	Sites of disease	Physician	On admission
Edmonton Functional Assessment Tool[9]	Function	Occupational and physical therapist	On admission
Constipation score[15]	Quantity and location of retained stool	Physician	On admission and as needed
Morphine equivalent daily dose	Type, dose, and route of opioid	Physician	Daily
Palliative Performance Scale[17]	Performance status	Nurse	On admission

used because cognitive failure is an extremely common and potentially distressing complication in palliative care patients, but one that is easily missed without the use of a screening tool.[11] Identification of a history of alcoholism with an instrument such as the CAGE Questionnaire[12] is important because of this condition's underdiagnosis and association with poor pain outcomes.[13] The Edmonton Staging System for Cancer Pain is valuable for describing patient populations in terms of prognosis for achieving good pain control.[6] The Edmonton Labeled Visual Information System has been shown to improve physician recall of patient information.[7] The Edmonton Functional Assessment Tool measures 10 domains of function relevant to palliative patients.[8] As constipation is a frequent problem in this patient population, the constipation score is used to objectively quantify and locate stool, based on a plain abdominal radiograph.[14,15] The type, total dose, and route of opioid are recorded daily to track patient progress. The Palliative Performance Scale describes functional status and prognosis.[16]

WARD ROUTINE

At the beginning of the day, the nurses' observations of the patients during the preceding shifts are relayed to the medical team. The physicians then spend the morning assessing the patients and negotiating a plan of care for the day. Interaction with the team occurs on an ongoing basis. Once a week, a team conference is held, during which the admissions of the previous week are discussed in detail and a comprehensive management plan is formulated. The progress

of the other patients is also reviewed and plans adjusted accordingly.

While discussions with patients and families take place throughout the course of admission, a designated family conference is often advisable to clarify goals and establish plans of care. The conference is coordinated by the social worker and attended by the team, the patient, and all family members whom the patient wishes to involve.

DISCHARGE PLANNING

Approximately half of the patients admitted to the TPCU are eventually discharged to other settings. Some may be able to return home. Usually, a discharge home is preceded by a family conference that includes the homecare case manager. It is important that the patient and family understand who will be responsible for care once the discharge has taken place. The primary roles of the family physician and the homecare case manager are therefore emphasized. If the success of the discharge is in question, a trial discharge is recommended, whereby the patient's bed on the TPCU is retained for a few days in case the patient needs to return. Once the patient has been discharged, a medical summary is immediately sent to the family physician and to the homecare office. Patients whose symptoms have stabilized but who are unable to return home are usually transferred to a hospice.

Other patients remain on the TPCU until death. Some cannot be discharged because of progressive deterioration, whereas others have ongoing needs that cannot be met in any other setting. For example, hospices do not have the

resources required to manage spinal analgesics, total parenteral nutrition, or respiratory care.

EDUCATION AND RESEARCH

All members of the team are expected to participate in education and research. Most of the physicians have appointments in the Division of Palliative Care Medicine of the Department of Oncology, University of Alberta.

The TPCU receives undergraduate and postgraduate medical trainees from the University of Alberta on a regular basis. A total of four residents and fellows may be accommodated at a given time. Family medicine residents undertake a mandatory 2-week palliative medicine rotation on the TPCU. An analysis of multiple choice question examinations given to family medicine residents at the beginning and the end of their palliative care rotations demonstrated a significant improvement in knowledge.[17] Oncology residents also spend part of their compulsory 4-week palliative medicine rotation on the TPCU. Residents in the 1-year palliative medicine program spend 6 months on the TPCU. Elective rotations are open to residents from other programs and to medical students. Learners from other disciplines such as nursing and social work are also welcome. The TPCU has a long history of training palliative care specialists from across Canada and around the world.

Clinical teaching is complemented by journal club, held three mornings per week, during which time articles with relevance to palliative care are presented and discussed. A survey revealed that a majority of trainees found this activity to be of value for education, clinical practice, and development of critical appraisal skills.[18] Other educational activities include seminars and weekly program-wide rounds, which incorporate medical, interdisciplinary, and research topics. Presenters from other specialties are invited to share their expertise as applied directly or indirectly to palliative care, thus fostering the exchange of knowledge between different healthcare fields.

Funding for research on the TPCU is derived from a variety of sources. The priority given to this activity is reflected in the numerous examples of innovations in symptom assessment and treatment developed in this setting.[4–8,19–21]

OUTCOMES

Tables 37.4 and 37.5 compare the characteristics and symptoms of patients admitted to the TPCU, those assessed by the acute care consultation teams, and those admitted to the hospices.[22] Patients on the TPCU were significantly younger and had a significantly higher frequency of positive CAGE scores, poor prognosis for achieving good pain control, and severe symptoms. This suggests that patients were being appropriately selected for admission to this setting. An analysis of ESAS scores revealed an improvement in total symptom distress during the first 5 days of admission.[4]

In 2002, the total number of patients admitted to the TPCU represented 17 percent of all patients seen by the Capital Health Regional Palliative Care Program that year.[23] Median length of stay was 19 days and bed occupancy was 91 percent. Fifty-eight percent of patients died on the TPCU, while 24 percent and 13 percent were discharged to

Table 37.5 *Frequency of severe symptoms (ESAS ⩾ 50/100) in different palliative care settings*

the home and hospice settings, respectively. The annual budget for the TPCU is approximately Can\$2 380 000, of which 88 percent is used to fund salaries (excluding physician salaries, which are paid from a separate source). Another 8 percent is directed toward drugs, while the remainder is allocated for supplies.

DISCUSSION

Tertiary palliative care units fulfill a unique clinical role in the continuum of care for patients with terminal illness. They are designed to care for patients with the most complex problems of a physical, psychologic, social, or spiritual nature. In a comprehensive, integrated palliative care program, approximately 15–20 percent of patients would be appropriate for admission to such a unit.

Given the complexity of the patient population, the ideal location for such a unit is in an acute care hospital that offers a full range of diagnostic and interventional procedures (e.g. magnetic resonance imaging (MRI), endoscopy), support services (e.g. respiratory therapy), and specialty and subspecialty consultation (e.g. anesthesiology, surgery, internal medicine, psychiatry). For units that admit cancer patients predominantly, access to oncological consultation and therapy is essential. Indeed, it is possible for such units to be situated in cancer centers, although access for patients with diagnoses other than cancer may be limited. In the opinion of some administrators, the optimal unit size for staffing efficiency is 16–24 beds and the minimum size is 10–12 beds.[24]

The issue of requiring a do-not-resuscitate status for admission to a palliative care unit is controversial. This policy is based on the finding that the chance of success of cardiopulmonary resuscitation, defined as survival to discharge

from hospital, is nil in patients with metastatic cancer.[25] Agreement on this issue prior to admission lessens the chance of subsequent confusion about the overall goals of care. Furthermore, patients and families are spared the distress of experiencing or witnessing a resuscitation attempt. However, this policy may pose a barrier to care for those patients who could benefit from the unit's services but are not willing to accept a do-not-resuscitate status. Moreover, some palliative care specialists perceive that selected patients may be appropriate for resuscitation, depending on prognosis, quality of life, and the patient's wishes.[26] Whatever decision is made regarding policy, discussion of do-not-resuscitate status presents a valuable opportunity to clarify the patient's and family's understanding of the illness and prognosis, as well as goals of care.[27]

In order that the limited resources of the TPCU may be used for the appropriate patients, a process for screening referrals is required. Direct assessment of the patient by a palliative care consultant is preferred. Besides determining whether or not the patient's concerns warrant admission to this specialized setting, the consultant is able to prepare the patient and family for the type of care that will be provided on the unit. Meticulous communication between the referring and receiving teams is important for continuity of care and to minimize unnecessary duplication of assessments.

Given the complex nature of the patients' problems, a specialist interdisciplinary team is required. The team should comprise members who together can address the breadth of concerns of the patients and families referred to the TPCU. The Edmonton TPCU does not currently have a psychologist on the team, but one would be desirable. Consultants from other specialties also make a significant contribution to the care of patients on a TPCU.

A disciplined approach to assessment and documentation of patient and family concerns is essential for achieving the goals of admission. First, it is a fundamental step in

identifying and characterizing the patient's issues. Second, it allows for tracking of the patient's course over time and outcomes of interventions. Third, it facilitates communication of the patient's situation to the various care providers involved. Finally, the data collected may be used for program management, quality assurance, and research. As much as possible, the tools should be validated, easy to understand, not burdensome to complete and clinically useful. Also, they should capture the multidimensional nature of patients' concerns. Ideally, the same tools should be used in all associated healthcare settings, as the use of a common language facilitates transfer of care between settings and allows for comparisons to be made among settings.[22,23] The acuity and complexity of the patients admitted to the TPCU necessitate frequent assessment, rapid adjustment of therapies, timely communication between team members, and careful coordination of efforts. The patient and family must be recognized as being central to the team.

In order that the TPCU beds remain readily accessible to patients requiring admission, an effective and proactive discharge planning process is required. Options for discharge depend on local resources. For those patients who are discharged home, clear and timely communication with community healthcare providers (e.g. primary care physician, homecare manager, pharmacist) is critical. Transfer to a hospice often poses a difficult transition for the patients and families, not only because of their need to adjust to a new environment and staff, but also because they may view hospice as a lower level of care and feel a sense of abandonment.[28] These concerns may be alleviated by noting that the fact that the patient no longer requires management on the TPCU is a positive outcome, providing reassurance that the patient's needs can be adequately met in hospice, and arranging for families to tour the hospice. Depending on the resources available outside the TPCU, there may also be patients who stay despite stable symptoms because their needs cannot be met in any other setting. Some of these patients may remain on the TPCU for a prolonged period of time.

As a setting for the management of the most complex cases, the TPCU has an inherent mandate to transfer its knowledge to others, as well as to advance the state of that knowledge. These roles are facilitated by locating the unit in a teaching hospital, and by appointing the staff to faculty positions in the university. The TPCU presents a number of advantages as a learning environment. It provides learners with the opportunity to be exposed to a broad range of problems in palliative care, to follow patients closely, to gain experience dealing with distressed families and to work with an interdisciplinary team, all under the direct supervision of experts in the field. The potential disadvantage is that the patients and problems encountered on the TPCU are highly selected and not necessarily representative of those encountered in other practice settings. Also, the interventions performed on the TPCU may not be transferable to other settings because of resource limitations. The TPCU

provides an environment that is well suited to the conduct of research. Since the patients are under the direct care of the team, the process of screening and recruiting for studies may be simpler. If the study involves medically complex interventions or monitoring, then this may be most readily achieved in an acute care setting such as the TPCU. Also, compared with patients admitted to hospices, patients on a TPCU are more likely to be cognitively intact.[23] On the other hand, patients on a TPCU have a greater degree of symptom distress and therefore may not be well enough to participate in studies. In addition, the results may not be generalizable to other palliative patient populations. Nonetheless, many patients admitted to palliative care units are willing to consider participation in clinical trials.[29]

A number of publications have reported variable symptom outcomes in patients admitted to individual palliative care units.[9,30–33] Generalizability of the data is uncertain, in part because the characteristics of these units are diverse or incompletely described. A prospective, multicenter study demonstrated that admission to palliative care units resulted in significant improvements in the physical, psychologic, and existential domains of quality of life.[34]

The economic impact of palliative care units has also been described. In a report from a 23-bed palliative care unit in a comprehensive cancer center, costs were shown to exceed revenues if length of stay was greater than 10 days. Also, cost was inversely proportional to patient census.[35] Analysis from a palliative care inpatient service in another comprehensive cancer center revealed that mean daily charges were 38 percent lower than in the rest of the hospital.[33] Both units are characterized by intensive interdisciplinary symptom management and discharge planning, high patient volumes, short lengths of stay and low mortality rates. Economic outcomes have been described for a different model of palliative care unit, located in an acute care facility but providing terminal care for patients with a variety of diagnoses. Charges and costs were 66 percent lower for days on the unit, compared with days in hospital prior to transfer to the unit, and almost 60 percent lower for patients who died on the unit versus matched controls who died elsewhere in the hospital.[36] Economic issues are of course influenced by the funding mechanisms particular to each healthcare system. For example, in the USA, the distinction between acute palliative care services and hospice services is essential for reimbursement purposes.[33]

CONCLUSION

By providing specialist interdisciplinary care for the most complex patients, tertiary palliative care units fulfill a unique and leading role in clinical care, education, and research within palliative care programs, healthcare systems and academic centers. Further study is needed to clarify the impact of such units on clinical, economic, and academic outcomes.

Key learning points

- Different models of palliative care units in acute care hospitals are possible.

- A TCPU admits patients with the most complex problems.

- The key roles of a TCPU are clinical care, education, and research.

- Effective use of a TCPU requires a process for selecting appropriate patients and for discharging them.

- Successful management of these patients requires a specialist interdisciplinary team and access to diagnostic and interventional procedures, support services and consultants.

- A disciplined approach to assessment and documentation is essential for achieving the goals of admission.

Combined care models

FREDERICK J MEYERS, ANTHONY F JERANT

INTRODUCTION

Often considered synonymous with end-of-life care, palliative care is increasingly viewed as encompassing intensive supportive care throughout an illness. The World Health Organization (WHO) updated definition of palliative care includes relief of suffering throughout illness (not just at end of life) for adults and children.[1] The integration of intensive palliative care at transition points of illness – when psychosocial and family trauma is often greatest – has the potential to remedy glaring shortfalls in the quality of healthcare.[2] Conceptually, patients should not be asked to arbitrarily choose between disease directed and palliative care. Rather patients should be able to simultaneously receive both, when appropriate.

The physical discomfort often associated with illness or therapy combined with the emotional distress is the essence of suffering and of the rationale for palliative care throughout illness. Progressive palliative care responds to unique patient problems and progressively increases in intensity as illness progresses, often best addressed in-between illness exacerbations. In this chapter, we explore the concept of palliative care as a quintessential example of patient-centered care and discuss relevant skills for providing comprehensive, longitudinal palliative care. We also present promising process improvement models for integrating 'best practice' palliative care into daily primary care practice, cancer centers, and longitudinal care facilities.

PERSPECTIVE: CANCER

At the time of diagnosis, cancer generates a sense of vulnerability for virtually every patient, engendering fear,

uncertainty, and significant new demands. In spite of this early trauma, the majority of adult patients with newly diagnosed cancer gradually adapt to the crisis of their diagnosis and related treatments.[3,4] The literature does not provide similar information for young adults[5*] nor for diverse populations, though psychosocial distress screening and problem-based data have demonstrated that patients of all ages have significant and clearly definable problems.[6***,7***] The study of the dynamic changes in the psychological response to cancer and appropriate interventions have expanded to include time points beyond the initial diagnosis.[8***] Survivorship begins on the day of diagnosis as cancer patients begin to redefine all aspects of their lives.

The effects of cancer reverberate throughout the family.[9,10] Families can exhibit significant variation in their ability to adapt and respond to the overall cancer experience. While a variation in family response exists, family members can experience increased anxiety and depression, disruptions in social roles, and diminished physical health with an escalation of somatic complaints.[11] Cancer generates demands that impose severe levels of stress that challenge even the most well-functioning family.[6,12] These struggles occur as families attempt to serve as the primary source of support for the patient, a buffer against stress, and a facilitator for effective decision making and problem solving.[13]

When family caregivers are incapacitated by their reactions to the cancer diagnosis and treatment, the healthcare team loses a significant resource in the overall care of the patient. Distress in the family undermines decision making and problem-solving skills.[14] Family members' capacity to be effective caregivers is related to family functioning along the dimensions of adaptability and cohesion. The level of family functioning may simply be inadequate to meet the caregiving expectations of the healthcare team. Nearly all families experience difficulties and problems if the role of

caregiving is prolonged over time.[15*] Consequently, an imperative in cancer care has emerged to develop effective methods that enhance the problem-solving abilities of family caregivers to resolve difficulties related to the care of the patient outside the hospital during these critical transition points. The healthcare team is most challenged by patients and families who fail to adapt to the psychological and social problems of illness and living, often not manifest to the healthcare team until a crisis.

Quantitative or qualitative evidence of the benefit of the simultaneous provision of palliative care and disease-directed therapy has been difficult to demonstrate. Problems around patient selection, important and accurate measurements of quality of life and quality of care at baseline and after intervention, and an intervention that is consistent and reproducible may be the most important considerations. A simple efficacious example of a palliative care intervention that can be provided with disease directed therapy is the provision of an antidepressant medication.[16**] Two psychosocial or mental health interventions as models of beneficial supportive interventions have been reported.[17*,18]

Integration of palliative care into cancer centers: simultaneous care

Chemotherapy is commonly administered in the last 6 months of life and has had the dichotomous result of increasing hospice referral but reducing the duration of hospice services per family.[19] The use of cancer chemotherapy without curative intent is considered by some as a palliative intervention. Several randomized studies in prostate carcinoma have reported reduced pain in patients receiving chemotherapy compared with corticosteroids.[20] The quality-of-life metrics in one study were inclusive and may have shown overall benefit, though methodological problems with patient dropout prevent a definitive answer. In addition, follow-up was relatively brief with no sustained endpoints such as hospice referral and open to the criticism that the improved quality of life seen with chemotherapy without a real attempt to address suffering will disappear and show a final deterioration at end of life and lead to high risk grief.

Thus palliative chemotherapy is widespread but of unproved benefit compared with best supportive care and may degrade the reputation of the oncology community.[21] No one receives best supportive care because in oncology practice such care is usual care – a standard that is often deficient in pain relief and psychosocial support. Welcome calls to integrate comprehensive palliative care with disease directed therapy may set the stage for well-done studies that adhere to highest quality study design and outcome analysis.[22] Investigational cancer chemotherapy programs can serve as a model example for the integration of palliative care and disease directed therapy. Entry into investigational clinical trials, i.e. phase I and early phase II trials, should be an unmistakable sign that palliative care needs will be prominent. Cancer centers should be the epitome of palliative care provision, but most are not.

Concomitant with progressive disease, thousands of patients consult comprehensive cancer centers each year and receive technically outstanding, often protocol-governed care. The goals of these phase I and early phase II investigations are to define toxicity patterns, establish maximum tolerated dose, and if responses are seen, lead to advanced disease specific phase II and phase III trials. Any responses measured in phase I and early phase II trials rarely convert into prolonged survival for patients.

The clinical and ethical problem is well defined.[23,24] Cancer patients on investigational therapy are not treated with curative intent and need palliative care. The consequences of this cognitive dissonance between care planning and research had led to serious deficiencies in quality including late referral to hospice, unaddressed end-of-life issues, and patient family dissatisfaction including family caregiver stress and complicated bereavement issues. In addition, anecdotal evidence indicates that the clinical research mission is undermined as some patients forego participation in clinical trials because they perceive the loss of palliative options.

Why does this situation continue?

- The clinical research mission is central to oncology's efforts to reduce cancer mortality. However cancer centers and patients are unable to focus on both therapy and supportive care. The precepts of patient-centered care are obscured.
- The regulatory barrier in the USA that prevents simultaneous hospice care and disease therapy payments extends to the pre-hospice phase and separates the two care modalities, palliative care and disease-directed therapy. Interestingly, the criteria for hospice entry and investigational therapy entry are the same, advanced recurrent or refractory illness for which there is no proved therapy.
- Many advanced-stage cancer patients who make decisions to participate in cancer clinical trials are also characterized by a highly motivated personality. They feel that active treatment is best for them.[25] Other factors identified with enrollment may include altruism and the influence of the physician.[26] Patient expectations include a response to therapy despite consent forms that are explicit in stating otherwise,[27] a reduction in symptoms, and improved and increased communication with their physician.[28,29] Therapeutic efforts are often equated with superior quality of life and are measured against no other options. In contrast, patients and families believe palliative care is a passive choice, the equivalent of 'no care'.
- As a corollary, patients with advanced cancer overestimate their survival, making them more likely to choose 'life-extending' therapy over palliative care.[30] Patients and occasionally physicians have a distorted

view of intent and prognosis.[31] Studies of physician prognostication have documented that physicians were accurate in their estimate of survival yet were unable to effectively communicate the prognosis to patients. The bioethical implications of physicians' ability to foresee but not foretell has been explored.[32] The challenge, therefore, is not knowledge, but communication between patients, their families, and physicians.

• Healthcare providers lack training and role models in palliative care and systems do not support providers.

• Distress varies between patients and families and thus treatment strategies should vary.[33]

• Investigations are not done with clarity. An example of asking a clear question and developing a clear answer is the finding that consent forms for investigational therapy are not a barrier to effective palliative care.[27]

Despite these barriers, there are some recent developments suggesting progress in this area. For example, inpatient palliative care units deliver support to patients with life-threatening illness and advanced chronic diseases. Acceptance of the inpatient palliative care unit model has been enthusiastic and the model has also been associated with reduced hospitalization and post-hospitalization costs. Furthermore, the National Cancer Institute has also recently issued a call for research proposals in palliative care and has completed a consensus conference on improving end-of-life care.[34***]

In addition, the American Society of Clinical Oncology (ASCO) has developed several strategies to enhance the education of oncologists. For example, ASCO has issued a report that emphasized simultaneous caring of patients throughout illness.[35] ASCO has also modified the highly successful Education in Palliative and End-of-life Care (EPEC) program to an EPEC Oncology educational program. The organization also has included several sessions on palliative care at national meetings, and their publication *Journal of Clinical Oncology* has a section for original reports in supportive care

and a series 'The Tumor is not the Target' that features profound and comprehensive articles. The ASCO curriculum template includes the integration of palliative care in tumor types and a comprehensive list of topics such as supportive care, survivorship, psychosocial aspects, communication skills, and geriatric oncology.[36]

In addition to these clinical and educational developments, process improvement provides perhaps the most promising mechanism for improving end-of-life care, one that is advantageous for both patients and the institution. Process improvement involves a cyclic approach to improving clinical practice by assessing the problem, planning an approach, implementing the approach, and reassessing the problem with measurable endpoints.

We have designed a series of interventions in investigational therapy patients predicated on the process improvement approach. The goal was to evaluate the role of the simultaneous provision of palliative care, by an advanced practice home nurse and social worker, whereas the patients enrolled in the study also received disease-directed therapy (Fig. 38.1). Between 1998 and 2001 a homecare-based intervention was completed (Fig. 38.1a). In this nonrandomized study, no patient, family, or physician adverse events were observed and in fact the model was enthusiastically accepted.[37*] Quality-of-life endpoints were not improved but one quality-of-care endpoint, referral to hospice, was improved whereas another, number of cycles of chemotherapy was not changed.

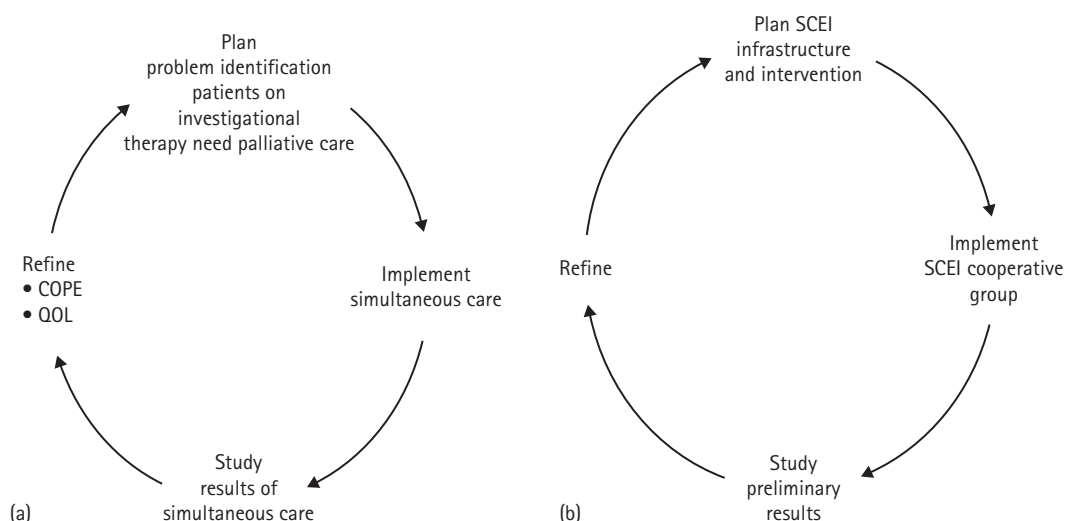
These results were analyzed, psychometrics were enhanced, and the intervention was refined in an ongoing a multi-institutional randomized study (Fig. 38.1b). The Simultaneous Care Educational Intervention (SCEI) teaches patients and caregivers to work as an effective team to manage symptoms and distress by acquiring a set of problem-solving skills. The SCEI intervention is based on the substantial body of social problem solving research conducted primarily by D'Zurilla and Nezu.[38] Through their


Figure 38.1
(a) Simultaneous care 1998–2001. (b) 2002 to present, QOL, quality of life; SCEI, Simultaneous Care Educational Intervention.

work, D'Zurilla and Nezu as well as others have developed conceptual frameworks for problem-solving therapy.[14,38] They have also conducted research that demonstrates that counseling caregivers who are under stress reduces their distress while increasing their problem-solving competence. This conceptual model has been applied successfully with a number of diverse health-related problems[39] including cancer.[3] Prior research has shown that problem-solving counseling of family caregivers has had beneficial effects, including lessened caregiver distress and reduced long-term depression in patients,[11] and is also highly appreciated by caregivers.[40]

Houts *et al.* have proposed a new conceptual model that adapts problem-solving counseling, and applies these principles in an educational format for family caregivers.[41] Houts' conceptual model has four components summarized by the acronym COPE for *Creativity, Optimism, Planning,* and *Expert* information. We employed the COPE operationalization of problem-solving education in our current study.

In summary, our study includes a simple and easily remembered framework for problem-solving counseling, a well defined patient population, robust psychometrics, and a randomized design powered for clinical significance. The intervention may be more ideal for patients at initial diagnosis and does not vary in intensity or type of intervention based upon baseline psychometric findings. The intervention is based on well established theory that translates to clinical research and, if successful, can readily be integrated into clinical practice.[42]

INTEGRATING PALLIATIVE CARE INTO 'MAINSTREAM' PRIMARY CARE PRACTICE

Does palliative care 'belong' in primary care practice? We and others[43,44] believe it does. The typical primary care physician only cares for 6–10 patients who die each year,[44] so if palliative care is conceptualized as a synonym for 'end-of-life care', then the role of the primary care provider in palliative care is indeed modest. However, when palliative care is viewed more broadly, to include early and ongoing communication regarding personal goals, effective discussions around the uncertainty of prognosis and outcome, and preferences for advanced directives, then the primary care provider is clearly integral to palliative care.[45]

Important barriers to greater integration of palliative care into primary care practice have been identified, including not only knowledge deficits but also attitudinal issues and practice structural barriers.[46] Most efforts to integrate palliative care into primary care practice have been focused exclusively on educating providers regarding technical topics (e.g. pain medication use). The underlying assumption is that primary care providers lack the clinical knowledge and skills to provide quality palliative care and that if these knowledge and skills deficits are corrected, palliative care will become an integral part of primary care practice.

While some research supports the idea that primary providers' palliative care knowledge base and skills may be suboptimal,[47] other research does not.[48] Furthermore, knowledge-oriented continuing medical education[49] and expert consultation[50*] interventions are generally ineffective in changing healthcare provider behaviors. Primary care provider communication behaviors and attitudes should be the primary targets linked to innovations in healthcare delivery processes and systems that facilitate delivery of palliative care.

Communication behavior changes: palliative care as patient–centered care

Primary providers are being encouraged to employ a patient-centered approach to healthcare. The patient-centered approach is generally preferred by patients compared to solely a disease-focused approach and may improve health outcomes.[51] Sociopolitical and ethical concerns[52] add to the considerable momentum for patient-centered care.[53] Mead and Bower recently outlined key components of a patient-centered approach to healthcare (Box 38.1).[54]

Box 38.1   Key facets of patient–centered care[54]

- A biopsychosocial perspective on medicine (e.g. exploring the illness experience as well as the disease)

- Understanding the patient as person

- Finding common ground regarding management of clinical concerns

- Enhancing the provider–patient relationship (fostering the therapeutic alliance)

- Understanding the provider as person

Exemplary palliative care can be considered as an example of ideal patient-centered care. For example, excellent communication is the *sine qua non* of effective palliative care.[55***] The manifestation of such communication is agreement on treatment and supportive care goals and on the evolution of those goals as disease progresses (finding common ground). The importance of recognizing transitions in illness and inpatients underscores the dynamic nature of palliative care, strengthening the provider–patient relationship over time. High patient family satisfaction with hospice programs may relate as much to coordination of care around patient and family concerns as symptom management.

The problem in the USA (as opposed to Canada, the UK, and some other countries) is that palliative care has

traditionally been provided only by a small cadre of 'special' individuals and 'saved' for those actively dying, despite its potential for transforming the quality and process of care throughout the trajectory of illness. For example, in the USA, primary care providers do not generally have conversations with patients and families early in the illness trajectory regarding the prognosis and typical course of illness and the patient's goals for therapy and remaining life – in other words, 'patient-centered' communication. Such conversations enhance understanding of the patient as person, allow common ground to be reached for management, and foster the therapeutic alliance. Missed communication opportunities early in the illness trajectory – for example, at the point where a chronically ill elderly person first begins to suffer irreversible decline in basic and/or instrumental activities of daily living, a marker for limited life expectancy – contribute to quality-of-care shortfalls such as the high number of hospital intensive care unit deaths[56] and very late referrals to hospice.[57] Beginning these critical conversations from the outset of diagnosis or close to it could allow the level of dialog around palliative care to be at a much higher level and might reduce intensive care unit deaths and late hospice referrals.[58***]

Attitude changes: cultivating mindful practice

Cultivating mindful practice may be somewhat less familiar than the other patient-centered care concepts. 'Understanding the doctor as person' means consciously considering the influence of one's own personal qualities, values, experiences, and interaction style on the process and outcomes of care. In the patient-centered care model, provider and patient continually influence each other through their actions.[54] The provider's unconscious internal reactions and external responses to various patients and clinical problems may be clinically constructive (empathy) or counterproductive (patients who 'push buttons'). Counterproductive reactions and responses can only be modified, and constructive reactions therapeutically harnessed, when the physician becomes fully cognizant of them. Thus, in the patient-centered method, the provider must become conscious of cues to their emotional relationship with the patient as it unfolds, cultivating self-awareness during clinical encounters.[59]

Many hospice staff tend to welcome self-awareness, exploration and, contemplation of spiritual and existential issues. However, for some primary care providers, such issues are initially frightening, painful, and even 'draining'.[60] Powerful unprocessed provider emotional reactions and feelings such as incomplete grieving for a loved one, can lead to a lack of self-efficacy in situations that call for palliative care. Cultivation of a mindful approach to practice will be required for adept palliative care, preventing patient abandonment and increasing tolerance for the anxiety that can accompany care of the dying and their family. Practical

approaches to cultivating mindful practice include journaling and peer discussion groups.

Systems changes: supportive primary care processes

Another fundamental challenge to integrating palliative care into primary care is the problem of competing demands.[61] In one encounter primary care providers must prioritize acute and chronic illnesses, psychosocial issues, and preventive services. Even if primary providers feel a strong clinical imperative to address palliative care concerns in a longitudinal, proactive manner, they may find that retooling their practice habits is simply not feasible without structural changes in the health system.

One potential partial solution is to 'frame' the issue of palliative care in primary care within the context of the patient-centered care. The chronic care model, a systems redesign approach to the continuous quality improvement of chronic illness, is instructive.[62] Several key elements to the model include reorganization of healthcare, delivery system redesign, increased access to decision support and clinical information systems, an emphasis on patient self-management, and linking with community resources.

One specific approach that is more effective than usual care and might be emulated in 'mainstreaming' palliative care practices is the collaborative model of mental healthcare.[63**] Patients with various mental illnesses (including depression and panic disorder) are provided access to a care manager supervised by a psychiatrist and a primary care expert and offered education, care management, and support of the patient's primary care physician with antidepressant medication management. A brief psychotherapy for depression intervention is offered, Problem Solving Treatment in Primary Care.[64] Other key aspects of the model involves a stepped care approach, in which the intensity and type of therapy are targeted to need.[63**]

Considering the success of the collaborative depression care model alongside the generally disappointing results of a recent study attempting to incorporate expert palliative care team recommendations into primary care is instructive.[50] The investigators asserted that primary care providers had simply 'ignored' many of the team's well-informed and reasonable recommendations. In contrast, the collaborative care model provides a framework for overcoming attitudinal and systems-based barriers and offers a useful model for integrating palliative care into primary care.

INTEGRATING PALLIATIVE CARE INTO LONG-TERM CARE FACILITIES

Assisted living facilities (ALFs) are congregate elderly residential settings that provide or coordinate personal services, supervision, activities, and health-related services. There are

about 1.5 million ALF beds in the USA, and demand is expected to grow as the population 'grays'. ALFs are an ideal setting in which to evaluate new models of palliative care. The elderly resident population is increasingly functionally impaired and frail. The 'typical' resident is an 80-year-old woman who needs assistance with two activities of daily living, and the estimated life-expectancy for people of this age and degree of frailty is less than 2 years.[65] Further, most residents suffer from multiple chronic illnesses for which accurate prognosis is difficult. The current approach of delaying palliative care until death is clearly imminent likely results in unnecessary, prolonged resident suffering.

We recently described a model – TLC – in ALFs that envisions palliative care as *Timely* and *Team*-oriented, *Longitudinal*, and *Collaborative* (including loved ones) and *Comprehensive*.[66] In a study evaluating palliative care improvement interventions grounded in the TLC model, no subjects were found to be eligible for hospice at baseline per National Hospice Organization criteria.[67*] Yet subjects' answers to two basic life values questions indicated a strong tendency to value maintaining the quality of remaining life over prolonging life at less than current quality. The TLC model has shown preliminary promise as a framework for improving palliative care in ALFs and might also be extended beyond the assisted living setting and applied to other populations of elderly patients, such as those in skilled nursing facilities and in the community.

Integrating palliative care into other settings

Failure to improve palliative care concomitant with intensive care because of late intervention is one of the lessons of the Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments (SUPPORT).[68**] Thoracic societies and palliative care experts have begun to campaign for improved palliative care within the ICU setting.[69,70] The emergence of a new intervention, inpatient palliative care consultation services, may overcome some of the barriers noted in the SUPPORT study and extend palliation earlier in patients with advanced chronic illness (www.capc.org). Position papers are available on the integration in many chronic illnesses including AIDS and neurodegenerative diseases (www.promotingexcellence.org).

Key learning points

Despite the variety among the palliative care innovations we have reviewed and the wide array of patient populations and clinical problems/conditions to which they have been applied, several common themes unify these 'best practice' approaches. They also serve as key learning points for those seeking to transform palliative care from a parallel system providing care to a small number of terminally ill patients by a

handful of experts to an integral part of the longitudinal care delivered by all providers to each and every patient:

- a patient-centered philosophy, including a focus on tangible, measurable health outcomes that matter to patients and their families

- deployment across the trajectory of illness rather than solely when death is imminent

- a simultaneous care approach that recognizes that co-existence of palliative and disease-focused or curative measures ought to be the rule rather than the exception in the setting of chronic, slowly progressive illnesses with often unpredictable trajectories

- an emphasis on integration of palliative care into existing 'mainstream' clinical settings (e.g. primary care, cancer centers) using a systems-based, process improvement approach

- targeting care approaches to suit the needs of well-defined and relatively homogeneous patient subpopulations (e.g. assisted living residents)

- recognition of patients' family members as essential members the palliative care team

- incorporation of coaching and problem-solving training to improve patient self-care and family caregiver care self-efficacy and skills.

PART 7

Overview of assessment

This page intentionally left blank

Multidimensional assessment in palliative care

ERNESTO VIGNAROLI, EDUARDO BRUERA

INTRODUCTION

Palliative medicine aims to decrease symptom burden and alleviate psychosocial distress in patients and families. Suffering is a state of distress that occurs when the intactness or integrity of the person is threatened or disrupted. Much of this suffering is often left unaddressed when healthcare is focused on the *disease* rather than the *person* with the disease.[1]

A patient's experience of advanced illness is complex: from physical symptoms, to coping, financial concerns, caregiver burden, social and family changes, and spiritual concerns. These issues should be managed through an interdisciplinary approach, with the focus of care being the patient and the family rather than the disease. Physicians must work together with many other professionals, such as nurses, psychologists, chaplains, occupational therapists, physical therapists, nutritionists, social workers, pharmacists and volunteers, to provide care and support.[2] This enables a multidimensional evaluation that includes assessment of the patient's clinical and psychosocial characteristics, identification of specific prognostic factors related to symptoms, and the patient's self-reported symptom burden (Fig. 39.1).[3]

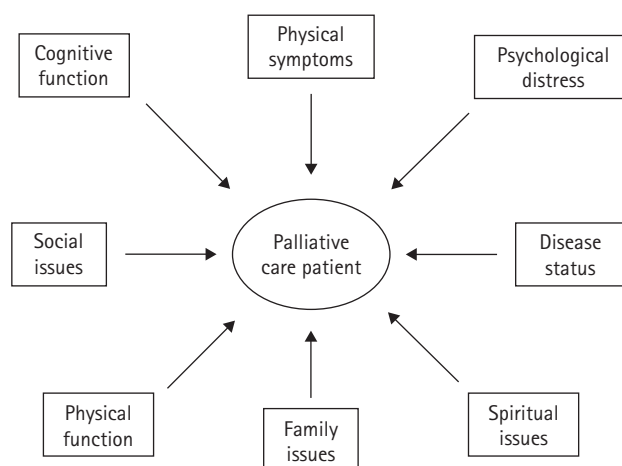
This chapter aims to bring together and summarize the different components of multidimensional bedside clinical assessment in palliative care and its importance for symptom control, quality of life, and decision making. The type of assessment tool and the intensity of assessment will vary according to the patient population (e.g. cancer patients, geriatric patients, etc.), the setting (palliative care unit, outpatients, home, etc.), and a variety of issues related to the


Figure 39.1 *Assessing the palliative care patient.*

team composition, culture, etc. The reader is referred to specific chapters in this book for a more comprehensive assessment and the use of specific tools for each particular symptom.

MULTIDIMENSIONAL ASSESSMENT

There are three steps in the experience of symptoms: production, perception, and expression. Production of a symptom is the process by which nociception occurs. In the case of cancer pain, for example, J receptor stimulation in the lung results in the production of dyspnea or the afferent

stimulus from the gastrointestinal tract or central nervous system results in the production of nausea. Production can be significantly different in one individual to another and in different areas within the same individual (e.g. some patients have multiple bone metastases of which only one hurts). Perception is the process by which the symptom reaches the brain cortex. This can also differ significantly from one individual to another (in the case of pain, endorphins or descending inhibitory pathways can significantly confound the intensity of the pain perceived). Unfortunately, these two stages cannot be measured. Finally, the expression of the distress is the only measurable part of the experience and is a target of therapy. However, this stage can also vary from one individual to another due to beliefs about the symptom experience, intrapsychic factors such as depression or somatization, and even cultural factors.

In summary, although it is important to measure the intensity of a certain symptom such as pain, fatigue, or nausea, it is important to recognize that this intensity of expression does not have the same unidimensional value of, for example, blood glucose in of the control of diabetes, or blood pressure in the control of arterial hypertension. Interpreting the intensity of pain expression as being only the expression of nociception would deny that in addition to variability in nociception, there is a great variability in both perception and expression. Rather, symptom expression should be interpreted as a multidimensional construct. In a given patient, a score of 8 out of 10 in pain intensity could be the result of nociception plus a certain level of somatization, coping chemically, and mild delirium. The multidimensional assessment should help in the recognition of the contribution of the different dimensions to the patient's symptom expression, and thereby assist in the planning of care. A purely unidimensional interpretation of intensity of pain would result in assuming that 100 percent success can be achieved with the simple use of higher and higher doses of analgesics. This simplistic approach could result in massive doses of opioids, opioid-related toxicity and excessive reliance on pharmacologic, as compared with nonpharmacologic, approaches to symptom control. A number of tools can be used to assess the contribution of different dimensions of the patient's symptom expression.[4–6] Figure 39.2 summarizes these steps with regard to the production of cancer pain. However, similar steps can be described for most other physical symptoms.

DISEASE STATUS

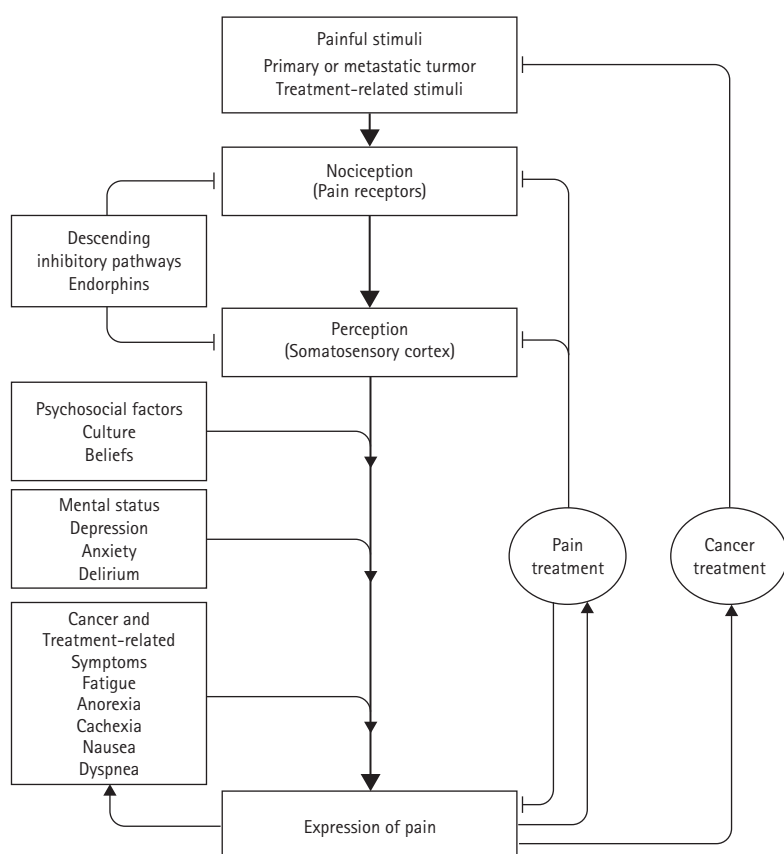
Patients are considered eligible for palliative care when they have a progressive life-threatening illness. It is therefore


Figure 39.2   *Steps in the expression of cancer pain. Redrawn from Bruera and Kim. Cancer pain.* JAMA *2003;**290**: 2476–9[6] with permission.*

important for the palliative care specialist to understand the stages of the underlying illness.

The initial step involves a complete medical history that reviews the disease diagnosis (cancer, acquired immune deficiency syndrome (AIDS), end-stage chronic obstructive pulmonary disease, congestive heart failure, or renal disease, etc.), the chronology of disease-related events, previous therapies, and all relevant medical, surgical, and psychiatric problems. A detailed history includes current and prior use of prescription and nonprescription drugs, 'alternative' medical therapies, drug allergies, and previous adverse reactions. The patient should be questioned about prior treatment modalities for each symptom and their perceived efficacy. Symptom assessment must include a thorough physical examination and review of the available laboratory and imaging data. Specific imaging, laboratory tests, or specialist referral may be appropriate to understand the pathophysiology of symptoms and their relationship to the disease.[7]

Walker *et al.*[8] developed and tested the Edmonton Labeled Visual Information System (ELVIS), a pictorial representation aimed at improving a physician's ability to comprehend and remember the basic details of the patient's disease status and prior treatments (Fig. 39.3). This instrument is a simple one-page line diagram that is used to graphically document the extent of disease in advanced cancer. It consists of two figures, of which one is used to document visceral and soft-tissue disease and the second, portraying the skeleton, is used to document bony disease. The diagrams are simple, and require the user to draw in, as necessary, sex-specific organs such as breasts, ovaries, the uterus, or testes, as well as other structures that have not been included. White space is provided to add labels to the visual representations and to document type and date of different treatments.

Palliative medicine specialists needs to be knowledgeable about the natural history and treatment of patients referred to their care. This allows for the appropriate recognition of
Figure 39.3 *The Edmonton Labeled Visual Information System (ELVIS). Redrawn from Walker* et al. *Impact of the Edmonton Labeled Visual Information System on physician recall of metastatic cancer patient histories. A randomized controlled trial.[8]* J Pain Symptom Manage *2001;* **21***: 4–11 with permission.*

patients referred to palliative care who might significantly benefit from life-prolonging, or occasionally even curative therapy. For example, a patient with advanced testicular cancer or Hodgkin disease may be severely symptomatic and appropriate for a palliative care referral. However, this patient should also immediately be referred to an oncologist because there is potentially curative therapy available. Similarly, a patient with opportunistic symptomatic infections related to AIDS with no history of previous triple antiviral therapy should be treated by the palliative care team in coordination with an AIDS specialist.

SYMPTOM ASSESSMENT

Symptoms are inherently subjective. They are perceptions, usually expressed by language.[9] Patient self-report is the primary source of information of symptom presence and severity. Communication is frequently difficult in terminally ill patients because of delirium or severe sedation due to drugs, metabolic abnormalities, infections, brain metastases, etc.[10] Proxies may be considered as an alternative or complementary source of information, especially during end-of-life care.[11] However, numerous studies have demonstrated that observer and patient assessments are not highly correlated, and that the accuracy of a clinician's assessment cannot be assumed.[12–14]

Healthcare providers often underestimate the severity of pain and other symptoms.[12,15] In studies of patients with terminal cancer assessed by healthcare workers as compared with the patients, agreement was higher for physical than psychological and cognitive symptoms, there was a greater agreement on absence rather than on the presence of a symptom,[10] and the variation in symptom scores was minimal when at least two individuals contributed in the assessment.[16]

Data about concordance of patient proxies' reports suggest that a patient's and their family members' reports of patient pain and performance status were highly correlated, although family members consistently reported more pain and disability.[13] Another study that assessed patients and their spouse caregivers suggests that caregivers agree with patients on objective measures with observable referents (e.g. ability to dress independently) but disagree with subjective aspects of patients' functioning (e.g. depression, fear of future, and confidence in treatment).[14]

Frequency of symptoms

Patients with advanced illnesses have an extraordinarily high frequency of physical and psychological complaints that impact on quality of life. Symptoms may vary with age, sex, primary tumor, and extent of disease.[17–21] In different studies[22–25] conducted in cancer patients referred to a palliative medicine program both as inpatients or outpatients the

median number of symptoms per patient was 11 (range 1–27). The 10 most prevalent symptoms were pain, lack of energy, dry mouth, dyspnea, feeling drowsy, anorexia, insomnia, feeling sad, constipation, and greater than 10 percent weight loss. The frequency of these 10 symptoms ranged from 50 percent to 84 percent. The most common symptoms were also the most severe. Gastrointestinal symptoms were also common in nongastrointestinal primary site cancers. Specific symptoms were influenced by age, sex, or performance status. For example, males had more dysphagia, hoarseness, >10 percent weight loss and sleep problems; females had more early satiety, nausea, vomiting, and anxiety. Vogl et al.[26] conducted a study in 504 AIDS outpatients and observed higher symptom distress and symptoms (mean number 16). The most prevalent symptoms were worrying, fatigue, sadness, and pain. Patients with intravenous drug use as an HIV transmission factor reported more symptoms and higher overall and physical symptom distress.

Assessment tools

In the process of instrument selection, the physician must carefully consider the goals of assessment and the practicality and acceptability of the assessment instrument by the terminally ill patient.[27] Simple assessment tools are the most appropriate for patients with advanced cancer. These patients may be weak and experiencing symptoms that make it difficult to complete a time-consuming and complex assessment tool.

Assessment tools are not only useful to diagnose and evaluate the intensity of the symptoms but also to monitor the effectiveness of therapy and to screen for side effects of medications. They play a role in the early identification of poor prognostic factors that can hamper the management of the symptoms of advanced cancer. Assessment tools should be used regularly, especially when patients experience new symptoms, an increase in the intensity of preexisting symptoms, or when therapy changes. The results should be documented in the patient's chart to ensure accuracy in the monitoring of the symptoms. The Memorial Symptom Assessment Scale[28] (MSAS), the Symptom Distress Scale[29] (SDS), the Rotterdam Symptom Checklist[30] (RSCL), and the Edmonton Symptom Assessment System[31] (ESAS) are examples of instruments that have been developed to monitor multiple symptoms in the setting of advanced cancer.

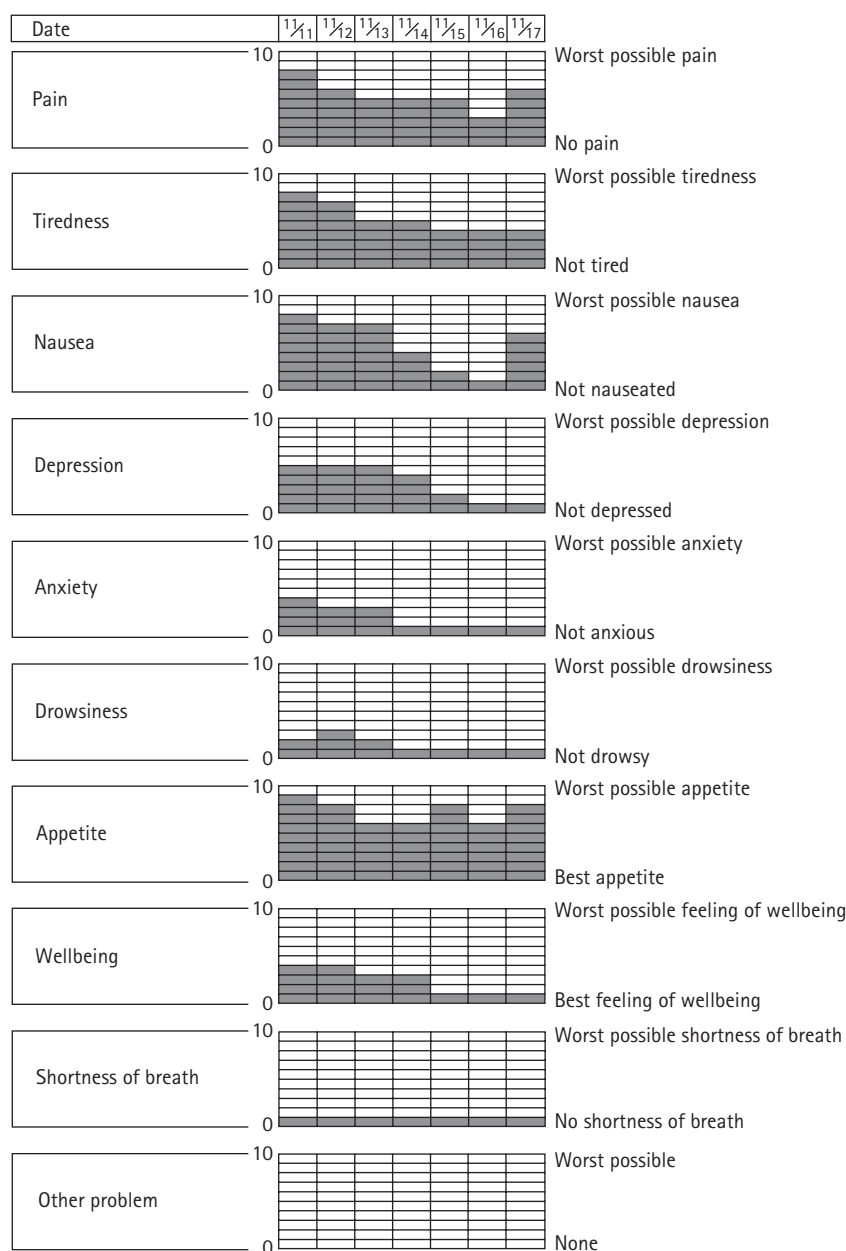
The ESAS is a concise, user-friendly, palliative care assessment tool that has been widely used in the clinical setting. It consists of a series of 10 visual analog scales that evaluate a mix of psychological and physical symptoms, in addition to a global sense of wellbeing[32] (Fig. 39.4). The visual analog scales are used by patients who are cognitively intact to rate symptoms from 0 to 10 and the resulting scores are then transferred to a graphical representation in the patient's chart. In patients with mild cognitive impairment, the ratings are


Figure 39.4 *The Edmonton Symptom Assessment System (ESAS). Adapted from Guidelines for using the Edmonton Symptom Assessment System (ESAS) with permission.*[32]

conducted in association with family or staff. For patients with moderate or severe cognitive impairment, especially during the last days of life, the family or staff provide the ratings.[33] Certain visual patterns which developed over time on the graphical display can alert the physician to the interdependence of the various symptoms and psychosocial influences. There appears to be a tendency for patients who experience psychosocial distress on a physical level consistently to rate many of their symptoms at a high level. Recognition of these patterns allows caregiving teams to be proactive and to focus on psychosocial influences as well as addressing the physical symptoms.

The validity and reliability of ESAS has recently been explored, and in advanced cancer it is apparent that it is a valid instrument.[34] The MSAS is a validated, patient-rated

instrument that assess the frequency, intensity, and distress level associated with 32 physical and psychological symptoms. It is mostly used in research settings[35,36] because it is lengthy and inconvenient to use on a regular basis. Recently, Chang et al. developed the Condensed Memorial Symptom Assessment Scale[37] (CMSAS), a 14-symptom instrument that contains both quality of life and survival information equivalent to the original 32 items. The symptoms identified by Chang et al. are also included in other widely used clinical symptom assessment instruments, such the ESAS, RSCL, and SDS. This report is also one of the first to demonstrate that scales from a shorter instrument can be predictive of survival, and that there is a core of symptoms that provide most of the information about health, quality of life and survival. The CMSAS needs to be further evaluated and

validated and the optimal number of symptoms in this version are still under study.

ASSESSMENT OF DELIRIUM AND COGNITIVE IMPAIRMENT

The presence of cognitive impairment, whether as a result of delirium or dementia, presents a major impediment in the assessment of symptoms in patients with advanced disease.[38] Delirium is an important source of distress to patients, family members, and caregivers. Patient assessment becomes difficult, communication of patients with caregivers and family members is impaired, the patient's expression of their symptoms is usually increased, and they are usually unable to participate in their own care.[39] The frequency of delirium in patients with advanced cancer varies from 28 percent to 40 percent on admission.[40,41] Eventually, up to 83 percent of patients develop delirium in their final days, and 10–0 percent of them may require palliative terminal sedation.[42,43] In some studies delirium was not detected in 22–50 percent of the cases.[44]

The diagnosis of delirium is made on the basis of acute onset, fluctuation in course, reduced sensorium, attention deficit, and cognitive and perceptual disturbance, which occurs in the presence of an underlying organic derangement.[45] The Mini-Mental State Examination (MMSE)[46] is a widely used screening tool for cognitive impairment as a component of delirium. The cut-off points depend on formal education reached and age, and may vary for elderly people in different countries.[47,48] Other tools have been developed and validated for screening or monitoring the course of delirium, such as the Memorial Delirium Assessment Scale[49,50] (MDAS), the Delirium Rating Scale,[51,52] and the Confusion Assessment Method[53–55] (CAM). See Chapter 72 for the different uses of these assessment tools in delirium.

Based on the level of psychomotor activity, there are three subtypes of delirium: hyperactive, hypoactive, and mixed, which is the most frequent form of presentation.[56,57] Misdiagnoses of hypoactive delirium as depression or agitated delirium as anxiety disorder is not unusual. The emotional lability, disinhibition, and psychomotor agitation components of delirium are frequently interpreted as worsening pain by relatives, and sometimes by medical and nursing staff,[58] especially in the absence of any objective cognitive testing. Fainsinger et al.[59] described a 'destructive triangle' created as a result of the family's misinterpretation of the patient's delirium as pain, and their consequent desire for nursing and the physician's efforts to 'do something'. The doctor may be placed under pressure to relieve the patient and family's distress. This emotional overload may lead to an increase in the opioid dose and aggravate the agitation, in particular when the opioid is already implicated as a precipitant.[60] A multidimensional assessment in this setting will lead to cognitive testing and the recognition of delirium. This assessment may result in more appropriate interventions, such as opioid rotation or dose reduction, and prescription of a neuroleptic for the symptomatic treatment of delirium.[61]

Delirium can result in misinterpretation of symptoms and emotion expression, and conflict between the patient's family and healthcare professionals, or even among different healthcare professionals with regard to the patient's behavior. Once the diagnosis of delirium has been confirmed by a thorough medical assessment it is important to appropriately inform the different disciplines in the team about the presence of this syndrome because a number of pharmacologic, rehabilitation, and counseling interventions may be inappropriate in patients with severe cognitive failure or delirium. Education for the family will also be important to help them understand the inhibited expression of physical or emotional distress in a cognitively impaired or delirious patient.

ASSESSMENT OF PHYSICAL FUNCTION

The majority of patients with terminal illness have impaired ability to perform everyday functions during the various stages of the disease. Functional status is an independent predictor of survival.[62] It is also essential for planning the setting of care, which can be the home, hospice, or acute service.

The Karnofsky Performance Scale[63] (KPS) and the Eastern Cooperative Oncology Group[64] (ECOG) have been used widely in the assessment of physical function in cancer patients. The KPS is considered a 'gold standard' for assessment of functional status in cancer patients.[65,66] However, in patients with advanced cancer in palliative care setting assessments these instruments tend to generate clustering of scores at the extreme end of impairment. Consequently, newer instruments such as the Edmonton Functional Assessment Tool[67] (EFAT) and the Palliative Performance Scale[68] (PPS) have been developed. The EFAT includes domains such as pain, mental alertness, sensory function, communication, and respiratory function, in addition to domains that more directly reflect physical function, such as balance, mobility, wheelchair mobility, activity, activities of daily living, and dependence performance status. This information can give physicians prognostic information about the patient. For example, a bedridden patient with severe pain due to a pathological hip fracture has a much better potential for recovery than a patient bedridden due to cachexia and delirium. A revised version of the EFAT has recently been validated.[69] The PPS is essentially a modification of the KPS and assesses ambulation, activity, self-care, intake, and conscious level.[70]

An objective assessment of physical functioning constitutes part of the multidimensional symptom assessment in palliative care. Impairment in physical functioning and distressing physical symptoms such as pain have the potential to adversely affect psychosocial function.[71,72] Physical

and occupational therapy assessments may reveal deficits and suggest interventions that can be essential to maintaining functional capacity, ensuring patient safety, conserving energy, and decreasing fatigue. A speech therapy assessment can provide valuable information regarding swallowing function, while a nutritional assessment by a dietician can aid in determining caloric intake.

The assessment of physical function in palliative medicine will allow for the identification of simple measures such as special wheelchairs, ramps if there are steps in the home, bathroom supplies, a trapeze for bed mobility, or the need for a formal rehabilitation approach. On the other hand, in some cases decreased function may be associated with conditions such as severe incidental pain, delirium, dyspnea with minimal efforts, or irreversible neurological damage and in these cases appropriate adaptation to the loss in function, and patient and family education will be the most appropriate course of action. Therefore, the assessment of physical function needs to be integrated with an understanding of the underlying disease status, symptom control, psychosocial distress, etc.

ASSESSMENT OF PSYCHOLOGICAL DISTRESS

The perception of different symptoms, such as pain or fatigue, may be accentuated by the emotional or psychological distress of the patient. Psychological distress impairs the patient's capacity for pleasure, meaning, and connection; erodes quality of life; amplifies pain and other symptoms;[73] reduces the patient's ability to do the emotional work of separating and saying good-bye; and causes anguish and worry among family members and friends. Finally, psychological distress, particularly depression, is a major risk for suicide and for requests to hasten death.[74] On the other hand, severe undertreated physical distress leads to severe psychological distress. Untreated or under-treated pain, nausea, dyspnea, or other uncomfortable physical symptoms can profoundly disturb mood, sleep, and make it impossible for patients to relate appropriately to their family and their healthcare professionals.

A psychological assessment should be done to evaluate mainly mood and coping. It is important for a team's members to become familiar with each of these areas, and to recognize when there are issues that need further assessment and/or intervention by another healthcare discipline.[2] Medical staff often fail to recognize and address psychological distress, and this impacts negatively on quality of life.[75]

Patients with terminal diseases have a variety of ways of coping with their diagnosis, including fear, anger, avoidance, denial, intellectualization, intense grieving, and existential questioning. The distinction is often difficult to make between the normal psychological burden that exists in relation to physical and psychological distress and certain aspects of psychopathology such as somatization, anxiety, adjustment

disorder, and depression.[58,76] In addition, physical symptoms of depression (such as fatigue, anorexia, sleep disturbance, etc.) may be attributable to the disease itself.

Numerous factors act as barriers to recognition and treatment of psychological symptoms. Both patients and clinicians believe that psychological distress is a normal feature of the dying process and fail to differentiate natural, existential distress from clinical depression. Physicians lack clinical knowledge and skills to identify depression, anxiety, and delirium, especially in terminally ill patients where the diagnostic clues are confounded by coexisting medical illness and appropriate sadness. Patients and clinicians often avoid exploration of psychological issues because of time constraints and concerns that such exploration will cause further distress. Physicians are reluctant to prescribe psychotropic agents, which can have additional adverse effects, and therefore may hesitate to diagnose a condition that they feel they cannot treat successfully. Finally, when caring for dying patients, physicians may feel a sense of hopelessness that can lead to therapeutic nihilism.[72,77]

Mood disorders

Studies conducted during the past decades have revealed that mood disorders are highly prevalent in oncology: figures ranged from 2 percent to 46 percent for anxiety, from 6 percent to 42 percent for depressive, and from 32 percent to 52 percent for adjustment disorders, depending on sample characteristics (e.g. stage of disease, outpatient or inpatient), mode of data collection (e.g. interviews vs. self-assessment) and diagnostic criteria (e.g. cut-off scores for determining pathological cases).[78–81]

The clinical interview is the gold standard for diagnosis of depression.[82,83] Chochinov et al.[84] found that the single question 'Are you depressed?' provides a sensitive and specific assessment of depression in terminally ill patients. Another useful question is: 'Have you often been bothered by having little interest or pleasure in doing things?' The first question targets mood, while the latter is an indicator of anhedonia.[85] A patient who responds affirmatively to any of these questions is likely to receive a diagnosis after a comprehensive interview.[86,87]

Patients who are at increased risk for developing psychiatric complications are those with low performance status, those receiving certain cancer treatments, and those with uncontrolled physical symptoms, functional limitations, lack of social support, and past history of psychiatric disorder, substance abuse, or family history of depression or suicide.[88,89]

Somatization

Somatization is broadly defined as the somatic manifestation of psychological distress. This should be distinguished

from the 'somatization disorder' in the somatoform disorders section of Diagnostic and Statistical Manual (DSM)-IV.[90] Somatoform disorders are rare in cancer patients and have a restrictive set of criteria.[91,92] Somatization is closely related to depression, anxiety, personality disorders, and cognitive impairment.[93–95] Patients who somatize will have a tendency to express pain intensity as higher, will have poorly defined etiology after appropriate investigations, will describe pain 'all over the body', and derive little benefit (but often toxicity) from pharmacological treatment.[57,96] In addition to a history of affective disorder, a history of functional somatic syndromes[97] (e.g. chronic pelvic pain, irritable bowel syndrome, fibromyalgia, tension headache, chronic fatigue syndrome), and the simultaneous presence of multiple highly intense symptoms (high ESAS scores in multiple domains) are all signs suggestive of somatization. Because of the absence of a gold standard, the diagnosis of somatization is made based on a number of repeated observations, and after extensive discussion with the patient and family.[98]

Patients who somatize frequently express increased symptom intensity associated with stressors, and many patients are unaware of this coping mechanism. It is important to recognize that in most palliative care patients, somatization consists of the increased expression of a symptom for which there is a clear pathophysiological mechanism, rather than the expression of symptoms for which there is no demonstrable pathophysiology, as is the case for somatoform disorders.

Chemical coping

Patients who have a past or active history of substance abuse present a special problem for symptom management. Their history of abuse reflects maladaptive coping strategies, which frequently lead to excessive expression of symptomatology. In patients with pain, this is often misinterpreted as nociception and may lead to an escalation of opioids and opioid-induced neurotoxicity.[57] The frequency of addictive disorders in the USA ranges from 3 percent to 16 percent with the higher rates reflecting prevalence of alcoholism.[99,100] Our group[101] reported a positive CAGE (*C*ut down, *A*nnoyed by criticism, experiencing *G*uilt, *E*ye-opener drink in the morning) score 2/4 or more in 27 percent of cancer patients who were admitted to a palliative care unit. The rates of alcoholism in cancer patients may also be higher, as alcohol use and abuse can play an etiological role in several types of malignant disease (e.g. head and neck or esophageal cancer). Opioid abuse and misuse are more likely to be seen in cancer patients with a history of drug or alcohol abuse.[102,103] The CAGE[104] alcohol questionnaire is frequently used as a brief screening tool for detection of alcohol abuse. A positive response to two of the four questions is indicative of alcohol dependence and may also indicate abuse of other substances.[97] The questions refer to lifetime experience and not to any specific or limited time-frames in the patient's

history. To improve the validity of the CAGE results, the questionnaire should be completed as part of the initial assessment, in particular before asking the patients about amounts of alcohol or drugs ingested.[3,5]

In palliative care the importance of a diagnosis of chemical coping is not related to the consequences of using alcohol or drugs. It rather relates to the patient's coping strategies and the increased likelihood that patients may cope chemically using opioid analgesics prescribed for pain control, mostly due to sharing a similar 'reward brain pathway' with alcohol (endorphins play a role in both).[105,106] A number of studies have observed that a history of chemical coping is an independent poor prognostic factor for pain control using opioid analgesia.[107,108] Fainsinger *et al.* have recently confirmed in a study on 619 patients, the independent prognostic value of chemical coping as a predictor of poor analgesic response to opioids.[109]

FAMILY ASSESSMENT

Chronic illness from advanced disease impacts on all the family members. A patient's relationship with their world changes with the news that their lifespan has been defined, thus altering their family interactions. Although the family is traditionally defined by individuals of blood relationship, a broader definition of family is most appropriate, best defined as those individuals considered as family by the patient.[110,111]

The patient's role/s within the family, as a provider, a caregiver, a parent, a spouse, or a sexual partner, may be challenged. Therefore the particular issues and needs of family members, in addition to the patient, must also be assessed.[112] Furthermore, because care will be provided by family members in the home setting, the family should also be consulted and educated about the diagnosis, treatment options, the illness trajectory, symptom burden and treatment, and caregiving.[2,113]

A genogram or family tree facilitates the understanding of a particular family's structure and dynamics. It helps to identify the family structure in a clear and comprehensive way. It highlights relationships and strengths and weaknesses, and can often clarify some of the family norms around disease/illness and coping. Family communication patterns, roles, and coping methods are components of family functioning affected by the cancer. For example, family members frequently do not share their thoughts or concerns with one another in an effort to protect each other. These 'conspiracies of silence' may complicate coping, and they should be diagnosed and treated.[114]

Caring for a person with cancer is demanding and overwhelming and can be a stressful experience that may erode the physical and psychological health of the caregiver.[115] For example, caregivers who provide 24-hour day care often experience cumulative sleep disruption, and fatigue is common.[116]

Also, caregivers of patients with cancer-related pain report even higher levels of depression, tension, and mood disturbances than caregivers of pain-free patients.[117,118] Therefore, to address and manage these issues, these patients should be managed together with psychologists and social workers, and this is important to reduce the psychological distress of caregivers. The patient–family unit is expected to make decisions about treatment options, goals of care, advance directives, and finances. The importance of advance care planning for the patient and family is stressed and this is best addressed early in the course of illness and frequently reassessed. Early discussions regarding prognosis, likely course of the disease, events to anticipate, and clarifying advanced directives all can serve to mitigate subsequent dilemmas, and increase control and lessen angst.

The family assessment is particularly important for patients who will receive care at home. The willingness of the family to deliver care at home is the most important predictor of a home death.[119] Family members will be involved in all aspects of patient care at home including hygiene, repositioning, and administration of multiple medications. Knowledge of the family's structure and function will help physicians organize medications and other aspects of care. Ultimately, the level of family care available will be the main defining factor in discharging a patient back to the community or to an institution. Family meetings should be conducted in the majority of cases when a palliative care team discharges a patient home.

Involvement of family caregivers is essential for optimal treatment of cancer patients at the end of life, especially in ensuring treatment compliance, continuity of care, and social support.[120] For example, family members who fear drug addiction or respiratory depression may undermedicate a patient even though the patient is experiencing unrelieved pain.

SOCIAL ASSESSMENT

A number of socioeconomic factors have great influence on the expression of symptoms, psychosocial distress, family dynamics, and even overall access to healthcare professionals and medications. Socioeconomic status is one of the main predictors of home death,[121] and it is particularly important in countries where there is no universal access to healthcare such as the USA. However, socioeconomic status can also be an independent predictor of home death in other countries. The appropriate assessment of social and cultural needs will provide for better counseling, better planning of the site of care, enhanced communication, and even better adherence to pharmacological therapy. For example, patients with limited coverage for medications may not be able to afford some expensive opioid analgesics or antibiotics and it may be preferable to prescribe less expensive medications to ensure adherence to the treatment. Even

patients with adequate insurance incur substantial burdens related to uncovered services such as transportation or home care, lost salaries and work, household modifications, and alternative treatments.[122]

In some cases a simple social assessment will reveal that patients may benefit from a disabled parking sign, application for benefits, preparation of a will or funeral arrangements, or assistance with financial planning. These issues can greatly improve the quality of life for the patients and their communication with healthcare professionals and their family.

SPIRITUAL ASSESSMENT

Spiritual wellbeing is increasingly recognized as an important factor for patients with cancer and their caregivers. Spirituality can have a profound influence on the distress, ability to cope, and quality of life of seriously ill patients and their family caregivers. While religion is defined as a specific set of beliefs and practices associated with a recognized religious denomination, spirituality is a thought process or belief system that allows a person to experience a transcendent meaning in life, including the conviction that one is fulfilling a unique role and purpose in one's life.[123–125] Some studies have demonstrated the relationship between spiritual factors and lower levels of anxiety and distress, and between spirituality and experiencing a better quality of life.[126] Spiritual beliefs also may help patients and caregivers construct a meaningful framework for their illness and resultant suffering, and this may promote acceptance of the situation.[127]

Spiritual care can be provided not just by pastoral care workers. Most literature supports the idea that all individuals involved in palliative care, to the degree that they are willing and able to do so, be involved with the spiritual issues of their patients.[128] The most important way by which caregivers can promote good spiritual care of patients is listening. Taylor et al.[129] surveyed what patients with cancer and primary family caregivers expect from nurses with regard to having their spiritual needs addressed. Although some patients or caregivers do not want overt forms of spiritual care, many others are eager for them. Spiritual needs identified by participants in Taylor et al.'s study included kindness and respect, talking and listening, prayer, connecting with symmetry, authenticity, and physical presence; quality temporal nursing care; and mobilizing religious or spiritual resources.

Assessment of spirituality is important because on one hand those patients who use spirituality and/or religion as part of their coping skills can be encouraged to increase their use of these resources with the help of either supportive individuals within the palliative care team or their own community of faith. On the other hand, occasionally, a patient at the end of life may have a severe crisis from existential or spiritual

distress resulting in severe psychological and/or physical symptom expression.[130] The identification of these issues may lead to appropriate spiritual support with improvement in symptom distress.

Clinical example

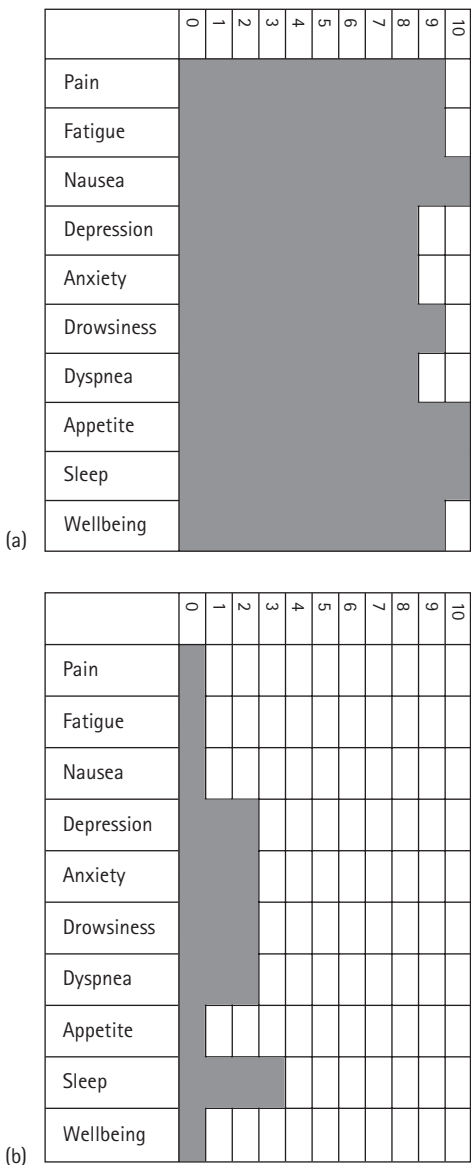
A 51-year-old man with nonsmall cell lung cancer, metastatic to lymph nodes and bone was referred to a palliative care service. He had been treated with cisplatinum and paclitaxel for three cycles with no response, and had received palliative radiation to the right hip, right lung, and associated mediastinum. Further disease progression was observed after second-line chemotherapy. He complained of increased chest wall pain for 2 weeks. The pain was sharp and stabbing, radiating from the anterior to the posterior chest wall on the right side. Intensity was 9/10. It was partially relieved with oxycodone ER 240 mg/day, hydro-morphone 48 mg/day, and oxycodone 40 mg as needed (approximately 160 mg/day). He also received temaze-pam 20 mg two tablets at bedtime, paroxetine 40 mg once daily, ondansetron 24 mg/day, and warfarin 1 mg daily. A unidimensional approach would have resulted in initially a large increase in the opioid dose followed by assessment in 3 days. In the multidimensional assessment high intensity levels of all symptoms were found in the ESAS (Fig. 39.5a). Other complaints included constipation (no bowel movement for last 3 days), sleep walking, confusion, myoclonus and hallucinations, and cough with white-to-clear colored sputum. The MMSE score was 23/30. The psychosocial history revealed that the patient was on disability benefits, and had a high school education. CAGE screening for alcoholism was 2/4. He was married for the second time and had a child from the previous marriage. His wife stated that she also had cancer. His daughter was supportive, but she had acquired immune deficiency syndrome (AIDS) and cervical cancer. Due to the symptoms and family issues, the patient was admitted to the palliative care unit. He underwent an opioid rotation to methadone because of the probable opioid-induced neurotoxicity (myoclonus, confusion, and hallucinations). Constipation was treated with senna and docusate. The dose of paroxetine was reduced and haloperidol was added for delirium. The patient and family were extensively counseled by the social worker, counselor, and pastoral care worker. After 3 days the patient showed significant symptom improvement (Fig. 39.5b). The oncologist commented that the patient was doing well, was maintaining an excellent performance status, and was interested in pursuing other treatment options.


Figure 39.5   *Edmonton Symptom Assessment System (ESAS) for a 51-year old man with nonsmall cell lung cancer, showing (a) high scores for all symptoms and (b) significant improvement after 3 days of treatment.*

The clinical example above summarizes the importance of multidimensional assessment and the impact that this has on quality of life. This patient had symptoms of opioid-induce neurotoxicity and significant psychological distress, which exacerbated the expression of his symptoms, leading to increased opioid doses and aggravated confusion.

The assessment of the patient's severe pain and high opioid requirement within the context of all other symptoms and the family situation resulted in a dramatic change in the medical management. This rapid identification of multiple problems allowed for interdisciplinary management and rapid resolution of distress. It is important to practice disciplined multidimensional assessment of palliative care patients to be able to find unexpected abnormalities such as delirium, serious family difficulties, or multiple symptom

distress. If the assessment only takes place in those cases in which problems are already suspected it is likely that a large number of patients with severe suffering will go undetected and untreated.

CONCLUSION

The traditional unidimensional model of assessment often equates symptom expression with symptom production. This approach has the potential for excessive reliance on pharmacological agents, with the likelihood of increases in toxicity, and under-utilization of nonpharmacological treatments. In turn, a multidimensional approach recognizes the interaction of many concurrent symptoms with one another and the influence of psychological distress, such as depression or somatization, and distress relating to financial, spiritual, and existential issues on symptom expression.

Recognition and relief of psychosocial and spiritual distress in terminally ill patients are among the fundamental principles of the multidisciplinary palliative care model, whose ultimate objective is the relief of symptoms and global patient distress, thereby helping to provide an optimal quality of life.

Key learning points

- Most palliative care patients suffer multiple physical and psychosocial symptoms.

- Symptom assessment needs to include the different dimensions that contribute to the production, perception, and expression of symptoms.

- Whenever possible, patients should be asked to score their symptoms.

- Mood disorders, somatization, and chemical coping have major influence on symptom expression.

- Social, spiritual, and family assessment is part of routine care in palliative medicine.

Tools for pain and symptom assessment in palliative care

VICTOR T CHANG

INTRODUCTION

The importance of symptoms was recognized by the convening of a National Institutes of Health (NIH) symposium to discuss the target symptoms of fatigue, pain, and depression.[1] All palliative care personnel assess and manage pain and symptoms.[2]

Why are tools needed? Advantages of the use of a tool are a certain regularity, and tabulation of their answers allows for data analysis and comparisons. Potential disadvantages of a tool are additional time and energy spent obtaining potentially irrelevant information, as well as resources required to store, track, and organize the data. The usefulness and interpretation of these tools in clinical practice is an area of ongoing research. While both symptom and quality-of-life tools emphasize patient-rated outcomes, symptom tools differ from quality-of-life instruments in emphasis on symptoms rather than general physical, social or emotional wellbeing.

FUNDAMENTALS OF SYMPTOM MEASUREMENT AND ASSESSMENT TOOLS

Biological underpinnings

Best understood for pain, the perceived intensity of a sensory stimulus is proportional to the rate of firing by sensory nerves, and the number of nerves which send impulses. Sensory impulses reach the cerebral cortex where they may be recognized, and trigger various responses such as evaluative (severity), affective (unpleasantness or distress), and behavioral (agitation).

Theoretical underpinnings of symptom instruments

CLINIMETRICS

Clinimetrics focuses on the quality of measurements in clinical medicine.[3] Descriptive statements (mensuration) are combined to express a numerical summary (quantification).[4] The descriptive statements are chosen on the basis of clinical relevance, usually by clinicians, and can be eclectic with a variety of symptoms, physical findings, and laboratory findings. An example is the Apgar score, where 5 items (heart rate, skin color, respiratory effort, muscle tone, reflex irritability) are combined to form a score to describe the condition of a newborn infant.[5]

PSYCHOMETRICS

The degree to which a respondent agrees with items (statements) allows an inference about whether the respondent has a particular, otherwise unmeasurable psychological state (latent trait), such as pain, anxiety or depression. Another analogy is the blind men describing an elephant. Each blind man is an item, and the latent trait is the elephant.

The extent of agreement between items is commonly determined with Likert scales, (e.g. not at all, a little bit, somewhat, quite a bit, very much). The intraclass correlation coefficient (Cronbach α) is a measure of self-consistency between the statements; α levels of 0.70 or greater are considered acceptable. Factor analyses and other statistical techniques are used to analyze the collection of statements to see whether they measure one factor, and are therefore unidimensional, or more than one factor. Longer instruments with more items are preferred to minimize variation, and maximize the Cronbach α.

ITEM RESPONSE THEORY (IRT)

In this very simplified explanation, IRT starts with the concept of item difficulty, the percentage of respondents who respond correctly to a test item. Similar to psychometrics, IRT tries to estimate a latent trait. The correspondence between the item difficulty and the latent trait is described by the item-characteristic curve (ICC), which is usually S shaped. Easier items are on the left of the trait scale, and more difficult items on the right. IRT models estimate the difficulty parameter for each item from questionnaire data, where the difficulty parameter is the trait level needed to answer the item correctly 50 percent of the time. The different kinds of IRT models differ in the numbers and types of parameter used to describe the ICC. The attractiveness of this approach lies in the potential improvements in symptom and other forms of assessment. These include shorter questionnaires, computerized adaptive testing, and comparisons of different instruments. Questionnaires will not be as dependent on variations in the population being tested. This is an area which should see much development in the future.[6]

Properties of symptom assessment instruments

VALIDITY, RELIABILITY

Validity means that the instrument measures what it claims to measure. Measures of validity include face validity (items are easy to understand), content validity, criterion validity, and construct validity. Content validity shows how the items in the instrument reflect what the instrument is trying to measure. For example, a pain instrument might include a rating of pain severity. Criterion validity is shown by correlation with other accepted measures of the symptom in question. Criterion validity can be demonstrated by expected agreement (convergent validity) or expected disagreement (divergent validity). Construct validity is an assessment of how well the instrument measures its goal.[7]

Reliability implies freedom from error, and is defined as the true variance divided by the true variance and variance from repeated administration of the instrument. Reliability can be measured by the degree of reproducibility (test–retest) and self-consistency (Cronbach α).[8]

RESPONSIVENESS

Responsiveness of the instrument to change has received increased attention recently, along with the notion of minimal clinically significant difference. Measures of clinically significant difference are important for sample size estimation in trials designed to improve symptom control or quality of life. They also illustrate the transformation of symptom instruments into outcome measures. Much of the work to date has been done with quality-of-life measures, where the minimal clinically important difference has been defined as 'the smallest difference in score in the domain of interest which patients perceive as beneficial and which would mandate, in the absence of troublesome side effects and excessive cost, a change in the patient's management'.[9]

Anchor-based and distribution-based methods have been used to define clinically important differences.[10] Anchor-based methods use established clinical criteria or patient ratings as ways to anchor interpretations of difference scores. An example is the Performance Status rating. Distribution-based methods rely upon the statistical aspects of the score distributions.[11] A half of the standard deviation may be a good approximation of the clinically significant difference.[12]

Instruments which are designed to evaluate the patient at a point in time may not be the optimal instruments for measuring changes.[13] An alternative approach has been the transition rating, a single item where the patient is asked to rate the change he or she perceives in the target measure. This can be expressed as a percentage, as a 7-point Likert scale ranging from very much worse to very much better, or on visual analog scales (VAS). Likert and VAS approaches were equivalent in one study.[14] While the ability of patients to remember their previous symptom status has been questioned, this approach is quick and sensitive, and corresponds to the usual clinical conversation between the patient and healthcare provider. The minimum difference has been estimated as 0.5 on a 7-point scale. The magnitude of the transition score is correlated with the pretreatment score.[15]

SCALES

Nominal scales have items that cannot be combined (e.g. list of pain descriptors). Ordinal scales have responses that can be ranked. Numerical scales ask the respondent to assign a number, and may be an interval scale or a ratio scale. In an interval scale, the difference between the scale values is a number, and linear transformations can be performed (e.g. conversion of temperature from Fahrenheit to Celsius). In a ratio scale, a zero point is present, and only multiplicative transformations can be performed (e.g. measures of length).[16]

DIMENSIONS

Symptoms have dimensions. A medical history will ask about the presence of a symptom, exacerbating and alleviating

events, temporal variation, descriptors, and relief. A palliative symptom history can additionally include severity, frequency, duration, distress, effect on function, and associated meanings for the patient. Many of these terms are self-explanatory. It remains an open question as to how many dimensions are needed. Is one dimension enough? Severity tends to be the most dimension most commonly used, followed by distress. However, symptoms are not always categorized easily by one dimension. A patient who has breakthrough bone pain may have difficulty deciding whether the severity or frequency or both are important. This has led to interest in the use of multidimensional symptom instruments, such as the Memorial Symptom Assessment Scale.

To summarize, potentially important dimensions of a symptom include frequency, severity, distress, duration, and associated meanings.

TYPES OF RESPONSE CATEGORY

- Visual analog scales (VAS): The symptom of interest is represented by a straight line 10 cm long. Anchors are no symptom on one end, and worst on the other end. The patient marks off with a straight line the severity of the symptom. Horizontal and vertical VAS have been described. Visual analog scales are one of the oldest forms of symptom assessment approaches, and have the advantage of providing a continuous variable for subsequent analyses.[17] VAS have been used for many symptoms. Disadvantages include a tendency for the marks to bunch up in the middle, and physical problems with completing the form in patients with impaired eyesight and/or motor disability. Mechanical VAS have been described, where patients move a marker along the line.
- Numerical rating scale: Patients are asked to rate the symptom on a numerical scale, such as 0–5 or 0–10. However, not all patients are able to express themselves numerically. In one study, 10 percent of hospice patients were unable to use a numerical rating scale for pain.[18]
- Categorical rating scales: Patients are asked to categorize the symptom by severity or other attributes. These categories often are none, a little bit, somewhat, quite a bit, and very much in the Likert version. Other categories have also been described. This presents an alternative for patients who cannot give numerical values.
- Ranking: Patients are asked to rank symptoms in order of priority. This provides a different way of characterizing symptoms, and may help the interviewer set priorities for symptom control. Patients in palliative care may have many severe symptoms and may have difficulty ranking symptoms.
- Pictorial approaches: Best known examples include the FACES design for children,[19] and the use of symbols such as fire to characterize intensity. These approaches are appropriate in populations where the ability to read may be a barrier.
- Descriptors: Patients select from a list of adjectives to capture qualitative aspects of the symptoms.

SINGLE SYMPTOM VERSUS MULTISYMPTOM INSTRUMENTS

Many instruments are devoted to information about one symptom. Because palliative care patients may have multiple symptoms, instruments which assess multiple symptoms have been developed. A related question is how many symptoms should be routinely covered? By the time patients reach palliative care status, the stamina can last for 5–10 questions at most. Many symptoms – pain, tiredness, nausea, difficulty sleeping, drowsiness, dry mouth, shortness of breath, and sadness – are common to most of the multisymptom instruments.

MODE OF ADMINISTRATION

Tools can be administered by an interviewer or can be completed by the patient in a variety of ways (pen and paper, telephone, computer, internet, interactive voice response, perhaps text messaging in the future!).

SPECIFIC SYMPTOM INSTRUMENTS

A large number of instruments have been developed.

Appetite

- Visual analog scale: A 10 cm line, where the left represented no appetite and the right anchor is 100 percent appetite.[20]
- The Bristol-Meyers Cachexia Recovery Instrument (BACRI):[21] This is a 7-item VAS where patients rated their improvement in eating.
- The North Central Cancer Treatment Group Patient Questionnaire:[22] This has seven items and a VAS score for quality of life.
- The Functional Assessment of Appetite Cancer Therapy[23] Subscale has 12 items rated on a Likert score.

Constipation

The Constipation Assessment Scale is a validated 8-item scale for assessment of constipation in cancer patients.[24]

Delirium

- The Confusion Assessment Method (CAM)[25] is based upon Diagnostic and Statistical Manual (DSM)-III

criteria and nonpsychiatrist clinicians can use an algorithm of four items – acute onset and fluctuating course, inattention, either altered level of consciousness or disorganized thinking. The CAM has been translated into Portuguese[26] and a version has been developed for patients in intensive care units (ICU).[27]

- The Delirium Rating Scale[28] is a 10-item instrument with clinician-rated symptoms. A revised longer 16-item version has been developed with improved sensitivity and specificity[29] The Delirium Rating Scale has been translated into Japanese[30] and validated for adolescents.[31]
- The Memorial Delirium Assessment Scale (MDAS)[32] is a 10-item tool which can be used for diagnosis, severity, and repeated assessments. A cut-off score of 13 is diagnostic, and a cut-off score of 7 has been proposed for advanced cancer patients in a palliative care setting.[33] The MDAS has been translated into Italian[34] and Japanese.[35]
- The Mini-Mental State Examination (MMSE)[36] was originally developed as a screening test for dementia, and has been used as a screen for other cognitive dysfunction. Norms should be adjusted for age and educational level.[37,38] The instrument has been translated into Chinese,[39] French,[40] Gujarati,[41] Hebrew,[42] Japanese,[43] Korean,[44] Sinhalese,[45] and Spanish.[46]

In a comparison of 12 different tools for delirium, the CAM was felt to be the best diagnostic tool and the Delirium Rating Scale best for screening symptom severity. The CAM-ICU was recommended for ICU patients and the MDAS for cancer patients.[47]

Depression

- Single-item VAS have correlated well with depression tools.[48]
- The Beck Depression Inventory[49] is a 21-item instrument where the patient rates the severity of attitudes and symptoms over a 1-week period. In 1996, the Beck Depression Inventory II was released to conform to the DSM-IV criteria. The Beck Depression Inventory has been translated into modern standard Arabic,[50] Chinese,[51] Japanese,[52] Russian,[53] and Spanish.[54]
- The Center for Epidemiologic Studies on Depression (CES-D)[55] is a validated instrument with 20 items and asks for patient-rated frequency and has been studied in cancer patients. The CES-D has been translated into Brazilian Portuguese,[56] Chinese,[57] Greek,[58] Japanese[59] Spanish,[60] and Turkish.[61] A 10-item version has been introduced.[62]
- The Geriatric Depression Scale (GDS)[63] is a 30-item instrument which can be administered by telephone[64] and has been translated into Chinese,[65] Hindi,[66]

Spanish,[67] and Swedish.[68] A GDS Short Form with 15 items has been validated[69] and translated into French,[70] Greek,[71] Korean,[72] and Spanish.[73] A shorter 5-item version has been reported[74] and translated into Chinese.[75] The GDS may not be valid in patients with moderate to severe dementia.
- The Hamilton Depression Rating Scale[76] is a 17-item severity rated scale and is widely used in trials of antidepressants. It has been translated into Chinese.[77] A 6-item version has been developed.[78]
- The Hospital Anxiety Depression Scale (HADS) is a validated instrument that has two subscales.[79,80] Patients rate frequency of symptoms for 14 items, seven related to anxiety and seven for depression. The HADS is widely used in Europe, and has been translated into Arabic,[81] Chinese,[82] French,[83] German,[84,85] Maltese,[86] Japanese,[86] and Spanish.[88]
- Screening questions: Single[89] and two question screens[90] have been validated.
- The Zung Self Rating Depression Scale is a 20-item instrument.[91] The Zung scale has been translated into Chinese,[92] Czech,[93] Dutch,[94] Finnish,[95] Greek,[96] studied in India,[97] and Spanish.[98] A shorter 12-item version has been translated into Dutch.[99] Both have been validated in ambulatory cancer patients.[100]

Common problems of these instruments are that as screening tools, the cut-off points have not been derived for palliative care patients, and that the patient's self-report may be influenced by stress and the desire to be socially acceptable.[101] In one literature review of depression screening tools for use in a palliative care population, the authors concluded that the single question 'Are you depressed' had the highest sensitivity and specificity, and identified cut-off values of 20 for the HADS, and 13 for the Edinburgh Postnatal Depression Scale.[102]

Dysphagia

Most studies have used an ordinal scale for measuring dysphagia in five categories: no symptoms, can take solids, can take soft food, can take liquids, cannot swallow at all. Many studies do not specify whether this is patient rated or observer rated.

Dyspnea

- The Borg scale measures symptoms with a vertical scale from 0 to 10 anchored by descriptive words, and requires an exertional test.[103]
- A VAS is a validated measure of dyspnea,[104] as is a numerical rating scale.[105]
- The Chronic Respiratory Questionnaire[106] and the St George's Respiratory Questionnaire[107] are quality-of-life instruments for patients with chronic obstructive

pulmonary disease (COPD), with an emphasis on dyspnea. The Chronic Respiratory Questionnaire has been translated into German,[108] Japanese,[109] and Spanish.[110] The St George's Respiratory Questionnaire has 50 items and has been translated into American English,[111] Chinese,[112] French,[113] Japanese, Polish,[114] Spanish,[115] and Swedish.[116] The minimal important difference for the St George's is estimated at 4 on a scale of 0–100.[117]

- The Baseline Dyspnea Index assesses functional impairment, magnitude of task, and magnitude of effort required to produce breathlessness and the Transition Dyspnea Index measures changes in these three components.[118] These instruments have been translated into German, Italian, Japanese, and Spanish.[119] A 1-point change in the Transition Dyspnea Index is clinically meaningful.[120]

Descriptions of many other instruments can be found in reviews (references 121–123).

Fatigue

- The Brief Fatigue Inventory assesses fatigue severity with a 0–10 numerical rating scales for worst and usual fatigue, and fatigue now, and has six interference items. It has been translated into Chinese,[124] German,[125] and Japanese.[126] In one study, worst fatigue ratings of 7–10 identified patients with severe fatigue.[127] In another study, a cut-off for worst fatigue of 3 or usual fatigue of 2 separated mild from moderate fatigue.[128]
- The Piper Revised Fatigue Scale[129] contains 22 items and four subscales: behavioral/severity, affective meaning, sensory and cognitive/mood. It has been translated into French[130] and Chinese.[131]
- The FACIT Fatigue module[132] is a 13-item subscale with Likert responses. An effect size for the FACT Fatigue subscale has been estimated to be between 0.51 and 0.89.[133]
- A single-item of distress from fatigue correlated well with responses to the Brief Fatigue Inventory and the FACIT Fatigue model.[134]
- The Schwartz Cancer Fatigue Scale is a 28-item instrument with four subscales: physical, emotional, cognitive, and temporal.[135] A minimal important clinical difference has been estimated to be 5, and per item 0.8.[136] A 6-item version with two subscales has also been developed.[137]

Nausea

The development of a solid accepted methodology for measuring chemotherapy-related nausea and vomiting, and response has helped advance the field of palliating–chemotherapy-related emesis. Nausea is measured with a

VAS and vomiting is quantitated as the number of episodes in a 24-hour period.[138]

Pain

- VAS: A mark of more than 30 mm is more than mild pain.[139] A clinically significant change was estimated at 13 mm for patients with initial VAS scores of 34 mm, and 28 mm for patients with initial VAS scores greater than 67 mm.[140]
- Numerical rating scale of 0–10: Analysis of pain severity in a multinational sample suggests that 1–4 may be mild pain, 5–6 moderate pain, and 7–10 severe pain.[141] Changes in severity of 2 may correspond to a minimally clinically significant difference.[142,143]
- The Brief Pain Inventory (BPI)[144] and the BPI Short Form are widely used and validated pain instruments. The instrument contains a body diagram, numerical rating scale ratings of pain severity, relief, and interference with function. The BPI has been translated into Chinese,[145,146] German,[147] Greek,[148] Hindi,[149] Italian,[150] Japanese,[151] Norwegian,[152] Spanish,[153] and additional languages.[154]
- The McGill Pain Questionnaire[155] has a present pain intensity item, and 20 sets of descriptors to assess for sensory, affective, and evaluative components of pain. It has been translated into Amharic,[156] Arabic,[157] Chinese,[158] Danish[159,160] Dutch,[161] Finnish,[162] Flemish, French,[163] German[164,165] Greek,[166] Italian, Japanese,[167,168] Norwegian,[169] Polish, Slovak,[170] and Spanish.[171,172]
- The McGill Short Form has 17 items: present pain intensity, pain severity VAS, and ratings of 15 descriptors.[173] It has been translated into Czech,[174] Greek,[175] and Swedish.[176]
- The Memorial Pain Assessment Card[177] has one item for each of the dimensions of severity, mood, relief, and a set of descriptors.

Neuropathic pain scales have been developed where patients rate the presence and severity of pain descriptors. The purpose of these research scales has been to distinguish neuropathic from nociceptive pain: the Neuropathic Pain Scale,[178] the Leeds Assessment of Neuropathic Signs and Symptoms,[179] and the Neuropathic Pain Questionnaire.[180] The ongoing development of prognostic systems for staging pain, such as the Edmonton Staging System,[181,182] and the Cancer Pain Prognostic Scale,[183] provides a different kind of assessment. Readers interested in pain assessment may find references 184 and 185 helpful.

MULTIPLE SYMPTOM INSTRUMENTS

- The Symptom Distress Scale (SDS) introduced the concept of distress to symptom assessment.[186,187]

The SDS has 13 items, with 11 symptoms; pain and nausea are each assessed twice. Variations include the Adapted Symptom Distress Scale 2[188] and the Symptom Experience Scale.[189] The Adapted Symptom Distress Scale has 31 items for 14 symptoms, and includes symptom occurrence. The SDS has been translated into Chinese,[190] Dutch, Italian,[191] Korean,[192] Spanish, and Swedish.[193] It has been studied in patients receiving cancer chemotherapy, home care,[191] and a variety of other settings.

- The Edmonton Symptom Assessment Scale (ESAS)[194] is a validated 9-item VAS scale with eight symptoms and a wellbeing item;[195,196] a modification with a numerical rating scale has been introduced. A French[197] version has been developed. The ESAS has been studied in multiple settings, including hospice, palliative care consultation teams,[198] home care,[199] and the ICU.[200]
- The Lung Cancer Symptom Scale[201] has nine patient-rated items and five observer-rated items.
- The MD Anderson Symptom Inventory[202] was derived from hierarchical cluster analysis on patient responses. A core number of 14 items accounted for 64 percent of the variance in symptom distress. Patients are asked to rate the severity of 13 symptoms and six interference items with a numerical rating scale.
- The Memorial Symptom Assessment Scale (MSAS) is a validated patient-rated instrument in which patients rate symptom severity, distress, and frequency for 32 highly prevalent physical and psychological symptoms.[203,204] Each symptom is rated on a Likert scale and scored from 0 to 4 ranging from 'no symptom' to 'very much'. The MSAS subscales include: the Global Distress Index (GDI), the Physical Symptom distress (PHYS), the Psychological Symptom distress (PSYCH). In the MSAS Short Form, patients rate symptom distress for physical symptoms and symptom frequency for psychological symptoms.[205] In the condensed MSAS, the number of items has been reduced to 14.[206] The MSAS has been studied in cancer chemotherapy, hospital settings,[207] hospice,[208] ICU,[209] and longitudinal studies.[210] The minimal clinically significant difference has been estimated for the MSAS Short Form.[211] A children's version has been developed.[212]
- The Rotterdam Symptom Checklist[213] is a validated 34-item instrument where patients rate distress. A physical and a psychological symptom subscale are described. It has been translated into French[214] Italian,[215] Spanish,[216] and Turkish.[217] A modified version has been validated in an American population of cancer patients.[218] This instrument has been used extensively in European cancer chemotherapy trials and symptom intervention studies.

APPLICATIONS OF SYMPTOM INSTRUMENTS

- Audit: The review of processes of palliative care with the goal of improving quality is the goal of clinical and organizational audits. The process of symptom control, especially where effective treatments are available, such as pain, nausea, and depression, can be monitored with the use of symptom instruments.[219]
- Epidemiology and descriptive studies: Symptom surveys with the ESAS, MSAS, and other instruments have established that multiple symptoms are highly prevalent. Descriptive longitudinal studies with symptom instruments are now being reported.[220–222]
- Improvement of symptom recognition: In surveys of medical records, data concurrently gathered with the ESAS show that routine symptom assessment by doctors and nurses often misses data captured by the ESAS.[223,224] There is a growing consensus that the use of symptom instruments is feasible and contributes important information.
- Patient triage: The use of instruments to screen for symptoms, in particular depression, is an area of interest. A distress thermometer was successful in identifying patients with psychological distress.[225]
- Patient prioritization: One British study used data from a symptom checklist to suggest that patients with lung cancer or brain tumors should be high priority for specialist palliative care.[226] Another British study found differences in symptom patterns by service component of patients referred to a hospice inpatient service, a community team, a National Health Service (NHS) hospital support team, and an outpatient service, suggesting that different symptom management strategies may be needed for different patient groups.[227]
- Prognosis: Patient ratings of symptoms can add prognostic information. In studies of patients with cancer, individual symptoms as well as combinations of symptoms provide prognostic information in addition to that provided by the Karnofsky Performance Score.[228] Physical symptoms may carry more of the prognostic information.[229]
- Symptom clusters: Factor analyses with the MSAS, Rotterdam Symptom Check List, and the Canberra Symptom Scorecard[230] have shown two major groups of symptoms – physical and psychological symptoms. The use of multisymptom instruments is a logical step in establishing the presence of these clusters.[231]
- Quality control: Tools may also be important to the program as evidence for the quality of care given, where the act of symptom assessment is taken as the process. In this concept tools may be important as a way of evaluating the structure of the program.[232]
- Treatment outcome: Tools can serve by recording the outcomes of symptom management.

- Caregivers' and patients' ratings: Ideally, patients should be the source of information about symptoms, but become unable near the end of life. The role of caregivers or other proxies in symptom assessment has been an area of ongoing research and studied with symptom scales.[233,234]
- Relationship of symptoms to other aspects of palliative care, such as spirituality[235] and dignity.[236]

SPECIAL POPULATIONS

In patients who are unable to communicate, the ascertainment of symptoms becomes more difficult. This is especially true for the pediatric, geriatric and ICU populations. One approach for pain has been the development of behavioral measures of pain which can be recorded by observers. For children, behavioral scales include FLACC (*F*ace, *L*egs, *A*ctivity, *C*ry, *C*onsolability),[237] and for demented patients, the PainAD[238] and Pain Assessment for the Dementing Elderly.[239] This area has been recently reviewed.[239a] Pain behaviors have been described for ICU patients.[240]

PRACTICAL ISSUES

The selection of tools for pain and symptom assessment reflects a balance, as elsewhere, between what is possible and what is desirable. These considerations include the nature of the organization, and the uses to which the information from the tool will be put.

Research and practical tools

The difference between research and practical tools lies in their purpose and function (Table 40.1). Most instruments in use started out as research tools to better describe symptom(s). As such, these reflected concepts about the symptom, tended to be longer, studied healthier patients, were administered by research personnel. These studies have provided many insights into symptom epidemiology and their relationship to other aspects of patient experience, and demonstrated feasibility. In the clinical context, pragmatism is emphasized, and time and personnel are limited. As instruments are converted from research to clinical application, there is then an evolutionary pressure for the development of shorter and simpler instruments which can be rapidly administered and interpreted.

Patient stamina is decisive. Many terminally ill patients may be unable to answer more than a handful of questions. In one study of patients with terminal cancer at an American hospital, only half were able to complete one of the three instruments offered – the McGill Pain Questionnaire, the Memorial Pain Assessment Card, or the FACES Pain Rating Scale.[241] In a study of hospice inpatients, only 30 out of 71

Table 40.1   *Differences between research and practical tools*

Research	Practical
Comprehensive	Screening
Based upon specific theories	Empirical
Longer	Shorter
Wide choice of answers	Yes/No
Specific	Global
Multiple item	Single item
Patient rated	Observer rated

patients with pain were available to participate in a study where they were asked to answer a 6-item questionnaire about pain, with each item scaled from 0 to 10. The ratings were completed without difficulty and showed good reproducibility 1 hour later.[242]

Availability of instruments

In addition to the time-honored practice of contacting the developers of an instrument or finding the journal, many instruments may be viewed on websites. These include the American Thoracic Society website (www.atsqol.org), the Center to Advance Palliative Care (www.capc.org), the International Hospice Association (www.hospicecare.com), the MAPI Research Institute (www.mapi-research-inst.com, www.qolid.org), the Regional Palliative Care Program in Edmonton, Alberta (www.palliative.org), the Robert Wood Johnson Promoting Excellence in End of Life Care (www.promotingexcellence.org), and the toolkit of instruments to measure end-of-life care (www.chcr.brown.edu/pcoc/Physical.htm) Another source for symptom items can be quality-of-life instruments, such as the FACIT system,[243] the EORTC QLQ-C30,[244] or the RAI-PC.[245] The first two instruments have developed disease-related modules, have been translated into many languages, and contain symptom items.

Choosing an instrument

Criteria for an ideal pain instrument, as listed by Chapman and Syralja, apply to symptom instruments in general.[246] These criteria include:

- Minimal patient burden
- Understandable by patients
- Produce a wide range of scores
- Sensitive to interventions
- Demonstrate appropriate reliability and validity
- Availability of appropriate norms

Their principles of selection are equally applicable. These ultimately depend on the needs of the clinician and limitations of the patient population. The principles include:

- Define the goal of assessment (complexity of problem and information required).

- Decide which dimensions are appropriate for the problem at hand (severity, behavior, and function).
- Select subparts of instruments most suitable.
- Consider development of a clinical database – layout to be suitable for analyses.
- Consider automated data collection.
- Avoid too much data.
- Be sure the test instruments fit the patient population.
- Take care to collect responses to all items on the forms.[246]

Translation of instruments

Even within the same language, symptoms, and aspects of symptoms may be difficult to describe for the purposes of a symptom questionnaire (e.g. British vs. American English). These problems are magnified further when translations are attempted as different connotations may be associated with the symptom or the items in the second language. However, it may be easier to translate an instrument than to develop one. If the reader would like to translate an instrument, it is advisable to work with the group that developed the original instrument. The instrument is translated into the new language, then back translated into the original language by a second team, and then retranslated into the new language by a third team. After each translation, the instrument is reviewed again.[247]

Validation

In a new population, or with a new language, the tool should be validated. A representative sample of at least 40 patients should complete the tool, a reference tool known to be valid, and have their performance status and demographic data recorded. Practical aspects, such as ease of administration and comprehension should also be recorded. These data can then be analysed for validity.[248]

Implementation of tools

Principles of implementation by Higginson[249] are applicable to symptom tools. These include:

- Measures that form a part of treatment planning and evaluation are more likely to influence clinical decision making than monitoring alone.
- Are the symptoms relevant?
- How long does it take to complete
- Will it measure differences?
- Who will use the measures?
- Involve staff and patients.
- Plan and begin training in both the use of the measure and associated clinical skills.

I would add that a plan of action for symptom control should be in place or no improvements will result.

UNEXPLORED AREAS

Symptom monitoring

The combination of symptom tools and new computerized technology has led to the concept of symptom monitoring.[250] A symptom monitoring program could cover more areas of patient concern, aid in better understanding the relations between multiple symptoms, identify symptoms before they become severe, complement measures of tumor response, and assist in clinical decision making. Frequency of assessments is unknown. The role of caregiver-rated and healthcare–professional-rated symptoms for noncommunicative patients remains an area of investigation.

PROPOSE AN IDEAL TOOL PACKAGE WITH GOOD PSYCHOMETRIC PROPERTIES AND MINIMAL OVERLAP: HOW IS IT DONE AT CERTAIN CENTERS?

- MD Anderson Center, University of Texas, Houston, USA:[251] ESAS, MMSE, CAGE questionnaire,[252] Morphine Equivalent Daily Dose, Functional Impairment Measure[253]
- Institut Jules Bordet, Brussels, Belgium:[254] MMSE, MDAS, Edmonton Functional Assessment Tool,[255] ESAS
- University of Cologne, Germany:[256] MMSE, BPI, Medical Outcome Study Short Form-12[257]

How to select a tool

No instrument is perfect and the package depends upon the local needs of the patients (types of disease and prevalence of symptoms) and resources available to the staff (manpower, time) and purpose (research or practice or screening). Areas of practical interest at intake include the ability of the patient to make decisions, the presence of key symptoms, and a performance status rating. Additional instruments can be added depending upon the interest of the group. At follow-up, we need to screen for new symptoms, and determine if older symptoms have changed.

If the reader is planning to set up a palliative care program, it is better to select an available validated instrument (or module) and add items than to pick and choose items from different tools. The reader may wish to try out different tools on a few patients to see which one works best in terms of comprehension and ease of administration. Possible combinations are presented in Table 40.2.

Table 40.2 *Suggested use of the various assessment instruments*

	Better KPS Research	Worse KPS (KPS < 50 percent) Practice/Screening
Symptoms	RSCL, MSAS	ESAS, CMSAS, SDS
Pain	BPI, MPQ SF	Numeric rating scale
Depression	Depression instrument	Screening questions
Noncommunicative	PAINAD	PAINAD
Mental Status	CAM	CAM, MDAS

RSCL, Rotterdam Symptom Checklist; MSAS, Memorial Symptom Assessment Scale; BPI, Brief Pain Inventory; MPQ SF, McGill Pain Questionnaire Short Form; CAM, Confusion Assessment Method; ESAS, Edmonton Symptom Assessment Scale; CMSAS, Condensed MSAS; SDS, Symptom Distress Scale; MDAS, Memorial Delirium Assessment Scale; KPS, Karnofsky Performance Score.

Key learning points

- Many validated and reliable tools are available for many symptoms, as well as for multiple symptoms.

- Responsiveness is being established.

- The usefulness and validity of these tools in different populations requires further study.

- The items of the symptom instruments selected should be perceived as useful, easy to understand, easy to answer, and easy to interpret.

- Follow-up plans for symptom treatment should be developed.

- Symptom tools are versatile in their applications. The choice of symptom tools depends on the priorities set by the palliative care staff and the stamina of the patients.

- Application of these instruments to clinical care is the next challenge.

Quality of life assessment in palliative care

S ROBIN COHEN

INTRODUCTION

The ultimate goal of palliative care is to optimize the quality of life (QOL) of people living with a life-threatening illness and that of their families. Assessment of QOL is therefore necessary if we are to provide the best care possible and ensure that we are eliminating unnecessary suffering. In this chapter I hope to clarify the concept of QOL at the end of life, and identify the questions that you must ask yourself before deciding how to best assess QOL in your particular situation.

WHAT IS QUALITY OF LIFE?

Quality of life remains an ill-defined concept, widely used but much argued about across and within disciplines.[1,2] Is QOL completely subjective, dependent only on a person's perception of their life situation, or does it also depend on the objective (directly observable) situation? Objective situations such as the availability of schools, or ability to safely walk the streets, are arguably important contributors to the QOL of the general population. However, I would argue that near the end of life, the world of the patient and even that of the family caregiver has shrunk, and the environmental setting that contributes to QOL is much more closely tied to the setting of care and healthcare system. Furthermore, I believe that the best definition of QOL for palliative care is *subjective well-being*, the key word being 'subjective'. How else can we explain that we may have two people in similar physical situations and close to death, but one judges their QOL to be good and cherishes each day,

while the other feels that life is not worth living? The psychological, sociological, and philosophical disciplines have debated the meaning of the term QOL for over half a century. Medicine, nursing, and allied health professions have adopted the term and considered QOL as an important outcome in many cases. However, in the healthcare setting, much less consideration has been given to the concept and it is often used without clarification.[1,3,4] Some published papers claiming to study QOL are in fact studying a single symptom such as pain or diarrhea, while others are truly trying to study subjective wellbeing. Health status is often mistakenly used as a surrogate term for QOL.

The term health-related QOL, which I and others consider a misnomer[1,5,6] was, depending on the point of view, developed to broaden the prevalent focus on physical health to also include physical and social functioning, as well as mental health, *or* to exclude from concern domains perceived as unrelated to healthcare, such as spirituality and life satisfaction. Whatever the reason for developing the concept of health-related QOL, it involves limiting the concept of QOL to certain aspects of the person whose QOL we want to assess. Whole person care is more than simply caring for all aspects of a person, it is also the recognition and understanding that all aspects of the person are interrelated, affecting one another. For this reason I believe that the concept of health-related QOL was created for the convenience of healthcare researchers with good intentions, but it is not a construct that has a match in reality. We cannot separate the physical, psychologic, and social aspects of the person from other essential parts, such as existential wellbeing or spirituality. Furthermore, good QOL is not simply the absence of problems, as it is often defined in health-related QOL measures. Quality of life is determined by the evaluation of both

the positive and negative aspects of one's life, and the value or weight you put on each aspect.[6–14] A concrete example: if you are treating pain that originates in a trapped nerve, and the patient also happens to believe that pain is a test from God, if you do not address the person's belief regarding the pain being God's will, you are unlikely to get the pain under control using only medication unless you use a dose so large that the person has a very clouded sensorium.

If QOL results not only from external circumstances but from an interaction between those and the person whose QOL we are assessing, then there are many things that need to be taken into account. What follows is a partial list of what we should keep in mind when assessing QOL.

- *QOL is the discrepancy or gap between a person's expectations and their actual situation.*[15–17] This provides us with two means of improving QOL (or decreasing the gap): we can improve the actual situation (e.g. reduce pain) and we can decrease expectations where we cannot improve the actual situation (e.g. desire to retain full physical functional status).

- *Response shift or adaptation.* People have an amazing capacity to adapt to new and even difficult circumstances. This is a powerful way of coping with a difficult situation which is in large part out of your control. When evaluating their QOL, people may have (i) changed their internal standards (called recalibration), (ii) focused on areas in which they are doing better and de-emphasized the importance of areas in which they are not doing well (change in values); or (iii) changed what areas they call to mind when they answer 'How is your QOL?' (called reconceptualization).[14] The data from Kreitler *et al.*[18] are an excellent cross-sectional example of the power of adaptation. We are only beginning to learn how response shift may come about, and the situations in which it is most likely to occur. If we are truly interested in subjective wellbeing, and recognize QOL as a perception, then the fact that response shift or adaptation is affecting our assessment of QOL is not a problem. However, when we are determining the effect of a noncoping intervention on QOL, then if there is differential response shift in two groups we are comparing, it is often important to know how response shift or adaptation is affecting our assessment of QOL. If the group that received the intervention improves a lot and therefore does not make a response shift (there is no need to adapt, as the situation has improved), but the group that did not get the intervention had a large response shift over the month that the intervention was being given to the other group, and de-emphasized the importance of the area in which they were not doing well, the two groups may give similar assessments of their QOL. In the case of the intervention group, it will be because the situation has improved. In the case of the control group, it will be because they have changed their

expectations or evaluation of the situation. Both are coping well, but this will hide the effectiveness of the intervention. Within-subject crossover trials may also be greatly influenced by response shift, since the washout period does not 'wash out' any response shift.[19] We are still exploring how to measure response shift and take it into account when it is important to do so.[11,12,20,21] Note that response shift is not limited to QOL and is a factor in all self-report measures, such as for pain or fatigue. This must be taken into account when interpreting the results of most clinical trials. Some factors likely to influence the ability to adapt are listed below.

- Social comparison. The theory[22] is that a factor in how we judge our situation is how we compare ourselves to others (are we doing better or worse in comparison), and who we choose to compare ourselves to (people in the general population? People with the same disease who are doing better than we are? People with the same disease who are doing worse than we are?).[19,23,24]
- Personality characteristics such as optimism[19,25–27] and sense of self-efficacy.[28]
- Existential wellbeing. Being able to see yourself in this situation as still being a valuable part of something larger than yourself (e.g. the world; nature; God's plan) and finding meaning in life.[7,8,29]

REASONS FOR ASSESSING QUALITY OF LIFE

Be clear about your purpose in assessing QOL. It will help you decide how best to do it. Do you want to:

- distinguish between groups of people?
- determine changes in the QOL of a group of people over time?
- assess an individual's (patient, or family caregiver), or even family's QOL at a specific point in time?
- assess changes in an individual's QOL over time?

BASIC REQUIREMENTS FOR ASSESSING QUALITY OF LIFE

Content validity

Any assessment of QOL, whether for clinical purposes or research purposes, needs to have content validity: you need to be assessing QOL, and not some other construct (such as health status). There is not complete agreement in the literature as to which domains are important for the QOL of palliative care patients, but there is a general consensus that it includes at least the physical, psychologic, social/relationship, and existential/spiritual domains.[30] Interestingly, these are the same as those generated by children with cancer.[31] Other

domains such as cognitive functioning,[8,32] environment,[8] and communication have been found to be important in some but not all studies.[8,30] When assessing QOL in different cultures, content validity needs to be assessed for each culture. It is not enough to know that the translation of the scale or interview is accurate and embraces the same concepts, it is necessary to be sure that the interview or questionnaire includes all the relevant content and only relevant content.

Acceptability/feasibility

Any assessment of QOL needs to be acceptable to the person whose QOL is being assessed. The questions must not be distressing. They may raise important feelings and even bring tears, but if these appear to be a welcome opening by the person to discuss important issues with the assessor, then I do not consider it distressing, provided they are given the opportunity to discuss these issues. I and others have informally noted that many palliative care patients find QOL assessments therapeutic. A formal study demonstrates this to be true for family caregivers as well.[33] The assessment must also be within the limits of the strength and other capabilities (e.g. reading) of the person whose QOL is being assessed.

Stability/test–retest reliability

When the person's or group's QOL is stable, the assessment should reflect that stability.

Responsiveness or sensitivity to change

When the person's or group's QOL changes, the assessment should reflect that change.

Interpretation of change

If QOL is being measured, so that a score is obtained, you need to know how to interpret a change in score. What amount of change in the scale is clinically meaningful to the patient? A statistically significant difference in scores between groups or over time is not necessarily an important one. Fortunately, recent work suggests that the minimal clinically important difference is similar across many QOL studies with different populations and represents about 0.2–0.5 standard deviations, or 5–10 percent of the scale range,[34] although it is always more reassuring if you have data available for the specific QOL instrument you are using. Can you put the change in scores into a clinically meaningful context (e.g. an improvement in score of 25 percent or 2 points on Psychological Subscale X corresponds to the difference between someone who is clinically depressed and someone who is not really enjoying every day but is not depressed)?

LEVEL AT WHICH TO ASSESS QUALITY OF LIFE

Quality of life can be assessed at different levels of detail.

1 Overall QOL.
2 Different areas or domains that contribute to QOL (e.g. physical; psychologic; social; existential).
3 Specific contributors to QOL (e.g. pain; anxiety about suffocating).

STANDARDIZED VERSUS INDIVIDUALIZED MEASURES

Standardized measures of QOL have fixed questions. Depending on the questionnaire, answers can be combined to obtain either a score for overall QOL, separate scores for different domains contributing to QOL, or both. In contrast, individualized QOL measures ask each person to name the areas of their life that are most important to their QOL, how satisfied they are in these areas, and the relative importance of each area named. Standardized measures can also include items asking people to rate the importance to them of various areas, but in practice these have been problematic.[35] Weighting the responses by the importance assigned to each area or question by each participant has not seemed to change the results when studying the QOL of groups of people, and it therefore is rarely used as it adds to participant burden.[36,37]

Because the specific contributors to QOL differ from person to person or for the same person over time, some argue it is not possible to measure QOL, or that if measurement is possible, it cannot be done using standardized measures.[38,39] I believe it depends on the purpose of QOL assessment. While the contributors to our QOL differ at the level of the specifics, at the level of domains, which can even be thought of as a deeper if less specific level, there is commonality among people and perhaps across cultures. For example, everyone wants to be physically comfortable, be neither depressed nor anxious, be comfortable with their place in the world, etc. This also remains to be tested. If this is the case, then standardized measures can be useful for measuring the QOL of groups, but may not be as useful as individualized measures for clinical care of individuals, where specific contributors to QOL may be of interest rather than wellbeing in domains. However, individualized measures have the drawback of not having everyone (or the same person over time) propose the same items as important to their QOL. Therefore, individualized measures provide a measure of overall QOL to compare across groups or for a group over time, but do not permit comparison of contributors to QOL at the level of domains, as not everyone will nominate the same domains. Since people may also change the weight assigned to different items in individualized questionnaires over time, interpretation of

changes or differences in QOL scores on individualized measures is complex. If people are asked to nominate items at each assessment rather than using the ones they nominated at the first assessment, some sensitivity to change may be lost.[40] However, if forced to use the same items at both times, the individualization at the second time of measurement is somewhat adulterated. Furthermore, sometimes people do not propose a certain item as important to their QOL simply because they have forgotten to mention it.[41]

HOW DO YOU MEASURE QUALITY OF LIFE?

Here are some questions you must answer in order to decide how best to assess QOL for your purpose.

- *Am I interested in QOL or rather in a specific contributor to QOL?* If the latter (e.g. physical functioning), choose a measure of that contributor rather than of QOL (although if you also expect overall QOL to be affected, or QOL in several domains to be affected, you may decide to make these secondary measures).
- *What level of QOL information do I need?* You may only want an answer to the question: how is your QOL? However, for many purposes, more detailed information is required, and you will want to know in what domains the person is doing well, and in what domains they are doing poorly. This is especially important in palliative care, where there is an inevitable decline in some areas such as physical wellbeing, but there may be improvement in others such as relationships or existential wellbeing.[42–45] If you only measure overall QOL over time, it may remain steady despite large changes in different domains. In this case you would select either an instrument that has well-established subscales for different domains (standardized measure with psychometrically sound subscales) or one that allows the person to name the domains important to their QOL and rate their status in each one (individualized measure).
- *Am I interested in comparing groups of people?* If yes, do these people have the same disease or different diseases? If you are comparing groups of people with different diseases, do the contributors to QOL differ at the level at which you want to measure QOL? If not, you can use a standardized measure. If the contributors to QOL differ for the two groups at the level you are measuring, the content of a standardized measure will not be equally valid for both groups, and an individualized measure is required for validity. If the contributors to QOL are the same for both groups, do you need to compare at the level of domains (in which case you will need a standardized measure) or at the level of overall QOL (in which case you can choose either an individualized or standardized measure).

- *Do I need information regarding everyone in the group, or is it acceptable to have only information regarding people capable of completing a questionnaire?* If you are in the camp that agrees that QOL is subjective, then it is clear that the person whose QOL is being measured is the best person to rate their own QOL. However, the physical or cognitive status of many palliative care patients precludes them being able to participate in rating their QOL. In this case, proxy measures may be considered. Ideally, someone who knows the patient well will rate the patient's QOL on his or her behalf. This may be a member of the staff or the family. However, proxy measures are known to differ from the patient's own ratings, and the difference tends to be greatest for areas that are less concrete (such as existential wellbeing) and where the patient is doing poorly. Many studies have been conducted regarding proxy measures, and the results are not particularly consistent.[4,46–48] There is no perfect solution in palliative care. You will have to balance the limitations of using proxy measures against the limitation of assessing only those who are well enough to complete a questionnaire.
- *How do I interpret a change in scores?* Note that the clinical importance of a change in scores may not be represented by the same amount of change in the directions of improvement and deterioration. Sometimes relevant information is available for the instrument you are using, but at this time this information tends to be limited. For example, the difference in score between bad, average, and good days is known for the McGill Quality of Life Questionnaire.[29] However, if you expect a more subtle change due to your intervention of difference between groups, you may need to be creative and think of ways of asking the person completing the questionnaire to in some way directly rate the importance of the change or indicate what it means clinically (e.g. if measuring physical functioning, what can you do now that you could not do before?).[49–52] In addition, in some circumstances response shift must be taken into account.
- *Do I want to assess QOL to help a particular patient (or family caregiver)?* If so, do I just want an initial assessment, periodic assessments, or do I want to track change in QOL over time? Will the answers to a formal assessment be useful (e.g. the scores), or should I use the QOL instrument as a guide for what to ask, without focusing on the numbers generated? For clinical purposes, I do not think any measure can replace a *good* clinical interview, although this remains to be tested. However, QOL measures are helpful as an initial interview guide or to flag areas that need further attention.[53–56] If QOL measurement turns out to be clinically useful, much work needs to be done to address barriers to its use in this way.[57]
- *How much can I expect my participants to do?* Can they complete the questionnaires on their own – do they

have the strength, concentration, sight, and reading skills? Or do I need to plan for someone to help explain the process of completing the questionnaire and read the questions to them? If so, who should this person be? Is it better to be a research assistant not involved in the patient's care, or should it be a staff member? What bias does each choice introduce to the answer to my question? What is feasible?

- *Will response shift (adaptation) interfere with my interpretation of the answer, or is the extent to which it occurs irrelevant to my question?* If it is not relevant, it simply needs to be taken into account when interpreting your results. However, if a response shift may greatly influence your conclusions, ideally you would plan some way of measuring the degree of response shift to help you interpret your data.[11,12,20,21]

- *If assessing over time, how will I use the data from the different times of data collection? How will I handle the inevitable missing data?* There are many established ways of dealing with data missing completely at random. However, in palliative care most of our missing data is *not* missing at random (it is informatively censored): usually it is missing because the patient has become too ill to respond or has died, or the patient's deterioration means that the family caregiver no longer has time to complete the questionnaire. Some headway has been made recently in dealing with this situation,[58] and if conducting a study you should check the recent literature to see if new papers on the topic have been published as it is presently an active area of research.

- *What time-frame should the questions refer to?* It is important that your questions clearly indicate the time period that people are to consider when answering. QOL measures developed for the general population often refer to the past month, while those that are disease-specific often use a time-frame of the past week. I have used the time-frame of the past 2 days in the measures I have developed for palliative care[42–44,59,60] because I believe that QOL often changes so rapidly near the end of life that it is too difficult to determine QOL over a longer period of time. Even with a time-frame of 2 days, sometimes people are having to average over a very good day and a bad one. However, I feel that 2 days is a better time-frame than a shorter one, which would only give a brief snapshot, taking into consideration that our population is probably not up to answering more than one to three times a week.

WHERE TO FIND MORE SPECIFIC INFORMATION ABOUT QOL MEASUREMENT TOOLS

Several reviews of the QOL instruments in the palliative care setting have been published in the scientific literature.[59,61,62]

In addition, compendiums of QOL instruments can be purchased.[63,64] The McGill Quality of Life Questionnaire,[42–44] and Hospice Quality of Life Index[65] are examples of standardized QOL instruments used for palliative care patients. The Palliative Outcome Scale[66–67] and Memorial Symptom Assessment Scale[68] have extensive overlap with QOL measures and are well-developed. The more recent Quality of Life at the End of Life (QUAL-E) was in fact developed based on data regarding what is most important at the end of life and to the quality of dying (rather than QOL *per se*); but there is much overlap with the content of the QOL questionnaires developed for palliative care.[69,70] The Edmonton Symptom Assessment System is not a measure of QOL but is widely used in conjunction with QOL instruments when specific symptoms are also of interest.[71] The Schedule for Evaluation of Individualized Quality of Life – Direct Weighting[9] and Patient Generated Index[10] are examples of individualized QOL instruments that can be used for patients or family caregivers. The Caregiver Quality of Life-Cancer instrument,[72] Caregiver Quality of Life Index,[73] and Quality of Life in Life-Threatening illness-Caregiver Version[59,60] have been used to measure the QOL of family caregivers. A retrospective measure of the quality of death and dying is the Quality of Death and Dying Scale.[74]

THE FUTURE

I look forward to a future where patients and family caregivers will be described not only in terms of their disease and symptom status, but also in terms of their QOL. Only then can palliative care really be addressing whole person care.

Key learning points

- Improving QOL is the main goal of palliative care, therefore assessing it is critical if we want to understand the extent to which we are achieving our goals.

- QOL assessment provides an assessment of the whole person. QOL is a perception. It is not a specific set of external circumstances, but rather the interaction of the person with external and internal circumstances.

- QOL assessment involves assessing what enhances someone's QOL as well as what makes it worse.

- The 'best' way of assessing QOL will depend on your purpose in assessing it.

- There is no perfect way to assess QOL in palliative care. Choose the best way, or combination of ways, and be aware of its strengths and limitations.

Pathophysiology of chronic pain

SEBASTIANO MERCADANTE

INTRODUCTION

Pain is a normal consequence of tissue injury or of intense stimuli that produce tissue injury. Peripheral nerves transmit this information from the body tissues to the spinal cord, from where neurons relay the information to the brain and simultaneously trigger reflexes that withdraw the body part involved in the painful stimulus. The higher brain centers organize the appropriate behaviors that restore health by protecting and facilitating healing of the damaged body site. Pain tends to diminish as healing progresses. Thus in healthy individuals, pain serves highly adaptive, survival-oriented purposes. However, pain can occur as a consequence of dysfunction of the peripheral or central nervous system, or prolonged and intense stimuli from damaged tissues. The differences between acute and chronic pain include peripheral responses of the organism and central nervous system modifications induced by the chronic afferent volley of nociceptor activity.[1]

The clinical picture of cancer pain varies depending on the pathophysiological mechanism, which further depends on the characteristics and progression of disease, and the preferential sites of metastases. Traditionally, pain related to malignant disease has been classified as nociceptive-inflammatory (somatic and visceral) and neuropathic. Somatic and visceral pains involve direct activation of nociceptors, and these pains are often a complication of infiltration of tissue by tumor or tissue injury as a consequence of oncological treatments. Neuropathic pain may be a complication of injury to the peripheral or central nervous system. This type of pain is often poorly tolerated and difficult to control. In the chronic pain situation that occurs following injury, infection, or inflammation of peripheral nerves, sensory processing in the affected body region is grossly abnormal. Environmental stimuli that would normally not result in the sensation of pain now do so, and painful stimuli elicit exaggerated perceptions of pain. Finally, pain is frequently spontaneous, that is, no stimulus can be identified to account for the pain.

Although nociceptive and neuropathic pains depend on separate peripheral mechanisms, they are both significantly influenced by changes in central nervous system function. It is now clear that cancer pain is a more complex entity, particularly regarding the response to analgesics, where numerous factors play a role. However, it remains unclear whether cancer pain is a unique type of pain or merely a subtype of inflammatory or neuropathic pain, as in cancer pain models there are changes in transmitters commonly produced in either neuropathic or inflammatory pain states. In contrast with inflammatory and neuropathic animal models, in a model of cancer pain no detectable changes were found in substance P, calcitonin gene-related peptide, and other peptides in either primary afferent neurons or the spinal cord. The greatest change observed in the spinal cord in response to cancer pain was a massive astrogliosis without neuronal loss, an increase in the neuronal expression of c-*fos*, and an increase in the number of dynorphin-immunoreactive neurons in the spinal cord ipsilateral to the limb with cancer.[2] Thus, the classical distinction may be of value only from an educational point of view.

PHYSIOPATHOLOGY OF NOCICEPTIVE PAIN

No specific histological structure acts as a nociceptive receptor. Primary afferent sensory neurons are the gateway by which sensory information from peripheral tissues is transmitted. Aδ and C nociceptors have been clearly identified in fibers innervating somatic structures, but not in the viscera where the situation is even more complicated. In cutaneous tissue thermal, mechanical, and chemical stimuli that induce tissue damage activate unmyelinated poly-modal transducers attached to Aδ and C fibers. Nearly all large-diameter myelinated A and B fibers normally conduct non-noxious stimuli. In contrast, most small-diameter sensory fibers (unmyelinated C fibers and finely myelinated Aδ fibers) are specialized sensory neurons, the main function of which is to detect and convert environmental stimuli, chemical or physical, into electrochemical signals that are transmitted to the central nervous system. As the intensity of the stimulus increases high-threshold receptors are involved. Various chemicals are released into damaged tissue cells. Sustained stimuli or damage to the nerve can alter the profile of several peptides such as substance P contained within primary afferents. Substance P is able to induce the production of nitric oxide, a vasodilator, and the degranulation of mast cells with further vasodilation and subsequent extravasation and release of bradykinin. Bradykinin is a powerful algogenic substance which also sensitizes nociceptors by means of prostaglandin E_2. Other factors, such as cytokines, are released after tissue damage under the influence of bradykinin. These substances have an important role in the inflammatory process. Although prostaglandins are weak algogens, they have a major role in the sensitization of nociceptors to other substances. The concerted effects of these mediators at the site of tissue damage underlie peripheral hyperalgesia, which accounts for much of the peripheral sensitization of nociceptors.[1]

Thus, a repeated and intense stimulus induces the release of several inflammatory mediators which reduce the threshold for activation, increase the response to a given stimulus, or induce the appearance of spontaneous activity. This sensitization of nociceptors is responsible for some features of hyperalgesia. Many inactive receptors may become excitable in conditions of inflammation and are recruited to amplify the stimuli in these circumstances. Sensory neurons may change their phenotype. Substance P, for example, binds and activates the neurokinin-1 receptor which is expressed by a subset of spinal cord neurons. Of interest, inflammation is able to unmask opioid receptors peripherally. Primary hyperalgesia involves increased sensitivity to noxious stimulation at the site of the injury and is mediated by peripheral mechanisms, whereas secondary hyperalgesia extends beyond the site of the injury and is related to central activity or sensitization. This latter is characterized by prolonged excitation of dorsal horn cells, resulting in an expansion of receptive fields of dorsal horn neurons. As a consequence of such sensitization the expression of c-*fos* in the superficial dorsal horn increases. Peripheral nerve injury leads to the abnormal expression of receptors and channels that may result in ectopic discharges from neurons.

After injury to somatic, visceral, and neural structures, there may be an alteration in the response of the autonomic nervous system, which may react by novel sprouting of sympathetic efferents and formation of rings around dorsal root ganglia. Central neural mechanisms are also involved, leading to a constellation of peripheral vasomotor and sudomotor changes.[3] Immune system cells, including macrophages, neutrophils, and T cells, either in the tumor mass or produced as a reaction, sensitize or directly excite primary afferent neurons. Local acidosis produced by cancer cells can activate or express further nociceptors. Moreover, tumor necrosis factors and inflammatory cells are able to express opioid receptors, which may influence the response to opioids due to initial sequestration first, and then by release of nitric oxide, known as hyperalgesic agent (see below).[4]

VISCERAL PAIN

The viscera have a complex peripheral nervous system, and different neurophysiological understandings of visceral pain have been reported. Unlike their cutaneous counterparts, visceral nociceptors do not appear to be a simple acute warning system. Many viscera are innervated by receptors that do not evoke conscious perception. Visceral nociceptors, however, have a wide range of responses, and may be activated in the presence of inflammation or tissue injury. Therefore, visceral afferents are considered polymodal, providing excitatory responses to different stimuli, including inflammation, stretching, and distension. Two distinct classes of nociceptive sensory receptors that innervate internal organs have been proposed:

- high-threshold receptors – mostly mechanical, activated by stimuli within the noxious range
- low-threshold receptors – activated in the range of stimulation intensity from innocuous to noxious.

According to this theory, high-threshold receptors contribute to the peripheral encoding of noxious events in the viscera. Other prolonged and intense stimuli, such as hypoxia or tissue inflammation, result in the sensitization of these receptors and bring into play previously silent receptors, normally unresponsive to innocuous stimuli. The activity of afferents and the excitability of dorsal horn neurons are increased with repeated or persistent stimuli due to a process of sensibilization of afferents, which occurs secondary to local release of chemical substances in damaged or ischemic tissues. A critical level of preceding activity in the afferents is required to induce facilitation of dorsal horn neuronal responses via central mechanisms.[5]

Neurons that transmit visceral sensory information to the spinal cord have cell bodies that reside in the dorsal root ganglia. These primary afferents travel through the paravertebral ganglia and the prevertebral ganglia and have sensory endings in the viscera themselves. These afferents occur in conjunction with motor fibers of parasympathetic and sympathetic nervous system. Most visceral afferents have relatively slow conduction velocities.

Visceral pain tends to be diffuse because of the absence of a separate visceral sensory pathway and a low proportion of visceral afferent nerve fibers compared with those of somatic origin. Thus, neurological mechanisms of visceral pain differ from those involved in somatic pain. The nature of referred pain is not clearly defined. Some spinal neurons are involved in the localization of pain and project to the brain, whereas another group of neurons has short ascending projections with collaterals into multiple spinal segments. The activation of visceral efferents should lead to changes in the excitability of multiple spinal units, including those responsible for somatic nociceptive sensory pathways, or direct activation of neurons receiving both visceral and somatic inputs. Alternatively, the brain may misinterpret activity in the viscerosomatic neurons. Convergent receptive fields are generally described as multidermatomal, centered in the dermatome corresponding to the spinal segment stimulated, and are significantly larger than the receptive fields of spinal neurons receiving only somatic input.[6,7] These observations explain why visceral pain is difficult to localize and is often referred to other areas of the body. Pain originating from any viscus cannot be easily differentiated from pain originating in another viscus, although some visceral pains are associated with specific etiologies, such as in the case of pancreatic pain or peptic ulcer pain.

Mechanic stimuli, such as torsion or traction of mesentery, distension of hollow organs, stretch of serosal and mucosal surfaces, and compression of some organs, produce pain in humans. These conditions are frequently observed in cancer patients with abdominal diseases and intraperitoneal masses. Human studies have revealed that pain is produced when the intraluminal pressure of hollow organs is maintained above certain pressure thresholds. Obstruction or inflammation within the biliary tract or pancreatic duct induces pain directly related to the increased intraluminal pressure with consequent inflammation, and release of pain-producing substances. Capsular stretch of liver due to cancer growth produces pain. Distension or traction on the gallbladder leads to deep epigastric pain, inspiratory distress, and vomiting. Spontaneous spasm of the sphincter of Oddi or that induced by morphine on the one hand leads to increases in pain sensation, resulting in a paradoxical opioid-induced pain. On the other hand, morphine and other opioids may counterbalance this effect, increasing the pressure threshold necessary to produce the sensation of pain due to distension of the biliary system.

Renal colic is usually secondary to ureteral obstruction and subsequent distension of the ureter and renal pelvis. This may be seen in circumstances in which an abdominal–pelvic mass compresses or invades the ureters, as often occurs in gynecological cancers. Reports of pain appear to be directly related to the compression of the urinary bladder. Bladder distension may also activate mechanisms related to the phenomenon of counter-irritation. Better localization of stimulus occurs when the disease extends to a somatically innervated structure such as the parietal peritoneum. Thus initially, visceral pain is poorly localized and dull because of the wide divergence of visceral afferents in the spinal cord. Poorly localized visceral pain becomes localized as visceral afferent input increases due to spinal facilitation or activation of visceral nociceptors. The greatest localization occurs when somatic structures such as the peritoneum become involved.

CHRONIC PAIN AND PLASTIC CHANGES OF THE CENTRAL NERVOUS SYSTEM

Chronic pain, regardless the initial etiology, produces important changes in the central nervous system. A prolonged stimulus from the periphery through either stimulation of nociceptors or ectopic firing after neural damage leads to repetitive activation of C fibers. This results in augmentation of activity in dorsal horn wide dynamic range neurons and a strong increase in the magnitude of the responses evoked by subsequent stimuli. Thus, increased input from injured neurons, ectopic nerve action potentials, and sensitization of nociceptors by the peripheral nerves produce tonic input to the spinal cord.

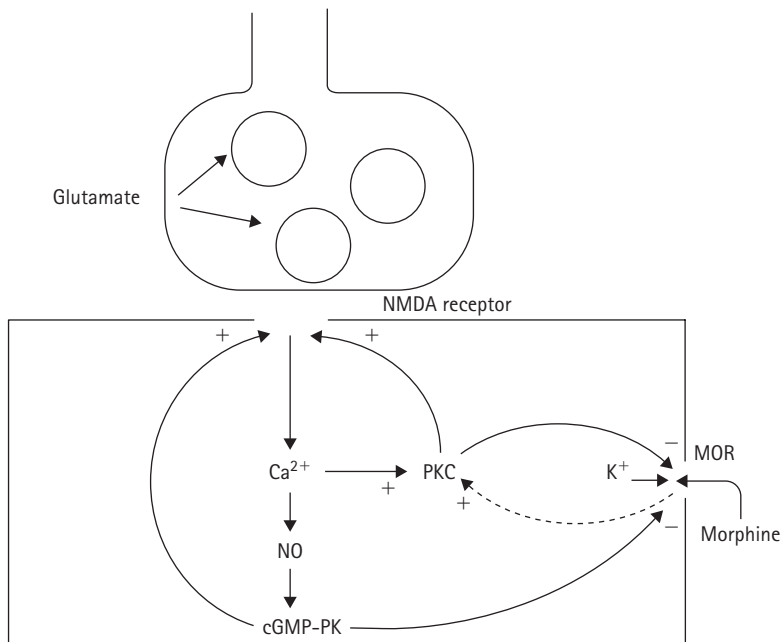
Central sensitization and a wind-up phenomenon at the spinal and supraspinal levels have been described to explain the pathophysiological background of chronic pain conditions due to persistent peripheral stimuli or nerve injury.[8] The existence of peripheral hyperalgesia has a bearing on the induction of central hypersensitivity in the spinal cord. The enhanced release of substance P and other neurokinins may provide the mechanisms by which the N-methyl-D-aspartate (NMDA) receptor for the excitatory amino acids becomes more easily activated. These transmitters cooperate to activate spinal cord neurons. The release of peptides such as substance P into the spinal cord on afferent stimulation removes the magnesium block of the channel of the NMDA receptor and thus allows glutamate to activate the NMDA receptor in the range of persistent pain states.[1] The ion channel for the NMDA receptor allows vast amounts of calcium to enter into the neurons, resulting in an amplification of the response underlying central hyperalgesia. The repetition of a constant intensity C fiber stimulus induces the phenomenon of wind-up, that is, the switch from a low level of pain-related activity to a high level without any change in the inputs arriving from the peripheral nerves. This results in prolongation and amplification of nociceptive activity even after the cessation of the peripheral input.


Figure 42.1   *Activation of N-methyl-D-aspartate (NMDA) receptors increases intracellular Ca^{2+} concentration and subsequent intracellular activation of protein kinase C (PKC) and nitric oxide (NO). Substrate phosphorylation by PKC or NO-mediated protein kinase may produce enhanced activity of glutamate receptor–Ca^{2+} complex, with development of hyperactive states. PKC and NO-mediated protein kinase actions may produce uncoupling of G-protein with mu opioid receptor (MOR), so reducing morphine anti-nociception.*

The activation of such receptors is involved in the development and maintenance of injury-induced central hyperactive states by initiating a variety of intracellular processes. These principally consist of an increase in intracellular calcium concentration, activation of protein kinase C (PKC) and the calcium–calmodulin-mediated production of nitric oxide, and, in a complex manner, lead to neuronal excitability. It has been suggested that feedback by nitric oxide increases the release of C fiber transmitters, further enhancing pain transmission. Protein kinase C translocation and nitric oxide production may enhance postsynaptic neuronal excitability, leading to the development of hyperactive states. Furthermore, PKC and nitric oxide may activate presynaptic NMDA receptors localized on primary afferent fibers by removing the magnesium blockade of the NMDA receptor. In so doing even small amounts of excitatory amino acid ligands may allow the opening of calcium channels, with further activation of a second pool of PKC (Fig. 42.1). Increases in intracellular calcium and activation of PKC also result in c-*fos* expression in postsynaptic dorsal horn neurons as well as in supraspinal areas. This is considered to be a third messenger, probably involved in encoding a variety of cellular responses that are responsible for the neural changes associated with hyperalgesia.[9] This has been demonstrated by similar time courses of c-*fos* expression and the development of hyperalgesia.[10] Whereas the entry of calcium can also activate phospholipases and lead to the spinal production of prostanoids, persistent activation of excitatory amino acid receptors within the spinal cord may contribute to central hyperexcitability. This is because irreversible morphological changes may occur with loss of function of spinal cord inhibitory interneurons. These excitotoxic processes may result in disinhibition phenomena, reinforcing the central hyperactivity state.[11]

Peripheral nerve injury also results in a number of dorsal horn effects, such as changes in the distribution and density of α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptors (better known as AMPA), releases of neurotrophins, sprouting of central terminals, and loss of inhibitory neurons containing γ-aminobutyric acid.[3] Mechanisms of normal synaptic transmission and intense and prolonged activation are shown in Figures 42.2 and 42.3. Similar mechanisms are presumably operating at the supraspinal level, although available data are less clear. Pain activates brain structures, such as the periaqueductal gray matter of the midbrain (which is involved in blood pressure regulation, respiration, vasomotor control and metabolic homeostasis) and the thalamus (which is a major relay in the transmission of nociceptive information). Prolonged activation of these structures can have a strong impact on psychological function, also inducing complex cognitive responses.

DESCENDING MODULATION OF NOCICEPTION

Brainstem descending pathways constitute a major mechanism for modulating nociceptive transmission at the spinal level. The rostral ventromedial medulla (RVM) includes the nucleus raphe magnus and adjacent lateral reticular formation. A biphasic descending modulation of nociception has been postulated, through the activation of facilitation and inhibition of nociceptive processes, consequent to activation of two types of cell group, 'on-cell' and 'off-cell', respectively. Descending pathways are activated by tissue injury to counteract the cascade of events that ultimately contribute to the development of inflammatory hyperalgesia. Opioidergic
Figure 42.2 *Normal synaptic transmission: presynaptic activation produces exocytosis of glutamate, which binds to postsynaptic receptors: (i) AMPA receptors, leading to opening of Na^+ and K^+ channels, and resulting in depolarization; (ii) metabotropic receptors, causing the binding of GTP to G-proteins and activation of second messengers (protein kinase C, adenyl cyclase); and (iii) NMDA receptors, potentially opening ion channels. Mg^{2+} blocks the ion flux.*
Figure 42.3 *Intense and prolonged activation causes abnormal release of glutamate. More AMPA receptors are activated, limiting the Mg^{2+} block on NMDA receptors. Ca^{2+} ions flow through these channels, interacting with the second messenger enzymes, resulting in more availability of AMPA receptors, as consequence of gene activation. Phosphorylation of ion channels makes the cell more excitable. Retrograde messengers also act on presynaptic nerve terminals causing the release of more glutamate.*

circuits are involved in descending inhibition of nociception, increasing the activity of the antinociception-inhibiting 'off-cells', and decreasing the activity of the nociceptive-facilitating 'on-cells' of the RVM. Studies suggest that descending serotonergic and noradrenergic pathways differently suppress the responses of spinal neurons.[12] The organization and functional significance of the facilitatory network is less known and is possibly involved in pro-nociceptive mechanisms. For example, prolonged administration of opioids induces neuroplastic changes resulting in enhanced ability of

cholecystokinin (CCK) to excite facilitatory pathways from the RVM, and/or upregulation of dynorphin levels, evoking release of excitatory transmitters from primary afferents (see below).[13] Ventrolateral periaqueductal gray matter could be one of the sites where the repeated administration of opioids induces opioid tolerance. There is evidence that endogenous or exogenous opioids lead to an enhancement of CCK activity, which in turn attenuates the antinociceptive effect of opioids and may be one of the mechanisms responsible for opioid tolerance.[14] The dynamic plasticity of descending

pathways may render the system vulnerable and lead to pathological consequences.

CHRONIC PAIN STATES AND OPIOID ACTIVITY

Opioids inhibit or block excitation of dorsal horn cells by depressing firing through both presynaptic and postsynaptic inhibitory effects in the spinal cord.[15] The physiological targets of both exogenous and endogenous opioids are receptors coupled to G-proteins: μ, δ, and κ receptors. The acute effects of the opioids include inhibition of cAMP formation, activation of inward K^+ channels, and inhibition of voltage-gated Ca^{2+} channels. These lead to presynaptic hyperpolarization, inhibition of excitatory neurotransmitter release, and activation of descending antinociceptive pathways.[16] Opioid receptors undergo adaptations such as desensitization, downregulation, and internalization in response to agonist treatment. Molecular processes underlying desensitization are thought to include rapid uncoupling of the receptor from its G-protein by phosphorylation of the receptor or binding of accessory proteins, such as β-arrestin. Receptor internalization has been implicated in the process of dephosphorylation and the resensitization recycle of the receptor. After prolonged treatment loss of receptor protein, named downregulation, may occur, leading to increased degradation or decreased synthesis of the receptor. Opioids differ in their capability of inducing such molecular events.

Repeated administration of opioids produces a decrease in analgesia, an effect termed tolerance. In opioid tolerance, a functional decoupling of opioid receptors occurs by cellular mechanisms regulated by second messengers, in addition to downregulation of opioid receptors and adaptive behavioral changes.[17] Loss of opioid presynaptic receptors as a result of a peripheral nerve injury has been reported at the level of the dorsal horns. However clinically, the degree and the time course of tolerance are influenced by several factors, including drugs, dosing schedules, and routes of administration.[18]

Several factors common to neuropathic pain and tolerance have been found, although some central changes at spinal cord level typically present in neuropathic pain states are not found with chronic exposure to morphine. Activation of spinal cord NMDA receptors, PKC activation, and nitric oxide production are biochemical steps capable equally of leading to a state of hyperalgesia or the development of morphine tolerance.[10,15] Substrate phosphorylation by PKC and nitric oxide may result either in enduring enhancement of synaptic activity at spinal cord level[19] and decreasing the μ-receptor activity, uncoupling of G-protein with the μ receptor or facilitating its desensibilization.[17,20] Thus, the reduction of morphine analgesia induced by nerve injury may share a mechanism similar to that of morphine tolerance. Reduction of morphine antinociception occurs after hyperalgesia induced by nerve injury in the absence of daily exposure to morphine,[10] as nerve injury would produce a reduction of morphine nociception prior to exposure to morphine itself.

In other terms, it is possible that a sort of tolerance and/or hyperalgesia develops before exposure to morphine and a neuropathic pain state may be equivalent to that of the development of morphine tolerance or facilitating hyperalgesia with a consequent pro-nociceptive effect.[10,21] This is consistent with the clinical observation of increased opioid requirements in patients with neuropathic pain.[22,23] However, these neuroplastic changes may be distinct and divergent intracellular events may take place, as the expression of hyperalgesia is not necessarily associated with the expression of tolerance and vice versa. A single dose of MK-801, an inhibitor of NMDA receptors, has been shown to reduce hyperalgesia but not to enhance morphine antinociception.[10,17]

Prolonged opioid treatment not only results in a loss of opioid antinociceptive efficacy but also leads to activation of a pro-nociceptive system characterized by a reduction of nociceptive threshold.[24] It has been suggested that the concurrent expression of hyperalgesia during chronic opioid administration counteracts antinociception, producing an impression of tolerance due to compensatory neuronal hyperactivity. Descending facilitation at RVM level has been reported. This pro-nociceptive activity has been found to be associated with increases in expression of dynorphin in the spinal dorsal horn, which promotes the release of excitatory transmitters from primary afferent neurons.[25]

Other aspects of pain modulation have been reported. The reduction in receptor function is hypothesized to contribute to opioid tolerance. Opioid receptor are desensitized on the cell surface through a phosphorylation process. On the other hand, receptor internalization is now believed to contribute to resensitization through a dephosphorylation during endosomal stages.[26] An inverse relation between tolerance liability and μ-opioid receptor endocytosis has been shown. On the other hand the loss of response to opioid agonists upon long-term treatment seems to be the result of two partially overlapping processes: the gradual loss of inhibitory opioid signal transduction and an increase in excitatory signaling.[27] Chronic opioid agonist treatment simultaneously desensitizes the inhibitory effects of the opioids and augments the stimulatory signaling, possibly through a time-dependent alteration of the specificity of opioid–G-protein coupling. The supersensitivity of neurons to the excitatory effects of opioids seems to be to a GM1-ganglioside–mediated conversion of the opioid receptors from an inhibitory (Gi coupled) to an excitatory (Gs coupled) mode.[28] These changes cause a compensatory increase in cellular cAMP formation, due to an increased activity of PKC. This superactivation is manifested by an apparent desensitization of the inhibitory opioid signaling. Removal of the agonist unmasks an underlying sensitization of cAMP formation to stimulatory inputs. Clinically, this may occur in circumstances where, for different pharmacokinetic reasons, opioid

concentrations significantly decrease at the receptor site, producing a sort of mini-withdrawal.

As it becomes clear that chronic pain, particularly cancer pain, is able to specifically modify the response of the central nervous system, recent data indicate a close relation between cancer disease and its metabolic and immunological consequences, and plastic changes of the central nervous system associated with the concomitant chronic administration of opioids, which require better knowledge of molecular events underlying such mechanisms. An integrated approach taking into account information from both experimental work and the bedside is advised.

Key learning points

- The clinical picture of cancer pain varies depending on the pathophysiological mechanism, which further depends on the characteristics and progression of disease, and the preferential sites of metastases. Although pain related to malignant disease can be classified as nociceptive-inflammatory and neuropathic, they are both significantly influenced by changes in central nervous system function.

- It is now clear that cancer pain is a more complex entity, particularly regarding the response to analgesics, where numerous factors play a role.

- Central sensitization and a wind-up phenomenon at the spinal and supraspinal level have been described to explain the pathophysiological background of chronic pain conditions.

- Brainstem descending pathways constitute a major mechanism for modulating nociceptive transmission at the spinal level. The dynamic plasticity of descending pathways may render the system vulnerable and lead to pathological consequences.

- Opioids produce inhibition or block excitation of dorsal horn cells within the spinal cord. Repeated administration of opioids produces a decrease in analgesia, an effect termed tolerance.

- There are several common factors in neuropathic pain and tolerance.

- Prolonged opioid treatment not only results in a loss of opioid antinociceptive efficacy, but also leads to activation of a pro-nociceptive system characterized by a reduction of nociceptive threshold.

Causes and mechanisms of pain in palliative care patients

SURESH K REDDY

INTRODUCTION

Pain due to cancer is one of the most common symptoms experienced by palliative care patients, as shown by many studies in this patient population.[1,2,3*] The consequences of undertreatment of pain are daunting, yet pain is underdiagnosed and undertreated for many reasons.[4*,5*] One of the main reasons for undertreatment of pain in patients with cancer continues to be a lack of appropriate pain assessment.[6*,7*] In cancer, pain is predominantly caused by the tumor and its consequences. Other reasons include treatment side effects and coexisting pain conditions[3,8] (Box 43.1). In noncancer situations pain may result from chronic degenerative disorders of the spine and joints:[9*10*,11*] central pain because of spinal cord injury, and neuropathic pain due to metabolic, infective and other causes[12,*13*,14*] (Box 43.2).

Box 43.1 Common clinical pain syndromes and their causes

Tumor pain

- Bone pain due to metastasis (somatic pain) from breast, prostate, and other cancers

- Plexopathy pain (neuropathic pain) due to Pancoast's tumor/pelvic tumor

- Abdominal pain (visceral pain) due to pancreatic cancer and liver metastasis

- Chest wall pain due to mesothelioma (somatic and neuropathic pain)

Cancer treatment pain

- Postchemotherapy pain syndromes

- Peripheral neuropathy due to cisplatin and paclitaxel

Post–irradiation pain syndromes

- Chronic throat pain due to radiation-induced mucositis

- Chronic abdominal pain due to radiation-induced enteritis in fistulas

- Radiation-induced plexopathy pain

Postsurgical pain syndromes

- Postmastectomy pain syndrome

- Postradical neck dissection pain syndrome

- Phantom limb pain syndrome

Noncancer pain

- Chronic low back pain due to degenerative process in the spine

- Pain secondary to osteoarthritis and rheumatoid arthritis

- Migraine headaches

Box 43.2 Noncancer pain syndromes

Headache

- Migraine

- Tension-type headache

- Cluster headache

- Miscellaneous

Facial pain

- Trigeminal neuralgia

- Temporomandibular joint pain

- Glossopharyngeal neuralgia

- Postherpetic neuralgia (PHN)

- Myofascial pain syndromes

Neck pain

- Diskogenic radicular pain

- Whiplash injury pain syndrome

- Cervicogenic pain

- Facet joint pain syndrome

Thoracic pain syndromes

- Costochondritis

- Intercostal neuralgia

- PHN

- Facet joint pain syndrome

- Chronic shoulder pain: frozen shoulder; rotator cuff tear

Abdominal pain

- Chronic pancreatitis

- Chronic peptic ulcer disease

- Postcholecystectomy syndrome

- Crohn disease

- Irritable bowel syndrome

Pelvic pain

- Chronic interstitial cystitis

- Chronic testicular pain

- Chronic prostatitis pain

- Chronic pelvic pain from inflammatory pelvic disease

- Endometriosis-related pain syndromes

Low back and lower extremity pain

- Central pain

- Lumbosacral spine disease: myofascial; diskogenic; osteoporotic; facet joint pain syndrome

- Peripheral vascular disease and ischemic pain syndrome

- Dorsal tunnel syndrome

- Complex regional pain syndrome

- Phantom limb pain

Medical diseases causing pain

- Chronic fatigue syndrome

- Sickle cell disease

- Peripheral neuropathy pain (e.g. diabetes)

- Rheumatoid arthritis, multiple sclerosis, osteoarthritis

HIV/AIDS pain syndromes

- Headache (e.g. cryptococcal meningitis)

- Oral cavity pain secondary to candidiasis, herpes simplex, or Kaposi sarcoma

- Chest pain secondary to candidal esophagitis

- Chronic abdominal pain from infections such as cryptosporidiosis, cytomegalovirus, cholecystitis, pancreatitis

- Pain syndromes related to Kaposi sarcoma

- Neuropathic pain syndromes (e.g. predominantly sensory neuropathy, myelopathy, radicular pain from Guillain–Barré syndrome)

Pain results from the activation of nociceptors by a variety of chemical mediators released from damaged cells. The mediators include potassium, serotonin, bradykinin, and histamine, and usually associated with the redness and swelling of inflammation. In addition, cells may be sensitized by other substances such prostaglandins, leukotrienes, and substance P. Sensitization can extend to areas away from the original damage, resulting in hypersensitivity of the area.

Cancer pain can occur after activation of peripheral nociceptors (somatic and visceral 'nociceptive' pain) or by direct injury to peripheral or central nervous structures (neuropathic or 'deafferentation' pain). In addition, both

nociceptive and neuropathic pain may be modified by involvement of the sympathetic nervous system, resulting in sympathetically maintained pain (SMP) or complex regional pain syndrome type 1 (CRPS). Each of these painful states has somewhat unique clinical characteristics which may aid in its identification and directed treatment. A key step, therefore, in the evaluation of a cancer patient with pain, is to elicit a careful history of the quality, nature, and location of perceived pain, as the descriptors may provide valuable clues to the etiology of the complaint.

Somatic pain results from involvement of bone and muscle structures. Metastatic bone disease is the most common pain syndrome in patients with cancer. Myelinated and unmyelinated afferent fibers are present in bone, and their density is greatest in the periosteum. Prostaglandins play a multifactorial role in the etiology of bone pain. Prostaglandin concentrations are increased at sites of bone metastasis.[15*] In addition, prostaglandins are now known to mediate osteolytic and osteoclastic metastatic bone changes. Prostaglandin E_2 is known to sensitize nociceptors and produce hyperalgesia. These observations have resulted in steroidal and nonsteroidal anti-inflammatory drugs (NSAIDs) as important therapy for metastatic bone pain. Reports suggest that NSAIDs are uniquely effective.[16**]

Visceral pain is also common in patients with cancer, and presumably results from stretching or distending or from the production of an inflammatory response and the release of analgesic substances in the vicinity of nociceptors. Visceral pain is commonly referred to cutaneous sites, which can mislead the examiner, particularly since those cutaneous sites may be tender to palpation. This property likely results from convergence of visceral and somatic afferent information onto common neuronal pools in the dorsal horn of the spinal cord.[17*] Neuropathic pain from neural injury such as brachial plexus infiltration by tumor is often severe. The pain is described as paroxysms of burning or electric-shocklike sensations which may result, at least in part, from spontaneous discharges in the peripheral and central nervous systems.

Somatic, visceral, and deafferentation pain may be modified by the sympathetic nervous system. Sympathetically maintained pain is often suspected when pain is severe in intensity (even after relatively trivial tissue insults) and described as burning in quality, with associated features of allodynia, hyperpathia, brawny edema, and osteoporosis.[18*] Several mechanisms involving both peripheral and central nervous systems have been postulated to explain SMP. For example, one peripheral mechanism may be the development of ephaptic connections at sites of tissue injury such that efferent sympathetic impulses produce activation of afferent nociceptive pathways. Others have postulated that traumatic injury to peripheral tissues may produce sensitization of spinal cord nociceptive neurons, which may then be secondarily activated by efferent sympathetic activity.

It is common for patients with cancer to present with mixtures of the pain types described above. Furthermore,

the pattern of pain intensity is often not constant, but rather includes episodes of pain exacerbations on a background of continuous pain, called 'breakthrough' pain (see Chapter 54).[19*]

SPECIFIC PAIN SYNDROMES IN PATIENTS WITH CANCER

There are several specific pain syndromes that may present difficult diagnostic and therapeutic problems, of which the palliative care specialist needs to be aware of during the evaluation of the cancer patient with pain.[20*] The characteristic clinical features of these syndromes are summarized in Box 43.3 and discussed below. Please note that notable but short-lived pain syndromes, such as mucositis, that complicate chemotherapy and radiation therapy, and the acute pain associated with diagnostic and therapeutic procedures, such as bone marrow aspiration are not included in Box 43.3.

Box 43.3 Clinical characteristics of intractable pain syndromes

- Tumor-related infiltration of bone – acute and chronic nociceptive pain

- Skull-base metastasis – severe head pain (usually referred to vertex or occiput) with associated cranial nerve deficits. Bone scan and plain films of the skull may show normal findings

- Vertebral metastasis – significant risk of associated spinal cord compression. Of patients with back pain and vertebral body metastasis, 30 percent will eventually develop epidural spinal cord compression, and pain alone may precede root or spinal cord signs by many months

- Pelvis and long bones – risk of pathological fracture with weight-bearing activities; orthopedic consultation helpful

- Tumor-related infiltration of nerve – acute and chronic neuropathic pain

- Brachial/lumbosacral plexopathy – may occur by contiguous spread of tumor or by hematogenous dissemination; radiographic studies helpful to distinguish from radiation-induced plexopathy

- Spinal cord compression – neurological emergency requiring prompt treatment with corticosteroids, radiation therapy, and/or surgery

- Meningeal carcinomatosis – headache and meningeal signs. Causes significant pain in about 15 percent of patients

- Visceral tumor infiltration – acute and chronic visceral pain that is poorly localized and widely referred. Common examples include pancreatic carcinoma, liver metastasis, pleural effusion
- Therapy-related post-surgical pain – chronic pain that persists well beyond healing of the incision and may or may not be associated with recurrent disease
- After thoracotomy – may be associated with recurrent tumor or may occur as a chronic intercostals neuralgia
- After mastectomy – occurs in 5 percent of women; more common in women undergoing modified radical procedure with axillary dissection; intercostal brachioradial neuralgia is one cause
- After radical neck surgery – mechanisms unclear; chronic infection may play a role
- After amputation – stump pain and phantom phenomena are common; role of preventive analgesic and anesthetic therapies are under investigation

TUMOR INFILTRATION OF BONE

Pain from invasion of bone by either primary or metastatic tumor is the most common cause of pain in patients with cancer. Several important pain syndromes are often misdiagnosed because physicians are unfamiliar with the characteristic signs and symptoms, and plain X-rays of the involved areas may show normal findings.

The pathophysiology of metastatic bone pain is poorly understood. Although most patients with bone metastasis report pain, a large proportion of patients with radiographic evidence of disease deny pain. This has been best studied in breast cancer,[21*] but is also true in prostate cancer. Tumor growth in bone may produce pain by several mechanisms:

- Relatively rapid growth causing expansion of the marrow space and increased interosseal pressure (beyond 50 mmHg). In theory, this may activate mechanoreceptive nociceptors in bone. In addition, elevation or invasion of the periosteum may also activate nociceptors that innervate this structure.
- Weakening of the bone leading to fractures.
- Edema and inflammation associated with tumor growth in bone may liberate chemical mediators that activate nociceptors.
- Recent data regarding mechanisms of bone destruction emphasize that osteoclasts may be stimulated by a

number of humoral factors associated with tumors. For example, carcinomas may secrete prostaglandins,[15*] which would have the dual role of activating osteoclasts and sensitizing nociceptors. These observations have provided a rationale for the use of corticosteroids and NSAIDs for the management of metastatic bone pain.[22**]

Metastatic bone pain is often associated with neurological dysfunction because of the close anatomical relations between the brain and cranial nerves and the skull vault, and the spinal cord and its roots and the vertebral column. Therefore, characteristic clinical syndromes may be identified by the site of bony involvement, the coexistence of mechanical instability secondary to fractures, and neurological dysfunction caused by tumor infiltration of contiguous neurological structures. Bone metastasis to the hip and pelvis often produces local pain that is exacerbated by movement, especially when weight bearing. In addition to palliative radiotherapy, this type of 'incident pain' may require specific orthopedic interventions.

Spread of cancer to the vertebral bodies and calvarium, especially the base of the skull, often produces distinctive neurological syndromes. These are important to recognize early because prompt initiation of antitumor treatments, especially radiation, may avoid neurological impairment. For example, local and radicular back or neck pain is the predominant symptom in epidural spinal cord compression complicating vertebral body metastasis in these locations. Pain may be the only symptom of impending spinal cord compression, and often precedes motor weakness and bowel or bladder incontinence by days or weeks. The spinal cord is compromised by growth of the tumor in an anterior direction from the vertebral body. Irreversible spinal cord injury may occur when the vascular supply is compromised as a result of severe compression. Thoracic spine vertebral body metastases often produce bilateral radicular pain and sensory symptoms (a 'bandlike' squeezing sensation across the upper abdomen or chest) because of the close proximity of the thoracic nerve roots to the vertebral body. On the other hand, metastases in the cervical or lumbar spine may produce unilateral pain and sensory loss as the vertebral bodies are wider in these areas and lateral extension of the tumor may compress only one root at the time.

Skull metastasis

Spread of tumor to the calvarium may produce neurological symptoms by two mechanisms. Metastases to the skull vault which grow to compress the sagittal sinus may produce a syndrome of severe headache with associated papilledema and seizures caused by elevation in the intracranial pressure. If untreated, focal neurological deficits may occur secondary to venous infarction of the brain. The cause of metastatic sagittal sinus occlusion is usually obvious, and is easily confirmed by magnetic resonance imaging (MRI)

of the brain. The gadolinium-enhanced MRI will not only demonstrate the tumor metastasis, but will also demonstrate the blood clot in the sagittal sinus. It is noteworthy that nonmetastatic sagittal sinus occlusion may also occur in prostate cancer as a complication of a hypercoagulable state induced by diethylstibestrol treatment.

Tumor metastasis to the base of the skull may also produce distinct neurological syndromes.[23*] Bone metastasis to this portion of the skull often produces severe headache referred to the top of the head or the occiput. Also, single or multiple cranial nerve palsies usually accompany basal skull metastasis. For example, clival metastasis often compresses the hypoglossal nerve producing unilateral weakness of the tongue and deviation of the tongue to the side of the lesion when protruded from the mouth. Bone metastasis to the middle cranial fossa may compress and infiltrate the facial nerve, producing ipsilateral weakness of the upper and lower face. Tumor invasion of the jugular foramen will produce severe head pain with associated dysphagia, dysphonia and hoarseness caused by dysfunction of the glossopharyngeal and vagal nerves, which exit the skull base through this foramen. Involvement of foramen ovale may result in compression of trigeminal nerve leading to facial pain.

Small lesions at the skull base may not be visible on plain X-rays or bone scans. It is mandatory that computed tomography (CT) scans with bone windows and 5 mm sections are done to demonstrate the tumor. It is sometimes necessary to do MRI scans of the base of the skull when CT scans are negative.[20*] Radiation therapy directed to the base of the skull is the preferred treatment. Again, prompt recognition of these syndromes and aggressive treatment is indicated to prevent irreversible cranial nerve palsies that often produce devastating neurological impairments.

Cervical spine metastasis

Metastatic disease involving the odontoid process of the axis (first cervical vertebral body) results in a pathological fracture. Secondary subluxation occurs and results in spinal cord or brainstem compression. The symptoms are usually severe neck pain radiating to the posterior aspect of the skull to the vertex, exacerbated by movement. The diagnostic evaluation may require MRI, as plain X-rays and bone scans may not show the problem. Imaging procedures must be carried out carefully to ensure spinal stability.

Pain in C5–6 is characterized by a constant dull aching pain radiating bilaterally to both shoulders with tenderness to percussion over the spinous process. Radicular pain in a C7–8 distribution occurs most commonly unilaterally in the posterior arm, elbow, and ulnar aspect of the hand. Paresthesias and numbness in the fourth and fifth fingers, progressive hand and triceps weakness are the neurological signs. Horner syndrome suggests paraspinal involvement. The diagnostic evaluation must be done carefully. Plain X-rays are often negative since this area is visualized poorly

in these, and CT or preferably MRI scans are necessary to define metastatic disease.

Thoracic spine metastasis

The onset of back pain in association with bandlike tightening across the chest or upper abdominal or radicular arm or leg pain may be the first sign of impending spinal cord compression. Motor and sensory loss occurs later, and autonomic disturbances producing bladder and bowel incontinence occur later still. Thus the evaluation of the patient should begin at the onset of pain for the best chance to preserve motor and sphincteric function. This should include plain X-rays of the entire spine, focused on the symptomatic area, and an MRI. This is necessary because there is about a 15 percent incidence of another epidural lesion.[24*] Corticosteroid therapy should be started even before the radiological evaluation, since this may decrease pain and protect the spinal cord from further compression caused by edema from the tumor or radiotherapy. Even if metastatic disease is found on plain spine films, the MRI should be done to define the extent of tumor invasion in the epidural space because this will influence the size of the radiation therapy ports and will determine the dose and duration of corticosteroid therapy. If anterior vertebral body subluxation has occurred and there is bony compression of the spinal cord, surgical decompression is indicated should the patient's medical condition permit. This is usually followed by radiation therapy. Surgery is usually not attempted as a primary modality of treatment because the results of radiation therapy and corticosteroid treatment are usually equal to surgical decompression.[24*] This is especially true if a simple posterior decompressive laminectomy is done. However, if patients have recurrent spinal cord compression in a previously irradiated port, then an anterior spinal approach with removal of tumor from the vertebral body, decompression of tumor from the spinal canal, and restructuring of the vertebral body with methyl methacrylate should be considered.[25*]

Lumbar spine and sacral metastasis

Dull and aching mid-back pain exacerbated by lying or sitting and relieved by standing is the usual presenting complaint of L1 metastasis. Pain may be referred to the hip, both paraspinal lumbosacral areas and referred pain to the sacroiliac joint or superior iliac crest. Aching pain in the low back or coccygeal region exacerbated by lying or sitting, relieved by walking is the common complaint with sacral metastases. Associated symptoms include perianal sensory loss, bowel and bladder dysfunction, and impotence.

Local invasion of tumor from the pelvis into the sacrum may produce the syndrome of perineal pain, which is often difficult to manage. This syndrome is characterized by local pain in the buttocks and perirectal area, which is often

accentuated by pressure on the perineal region such as that caused by sitting or lying prone. In its most extreme form, the patient cannot sit to eat meals or lie flat to sleep, and may spend much of their time standing. Because of the critical role of the parasympathetic sacral innervation to normal bladder and rectal sphincter function, continence is impaired early in the course of this syndrome, perhaps even before significant weakness can be discerned in the legs.

TUMOR INFILTRATION OR TRAUMA TO PERIPHERAL NERVE, PLEXUS, ROOT, AND SPINAL CORD

These syndromes present with radicular pain in the neck, chest, or trunk and the differential diagnosis includes tumor infiltration of the peripheral nerves, and surgical injury, partial, complete or secondary to direct surgical interruption or traction, and nerve compression secondary to musculoskeletal imbalance, diabetic peripheral neuropathy, acute herpes zoster and PHN.

Pain is characterized by constant burning pain with hypoesthesia and dysesthesia in an area of sensory loss. The most common causes are tumor compression in the paravertebral or retroperitoneal area or in association with metastatic tumor in rib causing intercostal nerve infiltration. Pain is usually the first sign of tumor infiltration of nerve and presents as either a local, radicular, or referred pain. Local and radicular pain is seen with tumor infiltration or compression of nerve peripheral to the paraspinal region, whereas referred pain with or without a radicular component is seen with tumor infiltration of the paraspinal region and more proximal areas. Associated autonomic dysfunction causing loss of sweating and loss of axonal flair response to pin scratch can help define the site of the nerve compression or infiltration. The pain is characterized initially by a dull, aching sensation with tenderness to percussion in the distribution of the nerve. Mild paresthesia or dysesthesia can occur as the next sensory symptom followed by the late appearance of motor symptoms and signs.

As tumor invades the perineurium or compresses nerve externally, the nature of the pain changes to a burning, dysesthetic sensation. A careful neurological examination followed by a CT scan to define the site of nerve compression is the diagnostic procedure of choice. Electromyography (EMG) can help to define the site of nerve involvement but it is not diagnostic. Rib erosion and retroperitoneal and paraspinal soft tissue masses are the most common associated findings. In patients with paraspinal tumor, MRI scanning is often necessary to exclude epidural extension. Antitumor therapy is the first-line therapy when possible, but interim pain management with analgesics is almost always necessary. Steroids may provide a useful diagnostic test, and provide both anti-inflammatory and antitumor effects, or may act to reduce local swelling, and secondarily to relieve pain.

Brachial plexopathy

Brachial plexopathy in patients with cancer may occur by metastatic spread of tumor to the plexus or radiation injury producing transient sensory and motor symptoms. More prolonged neurological dysfunction may result from previous radiation therapy to a port which has included the plexus, involvement of the plexus by radiation-induced tumor such as malignant schwannoma or fibrosarcoma, and trauma to the plexus during surgery and anesthesia.

Tumor infiltration and radiation injury are the most common causes.[26*] A review of 100 cases suggested that there are reliable clinical signs and symptoms to distinguish metastatic plexopathy from radiation injury. The characteristics of the pain are quite different and a useful distinguishing clinical sign.[26] Magnetic resonance imaging has been advocated as a better means to image the brachial plexus,[27*] and may be a useful means to diagnose metastatic brachial plexopathy. Rarely biopsy of the brachial plexus may be necessary to distinguish from radiation fibrosis versus a recurrent tumor or a new primary tumor.[28*] However, biopsy is not always definitive.

Metastases to the brachial plexus most commonly involves the lower cords of the brachial plexus, giving rise to neurological signs and symptoms in the distribution of the C8, T1 roots. In contrast, radiation plexopathy most commonly involves the upper cords of the plexus, predominantly in the distribution of the C5–C7 roots. Severe pain is most commonly associated with metastatic plexopathy, and Horner syndrome is more commonly associated with metastatic plexopathy than radiation plexopathy. A significant number of patients with metastatic plexopathy show epidural extension of disease. A primary tumor of the lung, the presence of Horner syndrome, or involvement of the whole plexus should alert the physician to the possibility of epidural extension and warrants immediate MRI. Neither a negative surgical biopsy nor observation for several years for other metastases rules out recurrence of tumor or a new primary tumor.[28*]

Brachial plexopathy in Pancoast tumors

Brachial plexopathy in Pancoast tumor, as described by Kanner et al.[29*] is an integral part of the disease. Pain in the distribution of C8–Tl is an early sign and is part of the clinical diagnosis of Pancoast syndrome. Pain is the most reliable sign to follow as it closely reflects progression of disease and may be the only sign of epidural cord compression. Plain X-rays and bone scans are not reliable diagnostic tests for this disorder and MRI yields the most important diagnostic information. As many as 50 percent of patients develop epidural cord compression, with pain being the earliest and most consistent clinical symptom. In patients who present with Pancoast syndrome and involvement of the brachial plexus, the initial diagnostic workup should

include MRI to determine the extent of tumor infiltration. Initial antitumor surgery should be directed at radial removal of all the local tumor and secondary treatment with external radiation therapy and brachytherapy.[30*]

The Pancoast syndrome is commonly misdiagnosed and confused with cervical disk disease, which appears in less than 5 percent of patients in a C8–Tl distribution.

Lumbosacral plexopathy

Lumbosacral plexus tumor infiltration most commonly occurs in genitourinary, gynecological, and colonic cancers. Pain varies with the site of plexus involvement. Radicular pain occurs in L1–L3 distribution (i.e. anterior thigh and groin) or down the posterior aspect of the leg to the heel when in an L5–S1 distribution. In some instances, there is only referred pain without local pain over the plexus. Common referred points are the anterior thigh, knee, and lateral aspect of the calf. These areas are commonly painful but the origin of the pain is in the plexus. Pain is the earliest symptom, followed later by complaints of paresthesia, numbness, dysesthesia leading to motor and sensory loss.

Jaeckle et al.[31*] have described the clinical symptoms and natural history of this disorder in a review of 85 patients with lumbosacral plexopathy. In this study the pain was noted to be of three types: local in 72 of 85 patients, radicular in 72 of 85 patients, and referred in 37 of 85 patients. Local pain in the sacrum or sciatic notch occurred in 59 percent of patients followed by low back pain in 27 percent and pain in the groin or lower abdominal quadrant in 21 percent. Referred pain to the hip or flank occurred in patients with upper plexus lesions whereas pain in the ankle or the foot occurred in patients with a lower plexopathy. Typically the pain precedes objective sensory, motor, and autonomic signs for weeks to months, with a mean of 3 months. Also, initially the CT scan may be negative. Unilateral and bilateral plexopathy with significant motor weakness is commonly associated with epidural extension and both CT and MRI are necessary to define the extent of tumor infiltration and/or epidural compression. Plain X-rays are not often helpful because the lumbosacral plexus lies within the substance of the psoas muscle and is not radiodense.

Pain occurs in 40 percent of patients with leptomeningeal metastases[32*] and is of two types:

- headache with or without neck stiffness
- back pain localized to the low back and buttock regions.

There may be associated confusion, delirium, cranial nerve palsies, radiculopathy, and myelopathy. Diagnostic workup should include MRI, with contrast to determine enhancement in the basal subarachnoid cisterns and to rule out hydrocephalus; MRI to rule out bulk disease on nerve roots which might require focal radiation therapy; and a lumbar puncture to determine cerebrospinal fluid (CSF) glucose, protein, cell count, cytology, and biochemical markers.

PAIN SYNDROMES ASSOCIATED WITH CANCER THERAPY

This category includes those clinical pain syndromes that occur in the course of or subsequent to treatment of cancer patients with the common modalities of surgery, chemotherapy, or radiation therapy.

Post-surgical injury to peripheral nerves

Four distinct pain syndromes involving the peripheral nerves occur following surgery in patients with cancer.

POST-THORACOTOMY PAIN

This pain occurs in the distribution of an intercostal nerve following surgical interruption or injury. The intercostal neurovascular bundle courses along a groove in the inferior border of the rib. Traction on the ribs and rib resection are the common causes of nerve injury during a surgical procedure on the chest. Kanner et al.[29*] prospectively followed 126 consecutive patients undergoing thoracotomy and defined several groups of patients. In the majority (79 patients) immediate postoperative pain was reduced at approximately 2 months, but in 13 of the 79 patients recurrence of the pain occurred. Recurrence of tumor in the distribution of the intercostal nerves was the cause of recurrent pain. The immediate postoperative pain is characterized by an aching sensation in the distribution of the incision with sensory loss with or without autonomic changes. There is often exquisite point tenderness at the most medial and apical point of the scar with a specific trigger point. In another group (20 of the 126 patients) pain persisted following the thoracotomy and increased in intensity during the follow-up period. In this group of patients, local recurrence of disease and/or infection were the most common causes of increasing pain. In the third group, 18 of the 126 patients had stable or decreasing pain which resolved over time and did not represent a difficult management problem.

Thus persistent or recurrent pain in the distribution of the thoracotomy scar in patients with cancer is commonly associated with recurrent tumor. However, a small number of patients will have a traumatic neuroma at the site of their previous thoracotomy scar, but this should not be the initial consideration in evaluating such cancer patients.

POST-MASTECTOMY PAIN

Post-mastectomy pain occurs in the posterior arm, axilla, and anterior chest wall following any surgical procedure on the breast from lumpectomy to radical mastectomy.[33*] It may be more likely to occur from axillary dissection and

lymph node dissection.[34*] There is marked anatomical variation in the size and distribution of the intercostal brachial nerve accounting for its variable appearance of this syndrome in patients undergoing mastectomy. The pain results from interruption of the intercostal brachial nerve, a cutaneous sensory branch of T1 – T2. The pain may occur immediately following the surgical procedure but as late as six months following surgery. It is characterized as a tight, constricting, burning pain in the posterior aspect of the arm and axilla radiating across the anterior chest wall. The pain is exacerbated by movement of the arm and relieved by immobilization of the arm. Patients often posture the arm in a flexed position close to the chest wall and are at risk to develop a frozen shoulder syndrome if adequate pain and post-surgical rehabilitation are not implemented early on.

Approximately 5 percent of women undergoing surgical procedures on the breast develop the syndrome. The nature of the pain and the clinical symptomatology should readily distinguish it from tumor infiltration of the brachial plexus. The syndrome appears to occur more commonly in patients with postoperative complications who are at risk for local fibrosis in and about the nerve following surgery, following wound infection or seroma. Typically a trigger point in the axilla or on the anterior chest wall may be found and this is usually the site of the traumatic neuroma. Breast reconstruction does not alter the tight, constricting sensation in the anterior chest wall that is associated with this syndrome.

AFTER RADICAL NECK SURGERY

Prospective studies of pain after radical neck dissection are lacking. In any patient in whom the pain occurs late, i.e. several months following the surgical procedure, and particularly any pain occurring several years following the surgical procedure, re-evaluation is necessary to exclude recurrence of tumor.

POST-AMPUTATION PAIN

Loss of a body part is often followed by psychological adjustment, which may include a grief reaction.[35*] The physiological phenomena of nonpainful and painful phantom sensations referred to the missing part, pain in the scar region after limb amputation, and involuntary motor activity also occur. Many patients note more sensations in the distal phantom limb or in the nipple of the phantom breast. A phantom visceral organ may be associated with functional sensations, e.g. the urge to urinate or defecate.

There are a few reports on the course of post-amputation pain in malignant disease. In a study of 17 patients with cancer who underwent forequarter amputation, none of the seven survivors had pain requiring the use of analgesics after an average of 69 months follow-up.[36*] Larger surveys of post-mastectomy patients reveal that at least 10 percent experience chronic phantom breast pain, more than is generally believed.[37*] Increasing pain in the cancer amputee may signify disease progression or recurrence.[38*,39*]

Chemotherapy–related pain syndromes

Painful dysesthesias follow treatment with several chemotherapeutic agents, in particular, the vinca alkaloid drugs such as vincristine and vinblastine. Cisplatin and taxol are also toxic to peripheral nerve.[40*,41*] These agents produce a symmetrical polyneuropathy as a result of a subacute with chronic axonopathy. Pain is usually localized to the hands and feet, and is characterized as burning pain exacerbated by superficial stimuli, which improves as the drug is withdrawn. Aseptic necrosis of the humeral and more commonly femoral head is a known complication of chronic steroid therapy.[42*] Pain in the shoulder and knee or leg is the common presenting complaint, with X-ray changes occurring several weeks to months after the onset of pain. The bone scan and MRI are the most useful diagnostic procedure.

Post-herpetic neuralgia[43*] can be thought of as a post-chemotherapy pain syndrome since immunocompromised patients are at risk for acute zoster infection or a recurrence of latent zoster. Persisting pain after healing of the cutaneous eruption of herpes zoster infection has generally three components:

- a continuous burning pain in the area of sensory loss
- painful dysesthesias
- intermittent shocklike pain.

Older patients are at greater risk of this complication.

Post–radiation therapy pain

These syndromes are becoming less common as the sophistication with which radiation therapy portals are planned decreases the likelihood of radiation overdose to tissues and spares surrounding normal tissues. Nonetheless, radiation fibrosis of peripheral neural structures such as the brachial and lumbar plexus still occurs, and radionecrosis of bone is occasionally seen.

Radiation fibrosis of the brachial plexus was discussed previously. Pain occurring in the leg from radiation fibrosis of the lumbar plexus is characterized by the late onset of pain in the course of progressive motor and sensory changes in the leg.[44*,45*] Lymphedema, a previous history of radiation therapy, myokymia on EMG, and X-ray changes demonstrating radiation necrosis of bone may help to establish this diagnosis.

Pain is an early symptom in 15 percent of patients with radiation myelopathy.[46*,47*] Some patients may have the Lhermitte sign, signifying transient demyelination in the posterior columns, which does not necessarily predict the development of myelopathy. Pain may be localized to the area of spinal cord damage or may be a referred pain with dysesthesias below the level of injury. The neurological symptoms and signs often start as Brown–Séquard syndrome, a lateral hemisection of the cord, such that pain and temperature sensation are lost contralateral to the side of weakness.

Position and vibration sensation are lost ipsilateral to the side of weakness. The incidence of myelopathy increases with increasing radiation exposure, and approaches 50 percent with 1500 ret exposure. The latency from completion of radiation to the onset of symptoms of myelopathy ranges from 5 to 30 months, with an average of 14 months in most series.

A painful enlarging mass in an area of previous irradiation suggests a radiation-induced peripheral nerve tumor.[48*,49*,50*,51*] In one study, seven of nine patients who developed radiation-induced nerve tumors presented with pain and progressive neurological deficit with a palpable mass involving the brachial of lumbar plexus; these nine patients developed their tumors 4–20 years following radiation therapy. Neurofibromatosis is associated with an increased risk for the development of radiation-induced peripheral nerve tumors.[48*]

NONCANCER PAIN SYNDROMES AND MECHANISMS

Like cancer pain syndromes, noncancer pain syndromes may be nociceptive or neuropathic in nature. Internists and family physicians deal with common degenerative, musculoskeletal pain syndromes along with specialist assessment as indicated. Palliative care specialists are likely to encounter pain in patients with human immunodeficiency virus (HIV) infection/acquired immune deficiency syndrome (AIDS).

Human immunodeficiency virus and pain

Pain is a common symptom in HIV and AIDS patients. With the increasing burden of this disease in Africa and Asia, palliative care specialists are likely to encounter these pain syndromes. Pain syndromes encountered in HIV and AIDS are diverse in nature and etiology. The most common pain syndromes include painful sensory peripheral neuropathy, pain due to extensive Kaposi sarcoma, headache, oral and pharyngeal pain, abdominal pain, chest pain, arthralgias and myalgias, and painful dermatological conditions.[52*,53*,54*,55*,56*,57] Hewitt and colleagues in 1997 demonstrated that although pains of a neuropathic nature (e.g. polyneuropathies, radiculopathies) certainly comprise a large proportion of pain syndromes encountered in AIDS patients, pains of a somatic and/or visceral nature are also common clinical problems.[56*] The etiology of pain syndromes seen in HIV disease can be categorized into three types:

- those directly related to HIV infection or consequences of immunosuppression
- those due to AIDS therapies
- those unrelated to AIDS or AIDS therapies.

In studies to date, approximately 45 percent of pain syndromes encountered are directly related to HIV infection or consequences of immunosuppression; 15–30 percent are due to therapies for HIV- or AIDS-related conditions and to diagnostic procedures; and the remaining 25–40 percent are unrelated to HIV or its therapies.[54*,56*]

Oropharyngeal pain

Oral cavity and throat pain is common, accounting for approximately 20 percent of the pain syndromes encountered in one study.[58*] Common sources of oral cavity pain are candidiasis, necrotizing gingivitis, and dental abscesses and ulcerations caused by herpes simplex virus (HSV), cytomegalovirus (CMV), Epstein–Barr virus (EBV), atypical and typical mycobacterial infection, cryptococcal infection, or histoplasmosis. Frequently no infectious agent can be identified and painful recurrent aphthous ulcers (RAU) are encountered.[59*]

Esophageal pain

Many HIV/AIDS patients experience dysphagia or odynophagia, most commonly caused by esophageal candidiasis. Ulcerative esophagitis is usually a result of CMV infection but can be idiopathic. Infectious causes of esophagitis include HIV, papovavirus, HSV, EBV, *Mycobacterium*, *Cryptosporidium*, and *Pneumocystis carinii*. Kaposi sarcoma and lymphoma have both been reported to invade the esophagus, resulting in dysphagia, pain, and ulceration.[59*] Nonsteroidal medications as well as zidovudine and zalcitabine have been implicated in esophagitis.

Abdominal pain

The abdomen is the primary site of pain in 12–25 percent of patients with HIV disease.[60*] Infectious causes of abdominal pain predominate, and include: cryptosporidiosis, *Shigella*, *Salmonella*, and *Campylobacter enteritis*, CMV ileitis and mycobacterial infection (MAI). Perforation of the small and large intestine secondary to CMV infection has been described.[61*] Repeated intussusception of the small intestine has been seen in association with *Campylobacter* infection.[62*] Lymphoma in the gastrointestinal tract can present with abdominal pain and intestinal obstruction.[59*,62*] Other causes of abdominal pain in HIV-positive patients[59*] include ileus, organomegaly, spontaneous aseptic peritonitis, toxic shock, herpes zoster, and Fitzhugh–Curtis syndrome (perihepatitis in association with tubal gonococcal or chlamydia infection).

Many antiretroviral agents are responsible for gastrointestinal symptoms but lactic acidosis, a rare but serious complication of some highly active antiretroviral therapy (HAART) regimens, can present with abdominal pain.[63*] Didanosine, zalcitabine, and stavudine can cause pancreatitis whereas patients taking indinavir are at increased risk for nephrolithiasis. Cholecystitis is a painful condition that may occur in HIV-infected patients as a result of opportunistic

infection.[64*] Cytomegalovirus and *Cryptosporidium* are the most common infectious agents. Drug-induced hepatic toxicities as well as viral hepatitis as coinfection may lead to abdominal pain. Pancreatitis is an extremely painful condition often related to adverse effects of HIV-related therapies such as didanosine, stavudine and dideoxycytidine.[65*] Intravenous pentamidine is also associated with pancreatitis. Other causes of pancreatitis include CMV infection, MAI, cryptococcal lymphoma and Kaposi sarcoma.

Anorectal pain

Perirectal abscesses, CMV proctitis, fissure-in-ano, and human papillomavirus and HSV infection often cause painful anorectal syndromes.

Chest pain syndromes

Chest pain is a common complaint in patients with HIV disease, comprising approximately 13 percent of the pain syndromes encountered in a sample of ambulatory AIDS patients.[56*] The index of suspicion for coronary artery disease, even in young patients with no other risk factors, must be high if the patient is being treated with HAART. In immunosuppressed patients, infectious causes of chest pain should be considered, particularly in the presence of fever and some localizing sign such as dysphagia, dyspnea, or cough. Infectious causes of chest pain include *Pneumocystis* pneumonia, esophagitis (CMV, candidiasis), pleuritis/pericarditis, and PHN.

Opportunistic cancers, Kaposi's or lymphoma invading the esophagus, pericardium, chest wall, lung and pleura may also be sources of chest pain. Rarely, pulmonary embolus or bacterial endocarditis may be the cause of chest pain.

Neurological pain syndromes

Pain syndromes originating in the nervous system include headache, painful peripheral neuropathies, radiculopathies, and myelopathies. The human immunodeficiency virus is highly neurotropic, invading central and peripheral nervous system structures early in the course of HIV disease. Consequently, many complications of HIV/AIDS and opportunistic infections result in neurological pain, and many commonly used HIV/AIDS medications can also be implicated in neurological pain. Rarely cerebrovascular events (e.g. thalamic stroke) occurring in hypercoagulable states can result in central pain syndromes.

HEADACHE

Headache is extremely common in the HIV/AIDS patient and can pose a diagnostic dilemma for providers in that the underlying cause may range from benign stress and tension to life-threatening central nervous system infection.[59*] The differential diagnosis of headache in patients with HIV disease includes:

- HIV encephalitis and atypical aseptic meningitis
- Opportunistic infections of the nervous system
- AIDS-related central nervous system neoplasms
- Sinusitis
- Tension
- Migraine
- Headache induced by medication (particularly azathioprine [AZT])

Toxoplasmosis and cryptococcal meningitis are the two most commonly encountered opportunistic infections of the central nervous system that cause headaches in patients with HIV disease. More benign causes of headache in the patient with HIV disease include AZT-induced headache; tension headache; migraine with or without aura; and unclassifiable or idiopathic headache.[66*]

NEUROPATHIES

Neuropathic pain occurs in about 40 percent of AIDS patients.[54*,56*] The most common painful neuropathy seen is the predominantly sensory neuropathy (PSN) of AIDS. However, other potentially painful neuropathies in HIV/AIDS patients can have other viral and nonviral causes or may be caused by demyelination leading to Guillain–Barré syndrome, nutritional deficiencies, alcohol, and HIV therapies.[67*] Predominantly symmetrical sensory neuropathy of AIDS is the most frequently encountered neuropathy. This is typically a late manifestation, occurring most often in patients with an AIDS-defining illness.[68*] The prevalence of this neuropathy in hospice populations ranges from 19 percent to 26 percent.[69*,70*] The predominant symptom in about 60 percent of patients is pain in the soles of the feet. Paresthesia is frequent and usually involves the dorsum of the feet and soles. Most patients have signs of peripheral neuropathy and, although the signs progress, the symptoms often remain confined to the feet.[71*,72*] Although patients' complaints are predominantly sensory, electrophysiological studies demonstrate both sensory and motor involvement.

Rheumatological pain syndromes

In studies conducted by the Memorial Sloan–Kettering group, over 50 percent of pain syndromes were classified as rheumatological in nature including various forms of arthritis, arthropathy, arthralgias, myositis, and myalgias.[56*]

The most frequently reported arthritis is a reactive arthritis or Reiter's syndrome.[73*,74*,75*,76*,77*] Acute HIV infection may present with a polyarthralgia in association with a mononucleosis-like illness. There is also a syndrome of acute severe and intermittent articular pain, often referred to as HIV-associated painful articular syndrome, which

commonly affects the large joints of the lower limbs and shoulders. Psoriasis and psoriatic arthritis have been reported in patients with HIV infection.[78*] Septic arthritis has been reported in patients with HIV disease, including arthritis due to bacterial infections and infections with *Cryptococcus neoformans* and *Sporothrix schenckii*.[73*,74*]

Key learning points

- Pain is the most common symptom for which palliative care specialists are consulted.

- Cancer pain is the most common pain encountered, but pain syndromes due to HIV/AIDS are on the rise in Africa and Asia.

- Pain is classified into nociceptive and neuropathic in broad terms, but the majority are mixed.

- Pain in cancer is caused by tumor, treatment, or as coexisting chronic pain.

- Tumor size may not correlate with pain intensity.

- There are well-defined pain syndromes described in the literature based on the cause and the location.

- Metastatic bone pain is often associated with neurological deficit due to close proximity between skull and cranial nerves, spinal cord and its roots with vertebral column.

- Not all bony metastatic sites hurt.

- Detailed history with emphasis on neurological examination will lead to early diagnosis of spinal cord compression.

- Suspect epidural disease with new onset neck, upper or lower back pain.

- Critical assessment of pain syndrome helps with optimal pain management, avoiding erroneous polypharmacy.

- A new pain or a sudden change in intensity of existing pain in cancer patient is invariably due to recurrence.

- Headache should always raise suspicion for base of skull metastasis or leptomeningeal disease.

- Exclude constipation as the cause of increased abdominal pain.

- Exclude infection as the cause of intractable pain, especially in head and neck cancers.

- Pain syndromes in HIV/AIDS often follow similar pattern as cancer. But neuropathic pain, rheumatic and musculoskeletal pain syndromes predominate, with high incidence of psychosomatic issues.

- Delirium can masquerade as pain.

- Generalized body pains may be a sign of somatization.

Opioid analgesics

PER SJØGREN, JØRGEN ERIKSEN

INTRODUCTION

Derivates of the opium poppy (*Papaver somniferum*) have a long history as pain-relieving agents. The main constituent, the alkaloid called morphine, was isolated by Sertürner in 1803, and was later shown to be almost completely responsible for the analgesic effects. Today morphine is still the most widely used opioid and remains the 'gold standard' when effects of other opioid analgesics are to be compared.

The concept of a specific opioid receptor was established in the middle of the twentieth century based on the stereospecificity and availability of selective antagonists to the analgesic actions.[1*,2*] In the 1970s, opioid receptors were recognized as specific biochemical structures and the evidence for the existence of multiple receptors was established.[3*,4,5*] Based on their activities *in vivo* opioids are now classified according to their sensitivity and selectivity in receptor-binding studies and it is now agreed that there are three main types of opioid receptor, μ (mu), δ (delta), and κ (kappa). In 1994, a fourth opioid receptor called the nociceptin/orphanin FQ (N/OFQ) receptor was discovered.[6*] Morphine as well as other opioids exert their analgesic action by a specific interaction with one or more subclasses of the three most important opioid receptors: μ, δ, and κ. Genes encoding for these receptors have been cloned. Based on their different pharmacology a number of subclasses have been described: $μ_1$ and $μ_2$, $δ_1$ and $δ_2$ and $κ_{1-3}$. Evidence for multiple μ-receptors came from binding studies, which showed biphasic binding properties of μ-agonists.[7*]

Clinically, differences were observed as patients who did not tolerate one μ-agonist could be switched to another, which was easily tolerated. Also incomplete cross-tolerance was observed in connection with 'rotation' from one

μ-agonist to another: far lower doses than predicted of the new drug were necessary to control pain.[8,9*] Similar incomplete cross-tolerance has been confirmed in animal models.[10]

Most of the clinically relevant opioids are relatively selective for the μ-receptor, reflecting their similarity with morphine at least within normal dose ranges (Table 44.1). However, higher doses used to overcome development of tolerance may result in interaction with additional receptor subtypes and result in changes in their pharmacological profile.

Opioids act by inhibiting the ascending nociceptive signal transmission from the dorsal horn in the spinal cord. The periaqueductal gray region is a major anatomical locus for opioid activation of descending inhibitory pathways to the spinal cord and is thus an important site for μ-receptor mediated analgesia. Opioids do not excite descending fibers directly, but inhibit spontaneous γ-aminobutyric acid (GABA) release from GABAergic interneurons. Furthermore opioid receptors have also been demonstrated in inflamed tissue in terminals of peripheral nerves in animals as well as in humans.[11]

In this chapter the most widely used and clinically relevant opioid analgesics in palliative care are described.

MORPHINE

Morphine is the most thoroughly investigated opioid drug and it is recommended as a first-line opioid in the World Health Organization (WHO) Cancer Relief Guidelines.[12] Morphine is a pure opioid agonist with affinity primarily to the μ-receptors and to a lesser degree to the δ- and κ-receptors (see Table 44.1). Morphine can be administered by the oral, rectal, intravenous, intramuscular,

Table 44.1 *Primary receptor binding and pharmacologic data of important opioids in palliative medicine*

Opioid	Primary site of action	Bioavailability (average) (%)	Major metabolites	Major metabolic* and excretion[+] pathways	Safety in renal failure
Morphine	μ-receptor agonist	25	M6G+ M3G±	Hepatic* Renal[+]	Not safe
Methadone	μ-receptor agonist	80	Pyrrolidine− Pyrroline−	Hepatic* Fecal[+] Renal[+]	Safe
Oxycodone	μ-receptor agonist	60	Noroxycodone− Oxymorphone+	Hepatic* Renal[+]	Uncertain

M6G, morphine-6-glucuronide; M3G, morphine-3-glucuronide.

subcutaneous, epidural, intrathecal, and intracerebroventricular routes.

Absorption

After oral administration morphine is almost completely absorbed from the gastrointestinal tract.[13] The rate of absorption from the gut depends on the pharmaceutical formulation. Immediate-release morphine tablets reach their maximum plasma concentrations within an average of 60–70 minutes and sustained-release morphine tablets designed for twice or thrice daily administration within an average of 140–200 minutes.[14,15**]

Pharmacokinetics

About 20–38 percent of morphine is bound to plasma proteins, primarily albumin.[16] The mean volume of distribution varies between 2.1 L/kg and 4. 0 L/kg in cancer patients and healthy individuals, decreasing to half the value in elderly individuals.[17–19] In cancer patients and healthy individuals mean elimination half-life varies between 1.6 and 3.4 hours and mean systemic plasma clearance between 9 mL/kg and 33 mL/kg/min.[18,20]

Extensive first-pass metabolism after oral morphine administration results in a low and variable bioavailability between 19 percent and 47 percent[19,21] (see Table 44.1). The two most important metabolites quantitatively and qualitatively are morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G) (see Table 44.1). Regardless of the route of administration approximately 44–55 percent of a morphine dose is converted into M3G, 9–10 percent to M6G and 8–10 percent is excreted in the urine unchanged.[19] The major pathway for morphine metabolism is conjugation with the co-substrate uridine-diphosphate

(UDP)-glucuronic acid. The process is catalyzed by UDP glucuronyltransferase (UDPGT) and takes place mainly in the liver, although a part takes place in the kidneys, gut, and brain[21,22] (see Table 44.1). Although the UDPGTs are a multienzyme family, it has been demonstrated that the human UGT2B7 is likely to be the major isoform responsible for morphine glucuronidation in humans, capable of catalyzing the glucuronidation process at the 3- as well as 6- positions.[23] A recent study indicated that during long-term treatment neither dose level nor treatment length influenced glucuronidation of morphine.[24]

Elimination

During the process of glucuronidation morphine is made more hydrophilic, and the enhanced water solubility eases its excretion via the kidneys (see Table 44.1). The role of the kidneys in the excretion process has been demonstrated in a study of patients with renal failure given intravenous morphine. Subsequent plasma concentrations of M3G and M6G were observed to be severalfold greater in these patients than in a control group with normal renal function.[25] The clearance of the metabolites is significantly correlated to the creatinine clearance.[26] As a consequence of the accumulation of M3G and M6G in patients with renal impairment toxic effects of morphine metabolites may be seen[27,28] (see Table 44.1).

Pharmacokinetics of M6G and M3G

In healthy volunteers the plasma protein binding of M3G and M6G has been found to be low, 15 percent and 11 percent, respectively. Formation of the metabolites takes time and T_{max} for M6G and M3G occur later than for morphine. After long-term administration of morphine to cancer

patients the cerebrospinal fluid (CSF) and plasma ratios for M3G and M6G range between 0.08 and 0.18 and 0.07 and 0.15, respectively.[29,30]

M6G and analgesia

Animal studies demonstrated that, although M6G and morphine were almost equally potent after peripheral administration, the analgesic potency of M6G was >100-fold higher than morphine after intracerebroventricular injection. These pharmacological data suggest that the brain penetration of M6G is significantly attenuated relative to that of morphine.[31] A study using transcortical microdialysis in rat brain cells showed that systemically administered morphine entered brain cells, whereas M6G crossed the blood–brain barrier extremely slowly and was trapped in the extracellular fluid. A high concentration of M6G in this limited space in the brain may account for the durable availability of M6G to opioid receptors.[32] Another explanation for the prolonged analgesia elicited by systemically administered M6G compared with morphine was a threefold slower rate of elimination of M6G than morphine from the mouse brain.[33]

Intravenous M6G has analgesic effects in cancer patients; however, its potency compared with morphine has not been established in humans.[34] A critical clinical issue is the role and contribution of M6G to the analgesic action seen after long-term morphine administration. In this respect controversy exists as a few clinical studies have found evidence for M6G being a contributor to the analgesic action observed after morphine administration,[35,36] whereas other clinical studies have not been able to demonstrate this.[24,30,37,38] In general these studies are confounded by a multitude of other factors that influence patients' perception of pain, including psychological factors and varying responses to morphine administration due to different pain mechanisms and opioid receptor properties, concentration of opioids at the target sites, variability of nonspecific endogenous opioids and varying plasma sampling times for determining M6G/morphine.

M3G: antagonism of antinociception and neurotoxicity

M3G appears to have little or no μ-agonist properties and therefore to be devoid of analgesic activity. In some studies subcutaneous or intracerebroventricular administration of M3G prior to or after the administration of morphine or M6G has been shown to reduce the antinociceptive response of the two analgesic agents.[39,40] In contrast, other studies in rodents have not found any influence of M3G on morphine analgesia.[41,42] Apart from its possible role as an antialgesic, M3G and high-dose morphine have also been associated with 'morphine-induced neurotoxicity' such as generalized hyperalgesia/allodynia and myoclonus.

Several studies in rodents have found that M3G and high-dose morphine administered by the intracerebroventricular[43,44] as well as the intrathecal routes produce symptoms of sensory and motor excitation.[45,46]

Clinically the symptoms of hyperalgesia, allodynia, and myoclonus have mostly been observed in cancer patients treated with high doses of morphine administered by several different routes,[47–49] although these side effects have also been associated with other opioids.[50,51] In several of the case reports describing these symptoms very high plasma levels of morphine and M3G as well as accumulation of M3G relative to morphine or M6G has been demonstrated.[47,49] A study has shown that although M3G does not cross the blood–brain barrier with the same ease as morphine, the mean steady state M3G concentration in the CSF is approximately twofold higher than the respective CSF morphine concentration following long-term morphine treatment.[52] Opioid switching or rotation, whereby a structurally dissimilar opioid (e.g. methadone (open-chain opioid analgesic) or fentanyl (anilinopiperidine opioid analgesic)) is substituted for a benzomorphan opioid, such as morphine (or hydromorphone) will also result in clearance of M3G from the brain tissue, giving a time-dependent resolution of the neuroexcitatory behaviors while maintaining analgesia with methadone or fentanyl.[49,53]

M3G has recently been given to healthy volunteers in small intravenous doses. In these doses, neurotoxicity did not occur.[54]

METHADONE

Methadone is increasingly being considered as a second-choice drug alternative to morphine in cancer pain treatment. It is a long-acting μ-receptor agonist with pharmacological properties qualitatively similar to those of morphine (see Table 44.1). Earlier reports of severe toxicity of methadone have given rise to misconceptions and render its effective use in cancer pain difficult.[55,56] With better understanding of the pharmacokinetics of methadone it has subsequently been found to be a safe, effective, and cheap alternative to other opioids when prescribed by physicians experienced in its use. Methadone is administered by the oral, rectal, and intravenous routes. Methadone is not suitable for subcutaneous administration because of the high frequency of local reactions.[57]

Absorption

Methadone is a synthetic opioid with an almost complete absorption when administered orally and rectally.[58**] Its oral bioavailability is generally high and considered to be higher than that of other oral opioids such as morphine; it is in the region of 80 percent and ranges from 41 percent to 99 percent[59,60] (see Table 44.1). It is a lipophilic drug and is

subject to considerable tissue distribution.[61] The peripheral tissue reservoir sustains plasma concentrations during long-term treatment.[62] Methadone is extensively metabolized in the liver to inactive metabolites via *N*-demethylation[63] (see Table 44.1). In most countries methadone is used in a racemic mixture of S- and R-enantiomers, although the latter form has significantly longer elimination half-life, larger volume of distribution, slower clearance, and more analgesic potency.[64,65]

Pharmacokinetics

Methadone is characterized by a rapid and extensive distribution phase (half-life, 2–3 hours) followed by a slow elimination phase (β-half-life, 15–60 hours). After oral administration measurable concentrations appear in plasma after 30 minutes.[61] There is a large interindividual variation of the elimination phase, which can be the reason for accumulation and potential toxicity.[66]

Elimination

Methadone is mainly excreted by the fecal route and only a minor part is eliminated in the urine (see Table 44.1). Renal clearance is enhanced by lowering the urinary pH.[67***] As the elimination is primarily via feces significant accumulation is not likely in renal failure (see Table 44.1).

Clinical aspects

In recent years methadone has been used extensively for opioid switching or rotation.[68,69] In cancer patients, when switching for uncontrolled pain and opioid-induced toxicity, significant improvements have been reported in pain intensity and a number of toxicities.[70***] A major problem encountered when switching to methadone from another opioid is the huge interindividual variations in the equianalgesic ratio of methadone to other opioids. This equianalgesic dose ratio varies dramatically depending on the extent of previous exposure to opioids. Methadone becomes relatively more potent with increasing prior exposure to other opioids and can be up to 10 times more potent in patients given daily doses >500 mg of morphine than in patients given daily doses <100 mg of morphine.[71] Some mechanisms for the dynamic equipotency relations can be hypothesized: (i) incomplete cross-tolerance of opioid receptors, (ii) *N*-methyl-D-aspartate (NMDA) receptor antagonism, and (iii) elimination of active metabolites. In addition of course combinations of these mechanisms may be in play. Regarding the NMDA receptor antagonism methadone may possess a dual effect on opioid receptors and NMDA receptors, which clinically may be advantageous to other opioids in decreasing development of tolerance and increasing analgesia in neuropathic pain conditions. However, methadone

has only been found to be a relatively potent NMDA inhibitor in *in vitro* studies.[72] A recent study in cancer patients comparing methadone with morphine orally did not indicate that methadone was advantageous in neuropathic pain conditions.[73**]

OXYCODONE

Oxycodone (14-hydroxy-7,8-dihydrocodeinone) has become the most commonly used opioid in the USA and can be administered by the oral, rectal, and intravenous routes. It is a μ-receptor agonist, but a part of its antinociceptive effects may be mediated by the κ-receptors (see Table 44.1).

Absorption

Oral bioavailability in humans is about 60 percent (range 50–87 percent)[74,75] (see Table 44.1). The mean lag time from oral administration to pharmacodynamic effect is 0.52 ± 0.33. Oxycodone is subject to extensive hepatic first-pass effects. Oxycodone is metabolized by the liver to the active metabolite, oxymorphone, and to the inactive, but quantitatively most prevalent metabolite, noroxycodone[76] (see Table 44.1).

Pharmacokinetics

T_{max} of oxycodone is approximately 1 hour, and the mean half-life after single-dose is 3.5–5.65 hours.[75,77] The half-life is not influenced by route of administration.[75] Oxycodone's physicochemical properties, liposolubility, and protein binding are similar to morphine.[77] Controlled-release oxycodone is absorbed in a bi-exponential fashion with a rapid mean half-life of 37 minutes and a slow phase of 6.2 hours. T_{max} is 3.2 ± 2.2 hours.[78]

Elimination

Oxycodone and its metabolites are mainly excreted via the kidneys. Oxycodone elimination is prolonged with renal failure and in end-stage liver disease[79,80] (see Table 44.1).

Clinical aspects

Oral equianalgesic ratios of oxycodone to morphine have varied from 1:1 to 1:2, 2:3, and 3:4 as a result of significant interindividual differences in oral bioavailability and unequal noncross-tolerance, and sex differences in the metabolism of oxycodone.[81**,82,83] Women seem to eliminate oxycodone 25 percent more slowly than men.[84]

FENTANYL

Fentanyl is a synthetic phenyl piperidine derivative and a chemical congener of the reversed ester of meperidine. It has selective high affinity for the μ-receptor, where it acts as a pure agonist[85] (see Table 44.1). Fentanyl has a short duration of action and is therefore administered continuously by the transdermal, subcutaneous, or spinal routes or used on demand by the intravenous and transmucosal routes. The transdermal therapeutic system (TTS) was designed to release fentanyl at a constant rate of 72 hours and has gained enormous popularity in Western countries for the treatment of cancer pain.

Absorption

A mean bioavailability of 92 percent (range 57–146 percent) has been reported for TTS fentanyl, although marked interindividual variation is apparent[86] (see Table 44.1). Although fentanyl has been detected in the blood 1–2 hours after initial application of TTS, considerable delays (17–48 hours) between patch application and occurrence of C_{max} were also apparent. The delay has been attributed to depot accumulation of the drug in the skin under the TTS before diffusion into the systemic circulation. Steady-state concentrations are achieved after application of the second patch.[87***]

Pharmacokinetics

Fentanyl is predominantly metabolized in the liver and produces phenylacetic acid, norfentanyl and small amounts of the active metabolite, p-hydroxy(phenethyl)fentanyl[87***] (see Table 44.1). It is highly lipid soluble, which facilitates rapid transfer across the blood–brain barrier and into the central nervous system (CNS). This is reflected in the half-life for equilibration between the plasma and CSF of approximately 5 minutes.[88]

Elimination

Renal elimination of fentanyl is prolonged after transdermal application compared with intravenous administration (see Table 44.1). Elimination half-life values of 13–25 hours have been reported after TTS.[87***]

Clinical aspects

The relative analgesic potency of intravenous fentanyl to morphine from single-dose studies is approximately 100:1 and the transdermal fentanyl to oral morphine during long-term administration is 150:1.[88,89] Two major difficulties have been identified with the transdermal route: a delay of 12–24 hours occurs in obtaining steady-state plasma concentrations and a prolonged period of continued fentanyl effect following removal of the patch.[90] In cancer patients the continuous subcutaneous route provides some advantages over the extensively described transdermal route in patients with unstable pain requiring rapid dose escalation or reduction. Furthermore on demand doses can be administered by the very same route for breakthrough pain.[88] Recently, oral transmucosal fentanyl citrate has been formulated as lollipops as well as intranasal sprays for breakthrough pain to achieve analgesic action within minutes.[91,92]

LONG–TERM CONSEQUENCES OF OPIOID TREATMENT

Apart from providing analgesia and other potentially desired effects opioids also induce side effects, which during long-term treatment often create substantial problems (see Chapter 45). However, long-term opioid treatment may also have other consequences that should be considered in palliative care.

Physical dependence

Physical dependence is a pharmacological phenomenon and the expected consequence of use of opioids. Physical dependence is defined by the appearance of withdrawal symptoms when the opioid dose is reduced or abruptly discontinued and may occur within few days of continuous use of opioids.[93,94] Withdrawal symptoms may include various physiological and psychological signs such as sweating, diarrhea, tremors and anxiety, irritability, and disturbed sleep. Also craving, pain or increased pain are common, often described as abdominal spasms, muscle pain, and bone pain.[94]

Intermittent withdrawal phenomena, breakthrough withdrawal symptoms, or on-off phenomena, which may appear as increased pain, are common in patients using short-acting opioids on demand.[95*] Hence, insufficient dosing may result in the so-called pseudo-addictive condition.[96]

Tolerance

Pharmacologically, tolerance may develop with the repeated use of opioids and is characterized by the necessity of increased doses in order to maintain the drug effects. A distinction, which may be due to the involvement of different neurotransmitter systems, could be made between associative (learned) tolerance and nonassociative (adaptive) tolerance.[97*] Associative tolerance involves environmental and psychological factors, whereas nonassociative tolerance is an adaptive process at the cellular level due to downregulation and/or desensitization of the opioid receptors.[98,99] In addition, changes in the metabolism, distribution or

degradation of the drug may be of importance for the development of tolerance.[100,101]

Tolerance does not always occur in long-term opioid therapy, but when it does, it will often be described by the patient as increased pain.

Abnormal pain sensitivity

Increasing evidence not only in laboratory but also in clinical settings indicates that prolonged opioid treatment may lead to increased pain sensitivity. As described by Mao,[102***] the development of opioid-induced pain sensitivity is closely linked to the development of pharmacological tolerance. The two components of apparent opioid tolerance may involve opposing cellular mechanisms: a desensitization process (pharmacological tolerance) and a sensitization process (opioid-induced pain sensitivity). These mechanisms may be related to the development of opioid-induced neurotoxicity described in cancer patients treated with high doses.[47,49]

The NMDA receptor is involved in tolerance development, and this receptor has also been shown to be of importance for the cellular mechanisms engaged in opioid-induced pain sensitivity. Furthermore basic science studies and few clinical observations have suggested that the development of both pharmacological tolerance and opioid-induced pain sensitivity may be reduced or prevented by combination of an opioid with an NMDA receptor antagonist such as ketamine.[103–105]

Addiction and abuse

Addiction in the context of opioid therapy for pain constitutes a constellation of maladaptive behaviors including loss of control over use, preoccupation with opioid use despite adequate pain relief and continued use of the drugs despite apparent obvious adverse consequences due to their use.[106*] Other suggestive signs of addiction may be unwillingness to terminate opioid treatment even if other treatment possibilities are offered, preference for short-acting opioids used on demand, and not being interested in other treatment possibilities. Abuse refers to the condition in which the medication is used for a pain indication, but in a way that may cause harm to self or others. Abuse may or may not be associated with physical dependency or addiction.

Addiction is anticipated to have a complex etiology including genetic, psychologic, social, and cultural influences, and drug exposure. Neurobiologically, addiction is believed to related to dopaminergic phenomena in the limbic reward centers, which stimulate drug craving and compulsive use in vulnerable individuals.[107]

The factors that promote addiction in some people are not fully understood, although it is known that individuals with a family history of alcoholism or drug addiction or persons with a prior history of addiction have some increased risk of addiction or of relapse to addiction in association with therapeutic use of opioids.[108]

The immune system

Opioids have for years been known to influence the immune system, and recently several studies have shown that opioids may have detrimental immunomodulatory effects on nearly all measurable parts of the system. Opioids have been shown to suppress lymphocyte proliferation,[109*,110] trafficking,[111] natural killer cell activity,[112] antibody production,[113] and the overall number of circulating leukocytes.[114] Animal studies indicate that short-term opioid treatment has fewer adverse effects than long-term exposure, and that abrupt withdrawal may enhance the immunosuppression.[115] Also different opioids seem to act differently on the immune system, as exemplified through methadone, which may be less suppressive than morphine.[116,117]

Even if an enhanced sensitivity to bacterial infections is seen in drug abusers, the existing clinical data are inconclusive, and conclusions regarding the clinical relevance of opioid-induced immunosuppression cannot yet be made.

The reproductive system

Disturbance of libido, amenorrhea, and loss of potency have been described in connection with long-term opioid treatment especially with opioids administered intrathecally.[118,119] Abs *et al.*[120**] found among patients treated with opioids intrathecally decreased libido or impotence in almost all the men and significantly lowered serum testosterone levels. Decreased libido was present in about 70 percent of women receiving opioids and all premenopausal females developed amenorrhea or an irregular menstrual cycle. Serum luteinizing hormone, estradiol, and progesterone levels were significantly lower in the opioid-treated group than among the controls. Finch *et al.*[121] and Roberts *et al.*[122] have also found decreased libido and testosterone levels in men, and it can be concluded that opioids administered intrathecally may induce hypogonadotropic hypogonadism, which is of clinical importance for the majority of men and in premenopausal women. Even if it has been demonstrated that heroine addicts show a diminished semen quality with maintenance or a slightly reduced testosterone levels,[123,124] the clinical importance in patients receiving long-term oral opioid therapy has yet to be established.

SUMMARY

This chapter discussed the history and recent evidence regarding opioid receptors along with clinical observations of individual responses and incomplete cross-tolerance to different opioids. The up-to-date pharmacology of the four

most commonly used strong opioids – morphine, methadone, oxycodone, and fentanyl was reviewed. Important clinical issues associated with long-term administration of these drugs were highlighted.

Key learning points

- Morphine is the most thoroughly investigated opioid drug, however, new and puzzling aspects of its metabolism are still unclear.

- Although M6G undoubtedly possesses analgesic effects its contribution to clinical analgesia is unknown. M3G may be involved in the development of antagonism of antinociception as well as opioid-induced neurotoxicity.

- Methadone is increasingly being considered as a second-choice drug alternative to morphine and has interesting properties when switching to it from other opioids. Methadone seems to become relatively more potent with increasing exposure to other opioids.

- Oxycodone has become the most commonly used opioid in the US, although its pharmacology at therapeutic dose levels seems to be closely related to that of morphine.

- The fentanyl patch is increasingly popular, however, in dynamic pain states titrating may be difficult.

- Long-term opioid treatment has other consequences than the 'classic' side effects and opioid-induced neurotoxicity. In palliative medicine physical dependence, tolerance, abnormal pain sensitivity and addiction should also be considered as they may be related to poor treatment outcomes.

- New knowledge concerning the potential influence of long-term administration of opioids on the immune and reproductive systems is emerging.

Assessment and management of opioid side effects

CATHERINE SWEENEY, CATHRYN BOGAN

INTRODUCTION

Opioids have been used as analgesics since at least 4000 BC and common side effects such as sedation, nausea, and constipation have long since been recognized. Over the past 20 years opioid use for symptom relief has increased significantly in developed countries.[1] In many countries opioids are now being introduced at earlier stages and used in higher doses in palliative care.[1,2] This appropriate increase in the use of opioids, coupled with increased vigilance, has resulted in increased detection of a number of previously unidentified side effects. The spectrum of neurotoxic side effects is the most notable of these. The increased awareness and identification of opioid side effects has resulted in the development and improvement of management strategies for dealing with these unwanted effects.

In recent years with increased long-term use of opioids such as in the chronic nonmalignant pain situation, effects of prolonged use on the endocrine and immune system are increasingly being recognized and researched. The clinical importance of these effects for palliative care patients is not yet clear.

This chapter will discuss assessment and management of opioid side effects (Table 45.1) in palliative care. It is beyond the scope of this text to discuss the pathophysiology of opioid side effects in detail.

NAUSEA AND VOMITING

Nausea and vomiting are common after an opioid is commenced or the dose is increased. In most patients this

Table 45.1 *Opioid side effects*

Traditionally recognized	Recently recognized
Nausea/vomiting	Opioid-induced neurotoxicity:
Sedation	Severe sedation
Respiratory depression	Cognitive failure/delirium
Constipation	Hallucinations
Noncardiogenic pulmonary	Myoclonus/grand mal seizures
edema	Hyperalgesia/allodynia
Pruritus	Immune system effects
Urinary retention	Endocrine effects
Allergy	(hypopituitarism, hypogonadism)

responds well to antiemetic medication and disappears spontaneously within 3 or 4 days.[3] Occasionally patients experience chronic and severe nausea; this may be more likely in those receiving higher doses of opioids. Opioids can cause nausea by a number of mechanisms, including stimulation of the chemoreceptor trigger zone or the vomiting center,[4] gastroparesis, and constipation. Opioid-induced nausea and vomiting is discussed in detail in Chapter 59.

Assessment

There are many potential causes of nausea and vomiting in patients receiving palliative care, and frequently the etiology is multifactorial in an individual patient. Therefore assessment of these symptoms should take into account other potential contributors. Table 45.2 summarizes common contributors to nausea in patients with cancer. The presence of other symptoms such as constipation, abdominal pain,

Table 45.2   *Possible contributors to nausea in patients with advanced cancer*

Complications of cancer	Disease-modifying and symptom treatments	Other problems
Metabolic abnormalities (e.g. hypercalcemia)	Chemotherapy radiotherapy	Peptic ulcer disease
Bowel obstruction	Opioids	Anxiety
Constipation	Other drugs	
Uncontrolled symptoms (e.g. pain)		
Raised intracranial pressure		

and distension may give clues as to the underlying cause. Assessment and management of nausea in palliative care is discussed in detail in Chapter 59.

Management

Antiemetic medication should be available to patients commencing opioid therapy or who are having a significant dose increase. A number of different antiemetic medications can be used to effectively treat opioid-induced nausea and vomiting in palliative care patients. These include prokinetic agents such as metoclopramide[5,6] and drugs with central nervous system effects such as haloperidol,[7] levopromazine[4] and cyclizine.[8,9] Antiemetic agents which act centrally on the central nervous system (CNS) have the potential to cause side effects, such as sedation, which can add to opioid toxicity in some patients. Corticosteroids have antiemetic effects; there is evidence that the addition of corticosteroids may improve nausea and vomiting in patients who do not initially respond to prokinetic agents.[10**]

Other factors thought to be contributing to nausea and vomiting should if possible be corrected; constipation which frequently coexists in these patients should be treated, metabolic abnormalities corrected and other medications which might contribute should be reduced or discontinued if possible.

SEDATION

Sedation commonly occurs after initiation of opioids and may occur following significant dose increases.[11,12] In the majority of patients this settles after a few days of stable doses. In some patients with severe pain, somnolence during the first days of treatment or after an increase in dose may simply reflect increased comfort after days of pain-induced insomnia rather than true somnolence. In a small percentage of patients, the opioid dose needed for symptom control causes persistent sedation. Sedation is also a feature of opioid-induced neurotoxicity; this is discussed in greater detail below.

Assessment

There are many possible causes of sedation in patients with advanced cancer (Box 45.1). Assessment of sedation should

---

Box 45.1 Possible contributors to sedation in patients with advanced cancer

- Opioid medications and their metabolites

- Metabolic abnormalities (e.g. hypercalcemia, hyponatremia)

- Renal or hepatic impairment

- Dehydration

- CNS sedatives (e.g. tricyclic antidepressants, benzodiazepines, alcohol)

- Other medications (e.g. nonsteroidal anti-inflammatory drugs [NSAIDs]) causing renal impairment

- CNS involvement with cancer

- Infection

take into account these possible contributors; it is common for a number of factors to be present in an individual patient.

Management

If sedation is present and pain relief is good, it may be possible to reduce the opioid dose. Other potential contributors to sedation should be addressed where possible; metabolic abnormalities and dehydration should be corrected, infection treated, and the use of sedative medication minimized where appropriate. In patients where there is persistent sedation at opioid doses necessary to achieve pain control, adjuvant analgesic measures should be considered to allow reduction in the opioid dose. Such measures include pharmacological and nonpharmacological interventions. Pharmacological interventions include the use of NSAIDs, bisphosphonates, corticosteroids, tricyclic antidepressants, or anticonvulsants. Nonpharmacological measures include radiotherapy and nerve blocks. Alternative routes of administration of analgesics such as intrathecal and epidural administration may also be useful in allowing significant reductions in opioid doses.

If a patient who is obviously sedated continues to complain of pain it is important to consider the possibility that spiritual or psychological distress (somatization) is contributing to their expression of pain (see Chapter 55). In this situation further increases in the opioid dose will lead to increased side effects and will not relieve the patient's suffering. If somatization is suspected, the approach to management should include counseling, treatment of underlying anxiety or depression, and reduction in the opioid dose. The expression of psychosocial suffering as physical symptoms has been identified as an independent predictor of poor pain control in cancer patients.[13]

PSYCHOSTIMULANTS

In patients in whom the dose of opioid needed for analgesia results in persistent sedation, a trial of psychostimulant medication may be helpful. There is evidence that psychostimulants can improve cognitive function and reduce sedation in cancer patients receiving opioids.[14–17**] In addition, the use of psychostimulants can allow increased opioid doses and improve analgesia in patients where sedation is limiting the dose of opioid that can be used.[15–18]

Psychostimulants have a number of potential adverse effects including neurotoxic side effects (such as hallucinations, delirium or psychosis), decreased appetite, tolerance and potential for addiction. Before prescribing psychostimulants, careful medical history must be taken to exclude any psychiatric disorder. This is important as stimulants are contraindicated in patients with a history of hallucinations, delirium or paranoid disorders. They are also relatively contraindicated with a history of substance abuse or hypertension.

The best type and dose of psychostimulant for the treatment of opioid-induced sedation has not been determined. Methylphenidate has been the most extensively studied of the group for this indication and is usually commenced at a dose of 5 mg twice daily. A beneficial effect is usually evident within 2 days of treatment and the dose can be increased to 10 mg twice daily. Morning and noon administration are recommended in an attempt to minimize potential sleep disturbance.

Recent preliminary research has highlighted a potential alternative to psychostimulants for the treatment of persistent opioid-induced sedation. Donepezil, a cholinesterase inhibitor used in the treatment of Alzheimer disease was found in an open label study in to reduce sedation and fatigue with cancer pain and opioid-induced sedation.[19] A retrospective study of 40 patients receiving opioids (mainly for cancer pain) also found a reduction in sedation with donepezil treatment.[20]

DRIVING AND OPIOIDS

Opioids have the potential to interfere with driving ability by impairing psychomotor skills and/or cognitive function.

A recent evidence-based review of driving-related skills in opioid-dependent/tolerant patients concluded that the majority of studies reviewed found no evidence of impaired driving-related skills.[21***] However, the review grouped three different populations of patients on opioids together: former addicts on maintenance programs, patients with chronic nonmalignant pain, and patients with chronic cancer pain. The majority of studies reviewed were carried out in the former population and there was some lack of consistency in the findings of studies in cancer patients.

In palliative care populations, the situation is more complicated. The underlying disease as well as other medications and treatments may contribute to impairment of skills that are considered to be important for driving. A number of studies looking at cognitive function and psychomotor abilities have been carried out in cancer patients receiving opioids.[22–26] In some studies, when compared with healthy controls, cancer patients receiving opioids have been found to have delayed continuous reaction times.[22,23] However, in studies comparing cancer patients receiving stable opioid doses with those not receiving opioids there appears to be some evidence that both populations are similar in terms of psychomotor and cognitive skills.[24*,25*] When both these groups were compared to healthy controls some deficits were found.[25] A study looking at the influence of opioid use, pain and performance status on neurophysiological function found that both pain and performance status appeared to affect neurophysiological tests; long-term use opioids did not in itself appear to negatively affect these tests.[26] Controlled studies of actual driving ability in cancer patients on opioids have not been carried out. Further research is needed in this area.

In general, cancer patients receiving opioids should be advised that their ability to drive may be compromised and that they should not drive if they feel drowsy or sedated. In addition, patients should be advised to avoid driving for 4–5 days after initiation of opioid medication or after a dose increase. They should also be informed that other medications used to treat symptoms can cause sedation and to check with their physician before driving if in doubt. Advising a patient to do a driving test may be appropriate if there is concern about a patient's driving ability and they are anxious to continue driving.

RESPIRATORY DEPRESSION

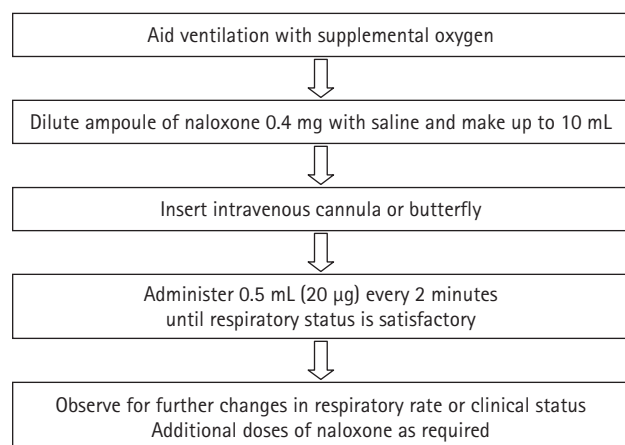
Respiratory depression is a potentially fatal side effect of opioids. It primarily occurs in opioid-naïve patients who are administered an excess dose of opioid. However it can occur in opioid-tolerant patients in a few situations. First, it may occur when there is a sudden reduction in opioid requirements, e.g. following a successful neurolytic block resulting in reduced pain. It is important to anticipate this possible situation and therefore consider reduction of opioid dose


Figure 45.1   *Guidelines for appropriate use of naloxone in opioid-induced respiratory depression based on recommendations of the American Pain Society.*[31]

following any intervention which may significantly reduce pain.[27] It may also occur following opioid rotation, in particular when rotating to methadone (see below).[28] Respiratory depression has also been described in a patient with renal impairment due to the build-up of morphine metabolites.[29]

Management involves reducing or omitting the next regular opioid dose or stopping an infusion temporarily to allow plasma levels to reduce and then recommencing the infusion at a lower dose. Opioid-induced sedation in the absence of respiratory depression is not an indication for using naloxone. Naloxone in these patients can result in opioid withdrawal syndrome and severe pain.[30] Naloxone is only indicated if there is significant respiratory depression, i.e. a respiratory rate of <8 breaths/minute, if the patient is barely rousable and/or cyanosed. Figure 45.1 summarizes the use of naloxone in opioid-induced respiratory depression. Naloxone has a shorter half-life than most opioids therefore it is important to observe patients carefully over a period of hours. Additional administration of naloxone may be required if the respiratory rate falls or clinical status changes.

CONSTIPATION

Opioids cause constipation by affecting the intestine by reducing gastrointestinal motility and secretions and increasing intestinal fluid absorption and blood flow.[32] Constipation is a common side effect of opioid therapy. It occurs in approximately 90 percent of patients treated with opioids.[33] Tolerance to constipation develops very slowly and most patients continue to require laxative therapy for the duration of opioid use. All opioids cause constipation although there is preliminary evidence to suggest that fentanyl may be less constipating than morphine,[34] and in a retrospective study of laxative use, laxative doses needed were found to be significantly lower with methadone than

with equianalgesic doses of morphine or hydromorphone.[35] Constipation is discussed in detail in Chapter 60 of this volume.

Assessment

Constipation should be suspected in all patients taking opioids. Frequently several other factors predisposing to constipation coexist in palliative care patients. Box 45.2 summarizes these factors.

Box 45.2 Factors contributing to constipation in palliative care patients

- Opioids
- Electrolyte disturbances (e.g. hypercalcemia, hypokalemia)
- Dehydration
- Other medication (e.g. tricyclic antidepressants)
- Reduced oral intake
- Abdominal surgery
- Abdominal involvement with cancer
- Immobility
- Autonomic failure

Assessment should include a history of the frequency and difficulty of defecation and consideration of other possible contributors. Physical examination should include palpation of the abdomen and a rectal examination. Occasionally an abdominal X-ray may be required if the history is unclear.[36,37]

Management

Prevention of constipation should be a priority when patients are starting opioid medication. Patients should be advised of the likelihood of developing constipation and have laxatives prescribed and the dose titrated until effective. Even patients with poor oral intake should be advised to use laxatives to prevent constipation. Patients should also be encouraged to take plenty of fluids.

Where a number of factors are thought to be contributing to constipation a multimodal approach to management will be required. Management can be divided into general and specific interventions. General interventions involve the elimination of medical factors that may be contributing to constipation (e.g. treatment of electrolyte abnormalities such as hypercalcemia, rehydration, discontinuation of all non-essential constipating drugs). Attention should be given

to providing comfort and privacy to patients during defecation. Specific interventions involve the use of laxatives, suppositories and enemas, and manual disimpaction. Usually a combination of laxatives with different modes of action is used. However, treatment with a combination of laxatives is not sufficient for all patients; up to 40 percent of patients with advanced cancer also require other measures such as the use of enemas and/or manual disimpaction.[33] For most patients, enemas and rectal suppositories are only needed for short-term management of more severe episodes of constipation. Occasionally the use of long-term rectal laxatives or enemas is required.

There is evidence that the opioid antagonist naloxone (used orally)[38**] can be effective in the treatment of opioid-induced constipation in patients with advanced cancer. However, opioid withdrawal occurs in some patients treated with oral naloxone for constipation.[38–40] The first peripheral opioid receptor antagonist methylnaltrexone (used intravenously) has been found in a randomized controlled trial to be effective in treating opioid-induced constipation in subjects in a methadone maintenance program.[41**] Oral methylnaltrexone also offers a potential treatment option for this problem[42] Methylnaltrexone does not appear to cause problems with analgesia or withdrawal.[41,42] Other treatment options for patients with persistent troublesome constipation not responding to the usual measures include the use of prokinetic agents (e.g. metoclopramide, domperidone)[43] or to consider opioid rotation to methadone or fentanyl.

NONCARDIOGENIC PULMONARY EDEMA

Noncardiogenic pulmonary edema is a rare opioid side effect which has been mainly reported following illicit opioid use. It has recently been described in patients receiving treatment for cancer pain.[44] In this setting it has usually been reported following rapid escalation of opioid dose in the days prior to onset. Patients usually present with acute onset of tachypnea and cyanosis. The pathophysiology of opioid-induced noncardiogenic pulmonary edema is not clearly understood.

Assessment

Physical examination of the patient usually reveals bilateral rales (crepitations) in the absence of other signs of cardiac failure. Chest X-ray may show bilateral infiltrates. An electrocardiogram should be performed to rule out an acute cardiac cause for the symptoms. A high index of suspicion is necessary to make the diagnosis.

Management

In a palliative care setting with a conservative approach to management there appears to be high mortality associated with the development of this side effect. Evidence on the best management approach in this setting is lacking. Measures such as reduction in opioid dose and avoidance of possible precipitating factors such as overhydration, excessive oxygen therapy, and use of corticosteroids have been suggested.[44] One approach is to attempt to reduce the risk of development of noncardiogenic pulmonary edema by avoiding rapid escalation of opioid doses where possible. The use of adjuvant analgesics, epidural or intrathecal administration of analgesics, and opioid rotation are all measures that may be considered in circumstances where pain control is inadequate and opioid requirements have been rising rapidly.

URINARY RETENTION

Opioids can increase smooth muscle tone, resulting in increased sphincter tone. Urinary hesitancy and retention can therefore result from opioid use. These side effects are commoner in elderly patients and in those receiving opioids intrathecally.[45] In patients who develop hesitancy or retention while on opioid medication, other potential causes of these symptoms should also be considered such as concomitant use of tricyclic antidepressants, severe constipation, bladder outlet obstruction, and impending spinal cord compression. Approaches to management include changing the route of administration, changing the opioid, and the use of a urinary catheter.

PRURITUS

Pruritus (itch) is a relatively common side effect following intrathecal and epidural administration of opioids[46] and is less common after oral administration. It can be a very troublesome symptom for individual patients.[47] The pathophysiology of opioid-induced pruritus is not clearly understood; it does not appear to be related to histamine release.[48] Many conditions common in palliative patients can cause itch; Chapter 78 discusses pruritus in detail.

Treatment options for opioid-induced itch have mainly been researched in patients undergoing surgical procedures or cesarean sections under epidural or spinal anesthesia and several of these studies have looked at agents as prophylaxis rather than treatment.[49] There is evidence supporting the use of naloxone,[50**] droperidol,[51] butorphanol,[52] and ondansetron[53] to prevent opioid-induced pruritus in surgical and obstetric settings. Treatments that have been suggested in palliative care include opioid antagonists and ondansetron.[48] Use of opioid antagonists can result in antagonism of analgesia. A change to an alternative opioid has been reported to be very effective in individual case reports.[47,54]

ALLERGIC REACTIONS

Hypersensitivity reactions to opioids appear to be rare. Patients often consider side effects of a medication (e.g. nausea, sedation) to be an allergy; hence it is important to check what problems a specific medication has caused for an individual patient. In the case of opioid side effects reassurance, explanation, and appropriate treatment should be offered to patients.

OPIOID-INDUCED NEUROTOXICITY

Opioid-induced neurotoxicity (OIN) describes a syndrome of neuropsychiatric side effects seen with opioid therapy. This syndrome has been described only relatively recently.[55–57] Features of OIN are listed in Table 45.1. These features can exist singly or in combination. If any of these features are present in a patient taking opioid medication, OIN should be suspected.

Sedation

Sedation associated with OIN is persistent and frequently severe. It is often present with other features such as cognitive impairment and delirium. Sedation and its management have been discussed earlier in this chapter.

Cognitive impairment and delirium

Cognitive impairment and delirium are common features in patients with cancer.[58] While there are many potential causes (Box 45.3), opioid use is considered to be a major factor.[59,60]

Box 45.3 Causes of cognitive impairment/delirium

- Drug induced (e.g. opioids, antimuscarinics, corticosteroids)
- Biochemical (e.g. hypercalcemia, hyponatremia)
- Infection
- Dehydration
- Renal or hepatic failure
- Brain metastases
- Constipation
- General deterioration
- Withdrawal (e.g. alcohol, benzodiazepines, nicotine)

The extent to which various opioids contribute to delirium has not been well studied.[61]

Classically delirium is associated with an agitated hyperactive state, however, it must be remembered that delirium can also present with withdrawn, hypoactive features. This nonagitated delirium may be underrecognized by healthcare professionals. Occasionally, features of hyperactivity and hypoactivity may occur concurrently.[62,63]

Hallucinations

In OIN, hallucinations are typically visual in nature, although tactile hallucinations are not uncommon. Auditory hallucinations may also occur. The overall prevalence of hallucinations in the palliative care setting is unknown. The prevalence of visual hallucinations has been reported as 1 percent[64] while more recent work has reported the figure to be nearer 50 percent.[65] Patients are often reluctant to spontaneously admit to experiencing hallucinations. They may find them frightening and could fear that they have developed a psychiatric illness. While hallucinations are a known feature of OIN, they are also caused by other conditions and numerous medications, therefore one should look for other symptoms and signs of OIN. Hallucinations are commonly associated with cognitive impairment but are occasionally seen in patients who have not experienced cognitive impairment.[66] A sudden change in mood (anxiety or depression) may be the only indication of the presence of hallucinations.[67]

Myoclonus and seizures

Myoclonus is a sudden, shocklike involuntary movement caused by active muscular contractions which may involve a whole muscle or may be limited to a small number of muscle fibers.[63] It has been postulated that generalized myoclonus is a type of tonic-clonic seizure.[68] Myoclonus is one of the more frequently observed features of OIN and if present there should be a high index of suspicion for the diagnosis. It has been described following administration of morphine,[56,69] hydromorphone,[70,71] meperidine,[72,73] fentanyl,[74,75] and diamorphine.[76] It has been proposed that myoclonus results from accumulation of neurotoxic opioid metabolites.[77] Myoclonus may occur more commonly in those patients taking antidepressants, antipsychotics or NSAIDs.[78] Myoclonus may also occur with renal failure alone.

Hyperalgesia and allodynia

Abnormally heightened pain sensations can occur with opioids. These are characterized by a lowering of the pain threshold (hyperalgesia) and pain elicited by normally innocuous stimulation (allodynia).[79] Hyperalgesia may

present as an exaggerated nociceptive response to a painful stimulus or as a worsening of the underlying pain syndrome, termed paradoxical pain.[80] This paradoxical pain may be misinterpreted by clinicians and the opioid dose increased further, resulting in worsening OIN. Morphine-3-glucuronide, normorphine, and hydromorphone have been shown to produce allodynia in rats after intrathecal administration; however, the exact mechanism is still unclear.[81,82]

Mechanism of opioid–induced neurotoxicity

It has been reported that several opioids and their active metabolites may contribute to OIN. Morphine, hydromorphone, and fentanyl have all been found to cause agitation, myoclonus, hyperalgesia, and tonic-clonic seizures in animals when administered systemically or intrathecally.[68,83–85] Morphine has been investigated extensively and is predominately metabolized to morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G).[86,87] It has been postulated that M3G is responsible for some of the neuroexcitatory effects of morphine, while being devoid of analgesic properties.[88] Evidence for the role of M3G or similar metabolites is conflicting. More recent research reports that M3G failed to produce excitatory and antianalgesic effects in rats[89] and in a phase I healthy volunteer study M3G did not illicit any clinical effects when given alone nor did it antagonize the effects of morphine or M6G.[90] The possibility of interindividual variation in metabolism of opioids is but one of a number of possibilities for these conflicting findings. The precise mechanism of OIN remains unclear. Further research is required to gain a better understanding of the pathophysiology of OIN.

ASSESSMENT

Numerous risk factors predispose patients to the development of OIN. These are summarized in Box 45.4. Assessment includes an accurate history focusing particularly on symptoms of OIN. It is important to enquire specifically about hallucinations. Vivid dreams are sometimes a feature of OIN. A detailed medication history is important; information should be sought about the onset of features following commencement or dose increases of opioids, addition of psychoactive medications or drugs that may impair renal function.

Examination should look for signs of infection, dehydration and jerking movements should be noted. Cognitive function should be assessed as a matter of routine. A number of tools exist to assess cognitive function.[62] Although no gold standard tool has been identified, the Mini-Mental State Examination [91] has been widely used in this population.[92] Other tools include the Memorial Delirium Assessment Scale (MDAS)[93] and the Delirium Rating Scale (DRS).[94] Confusion and delirium assessment is covered in more detail in Chapter 72.

Box 45.4 Factors predisposing to OIN

- Large doses of opioids

- Extended period of treatment with opioids

- Dehydration

- Renal failure

- Infection

- Rapid opioid dose escalation (more likely to occur with): neuropathic pain; incident pain; tolerance; somatization/emotional pain; substance abuse

- Recent reduction in analgesic requirements (may follow): addition of nonopioid drugs (e.g. NSAIDs) or adjuvant analgesics (e.g. anticonvulsants, recent radiotherapy or chemotherapy or anesthetic intervention)

- Borderline cognitive impairment/delirium

- Use of other psychoactive drugs (e.g. benzodiazepines)

- Older age

If OIN is suspected, blood should be sent for biochemical and hematological analysis. An elevated white cell count may indicate the presence of infection, and the existence of renal failure or hypercalcemia must be excluded.

MANAGEMENT

Box 45.5 outlines the approaches to management of acute episodes of OIN. There are numerous reports detailing reduction in dose or discontinuation of opioids as successful treatment of OIN.[92,95,96] Dose reduction may not always be possible, especially if uncontrolled pain is a problem. In this situation the addition of nonopioid co-analgesics, adjuvant analgesics, and the use of specific antitumor therapies such as radiotherapy, chemotherapy, or anesthetic intervention to reduce opioid requirements should be considered.[97]

Opioid rotation, or opioid switching, is the term given to the practice of substituting one strong opioid with another to obtain better analgesic control and reduce opioid side effects. It requires knowledge of the approximate conversion ratios of the two different opioids. When switching it is common practice to use lower doses than predicted according to opioid dose conversion tables.[97,98] The situation with rotations involving methadone is more complex. The relation between increasing opioid doses and methadone dose is not linear; the higher the previous opioid dose the greater the relative potency of methadone.[99] It also should be remembered that methadone has complex pharmacokinetics resulting in a long and variable elimination half-life.

Box 45.5 Approaches to management of OIN

- Hydration (oral or parenteral)

- Treat reversible causes (antibiotics for infection, bisphosphonates for hypercalcemia)

- Opioid reduction or in severe cases discontinuation of regular opioid

- Stop other contributing drugs (e.g. hypnotics)

- Maximize use of nonopioid analgesics (e.g. NSAIDs)

- Commence/titrate adjuvant analgesics (e.g. anti-convulsants, tricyclic antidepressants)

- Opioid rotation

- Symptomatic treatment (benzodiazepines for myoclonus, haloperidol for hallucinations)

- Reassurance and explanation

Box 45.6 Prevention of further episodes of neurotoxicity

- Identify and manage risk factors for OIN

- Carefully monitor for early signs of OIN

- Educate patient and family about risk factors and early signs of OIN

- Educate primary care physician about risk factors and early signs of OIN

- Careful monitoring post radiotherapy, chemotherapy or anesthetic intervention

---

Numerous conversion regimens exist[100–103] however, no gold standard has emerged. The most common error when opioid rotating to methadone is to underestimate its duration of action. Late toxicity may develop, possibly even 10 days following rotation. Extreme caution should be exercised when opioid rotating to methadone and one should be vigilant for signs of toxicity which may be subtle. Variations in analgesia or adverse effects following rotation are thought to result from a variety of mechanisms including receptor activity, asymmetry in cross-tolerance among different opioids, differing opioid efficacies, and accumulation of toxic metabolites.[98] Numerous studies have described the use of opioid rotation as a safe and effective method for reducing neurotoxicity while simultaneously retaining analgesia.[88,101,102,104–107] Although the success of opioid rotation has been extensively reported in the literature, these have been mainly case reports, retrospective studies or prospective uncontrolled studies. Despite the fact that opioid rotation is widely accepted in clinical practice, evidence to date is largely anecdotal or based on observational and uncontrolled trials.[108] Opioid rotation has, as yet, not been systematically studied in randomized controlled trials. Once OIN has been recognized and treated, steps must be taken to reduce the risk of further episodes (Box 45.6).

ENDOCRINE AND IMMUNE SYSTEM EFFECTS

Evidence is emerging that opioids have potential effects on the functioning of endocrine and immune systems. In one study patients with nonmalignant pain receiving long-term intrathecal opioid (n = 73) were compared with a group with similar pain syndromes; the opioid treatment group were found to be significantly more likely to have hypogonadic hypogonadism. Growth hormone deficiency and hypocorticism were also more likely in this group.[109] In intravenous drug users, opioids appear to affect the immune defense system and have been implicated in the pathogenesis of infection.[110]

The implications of these findings for palliative care patients and in particular for those with advanced disease are unknown and further research is required before evidence-based recommendations can be made on appropriate assessment and management.

PSYCHOLOGICAL DEPENDENCE AND SUBSTANCE ABUSE

Opioids are potential drugs of addiction. Psychological dependence is a key feature of addiction and involves compulsive behavior to obtain and take a drug for its psychological effects. Hence, psychological dependence involves substance misuse or abuse. Fear of addiction is common in patients and physicians and can lead to under-use of opioids in palliative care populations. Opiophobia should not prevent opioids being prescribed where they are needed. In clinical practice psychological dependence and opioid abuse are rare in patients who do not have a preexisting history of drug or alcohol abuse.[111,112] Physical dependence is often confused with psychological dependence. However, physical dependence (the appearance of withdrawal symptoms and signs when a drug is abruptly discontinued) is common when patients have been taking opioids for a period of time; this does not mean that a patient is addicted to an opioid. Abrupt discontinuation or dramatic reductions in opioid doses should be avoided. If a major dose reduction or discontinuation is desired, doses should be gradually reduced over several days. The management of pain in patients with drug and alcohol dependence is discussed in detail in Chapter 56.

Key learning points

- There are a number of common opioid side effects. It is important that these are identified as they can add significantly to symptom burden in palliative care patients; most are preventable or treatable with relatively simple measures.

- In palliative care patients there may be other contributors to common opioid side effects; these should be identified and corrected where possible.

- Nausea and vomiting are common after initiation or recent opioid dose increases. These symptoms often resolve spontaneously after a few days. Antiemetic medications such as metoclopramide, haloperidol or cyclizine are usually effective. Addition of corticosteroids can be helpful in resistant cases.

- Sedation is a common problem after initiation or recent opioid dose increases and usually resolves after 3–4 days. If it is a persistent problem the following measures can be considered: (i) reduction in opioid dose if pain control is good; (ii) reduce opioid requirements by treating pain with addition of nonopioid or adjuvant analgesic medications, alternative route of opioid delivery (epidural or intrathecal), radiotherapy or nerve blocks; (iii) if OIN is thought to be present it should be managed as described in text; (iv) psychostimulants or donepezil; (v) psychological or spiritual distress may be contributing to the patient's expression of pain. These issues should be explored and managed appropriately.

- Constipation is extremely common; the majority of patients require initiation of laxative treatment when opioids are started and continuation of this for the duration of treatment with opioids.

- Opioid-induced neurotoxicity is a relatively recently identified syndrome of opioid side effects. Features include severe sedation, cognitive failure, delirium, hallucinations, myoclonus, hyperalgesia, and allodynia, and one or more of these may be present. Treatment options include a combination of hydration, opioid dose reduction/opioid rotation, and correction of possible contributors such as infection and electrolyte abnormalities (see text).

Adjuvant analgesic drugs

DAVID LUSSIER, RUSSELL K PORTENOY

INTRODUCTION

Pain due to cancer can be relieved by a simple opioid-based regimen in more than 70 percent of patients.[1,2**] Some patients are relatively less responsive to opioids, however, and require implementation of strategies to improve the balance between analgesia and adverse effects.[3***] Among these strategies is the use of adjuvant analgesics.

Adjuvant analgesics are drugs with a primary indication other than pain, but with analgesic properties in some painful conditions.[4] Although they can be used alone, they are usually coadministered with analgesics (acetaminophen, nonsteroidal anti-inflammatory drugs [NSAIDs], opioids) when treating cancer pain. They can be added to an opioid regimen to enhance pain relief provided by the opioid, address pain that has not or insufficiently responded, or allow the reduction of the opioid dose and hence reduce adverse effects (Box 46.1).[4] Numerous classes of drugs with diverse primary indications can be used as adjuvant analgesics. Some have been shown to have analgesic properties in diverse pain syndromes and warrant description as multipurpose adjuvant analgesics. Others are used for more specific indications, like neuropathic pain or bone pain (Table 46.1).

Box 46.1 Using adjuvant analgesics for pain management in the palliative care setting

1 Consider optimizing the opioid regimen before introducing an adjuvant analgesic

2 If appropriate, consider the use of other strategies for pain that is poorly responsive to an opioid, including opioid rotation, more aggressive adverse effects management, spinal drug administration, and trials of nonpharmacological approaches (e.g. nerve block, rehabilitative or psychological therapies)

3 Select the most appropriate adjuvant analgesic based on a comprehensive assessment of the patient (symptoms, comorbidities, goals of care) and the inference about the predominating type of pain.

4 When selecting an adjuvant analgesic, consider its pharmacological characteristics, actions, approved indications, unapproved indications accepted in medical practice, likely adverse effects, potential serious adverse effects, and interactions with other drugs

5 Administer the adjuvant analgesics with the best risk:benefit ratios as first-line treatment

6 Avoid initiating several adjuvant analgesics concurrently

7 In most cases, initiate treatment with low doses and titrate gradually according to analgesic response and adverse effects

8 Reassess the efficacy and tolerability of the therapeutic regimen on a regular basis, and taper or discontinue medications that do not provide additional pain relief

9 Consider combination therapy with multiple adjuvant analgesics in selected patients

Table 46.1 *Classification and dosing guidelines of adjuvant analgesics*

Drug	Starting dose	Usual effective dose	Drug	Starting dose	Usual effective dose
(I) Multipurpose adjuvant analgesics			Lidocaine topical	1–3 patches 12 hours/24	
Antidepressants					
Tricyclic antidepressants			*N*-methyl-ᴅ-aspartate receptor antagonists		
Amitriptyline	10–25 mg HS	50–150 mg HS	Ketamine	Different regimen (see text)	
Nortriptyline	10–25 mg HS	50–150 mg HS	Dextromethorphan	15–20 mg tid	Unclear
Desipramine	10–25 mg HS	50–150 mg HS	Amantadine	100 mg qd	100–150 mg bid
Selective serotonin reuptake inhibitors (SSRIs)			**(III) Adjuvant analgesics for bone pain**		
Paroxetine	10–20 mg qd	20–40 mg qd	Corticosteroids		
Citalopram	10–20 mg qd	20–40 mg qd	Calcitonin	1 IU/kg subcutaneous qd 200 IU intranasal qd	
Norepinephrine/serotonin reuptake inhibitors (NSRIs)					
Venlafaxine extended-release	37.5 mg qd	37.5–112.5 mg qd	Bisphosphonates		
Duloxetine	20–30 mg qd	60 mg qd	Pamidronate	60 mg IV q month[a]	60–90 mg IV q month[b]
Others			Ibandronate	6 mg IV q 3–4 weeks[a,b] 50 mg po qd	
Bupropion	50–75 mg bid	75–150 mg bid	Zoledronic acid	4 mg IV q 3 weeks[a]	
Corticosteroids			Radiopharmaceuticals		
Dexamethasone	1–2 mg qd or bid	Variable			
Prednisone	7.5–10 mg qd	Variable	**(IV) Adjuvant analgesics for pain from bowel obstruction**		
α₂-Adrenergic agonists			Octreotide	0.2–0.3 mg/day SC infusion	
Clonidine	0.1 mg po qd ½TTS-1 patch	Variable 0.3 mg transdermal/day	Anticholinergics		
			Hyoscine (scopolamine)	40 mg/day SC infusion	60 mg/day SC infusion
Tizanidine	2 mg HS	Variable	Glycopyrrolate	0.1 mg SC or IV 3–4 times/day	Unclear
Neuroleptics					
Olanzapine	2.5 mg qd	Unclear efficacy	Corticosteroids		
Pimozide	1 mg qd	Unclear efficacy	Dexamethasone	4 mg bid	Variable
(II) Adjuvant analgesics for neuropathic pain			Methylprednisolone	10 mg tid	10–20 mg tid
Anticonvulsants			**(V) Other adjuvant analgesics**		
Gabapentin	100–300 mg HS	300–1200 mg tid	Baclofen	5 mg tid	10–20 mg tid
Pregabalin	50–75 mg qd-bid	75–150 mg bid	Cannabinoids		
Lamotrigine	25 mg qd	100–200 mg bid	Dronabinol	2.5 mg bid	5–10 mg bid
Oxcarbazepine	75–150 mg bid	150–800 mg bid	Psychostimulants		
Topiramate	25 mg qd	100–200 mg bid	Methylphenidate	2.5 mg q AM	Variable
Levetiracetam	250–500 mg bid	500–1500 mg bid	Modafinil	100 mg q AM	Variable
Tiagabine	4 mg HS	4–12 mg bid			
Zonisamide	100 mg qd	100–200 mg bid			
Carbamazepine	100–200 mg qd-bid	300–800 mg bid			
Valproic acid	250 mg tid	500–1000 mg tid			
Phenytoin	300 mg HS	100–150 mg tid			
Local anesthetics					
Mexiletine	150 mg qd	100–300 mg tid			
Lidocaine intravenous	2 mg/kg over 30 min	2–5 mg/kg			

[a] Pamidronate should be infused over 2–4 hours, ibandronate over 1–2 hours and zoledronic acid over 15 minutes.
[b] High-dose IV ibandronate can also be used with 6 mg qd on three consecutive days, followed by q 4 weeks.
qd, once a day; bid, twice a day; tid, three times a day; HS, every night; q, every; IV, intravenous; SC, subcutaneous; IU, international units; AM, morning.

Few adjuvant analgesics have been studied in cancer populations. To a large extent, therefore, drug selection, dosing, and monitoring approaches are extrapolated from the literature on nonmalignant pain. Table 46.1 provides a list of the adjuvant analgesics for which there is some evidence of analgesic efficacy, along with dosing guidelines. Table 46.2 summarizes the postulated mechanisms of the analgesic activity of the main adjuvant analgesics.

MULTIPURPOSE ANALGESICS

Antidepressant drugs

TRICYCLIC ANTIDEPRESSANTS

The tricyclic antidepressants have been extensively studied, and there is compelling evidence for their analgesic properties in a variety of chronic nonmalignant pain conditions.[10,11**] Both the tertiary amines (amitriptyline, imipramine, doxepin, and clomipramine) and the secondary amines (nortriptyline and desipramine) are analgesic.[10,11**] Although few clinical trials have specifically evaluated these drugs for cancer pain, partially controlled[12–14**] and uncontrolled trials,[15*] as well as clinical experience, generally support their analgesic effects.

The use of the tricyclic antidepressants in medically ill or elderly patients may be limited by the frequent occurrence of adverse effects,[16] which include cardiotoxicity (arrhythmias), orthostatic hypotension, drug-induced delirium and precipitation of an acute glaucoma attack. The secondary amines, desipramine and nortriptyline, are less anticholinergic and, therefore, better tolerated than the tertiary amine drugs. Patients who are predisposed to adverse effects from tricyclics, or who have distressing adverse effects during a trial of a tertiary amine drug, should be considered for a trial of desipramine or nortriptyline.

The analgesic effect of tricyclic antidepressants is not dependent on their antidepressant activity. The usually effective analgesic dose is often lower than that required to treat depression, and the onset of analgesia typically occurs sooner, usually within a week.[10,11]

OTHER ANTIDEPRESSANTS

Although the evidence is far less than for tricyclics, randomized controlled trials suggest that other antidepressants are analgesic.[17**] The main advantage of the non-tricyclic antidepressants is their favorable side-effect profile, which makes them safer and better tolerated.

Among the selective serotonin reuptake inhibitors (SSRIs), the only ones for which controlled studies have suggested benefit are paroxetine[18**] and citalopram.[19**] No studies have been done in cancer pain. Venlafaxine, which inhibits the

Table 46.2 *Probable mechanisms of analgesic activity of adjuvant analgesics[4]*

Drug	Mechanism(s) of analgesic activity
Multipurpose adjuvant analgesics	
Antidepressants	
Tricyclics	Blockade of reuptake of norepinephrine and serotonin
Selective serotonin reuptake inhibitors	Blockade of serotonin reuptake
Venlafaxine	Low dose: blockade of serotonin reuptake
	High dose: blockade of norepinephrine reuptake
Bupropion	Blockade of reuptake of norepinephrine and dopamine
Corticosteroids	Decreased compression of pain-sensitive structures by reduction of peritumoral edema
	Shrinkage of steroid-sensitive tumor masses
	Decreased activation of nociceptors due to lower tissue concentrations of inflammatory mediators and lessened aberrant electrical activity in damaged nerves
α_2-Adrenergic agonists	Interaction with α-2 receptors in the spinal cord or brainstem activates endogenous systems that reduce nociceptive input to the central nervous system[5]?
Neuroleptics	Dopaminergic blockade[6]?
Adjuvant analgesics for neuropathic pain	
Anticonvulsants[7]	
Phenytoin, lamotrigine	Blockade of sodium channels
	Inhibition of presynaptic release of glutamate
Carbamazepine, oxcarbazepine	Blockade of sodium and calcium channels
Topiramate	Blockade of sodium channels
	Increase of inhibitory action of GABA
	Inhibition of excitatory action of glutamate
Gabapentin, pregabalin	Binding to the $\alpha2\delta$ subunit of calcium channels blocks calcium influx and prevents presynaptic release of neurotransmitters[8]
Tiagabine	Direct agonist effect on GABA receptors
Levetiracetam	Unclear
Local anesthetics	Blockade of sodium channels
NMDA antagonists	Inhibition of the 'wind-up' phenomenon caused by activation of NMDA receptors by glutamate and aspartate[9]

GABA, γ-aminobutyric acid; NMDA, *N*-methyl-D-aspartate.

reuptake of both serotonin and norepinephrine, has been shown to provide good pain relief in nonmalignant painful polyneuropathy[20,21**] and pain following mastectomy for breast cancer;[22**] it also has reduced the incidence of postmastectomy pain if given prior to surgery.[23**] Duloxetine, another mixed reuptake inhibitor, is effective in treating painful symptoms associated with depression.[24**] Animal studies suggested that duloxetine might have a role in the treatment of neuropathic pain[25] and subsequent clinical trials led to approval by the US Food and Drug Administration as a treatment for painful diabetic polyneuropathy. The dual noradrenergic and dopaminergic compound bupropion can relieve nonmalignant neuropathic pain;[26,27**] its activating effects can be particularly helpful in hypoactive depressed, sedated or fatigued patients often encountered in the palliative care population.

Corticosteroids

Corticosteroids possess analgesic properties for a large variety of cancer pain syndromes, including bone pain, neuropathic pain from infiltration or compression of neural structures, headache due to increased intracranial pressure, arthralgia, and pain due to obstruction of a hollow viscus (e.g. bowel or ureter) or to organ capsule distension.[28***] They are also effective in the initial management of pain and symptoms from metastatic spinal cord compression[29,30**] while awaiting more definitive treatment (usually radiation therapy) if justified by the goals of care. Even though the risks and benefits of the various corticosteroids are unknown, dexamethasone is often selected because of its relatively low mineralocorticoid effects. Prednisone and methylprednisolone can also be used.

A high-dose regimen of corticosteroids is recommended for patients who experience spinal cord compression and can be helpful in an acute episode of severe pain that cannot be promptly reduced with opioids.[31***] There is a large experience in the administration of dexamethasone at an initial dose of 100 mg, followed by 96 mg/day in divided doses and a subsequent tapering over days or weeks after the initiation of other analgesic approaches (e.g. opioid therapy or radiation therapy). A low-dose corticosteroid regimen (e.g. dexamethasone 2–4 mg once or twice daily) can be used for patients with advanced cancer who continue to have pain despite optimal dosing of opioid drugs. Long-term usage of a corticosteroid in this dose range is associated with the possibility of adverse effects, including hypertension, hyperglycemia, fluid retention, gastrointestinal bleeding, skin fragility, and delirium. In patients with good prognoses for prolonged survival, repeated assessments are required to ensure that benefits are sustained. In all cases, the dose should be tapered to the lowest effective dose. The coadministration of a gastroprotective drug (usually a proton pump inhibitor) can be justified for patients

who present other risk factors for peptic ulcer disease, particularly the concomitant administration of an NSAID.

α_2-Adrenergic agonists

Although the α_2-adrenergic agonists may be considered multipurpose adjuvant analgesics, the limited supporting data and clinical experience, as well as the potential for adverse effects (mostly somnolence and hypotension) relegate these drugs to second-line use, after others have proved ineffective. Clonidine, administered either orally, transdermally or intraspinally, has been shown to be analgesic in nonmalignant neuropathic pain.[32–34***] Fewer than a quarter of patients who receive the drug systemically experience pain relief,[32] and adverse effects are a particular concern in frail palliative care patients. Intraspinal clonidine has been shown to reduce pain (especially neuropathic pain) in patients with severe intractable cancer pain partly responding to opioids.[35**] Tizanidine, which is more specific for the α_2-adrenergic receptor than clonidine, is approved as an antispasticity agent and is often better tolerated. Evidence of its analgesic efficacy is however limited to the nonmalignant syndromes of myofascial pain and chronic daily headache.[36***]

Neuroleptics

The second-generation 'atypical' neuroleptic, olanzapine, was reported to decrease pain intensity and opioid consumption, and improve cognitive function and anxiety in a case series of cancer patients.[37*] Nonetheless, the limited evidence of efficacy, combined with the potential for adverse effects, suggests a very limited role for neuroleptics as analgesics. They can be useful in the presence of a delirium or agitation, in which case the analgesic properties might provide better pain control and allow a decrease of opioid consumption, which might in turn be helpful in resolving the delirium.[38***]

ADJUVANT ANALGESICS SPECIFIC FOR NEUROPATHIC PAIN

The term 'neuropathic pain' is applied to those pain syndromes for which the sustaining mechanisms are presumed to be related to aberrant somatosensory processes in the peripheral nervous system, central nervous system (CNS), or both.[39] Surveys have reported that up to 40–50 percent of cancer pain syndromes can be categorized as exclusively or partly neuropathic.[40,41***]

Neuropathic pain may be relatively less responsive to opioid drugs that other types of pain. Adjuvant analgesics therefore play a very important role in the management of neuropathic pain. The use of opioid drugs as first-line analgesics should not, however, be abandoned when the pain is

neuropathic, especially now that randomized controlled trials have established their potential efficacy in nonmalignant neuropathic pain syndromes.[17**] Addition of an adjuvant analgesic to the therapeutic regimen usually should follow the optimization of the opioid regimen.

Anticonvulsant drugs

There is good evidence that the anticonvulsant drugs are useful in the management of nonmalignant neuropathic pain.[7,42,43**] Gabapentin is recommended as a first-line agent for the treatment of nonmalignant neuropathic pain of diverse etiologies.[17] Randomized controlled trials have established its analgesic efficacy in several types of nonmalignant neuropathic pain.[44–47**] As an 'add on' therapy to patients whose neuropathic cancer-related pain is not controlled satisfactorily with an optimal dose of opioids, gabapentin 600–1800 mg daily reduces average pain and dysesthesias when compared with placebo.[48**] Gabapentin appears to be widely used to treat cancer-related neuropathic pain in palliative care units.[49*] It should be initiated at a daily dose of 100–300 mg at bedtime and can be increased every few days. The usual effective dose ranges between 900 mg and 3600 mg daily. An adequate trial should include 1–2 weeks at the maximum-tolerated dose. The most common adverse effects are somnolence, dizziness, and unsteadiness. If titrated carefully, gabapentin is usually well tolerated, but in frail palliative care patients, somnolence can be a limiting factor.[49] Since it is not metabolized by hepatic enzymes, gabapentin rarely has drug–drug interactions.

Although none of the other anticonvulsants have been studied in malignant neuropathic pain, there is evidence of analgesic efficacy in nonmalignant neuropathic pain. Lamotrigine was reported to be analgesic in several randomized trials.[50–53**] The risk of adverse effects (e.g. somnolence, dizziness, ataxia and cutaneous hypersensitivity syndromes including Stevens–Johnson syndrome) is lessened by slow dose titration. Pregabalin, a new anticonvulsant with a mechanism identical to that of gabapentin, now has a strong evidence of analgesic efficacy supported by randomized controlled trials.[54–56***] Oxcarbazepine, a metabolite of carbamazepine, has a similar spectrum of effects and better tolerability; it appears promising based on a few open-label trials.[57–60*] Topiramate,[61**] tiagabine,[62*] and zonisamide[63*] have some evidence of efficacy, and there is some favorable clinical experience with levetiracetam.[64,65*] Like gabapentin, pregabalin and levetiracetam lack any significant drug–drug interactions.

Among the older anticonvulsants, evidence of efficacy is best for carbamazepine and phenytoin. In cancer pain, phenytoin can provide mild to moderate analgesia and enhance opioid analgesia.[66**] An intravenous infusion of phenytoin has also been reported to be effective in reducing overall pain, as well as burning pain, shooting pain, sensitivity and numbness in acute flare-ups of nonmalignant neuropathic

pain.[67**] Even though this effect is usually of short duration, it might be useful in refractory neuropathic pain. Valproate and clonazepam have been widely used but lack clear evidence of analgesic activity.

Oral and parenteral local anesthetics

Local anesthetics have analgesic properties in neuropathic pain.[4**] Due to their potential for serious side effects, they usually have been positioned as second-line therapies.[17,68]

A brief intravenous infusion of lidocaine has been shown to be effective in nonmalignant neuropathic pain.[69,70**] Although controlled trials in neuropathic cancer pain[71,72] have not demonstrated efficacy, clinical experience justifies a trial of intravenous lidocaine infusion in selected patients with severe refractory neuropathic pain. Brief infusions can be administered at varying doses within the range of 1–5 mg/kg infused over 20–30 minutes. In the medically frail patient often encountered in the palliative care population, it is prudent to start at the lower end of this range and provide repeated infusions at successively higher doses. A history of significant cardiac disease may relatively contraindicate this approach and should be evaluated before it is administered. An electrocardiogram should be done before starting the infusion or increasing the dose, and careful monitoring of vital signs is necessary during the period of the infusion and immediately thereafter.

Although prolonged relief of pain following a brief local anesthetic infusion may occur, relief usually is transitory. If lidocaine appears to be effective but pain recurs, long-term systemic local anesthetic therapy should be considered using an oral local anesthetic, such as mexiletine. For rare patients with refractory neuropathic cancer pain who respond only to intravenous lidocaine infusion, long-term subcutaneous administration has been reported to provide sustained relief.[73*]

There is no definitive evidence that an intravenous infusion of lidocaine predicts the response to an oral local anesthetic, the dose of which is slowly titrated. For this reason, an oral formulation, such as mexiletine, can be considered without a prior infusion and even those who do not respond to an infusion may be considered for a subsequent trial of an oral drug. Given the side-effect liability of these agents, they are typically positioned after trials of both anticonvulsants and antidepressants.

N–Methyl–D–aspartate receptor blockers

Interactions at the *N*-methyl-D-aspartate (NMDA) receptor are involved in the development of central nervous system changes that may underlie chronic pain and modulate opioid mechanisms, specifically tolerance.[74] Antagonists at the NMDA receptor may offer another novel approach to the treatment of neuropathic pain in cancer patients.

An intravenous infusion of ketamine can be effective in relieving cancer pain[75*,76**] and reducing opioid requirements,[77**] and may be therefore be considered in patients with refractory pain. The side-effect profile of ketamine, which includes hypertension, tachycardia, and serious psychotomimetic effects (such as a dissociative reaction), can be daunting, however, particularly in medically frail patients. Typically, ketamine therapy is initiated at low doses given subcutaneously or intravenously, such as 0.1–0.15 mg/kg by brief infusion or 0.1–0.15 mg/kg per hour by continuous infusion. The dose can be gradually escalated, with close monitoring of pain and adverse effects. For patients with refractory pain and limited life expectancy, long-term therapy can be maintained using continuous subcutaneous infusion or repeated subcutaneous injections.[78,79*] Oral administration also has been used, but experience is more limited.[80*] The ratio of doses needed to maintain effects when converting from parenteral to oral dosing is uncertain. Based on anecdotal data, some authors have suggested a 1:1 ratio,[81*] or an oral dose equivalent to 30–40 percent of the parenteral dose.[82*] It is also recommended to lower the opioid dose when starting ketamine.[82*]

The anti-tussive dextromethorphan is an NMDA-receptor antagonist. Following surgery for bone malignancy, dextromethorphan was shown to augment analgesia and lessen analgesic requirements.[83,84**] Other studies and clinical experience have yielded mixed results. If prescribed, a prudent starting dose is 45–60 mg/day, which can be gradually escalated until favorable effects occur, adverse effects supervene, or a conventional maximal dose of 1 g is achieved.

Amantadine is a noncompetitive NMDA antagonist, and limited data suggest that it might reduce pain, allodynia, and hyperalgesia in chronic neuropathic pain[85,86**] and surgical neuropathic cancer pain.[87**] Currently available data are, however, too meager to support recommending its use. Memantine is an NMDA antagonist approved for the treatment of Alzheimer disease. Although a preliminary study of analgesic effects was encouraging,[88] controlled trials have been disappointing thus far.[89,90] New NMDA receptor antagonists are in development and may ultimately prove useful for a variety of medical indications. Advances in this area have occurred rapidly, and it is likely that the role of these agents in the management of pain will be much better defined within a few years.

Other systemic drugs

BACLOFEN

Baclofen, an agonist at the γ-aminobutyric acid type B (GABA$_B$) receptor, has established efficacy in trigeminal neuralgia[91***] and is often considered for a trial in any type of neuropathic pain. The effective dose range is very wide (20 mg/day to >200 mg/day orally), and titration from a low initial dose is necessary. The possibility of a serious

withdrawal syndrome on abrupt discontinuation must be avoided by a gradual dose taper.

CANNABINOIDS

Cannabinoids have antinociceptive effects in animal models and oral delta-9-tetrahydrocannabinol has been shown to be effective in cancer pain.[92**] Not all data are positive, however,[93] and more studies on the various cannabinoids are needed.

BENZODIAZEPINES

The evidence for analgesic effects from benzodiazepines is limited and conflicting, and overall provides little support for an analgesic activity of these drugs in neuropathic pain.[94,95]

PSYCHOSTIMULANTS

There is some evidence that psychostimulant drugs, including dextroamphetamine, methylphenidate and caffeine, have analgesic effects.[96***] Although pain is not considered a primary indication for these drugs, the potential for analgesic effects may influence the decision to institute a trial. In cancer patients, methylphenidate can also reduce opioid-induced somnolence, improve cognition, treat depression, and alleviate fatigue.[97**] The analgesic properties of the psychostimulants modafinil and atomoxetine have not yet been studied.

Topical analgesics

The development of a lidocaine 5 percent patch has facilitated the topical application of local anesthetics. This formulation has been shown to relieve pain from postherpetic neuralgia.[98**] Although never specifically studied in populations with advanced medical illness, clinical experience justifies a trial in diverse types of neuropathic pain and other types of focal pain problems. The patch is usually applied 12 hours per day, but a few studies indicate minimal systemic lidocaine absorption and a high level of safety with up to three patches for periods up to 24 hours.[99**] An adequate trial may require more than 1 week of applications. The most frequently reported adverse event is mild to moderate skin redness, rash, or irritation at the patch application site. EMLA®, an eutectic mixture of local anesthetics (prilocaine and lidocaine), can produce dense local cutaneous anesthesia but its use on large areas is limited by its fairly high cost. Topical lidocaine may be tried in various concentrations (up to a compounded formulation of 10 percent) as an alternative.

Capsaicin is the ingredient in chili pepper that produces its pungent taste. When applied topically, it causes the depolarization of C-fiber nociceptors and release of substance P. Regular use eventually leads to depletion of substance P from the terminals of these afferent C-fibers, potentially leading to decreased pain perception. In cancer patients, capsaicin

cream was shown to be effective in reducing neuropathic postsurgical pain (such as postmastectomy pain).[100**] There are two commercially available concentrations (0.025 percent and 0.075 percent), and an initial trial usually involves application of the higher concentration three to four times daily. A trial of several weeks is needed to adequately judge effects. Many patients experience severe burning pain after the first applications (related to the initial release of substance P), which usually decreases gradually over a few days if the cream is applied regularly. Some patients tolerate the lower concentration cream better, or tolerate application only if preceded by a topical local anesthetic or ingestion of an analgesic.

Because of its presumed peripheral action at both opioid and sodium-potassium channels, topical ketamine (gel, ointment, cream) might provide local analgesia of neuropathic pain without any systemic absorption. Scientific evidence is limited to small open-label trials and case series.[101,102*] One small randomized controlled trial reported that ketamine cream applied for 2 days did not provide any analgesia; however, a 1-week application of a combination cream of ketamine and amitriptyline decreased local pain intensity.[103**] One anecdotal report suggests that ketamine oral rinse might provide effective analgesia for radiation-therapy induced mucositis.[104]

Numerous anti-inflammatory drugs have been investigated for topical use in populations with neuropathic pain, with mixed results from small controlled trials.[105,106] The analgesic effects of these formulations for musculoskeletal pain are also unclear.[107,108]

ADJUVANT ANALGESICS SPECIFIC FOR BONE PAIN

Bone pain is a common problem in the palliative care setting. Radiation therapy is usually considered when bone pain is focal and poorly controlled with an opioid, or is associated with a lesion that appears prone to fracture on radiographic examination. Multifocal bone pain may benefit from treatment with an NSAID or a corticosteroid. Other adjuvant analgesics that are potentially useful in this setting include calcitonin, bisphosphonate compounds, and selected radiopharmaceuticals.

Calcitonin

Calcitonin may have several pain-related indications in the palliative care setting, including pain from bone metastases.[109–111**] It can be administered subcutaneously or intranasally. If subcutaneous boluses are used, they should be preceded by skin testing with 1 IU to screen for hypersensitivity reactions. The optimal dose is not known. The intranasal formulation avoids the need for subcutaneous injections, facilitating the use of this drug in home care. Apart from infrequent hypersensitivity reactions associated with subcutaneous injections, the main side effect is nausea. The likelihood and severity of this effect may be reduced by gradual escalation from a low starting dose. It usually subsides after a few days and is less frequent with the intranasal form.

Bisphosphonates

Bisphosphonates are analogs of inorganic pyrophosphate that inhibit osteoclast activity and, consequently, reduce bone resorption in a variety of illnesses. The analgesic efficacy of these compounds, particularly pamidronate, has been well established. Pamidronate has been extensively studied in populations with bone metastases.[112**] Its analgesic effects have been shown in breast cancer[113–115**] and multiple myeloma.[116**] The dose usually recommended is 60–90 mg intravenously (IV) (infused over 2–4 hours) every 3–4 weeks.[113] There are dose-dependent effects, and a poor response at 60 mg can be followed by a trial of 90 mg or 120 mg. The reduction of skeletal morbidity (pathological fractures, need for bone radiation or surgery, spinal cord compression, and hypercalcemia) is another incentive to use it as an adjuvant.[117,118**] Adverse effects, including hypocalcemia and a 'flulike syndrome, are dose related and typically transitory. Nephrotoxicity occurs rarely, usually following relatively rapid infusions, and typically is transitory; the drug can be used in those with impaired renal function, but renal function must be followed closely and the drug should be discontinued if deterioration occurs.

Zoledronic acid is a new bisphosphonate that is approximately two to three times more potent than pamidronate. It has been shown to reduce pain and the occurrence of skeletal-related events in breast cancer,[114,116,119**] prostate cancer,[120,121**] and multiple myeloma,[116**] as well as a variety of solid tumors, including lung cancer.[122**] It is as effective as pamidronate,[114,116**] and its use is more convenient, as it can be infused safely over 15 minutes at a dose of 4 mg every 3 weeks. The side effects are similar to those encountered with pamidronate, and the dose does not have to be adjusted in patients with mild-to-moderate renal failure.[123**]

Oral clodronate can reduce metastatic bone pain[124,125] but results are conflicting.[112] The main advantage of clodronate over pamidronate is its good oral bioavailability, which avoids the need for IV administration. An oral dose of 1600 mg daily seems to be optimal.[112] Clodronate is not available in the USA.

In a recent randomized controlled trial in patients with metastatic breast cancer, an intravenous infusion of 6 mg ibandronate every 3–4 weeks reduced bone pain, analgesic use and new bone events; the effects lasted for up to 2 years.[126**] Intravenous ibandronate administration of 6 mg for 3 consecutive days, repeated at 4-week intervals, provided relief from bone pain due to metastatic urological cancer.[127**] Oral ibandronate 50 mg daily decreased bone pain from metastatic breast cancer, starting at 6 weeks and

persisting up to 2 years; it also had a positive effect on analgesic use and quality of life.[128**]

Radiopharmaceuticals

Radionuclides that are absorbed at areas of high bone turnover have been evaluated as potential therapies for metastatic bone disease. Strontium-89 and samarium-153, which are commercially available in the USA, may be effective as monotherapy or as an adjunct to conventional radiation therapy.[129–132**] Given the potential for myelosuppression associated with their use, these drugs usually are considered when pain is refractory to other modalities and no further cytotoxic chemotherapy is planned.

ADJUVANT ANALGESICS USED FOR PAIN CAUSED BY BOWEL OBSTRUCTION

The management of symptoms associated with malignant bowel obstruction may be challenging. If surgical decompression is not feasible, the need to control pain and other obstructive symptoms, including distension, nausea and vomiting, becomes paramount.

Octreotide

The somatostatin analog octreotide inhibits the secretion of gastric, pancreatic, and intestinal secretions, and reduces gastrointestinal motility. These actions, which can occur more rapidly than similar effects produced by anticholinergic drugs,[133**] probably underlie the analgesia and other favorable outcomes that have been reported in case series[134*] and one randomized trial[135**] in patients with bowel obstruction. Octreotide has a good safety profile, and its considerable expense may be offset in some situations by the avoidance of the necessity of gastrointestinal drainage procedures.

Anticholinergic drugs

Anticholinergic drugs could theoretically relieve the symptoms of bowel obstruction by reducing propulsive and nonpropulsive gut motility and decreasing intraluminal secretions. Two small series demonstrated that a continuous infusion of hyoscine butylbromide (scopolamine) at a dose of 60 mg daily can control symptoms from nonoperable malignant bowel obstruction, including pain.[134,136*] Glycopyrrolate has a pharmacological profile similar to that of hyoscine butylbromide, but may produce fewer adverse effects because of a relatively low penetration through the blood–brain barrier; this drug, however, has not been systematically evaluated in a population with symptomatic bowel obstruction.

Corticosteroids

The symptoms associated with bowel obstruction may improve with corticosteroid therapy. The mode of action is unclear, and the most effective drug, dose, and dosing regimen are unknown. Dexamethasone has been used in a dose range of 8–60 mg/day,[137*] and methylprednisolone has been administered in a dose range of 30–50 mg/day.[138*] The potential for complications during long-term therapy, including an increased risk of bowel perforation,[139,140] may limit this approach to patients with short life expectancies.

COMBINATIONS OF ADJUVANT ANALGESICS

When treating a complex pain pathology in palliative care patients, clinicians often use a combination of several analgesics (opioid and nonopioid) and adjuvant analgesics (e.g. an anticonvulsant, an antidepressant, and a lidocaine patch). This approach offers the advantage of acting on different pain mechanisms (Table 46.2) and minimizes the adverse effects associated with a specific drug by using a lower dose.[68] Scientific data on the additive analgesic effects obtained by combining several adjuvant analgesics are minimal. One small randomized controlled trial suggested that adding lamotrigine to phenytoin or carbamazepine was beneficial.[53**] For nonmalignant neuropathic pain, a combination of gabapentin and long-acting morphine has recently been shown to provide better pain relief with lower doses than each drug used separately.[141] An open-label trial suggested that the addition of levetiracetam in patients who responded only partially to gabapentin provided synergistic relief.[65*] Finally, a case series described 11 patients with multiple sclerosis and trigeminal neuralgia who did not respond satisfactorily to phenytoin or carbamazepine and for whom the addition of low dose gabapentin (300–1200 mg/day) provided good pain control.[142*]

Due to this lack of scientific evidence, the optimal sequences for the administration of drug combinations are unknown. Drug selection is a trial-and-error process based on the clinical situation and the clinician's experience.[143***] In all cases, careful attention should be given to potential interactions between the medications used.

DRUG INTERACTIONS

The risk for adverse drug–drug interactions is inherent in the use of drug combinations to optimize clinical effects. The common pharmacokinetic and pharmacodynamic interactions, which have been reviewed elsewhere recently,[143,144] must be appreciated to minimize risk when selecting drugs and adjusting doses.

CONCLUSIONS

The scientific evidence on the utility of adjuvant analgesics in the treatment of pain that responds only partly to the administration of opioid analgesics has evolved substantially in the past few years. The development of new molecules with a better adverse effect profile has greatly facilitated their use. Ongoing clinical and translational research should further improve our knowledge and offer new therapeutic options. The data on the use of adjuvant analgesics in cancer and palliative care patients are still relatively scarce, and the clinician must rely on studies of populations with nonmalignant pain and clinical experience. Hopefully, research in this area will continue to evolve.

Key learning points

- Adjuvant analgesics are drugs initially developed for an indication other than pain, but with analgesic properties in some painful conditions.

- Adjuvant analgesics can be classified as multipurpose nonspecific (e.g. antidepressants, ∴ α_2-adrenergic agonists, corticosteroids), specific for neuropathic pain (anticonvulsants, local anesthetics, NMDA antagonists), specific for bone pain (corticosteroids, calcitonin, bisphosphonates, radiopharmaceuticals) and specific for pain from bowel obstruction (octreotide, scopolamine, glycopyrrolate).

- In the treatment of pain in populations with advanced medical illness, adjuvant analgesics can be useful for pain that is only partly responsive to opioids and should usually be used in combination with an opioid regimen.

- The evidence on the use of most adjuvant analgesics for the treatment of pain due to advanced illness is often limited, and selection of the most appropriate adjuvant analgesic should be based on literature from nonmalignant pain and clinical experience.

- The adjuvant analgesics with the most favorable benefit:risk ratio should be used as first-line therapy.

Alternative routes for systemic opioid delivery

CARLA RIPAMONTI, MAURO BIANCHI

INTRODUCTION

It is well recognized that oral administration of the opioid drugs is the mainstay of analgesic therapy in cancer patients. Indeed, it is safe, effective, and convenient. Moreover, the oral route for drugs makes home management more simple. However, in some clinical situations such as severe vomiting, bowel obstruction, severe dysphagia, or severe confusion, and in situations where rapid dose escalation is necessary, oral administration of opioids is impossible and an alternative route has to be implemented.

Recent data suggest that 53–70 percent of patients with cancer-related pain require an alternative route for opioid administration hours and months before death.[1,2*] In the last few years, a number of modes for opioid administration have been explored. Bruera suggested that our ability to deliver opioids safely using alternative routes is the single most important development in home management of cancer pain.[3] This chapter deals with the characteristics, the main aspects of pharmacokinetics, the clinical efficacy and indications of the following routes: rectal, sublingual, buccal (gingival, transmucosal), subcutaneous, intravenous, intranasal, and transdermal.

Table 47.1 shows the potential clinical applications of the above mentioned routes of opioid administration. Box 47.1 gives the recommendations of the European Association for Palliative Care (EAPC) regarding the different routes of opioid administration.[4]

Table 47.1 *Potential applications of alternative routes for systemic opioid administration*

Box 47.1 Opioid administration according to the EAPC recommendations[4]

- A small proportion of patients develop intolerable adverse effects with oral morphine (in conjunction with a nonopioid and adjuvant analgesic as appropriate) before achieving adequate pain relief. In such patients a change to an alternative opioid or a change in the route of administration should be considered.

- If patients are unable to take morphine orally the preferred alternative route is subcutaneous. There is generally no indication for giving morphine intramuscularly for chronic cancer pain because subcutaneous administration is simpler and less painful.

- The average relative potency ratio of oral morphine to subcutaneous morphine is between 1:2 and 1:3 (i.e. 20–30 mg of morphine by mouth is equianalgesic to 10 mg by subcutaneous injection).

- In patients requiring continuous parenteral morphine, the preferred method of administration is by subcutaneous infusion.

- Intravenous infusion of morphine may be preferred in patients:

   (a) who already have an indwelling intravenous line

   (b) with generalized edema

   (c) who develop erythema, soreness or sterile abscesses with subcutaneous administration

   (d) with coagulation disorders

   (e) with poor peripheral circulation.

- The average relative potency ratio of oral to intravenous morphine is between 1:2 and 1:3.

- Rectal administration may be preferred by some patients. The equianalgesic dose by oral and rectal routes is about 1:1.

- The buccal, sublingual, and nebulized routes of administration of morphine are not recommended because at the present time there is no evidence of clinical advantage over the conventional routes.

- Oral transmucosal fentanyl citrate (OTFC) is an effective treatment for 'breakthrough pain' in patients stabilized on regular oral morphine or an alternative step 3 opioid.

- Transdermal fentanyl is an effective alternative to oral morphine but is best reserved for patients whose opioid requirements are stable. It may have particular advantages for such patients if they are unable to take oral morphine, as an alternative to subcutaneous infusion.

- Spinal (epidural or intrathecal) administration of opioid analgesics in combination with local anesthetics or clonidine should be considered in patients who derive inadequate analgesia or suffer intolerable adverse effects despite the optimal use of systemic opioids and nonopioids.

RECTAL ROUTE

The surface area of the human rectum is small (200–400 cm^2) because of the absence of villi. Its fluid contents have a pH of 7–8. The main mechanism of absorption from the rectum is passive diffusion and is probably no different from that in the upper part of the gastrointestinal tract despite the fact that pH, surface area, and fluid content differs substantially.[5] The rectum is drained by the superior rectal vein into the portal system and by the middle and inferior rectal veins into the inferior cava vein. It is impossible to predict the quantity of drug that will bypass the hepatic filter, because there are several extensive anastomoses between the superior rectal vein

that drains to the portal system and the median and inferior rectal veins that drain towards the systemic circulation.[5,6] Rectal drug vehicles may be liquid or solid.[5–7] The absorption of aqueous and alcoholic solutions may occur very rapidly but the absorption of suppositories is generally slower and very much dependent on the nature of the suppository base, the use of surfactants, and other factors such as the presence/absence/quantity of fecal mass and the total volume content inside the rectum. Although an almost complete absence of presystemic metabolism has been found for intrarectal lidocaine in humans, several other drugs have been found to metabolize equal to or more than orally when administered intrarectally.[5] Davis et al.[7] reviewed the

clinical, pharmacologic, and therapeutic role of suppositories and rectal suspension of opioids and other analgesics.

Bioavailability studies have shown considerable interindividual variation.[5–7] Johnson et al.[8] found that after 24 hours of rectal and intravenous (IV) administration of 10 mg of morphine chloride in eight patients, the bioavailability of morphine after rectal administration was 53 ± 18 percent of the values obtained after IV administration. The authors conclude that probably first-passage elimination of morphine was partially avoided by the rectal administration since a previous study suggested that the bioavailability of oral morphine is 37 percent.[9] The bioavailability of free morphine and morphine-6-glucuronide (M6G) was found to be comparable after oral, sublabial and rectal administration of morphine in cancer patients.[10–12]

In a comparative study[13] between 10 mg of morphine sulphate in oral solution and rectal suppository carried out in 10 patients with cancer pain, a significantly higher mean concentration of free morphine was found after rectal administration at all evaluation times throughout a period of 4.5 hours, whereas there were no differences between the routes in mean morphine-3-glucuronide (M3G) concentrations. These data suggest the presence of some avoidance of first-pass metabolism. Moolenar et al.[14] studied the rectal absorption of morphine hydrochloride from different aqueous solutions with different pH values in seven volunteers. The rectal absorption of morphine appeared to be dependent on the pH of the solution: a significant improvement in the absorption was found with a rectal solution adjusted to pH 7–8. Kaiko et al.[15] carried out a randomized crossover multiple-dose study in 14 healthy men to compare the bioavailability of 30 mg of morphine sulfate tablets (MS Contin) administered orally and rectally. There was no significant difference in morphine absorption between the two methods of administration. At 24 hours the area under the curve for the rectal treatment group was 90 percent of that of the oral group. However, the rectally administered slow-release morphine tablet was associated with an attenuated maximum morphine concentration level. Furthermore, the highest plasma morphine concentrations occurred significantly later, delayed from 2.46 hours after oral ingestion to 5.38 hours after rectal administration. The results suggest that there is a slower rate of absorption for MS Contin administered rectally than when given orally. Rectal administration of drugs can be used to produce local or systemic effects. In some countries, preparations of opioids in the form of suppositories are not commercially available. To overcome this situation, microenemas made up of liquid opioid (the same used for parenteral administration) are prepared and then given rectally as a bolus using a needleless insulin-type syringe with the advantage of a rapid absorption.

Most of the cancer pain treatment studies are of the non-controlled type. Brumley[16] treated 30 patients with cancer pain who had good pain control on oral morphine tablets with an equianalgesic dose of the same tablets inserted rectally in two gelatin capsules. Up to six tablets were inserted into each gelatin capsule and several patients required the use of several gelatin capsules at the same time. The capsules were administered every 4 hours regularly. The authors report that 26 out of 30 patients required no further titration of dose for effective pain control. The highest dose was 330 mg every 4 hours in one patient. The homemade morphine sulfate suppositories were found to be much more economical and better tolerated by patients than the commercially prepared suppositories. Maloney et al.[17] reviewed the experience with 39 terminally ill patients who received slow-release morphine as a rectal suppository. All patients had terminal cancer and 38 patients were receiving oral slow-release morphine before starting the rectal administration. Good pain control was reported in all cases. In two patients the slow-release morphine tablets were administered into a colostomy and in one case a female patient with diarrhea received the tablets intravaginally. No local side effects using the standard commercial preparation of 30 mg tablets were reported. Patients were treated for an average of 11.5 days (range 1–30 days).

Long-term rectal administration of high-dose sustained-release morphine tablets was reported by Walsh et al.[18] Based on this case, the correct milligram relative potency conversion ratio for rectal to IV morphine during repeated dosing appears to be 3:1, which is similar to that for the conversion from oral to IV. For rectal to oral morphine dosing the conversion ratio seems to be 1.1. Table 47.2 presents the randomized controlled trials (RCTs) on rectal morphine compared with oral or subcutaneous morphine.[19–22**]

Few data are available on the analgesia and tolerability of rectally administered methadone. A study[23] was carried out to assess the pharmacokinetics and pharmacodynamics of 10 mg of methadone hydrochloride administered rectally (in the form of microenema) in six opioid-naïve cancer patients whose pain no longer responded to treatment with non-steroidal anti-inflammatory drugs (NSAIDs) given at fixed times. The pharmacokinetics of rectal methadone showed rapid and extensive distribution phases followed by a slow elimination phase. The plasma concentrations presented a great intraindividual variability, with no correlation between analgesia and plasma methadone concentration. Pain relief was statistically significant already after 30 minutes and continued more than 8 hours after administration. In five patients pain control lasted between 24 and 48 hours. Only one patient reported vomiting, confusion and vertigo after the administration of rectal methadone.

In a prospective, open study, Bruera et al.[24] demonstrated that custom-made capsules and suppositories of methadone were safe, effective, and low cost in 37 advanced cancer patients with poor pain control receiving high doses of subcutaneous hydromorphone. These patients had significant improvement in pain control with minimal toxicity, using doses higher than those reported in the literature. This study also demonstrated a large interindividual variation between methadone dosage and plasma level. Rectal methadone can be considered an effective, safe, and low cost therapy for

Table 47.2 *Randomized controlled trials on rectal morphine compared with oral or subcutaneous morphine*

Study	Study design	No. of patients	Route 1	Route 2	Results
Bruera et al.[19]	Double blind, crossover	23	CR morphine sulfate suppository every 12 hours	SC morphine Rectal/parenteral ratio 2.5:1	Comparable analgesia and side effects
Babul et al.[20]	Double blind, crossover	27	CR morphine suppository every 12 hours	CR morphine tablets every 12 hours Conversion rate 1:1	No difference in pain and sedation; small but significant difference in nausea in favor of rectal administration
De Conno et al.[21]	Double blind, double dummy, crossover, single dose study	34 opioid-naive	Rectal morphine prepared as microenema	Oral morphine Conversion rate 1:1	Rectal morphine had a faster onset of action and longer duration of analgesia than an acute dose of oral morphine No significant difference in intensity of sedation, nausea, or number of vomiting episodes between the two routes
Bruera et al.[22]	Randomized, double blind crossover	126 evaluable	CR morphine sulfate suppository every 12 hours	CR morphine sulfate suppository every 24 hours	There was no significant difference between the q12h and q24h treatment groups in symptom (pain, nausea, sedation) intensity, adverse effects, patient choice

SC, subcutaneous; CSI, continuous subcutaneous infusion; CR, controlled release; IV, intravenous; q, every.

patients with cancer pain where oral and/or parenteral opioids are not indicated or available.

Oxycodone pectinate suppositories are available in countries such as the UK and need to be given every 8 hours. The single-dose pharmacokinetics and pharmacodynamics of oxycodone administered by intravenous and rectal routes were determined in 12 cancer patients. Intravenous oxycodone was associated with a rapid onset of analgesia (5–8 minutes) with respect to rectal route (0.5–1 hours) but with a shorter analgesic effect (4 hours via IV route compared with 8–12 hours via rectal route).[25] In a controlled clinical trial rectal administration of tramadol was as effective as oral tramadol in relieving cancer-related pain.[26**]

The colostomy administration route of opioids is not recommended. The results of the study of Hojsted et al.[27] comparing the pharmacokinetics of hydrochloride morphine administered via rectal and colostomic routes demonstrated that the bioavailability via colostomy showed a very wide variation, but the mean value as compared to rectal administration was 43 percent (range 0–127 percent). The authors suspect that the main reason for lower bioavailability may be poor vascularization of the colostomy, adsorption of morphine to feces, and the presence of first-passage elimination. Anecdotal reports of rectal administration of controlled-release morphine suggest

that these routes may be used for patients unable to take oral medications.

The rectal route of drug administration may present some disadvantages when used long term and when feces or diarrhea is present. This alternative route can be used successfully in patients with breakthrough pain (defined as transient flares of severe or excruciating pain in patients already managed with analgesics) and in some clinical situations as shown in Table 47.1. Compared with the subcutaneous and IV routes, the rectal route has the advantage of not requiring needles to be inserted or pumps to be carried. On the negative side, chronic and frequent rectal administration can lead to discomfort, and the presence of feces in the rectum, diarrhea, or normal peristalsis can reduce absorption.

There are some barriers to the development of rectally administered drugs. Sometimes physicians, caregivers, and patients find this route unappealing.

SUBLINGUAL AND BUCCAL ROUTES

The mouth has many areas with a potential for transmucosal administration: sublingual (beneath the tongue) and

buccal (between the gingival edge of the upper molars and the cheek). The permeability is greatest in the sublingual area and lowest at the gingival level. The surface of the buccal and sublingual area is small (200 cm^2) with a pH of 6.2–7.4. However, this region is rich in blood and lymphatic vessels and the possibility exists for rapid absorption with direct passage into the systemic circulation avoiding the hepatic first-pass metabolism.[5]

The conditions for the penetration of the drug improve with the smallness of molecules, a high concentration of nonionized drug, and a high degree of lipophilia. Thus, the amount of drug absorbed will depend on several factors including the pK_a, rate of partition of the nonionized form of the drug, the lipid/water partition coefficient, molecular weight of the drug, passive diffusion, and the pH of the solution in the mouth. Lipophilic drugs such as buprenorphine, fentanyl, and methadone are better absorbed than polar ones.[28] Studies on the buccal absorption of morphine report different results.[5,6]

The preferred preparation is the tablet form rather than liquids and pastes, which can spread all over the mouth and consequently increase the possibility of swallowing the drug. Saliva affects the absorption of the drug by dilution and by increasing the likelihood of the drug being swallowed before absorption.

Buprenorphine is the only commercial opioid formulated in a sublingual preparation. Single dose crossover studies have shown it to be 15 times as potent as morphine in terms of total analgesic effect.[29] The absorption half-life of sublingual buprenorphine is about 76 minutes, and peak plasma concentrations range from 20 to 360 minutes (mean 180 minutes) after administration, although there is a large intersubject variability.[30] A dose of 0.4 mg sublingually gives similar analgesia to 0.2–0.3 mg intramuscularly (IM), with an onset of analgesia within 30–60 minutes of administration and a duration of 6–9 hours.[31] The long duration of analgesia with buprenorphine may be related to its affinity for the μ-opioid receptor and an unusually slow dissociation constant for the drug-receptor complex.

Robbie[32] treated 141 cancer patients with sublingual buprenorphine in doses of 0.15–0.8 mg for an average of 12 weeks. This treatment was effective in most of the patients, particularly those with pain from head and neck cancer. Drowsiness was the most common side effect (seen in 22 patients maintained on sublingual buprenorphine), but dry mouth and nausea also occurred. De Conno et al.[33] found that patients previously treated with sublingual or IM buprenorphine required a dose of morphine significantly higher than those treated with other opioids (codeine, oxycodone, dextropropoxyphene, pentazocine) to obtain the same pain relief. Like the mixed agonist–antagonists, buprenorphine may precipitate withdrawal in patients who have received repeated doses of a morphine-like agonist and developed physical dependence. Naloxone is relatively ineffective in reversing serious respiratory depression caused by buprenorphine.[34]

There is still some controversy on the efficacy of sublingual morphine[35] because of the lack of controlled clinical studies. The few reports on the clinical effects of sublingual and buccal morphine are related to one-time dosage or anecdotal experience. Whitman et al.[36] report that 70–80 percent of 150 patients with cancer pain who were treated with sublingual morphine obtained 'adequate to good pain control'. Patients were treated with morphine sulfate tablets in a dose of 10–30 mg every 3–4 hours around the clock. The main side effects reported were intolerance to the taste of the drug and occasional confusion or unpleasant dreams. Pannuti et al.[12] treated 28 patients with cancer pain with sublingual drops of morphine hydrochloride every 4 hours. Patients were treated for an average of 5 weeks. Although the authors reported more rapid and significant pain remission for the sublingual route as compared to the rectal and oral route, no significant difference in the incidence or severity of side effects were reported. No patient required discontinuation of sublingual treatment because of toxicity.

The effects of sublingual fentanyl citrate (SLFC) were assessed in 11 hospice inpatients with cancer-related breakthrough pain.[37] SLFC was started at 25 μg (using parenteral formulation of 50 μg/mL) and the dose was progressively increased by 25 μg till pain was controlled. The maximum dose used was 150 μg as volumes greater than 3 mL were difficult to retain sublingually. Fifty-five percent of patients reported pain reduction after 10 minutes and 82 percent after 15 minutes. Ratings for SLFC were very good (18 percent), good (36 percent), moderate (28 percent), and bad (18 percent). Compared to the usual breakthrough medication (mostly normal release morphine), SLFC was better (46 percent), the same (36 percent), or worse (18 percent). No systemic adverse effects were reported. SLFC may be an option for patients unable to tolerate oral morphine in treating breakthrough pain.

Sublingual sufentanil at a dosage of 25 μg every 3 minutes × 3 doses, produced pain relief with minimal sedation in one patient previously treated with oral morphine and with sublingual fentanyl.[38] Sufentanil 25 μg is approximately equianalgesic to 70–100 mg sublingual morphine, whereas 50 μg sublingual fentanyl is equianalgesic to about 7–10 mg sublingual morphine.[39]

Oral transmucosal fentanyl citrate (OTFC) is a synthetic opioid agonist manufactured in a matrix of sucrose and liquid glucose base and fitted onto a radiopaque plastic handle. It is a drug delivery formulation used for management of breakthrough cancer pain. Doses are available in six different strengths (200 μg, 400 μg, 600 μg, 800 μg, 1200 μg, and 1600 μg). Absorption is via the oral mucosa. Administration of a drug through this route avoids the first-pass effect, and allows easy and rapid dose titration. From the pharmacokinetic point of view, OTFC is similar to IM and IV fentanyl, whereas the plasma concentrations are double in respect to oral fentanyl and are reached 86 minutes before.[40,41] Peak effect occurs in about 20 minutes. Approximately 25 percent

of the dose of fentanyl goes directly into the bloodstream through mucosal absorption and accounts for 50 percent of the dose that reaches the plasma. Total bioavailability is approximately 50 percent as duration of action ranges from 2.5 to 5 hours. The onset of analgesic effect is obtained within 5 to 15 minutes,[42] in contrast to the 30–60 minutes with normal-release oral opioids. Seventy-six percent of patients with incident and breakthrough pain have experienced favorable results.[43]

In a multicenter, randomized, double-blind, placebo-controlled trial of OTFC for cancer-related breakthrough pain carried out by Farrar et al.,[44**] OTFC produced significantly larger changes in pain intensity and better pain relief than placebo. In another controlled dose titration study[45**] in cancer patients treated with OTFC, 74 percent of them were successfully titrated. Moreover, OTFC provided significantly greater analgesic effect at 15, 30, and 60 minutes, and a more rapid onset of effect, than the usual rescue drug. There was no relation between the total daily dose of the fixed schedule opioid regimen and the dose of OTFC required to manage breakthrough pain. As the optimal dose cannot be predicted, treatment should begin with a dose of 200 μg and increased at 15 minutes intervals. It emerged from controlled and uncontrolled studies that the adverse effects of the OTFC were similar to other opioids and very few adverse events were severe or serious.

In a double-blind, double-dummy, randomized, multiple crossover study, Coluzzi et al.[46**] compared OTFC and immediate-release morphine sulfate for management of breakthrough pain in 134 outpatients receiving a fixed scheduled opioid regimen equivalent to 60–1000 mg/day oral morphine or 50–300 μg/h transdermal fentanyl. Sixty-nine percent of patients (93/134) found a successful dose of OTFC and it was more effective than immediate-release oral morphine in treating breakthrough pain. In an open-label study,[47] OTFC was also shown to be safe and effective during long-term treatment of breakthrough pain in cancer patients cared for at home.

OTFC is approved the US Food and Drug Administration (FDA) solely for the management of breakthrough pain in opioid-tolerant cancer patients.[48] It is not recommended for treating acute and or postoperative pain. Future studies are required in order to establish the OTFC dose to be used as rescue dose in patients with breakthrough pain in respect to type and dose of opioid taken by the patient.

SUBCUTANEOUS ROUTE

The rate of absorption of a drug strongly depends on the blood flow to the site of absorption. In normal conditions, the perfusion of subcutaneous tissue is similar to that of muscles. However, the rate of absorption is slower. The main factors determining the subcutaneous absorption are the solubility of the drug, the site of the injection, the surface exposed, the blood pressure, the presence of cutaneous vasoconstriction, edema, or inflammatory processes.

Subcutaneous opioid administration can be intermittent or continuous. Intermittent injection may represent a valid option in some circumstances.[49] However, it can be associated with a 'bolus effect' characterized by acute toxicity and a brief analgesic effect. Moreover, because of the short duration of action of most opioids, injections need to be repeated frequently, usually at intervals of 4 hours or less. In palliative medicine, the results of this method are undesirable because it is painful for the patient, time consuming for the caregivers, and difficult to maintain in the home setting. Therefore, continuous subcutaneous infusion (CSI) is recommended. A recent review demonstrated that CSI is effective and safe for use in terminal illness.[50] Consistently with this evidence, it is gradually becoming a standard practice in palliative medicine.
