The subcutaneous route can also be used for patient-controlled analgesia (PCA) using portable pumps.[51] PCA is a relatively new technique for managing pain in which patients are able to self-administer small doses of opioid analgesic when needed. This technique offers an alternative to traditional regimens and was developed in response to the under-treatment of pain in hospitalized patients. A number of uncontrolled and controlled trials have confirmed the safety and efficacy of PCA for postoperative pain in adults[51] as well as in children ranging from 5 to 15 years.[51] PCA is a very specific way of prescribing 'as needed' analgesics because all parameters such as route, drug concentration, dose, frequency, and maximum daily or hourly dose are actually prescribed by the physician, but the patient decides whether or not they should take a dose. The decision is not subject to external judgment and the administration is not slowed down by the intervention of the nurse or the doctor. A large variety of pumps are available for PCA. Most of them consist of a drug reservoir and an injection or infusion system, either manually or electronically operated. PCA devices permit the patient to choose an intermittent (demand) bolus, continuous infusion, or both intermittent, and continuous modes of administration. A continuous infusion plus an intermittent bolus dose allow patients to maintain a baseline level of opioid administration plus additional doses for breakthrough pain. The device can be used to deliver the drug through continuous intravenous, epidural, subcutaneous infusions. Whenever the patient feels that pain relief is necessary, he or she can activate the system by pressing a button. The unit dispenses an amount of analgesic that has been programmed by the physician. In some devices, unauthorized alteration of dose parameters is excluded by a number of safety factors. A lock-out time is available to prevent overdosage. Other simpler and less expensive devices do not contain a lock-out system. Although a lock-out system may be desirable for patients with confusion and/or a history of addiction, it is important to consider that oral prescriptions contain no lock-out mechanisms. The indications and contraindications for PCA are given in Box 47.2.

Box 47.2 Indications and contraindications for PCA

Indications

- Incident pain
- Circadian variation of pain intensity
- Patients with reduced 'therapeutic window'
- Renal failure
- Drugs with an unpredictable half-life (methadone)
- Patients who have a need to maintain control over their life (high locus of control)
- Patients who have an extreme fear of side effects

Contraindications

- Severe alcoholism
- History of drug addiction
- Cognitive failure
- Lack of knowledge and skill to use the technique safely and effectively

This is a well-known therapeutic strategy in analgesia. Many different portable pumps or nonportable devices are available for CSI, including a syringe pump, disposable plastic cylinder, and battery-operated computer-driven pumps. It is important to select the most suitable solution for each patient. The disadvantages of these devices are their cost and complexity. Simpler and less expensive devices should be developed in order to decrease the cost and increase the comfort of patients, families, and nurses. The most common problems that can occur with PCA systems are listed in Box 47.3. Subcutaneous PCA is particularly suitable also for the treatment of several types of postoperative pain.[52,53] This method is contraindicated in patients with coagulation disorders, cognitive failure or with a history of substance abuse.

Box 47.3 Most common problems with PCA

Operator errors

- Misprogramming of PCA device
- Failure to clamp or unclamp tubing
- Improper loading of syringe
- Failure to respond to safety alarm
- Misplacing pump key

Patient errors

- Poor understanding of PCA therapy
- Poor understanding of how to use PCA pump device

Mechanical problems

- Failure to deliver on demand
- Cracked drug vials or syringes
- Defective valves
- Faulty alarm system
- Malfunctions (e.g. lock-out feature)

Most studies of subcutaneous opioid administration have used morphine or hydromorphone. These drugs have short half-lives and hence reach the steady state rapidly. It has been reported that the blood levels of morphine during CSI are similar to those reached during continuous intravenous infusion.[54] Another study in healthy volunteers provided different results, indicating that the bioavailabilities of morphine and of its main metabolites (M6G and M3G) are significantly lower after subcutaneous than after IV administration. Despite this observation, the authors concluded that the subcutaneous route is an effective method for the systemic administration of morphine.[55] No clear differences seem to exist between subcutaneous morphine and hydromorphone from both the pharmacokinetic and the pharmacodynamic points of view.[56**,57**]

Drugs with longer half-lives, such as methadone, have also been evaluated. In most patients, CSI of methadone produced signs of local toxicity (specifically erythema and induration). Such a toxicity is manageable by changing the position of the needle and infusing dexamethasone concurrently with the methadone.[58,59] In general a 25 or 27 gauge butterfly needle inserted in the anterior chest or abdomen is recommended for infusion. The subcutaneous route, with special reference to SCI, should be considered as the standard alternative route for systemic opioid delivery.

INTRAVENOUS ROUTE

Intravenous administration of opioids permits complete systemic absorption, and produces rapid analgesia that is correlated to lipidic solubility (10–15 minutes for morphine, 2–5 minutes for methadone) but is of short duration. This makes it necessary to repeat infusions at least every 4 hours. Thus, this route of administration is painful for the patient, time-consuming for the nursing staff, and difficult to carry out in the home setting. Bolus administration can be substituted by continuous intravenous infusion (CIVI) using a pump. This is common among hospitalized cancer patients, above all in

those with central venous catheters. Continuous intravenous infusion of opioids has been reported to be effective and safe in managing cancer pain in patients who are less responsive to analgesics administered at the maximum tolerated dose by other routes.[60,61] Patient-controlled analgesia is also possible by the IV route.[51]

The most frequently used drugs are short-acting opioid agonists such as morphine, hydromorphone, and fentanyl.[51,62**] Because these drugs have a short half-life, the risk of delayed toxicity due to gradually increasing their plasmatic levels will be less likely than with drugs having longer half-lives such as methadone or levorphanol. In the largest series reported to date, 117 consecutive cancer patients were treated with morphine (93 percent) or hydromorphone (7 percent) administered subcutaneously (87 percent) or IV (13 percent) with a PCA bolus set at 25 percent of the hourly infusion rate for breakthrough pain.[63] The mean duration of treatment was 23 days; 69 percent of patients were cared for at home, and the remaining patients were treated in an inpatient hospice. Most of the patients remained on PCA until death. After the initiation of PCA, 95 percent of patients achieved pain relief. Significant variability in opioid consumption was reported; the dose of morphine used ranged from 1 mg/h to 33 mg/h in the subcutaneous group and from 2 mg/h to 180 mg/h in the IV group. Complications developed in two patients (infection at the subcutaneous site in one patient and respiratory arrest within 24 hours of starting PCA in the other). The authors report that patients using the subcutaneous route who then required more than 40–50 mg/h were switched to the IV route. PCA has been successfully used in patients presenting severe oral pain due to mucositis who required systemically administered opioid medication.[51]

Over a certain period of time, some patients develop analgesic tolerance to this type of regimen, requiring frequent dose escalation. As noted above, if lower doses of opioid reduce psychological distress, one might rely on PCA alone during the day and a combination of PCA and continuous infusion during the night. Thus, these two modes of delivering PCA can be used together. Patient-controlled analgesia should be monitored by assessing the patient's respiratory rate and mental status with adequate modification of the opioid dosages if there is a decrease of the respiratory rate or hypoxemia or somnolence occur. Although morphine is the drug of choice, clinical experience has shown that other drugs, such as methadone, hydromorphone, and fentanyl, can also be used successfully.[61,64,65]

The choice of a drug for CIVI depends on the previous antalgic treatment and on the pharmacokinetic profile of the drug employed. A patient who reports good analgesia with a particular opioid but presents adverse effects to a bolus administration (plasma peak toxicity or pain during the reduction of the plasma concentration) is a suitable candidate for CIVI with the same drug. On the other hand, if the patient presents adverse effects at plasma peak and also reports poor or the absence of analgesia, the CIVI must be initiated with a different opioid. In choosing an analgesic drug, its half-life is by far the most important pharmacokinetic factor. For this reason morphine and hydromorphone, both having short half-lives, are the preferred infusion drugs. With the use of long half-life medication such as methadone, the delay to steady-state may result in the slow onset of analgesia when CIVI is increased or in the late appearance of toxicity developing after analgesia appears.

The opioid dosage at the beginning of treatment depends on the patient's pharmacological intake. Patients being treated with repeated parenteral doses can switch to CIVI with the same drug using the same daily dosage, whereas the administration of a different opioid would require a dosage reduction of between half to two-thirds.

Portenoy et al.[61] reviewed the clinical experience of 36 patients who received CIVI. Mean doses during CIVI were equivalent to maximum morphine initial doses of 17 mg/h (range 0.7–100), with maximum doses reaching 69 mg/h (range 4–480) and 52 mg/h (range 1–480) at the end of the treatment. Pain relief was acceptable in 28 CIVIs, unacceptable in 17, and unknown in one. The most important side effects, beginning or progressing during the CIVIs, were sedation, confusion, constipation and myoclonus. This review suggests that CIVI is safe, that analgesia may require rapid dose escalation, and that although not all the patients experienced acceptable analgesia, failure of CIVI with one medication because of incomplete cross-tolerance could be followed by effective analgesia obtained with a different opioid. In a case report[66] hydromorphone administered via CIVI and then orally was able to abolish itching present during IV morphine administration. Oral and IV oxycodone were compared in a single-dose study.[67] Although IV oxycodone produced a faster onset of pain relief, the duration of analgesia was about 4 hours with both routes of oxycodone administration; IV oxycodone produced significantly more adverse effects.

The pharmacokinetics of IV methadone showed rapid and extensive distribution phases followed by a slow elimination phase.[68] Manfredi et al.[69] described the dramatic beneficial effects of IV methadone in four patients in whom IV morphine and hydromorphone failed to produce adequate pain relief despite titration to dose-limiting side effects. All the patients had long-lasting pain relief without significant side effects at a methadone dose equal to 20 percent of the hydromorphone dose. Fitzgibbon et al.[70] described the successful use of large doses of IV methadone administered by PCA and continuous infusion for pain refractory to large doses of IV morphine. Morphine was stopped, and treatment with methadone via PCA was initiated (incremental dose 10 mg every 6 minutes) with a continuous infusion of methadone at a rate of 40 mg/h. On day 3, methadone was decreased to 200 mg with a good pain management and no adverse effects. The patient was discharged after 5 days with a dose of 220 mg/day (average daily methadone was approximately 1/10 that of morphine). After 6 weeks the dose was

methadone).[65] Self-administered bolus doses of IV methadone equal to 50–100 percent of the hourly infusion rate were allowed every 20 minutes and additional boluses of 100–200 percent of the hourly infusion rate every 60 minutes. To control pain, there was a 10 percent increase in the median hourly infusion dose of methadone from day 1 (64.45 mg) to day 2; after day 2 the median hourly infusion dose of methadone was the same and decreased to 54 mg on day 4.

Numerous medications prolong the rate-corrected QT (QTc) interval and induce arrhythmias by blocking ionic current through cardiac potassium channels composed of subunits expressed by the human ether-a-go-go-related gene (*HERG*). Recent reports suggest that high doses of

methadone cause *torsades de pointes*.[71] Kornick *et al.*[72] found that methadone in combination with chlorobutanol (the preservative present in the formulation of parenteral methadone) is associated with QTc interval prolongation.

Even if the titration with strong opioids is routinely performed using immediate-release oral morphine every 4 hours, there are some clinical situation such as severe pain where pain relief has to be achieved as quickly as possible. Tables 47.3[73,74,75**] and 47.4[76,77] present the studies reporting 'fast titration' resulting in rapid pain relief of moderate to severe pain in cancer patients treated with bolus doses of intravenous morphine or fentanyl and then switched to oral morphine or transdermal fentanyl. These authors have shown that 'fast titration' with IV opioids is effective and safe.

At the Memorial Sloan–Kettering Cancer Center in New York the patients on transdermal fentanyl presenting severe episodes of pain are switched (transdermal therapeutic system [TTS] removed) to CIVI of fentanyl using a transdermal:IV conversion of 1:1.[78] PCA IV fentanyl is used to administer rescue on demand doses (50–100 percent of the CIVI rate). Relief of pain without serious adverse effects is reported.[78] Continuous parenteral (subcutaneous or intravenous) opioids have been shown to improve analgesia and tolerability in 71 percent of cancer patients previously treated with oral opioids (codeine, tramadol, morphine, methadone) or with transdermal fentanyl. On the basis of this study, parenteral opioids may be considered a good alternative to spinal opioids.[79]

Continuous intravenous infusion of opioids in cancer-related pain is specifically indicated in cases of generalized edema, coagulation disorders, increased frequency of subcutaneous local site infections, reduced peripheral circulation, when frequent IM or IV injections are required to maintain pain control, in the presence of prominent 'bolus effects' on repetitive injection and when rapid titration of drug doses is required to produce rapid pain relief.

Opioid administration through CIVI can be carried out via central venous catheters, however, these catheters are expensive and need to be surgically implanted and require considerable nursing expertise and/or teaching the patient's family. For these reasons CIVI should be considered only for patients with an implanted catheter and for patients who present bleeding diathesis or diminished muscle mass who develop intractable vomiting, bowel obstruction, or malabsorption.

INTRANASAL ROUTE

The nasal administration of opioids has been widely investigated in recent years. This route offers the advantage of more rapid drug absorption and onset of pain relief compared with oral dosing. This is due to the large surface area, porous endothelial membrane, high total blood flow, the avoidance of first-pass metabolism, and ready accessibility.[80] Pharmacokinetic data in volunteers are reported for fentanyl, alfentanil, sufentanil, butorphanol, oxycodone, morphine, diamorphine, hydromorphone, methadone, heroin, and buprenorphine.[80–85] From a clinical point of view, patient-controlled intranasal (PCIN) fentanyl has been compared with oral morphine for procedural wound care in patients with burns.[86**] It has been observed that PCIN fentanyl is similar in efficacy and safety to oral morphine. A rapid onset of analgesia and potential clinical utility for the treatment of postoperative pain have been suggested for a formulation of nasal fentanyl spray.[87]

Jackson et al.[88] reported the experience of the first seven applications of intranasal sufentanil via PCIN for breakthrough and incident pain in four cancer patients. The initial dose of 4.5 µg could be repeated at 10 minutes and 20 minutes until a maximum of three doses of 36 µg/daily. Very good pain relief was achieved within 30 minutes and lasted for around 2 hours. No serious adverse effects were reported. An open-label, uncontrolled study evaluated the pharmacokinetics, safety and efficacy of a single 40 mg dose of nasal morphine gluconate administered to 11 cancer patients in response to an episode of breakthrough pain.[89] This treatment was associated with effective plasma morphine concentrations, rapid onset of pain relief, and minor side effects (nasal irritation). Patient satisfaction ratings were high.

As morphine administered nasally has a bioavailability of the order of 10 percent compared with IV administration, a novel chitosan-morphine nasal formulation has been produced and tested in both healthy volunteers and in 14 cancer patients with breakthrough pain.[90,91] Morphine was rapidly absorbed (T_{max} of 15 minutes or less), with a bioavailability of nearly 60 percent. In clinical settings, encouraging results have been obtained in patients receiving 5–80 mg of nasal morphine-chitosan, with an onset of pain relief 5 minutes after dosing. Finally, it is interesting to note that transnasal butorphanol has proved to be effective in the treatment of opioid-induced pruritus unresponsive to 50 mg of IV dyphenhydramine.[92]

Inhalation route

In 1996 Lichtman et al.[93] demonstrated that the inhalation exposure to several opioids produced dose-dependent antinociception in mice, and suggested that the relative potency of morphine was greater when inhaled than when injected by IV route. Subsequently, variable results have been obtained using inhaled morphine in postoperative pain. More recently, promising results have been reported in patients with acute pain.[94,95] The pharmacokinetics of nebulized opioids needs to be studied in detail in order to design reliable clinical trials.

TRANSDERMAL ROUTE

Substances with high lipid solubility and molecular weight below 800–1000 kDa can pass through the skin. The absorption rate varies according to different factors such as the type of the vehicle, the skin characteristics (the thickness of stratum corneum) and conditions, the body surface. In general drugs that are successfully administered transdermally are those in which the daily dose is very low (no more than a few milligrams). Patient compliance with this route of administration is excellent, and skin reactions are rarely observed.

Among opioids, the potent synthetic drug fentanyl citrate is particularly suitable for transdermal administration, and its utility in pain therapy has been extensively evaluated. Transdermal fentanyl systems (TTS) are available in four release programs of 25, 50, 75, 100 µg/h depending on

the patch size, and the drug is released continuously for 3 days. A substantial amount of fentanyl remains in used systems even after 3 days of application.[96] When a TTS is removed, fentanyl continues to be absorbed into the systemic circulation from the cutaneous depot. However, opioid withdrawal symptoms may occur after discontinuation of TTS administration, as well as after conversion from other opioids to TTS.[97,98] Moreover withdrawal symptoms were reported during chronic TTS administration and were managed with oral methadone.[99] Pharmacokinetic studies demonstrated that the rate of absorption of fentanyl from the transdermal delivery is constant beginning 4–8 hours after placement of the patches. Steady state is reached on the third day. However, a wide individual variability exists.[100] There is a lag period after patch application before plasma concentrations approach therapeutic levels. This lag period is highly variable, with a mean value of about 13 hours.[101] The TTS should be changed every third day. However, published data show that application intervals have to be shortened in about 25 percent of patients[102] at 48–60 hours because on the third day of each patch period the need for rescue doses of short-release oral morphine was more than on the first and second day.[101,102] In 11–43 percent of patients on long-term treatment, the patch had to be changed every 48 hours.[100]

The effectiveness of TTS fentanyl was first demonstrated in postoperative pain. Especially for the high incidence of respiratory depression, this use is now contraindicated. Conversely, in stable, chronic, cancer pain this formulation offers an interesting alternative to oral morphine.[101,103–105] In comparison with oral morphine TTS fentanyl seems to cause fewer gastrointestinal side effects, with special reference to constipation.[106,107] Its usefulness also in chronic, non-malignant pain is strongly suggested by recently published papers.[108,109] Of course, this formulation is contraindicated during the titration phase, or to control breakthrough pain. The cost of TTS fentanyl is higher than that of other opioids. However, some pharmacoeconomic analyses suggest that its cost is closer to that for long-acting oral opioids when total medication costs are considered.[110–112]

The permeability coefficient for fentanyl is affected by temperature. A rise in body temperature to 40°C may increase the absorption rate by about a third.[106] Acute toxicity related to increased absorption secondary to high temperature has been reported.[113] A recent study in volunteers demonstrated that the application of local heat to the transdermal patch significantly increased systemic delivery of fentanyl.[114]

Four cases of death due to the intravenous injection of fentanyl extracted from transdermal patches have been recently reported.[115] To minimize the problem of the 'dose dumping' due to membrane damage, and the risk of illegal diversion, a transdermal matrix patch formulation of fentanyl has been developed. Furthermore, a new system, called the electrotransport transdermal system has been developed, which allows the drug delivery rate to be varied electrophoretically. Further studies are necessary to verify the utility of this new formulation.

The partial agonist buprenorphine is another ideal candidate for delivery via a transdermal patch.[116] In the currently available formulation (buprenorphine transdermal delivery system) this drug is incorporated in a polymer adhesive matrix from which it is released through the skin. Transdermal buprenorphine has a bioavailability of about 50 percent, which is comparable with that observed after sublingual administration.[117] Buprenorphine patches are available in three dosage strengths. The patches are loaded with 20, 30, or 40 mg of buprenorphine and are designed to release the opioid at a controlled rate of 35, 52.5, and 70 μg/h, corresponding to a daily dose of 0.8, 1.2, and 1.6 mg, respectively. All of the patches are designed for a 72-hour application period. They should be applied to a flat and hairless area of noninflamed skin, preferably on the upper back, subclavicular region, or chest. Following their removal, buprenorphine plasma levels slowly decrease. The manufacturers suggest that additional opioids should not be administered within 24 hours of patch removal. Transdermal buprenorphine has been used and investigated less extensively than fentanyl TTS. The available data suggest that it may represent an effective analgesic against chronic pain.[118]**

Key learning points

- An alternative route for opioid administration should be considered when oral administration is not possible or in presence of poor pain control and/or adverse effects.

- The oral route is not suitable in clinical situations such as severe vomiting, bowel obstruction, dysphagia, severe confusion, and where rapid dose escalation is necessary.

- Each alternative route has indications or contraindications depending on the clinical history of the patient.

- Pharmacokinetic and pharmacodynamic characteristics of the different opioid analgesics should be carefully considered to individualize the therapy.

- The rectal route has the advantage of being simpler than the subcutaneous or IV routes; however chronic rectal administration can lead to patient discomfort.

- Sublingual and buccal routes may deserve special attention for the administration of highly lipophilic opioids such as methadone, fentanyl, and buprenorphine.

- Continuous SCI ± extra boluses (PCA), represents the standard alternative route for systemic opioid delivery.

- Intravenous administration is particularly indicated for 'fast titration' and dose finding in patients with severe pain and in those with an implanted central venous catheter.

- The intranasal route may offer some advantages; however further studies are needed in the palliative care setting.

- The transdermal route is a widely used and a comfortable way for opioid delivery. However, it should be reserved for patients whose opioid requirements are stable after the end of the 'titration phase'.

Epidural and intrathecal analgesia and neurosurgical techniques in the palliative setting

PHILLIP C PHAN, MADHURI ARE, SAMUEL J HASSENBUSCH III, ALLEN W BURTON

INTRODUCTION

According to the World Health Organization (WHO), an estimated 6.6 million people die from cancer every year, with cancer-related pain continuing to be a significant source of global health concern.[1] As cancer progresses, 65–85 percent of patients with advanced cancer will experience pain, with up to 80 percent of cancer patients describing their pain as having moderate to severe intensity.[2]

The WHO has established a three-step analgesic ladder that can be used to treat cancer pain.[1] The use of this analgesic ladder is described elsewhere in this book. Although effective in treating most cancer pain some 10–20 percent of patients with cancer fail to achieve adequate pain relief after use of the WHO analgesic ladder.[3] This failure of the WHO ladder approach arises either from pain that is refractory to opioids or the inability of the patient to tolerate the side effects of the opioids at higher doses.

It has been suggested that a fourth, 'interventional' step be added to the three-step WHO analgesic ladder[3,4] (Fig. 48.1). This step would encompass the vast armamentarium of interventional procedures to help alleviate pain not controlled with pharmacological treatment. One major class of interventions is neuraxial therapy, with the administration of epidural and intrathecal analgesics at the level of spinal cord.

INTRASPINAL ANALGESIA

Administration of neuraxial or spinal analgesics offers many advantages over irreversible neurodestructive procedures to
Figure 48.1 *The World Health Organization analgesic ladder with Step 4 'interventional management of pain' added. Adapted from Miguel[3] and Krames.[4]*

control pain, i.e. neurolytic blockade. It is very effective in patients with multiple pain sites, such as in those with advanced cancer with multiple sites of metastases.[5] An indwelling neuraxial catheter allows titration of opioid dosage and rotation of analgesic agents, if necessary. The use of intraspinal opioids is selective for the pain transmission pathway at the spinal level, without any discernable effect on the motor, sensory, or sympathetic systems. Further, for certain refractory syndromes, neurosurgical

ablative procedures may have a favorable risk–benefit profile as described in the last section of this chapter.

Mechanism of action

The goal of intraspinal analgesics, including opioids, is local inhibition of nociceptive transmission at the spinal cord level. Intraspinally administered opioids modulate pain transmission by acting on receptors in the dorsal horn of the spinal cord where the primary sensory neuron synapses with the wide dynamic range interneurons and the second-order nociceptive neurons in the spinothalamic tract. Opioid receptors are concentrated in the dorsal horns in laminae I, II, V, and X of the spinal cord. Morphine was the first intraspinal opioid to be administered, and it is the standard for comparison of other intraspinally active analgesics.[6*,7] Opioids suppress postsynaptic excitability of second-order neurons at the level of spinal cord.[8–12]

Intraspinal analgesics

OPIOIDS

Many medications have been investigated for use as intraspinal analgesics, but data from controlled clinical studies are limited. Opioids as a class have been the most extensively studied.[13,14] Morphine is the only opioid approved for spinal administration by the US Federal Food and Drug Administration (FDA) although there is a growing body of literature supporting the use of other opioids, including hydromorphone, meperidine, fentanyl, alfentanil, sufentanil, and methadone.[15***]

The intraspinal analgesics target the receptor system within the spinal cord. Specifically for opioids, the target is the opioid μ receptors located within the dorsal horn. Many of the pharmacokinetic and pharmacodynamic properties of intraspinal opioids are related to their lipid solubility, specifically their ability to diffuse across the dura, spread within the cerebrospinal fluid (CSF), and diffuse into the dorsal horn. The oil–water coefficient of an analgesic agent is a good indicator of the hydrophilic or hydrophobic nature of that agent. Morphine, with an oil–water coefficient of 1.40, is a hydrophilic opioid. Thus, it will take longer to diffuse across the dura and to diffuse into the spinal cord. Furthermore this will result in slow receptor saturation, longer onset to peak action, and longer time to clearance from the spinal cord.[16] Slow clearance of hydrophilic morphine from spinal CSF accounts for delayed respiratory depression sometimes seen with intraspinally administered morphine. This is due to the rostral spread of morphine remaining within CSF and morphine's action on the respiratory centers in the brainstem.[17] This delayed effect, however, is rarely seen in opioid-tolerant patients.

Sufentanil, with an oil–water coefficient of about 1800, is the prototypical hydrophobic opioid. Once administered via either the epidural or the intrathecal route, this hydrophobic agent will quickly diffuse across the dura and be taken up into the spinal cord and vascular system. Receptor saturation of the spinal cord level corresponding to the catheter tip location is expected to be relatively rapid with rapid clearance from the CSF.[18]

OTHER INTRASPINAL AGENTS

Clonidine is a well-studied analgesic considered to be useful as an adjuvant in neuropathic pain states.[19] It acts on central α_2 adrenergic receptors, thereby modulating the spinal pain pathway. Clonidine binds to postsynaptic α_2 receptors within the dorsal horn and activates the descending noradrenergic inhibitory systems.[20,21] This spinal mechanism explains why clonidine is a poor analgesic when administered systematically.[22] Clonidine is hydrophobic, with an oil–water coefficient similar to fentanyl. It is quickly taken up in from the CSF and has a pronounced local effect at the spinal level.[23,24] Use of spinal clonidine has been investigated in both the postoperative pain control and in cancer pain management.[25**,26***] When clonidine is combined with an opioid, the intraspinal opioid requirement is less and tolerance takes longer to develop.[26***] The main side effect of intraspinally administered clonidine is postural hypotension.[27]

Spinally administered local anesthetics have a synergistic effect when combined with opioids. Bupivacaine, an amide local anesthetic, is commonly used in postoperative epidural infusions, but is also widely given by the intrathecal route in combination with opioids for cancer pain. Like clonidine, bupivacaine is more effective when used in combination with opioids than opioids alone in the treatment of neuropathic pain, however, bupivacaine is also used to treat nociceptive pain.[28***] The mechanism of action of local anesthetics involves blockade of voltage-sensitive sodium channels and preventing generation and conduction of nerve impulses across pain transmission pathways. As with other local anesthetics, bupivacaine dosing is limited by the occurrence of motor blockade at higher local anesthetic concentrations. Intrathecally administered, bupivacaine can cause a motor block at doses as low as 10 mg/day. However, with slow dose titration, bupivacaine doses up to 25–30 mg/day can be used without producing a motor blockade.

Ziconotide, a calcium channel blocker, produces its analgesic effect by selectively blocking neuronal N-type voltage-sensitive calcium channels. Calcium channel blockade prevents calcium ion influx and neurotransmitter release. This selectively inhibits transmission of primary afferents located in the dorsal horn of the spinal cord. Ziconotide is currently being evaluated in clinical studies for treatment of severe chronic pain in patients refractory to systemic opioid therapy.[29**] It was approved for intrathecal use by the FDA in December 2004. This is the first agent developed specifically for intraspinal administration in chronic pain states.

Its ultimate use will most likely be for those with pain states refractory to intraspinal opioids and severe neuropathic pain states.[15]

Neostigmine is another interesting nonopioid that may have a role as an intraspinal analgesic.[30,31] The drug is effective with minimal toxicity, but initial trials have seen some troublesome systemic dose-related side effects including nausea and vomiting and somnolence.[32]

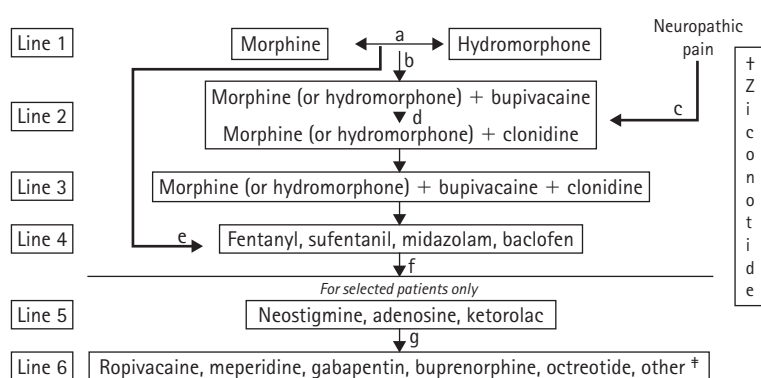
A number of other α_2 adrenergic agonists, local anesthetics, and drugs from other classes (γ-aminobutyric acid [GABA] agonists such as baclofen, N-methyl-D-aspartate [NMDA] antagonists such as ketamine) have been delivered via the intraspinal route to treat intractable cancer pain, with varying degrees with success. According to a 2002 review, satisfactory analgesia has been reported with the use of these agents delivered intraspinally.[15] However, most of these agents are considered investigational at this time for intraspinal therapy. Clinical guidelines emerged in 2000 and have been recently revised in 2003. These form the basis for a treatment algorithm in intraspinal therapy to aid decision making (Fig. 48.2).[15]

Indications

As discussed earlier, intraspinal analgesics are effective in modulating pain pathways at the spinal level. The significant side effects from systemic high-dose opioid administration (including nausea, constipation, confusion, increased somnolence, or lethargy) can be minimized with intraspinal delivery of opioids. This therapy is effective in two broad groups of patients: those with refractory pain syndromes and those with intolerable opioid-related side effects. If the opioid is delivered to an epidural location, only 20–40 percent of the systemic dose is required to achieve analgesia equivalent to that achieved with systemic opioids. The intrathecal route is even more potent, requiring only 10 percent of the systemic dose for equianalgesia.[28,15] The ability to treat pain effectively while minimizing these side effects has a significant impact on the quality of life.[33]

Patient selection

When a comprehensive trial of pharmacological therapy fails to provide adequate analgesia or leads to unacceptable side effects, consideration should be given to alternative modalities. These modalities include parenteral opioid infusions, neuraxial medication infusion, neurolytic blockade, and other procedures such as vertebroplasty. Consultation with a pain specialist may help select patients most likely to benefit from one or another of these interventions. One advantage of intraspinal analgesia is that a trial therapy can be undertaken with minimal risk to the patient. If no benefit is seen with trial intraspinal therapy, a more permanent catheter or pump system need not be implanted. The trial is described below in more detail. With regard to placement of the permanent system, i.e. intrathecal pump, deciding which patients with cancer will benefit from such implantation is a complex process and involves multiple factors.

The role of interventional therapies must be placed in the proper context. In most cases, they cannot be employed as the sole treatment for cancer pain. Spinal analgesia should be used as part of a multimodality approach in treatment of cancer pain.[34***] As discussed previously, the causes of


† The specific line to be determined after FDA review

a. If side effects occur, switch to other opioid.
b. If maximum dosage is reached without adequate analgesia, add adjuvant medication (Line 2).
c. If patient has neuropathic pain, consider starting with opioid monotherapy (morphine or hydromorphone) or, in selected patients with pure or predominant neuropathic pain, consider opioid plus adjuvant medication (bupivacaine or clonidine), (Line 2).
d. Some of the panel advocated the use of bupivacaine first because of concern about clonidine-induced hypotension.
e. If side effects or lack of analgesis on second first-line opioid, may switch to fentanyl (Line 4).
f. There are limited preclinical data and limited clinical experience, therefore, caution in the use of these agents should be considered.
g. There are insufficient preclinical data and limited clinical experience: therefore, extreme caution in the use of these agents should be considered.

Figure 48.2 *Treatment algorithm for intrathecal analgesia. Redrawn from reference 15.*

cancer pain are diverse, with nociception being one part of the constellation of symptoms experienced by the patients with cancer. Therefore, a comprehensive multidisciplinary approach to treatment of cancer pain is optimal. This would include appropriate palliative antineoplastic therapy, management of analgesics and adjuvant pain medications, behavioral and psychiatric support, and, finally, interventional therapies. Interventional pain procedures will not completely eliminate the need for pain medications, but should help significantly to minimize the nociceptive burden. The therapeutic goal of such procedures is to help alleviate cancer pain, reduce the overall analgesic need, and thereby minimize associated opioid-related side effects.

Communication

Prior to proceeding with any invasive pain procedure, communication between the pain physician and the relevant parties is absolutely essential. Effective communication with the patient entails a thorough discussion including outcomes of the procedure, duration of effectiveness, possible complications and their treatment, and the place of the interventional treatment in their overall treatment strategy. This discussion must be accomplished in terms the patient can understand and with involvement of the patient's family and/or caregivers. The patient and family must be given ample opportunity for questions, and, like the patient, the family must be also educated so that they have realistic expectations about the procedure.

Effective communication with other professional members of the care team is important for the optimal outcome. The team members include the patient's oncologist(s), primary care provider(s), and all the relevant consultant(s). As stated above, treatment of cancer is a multidisciplinary effort and the interventional procedure should be planned in coordination with the overall cancer treatment. For example, a patient with cancer may undergo chemotherapy with resultant thrombocytopenia. In such situations, an interventional procedure must be carried out prior to chemoinduction or afterward when the patient's platelet count has normalized. As a routine, other members of the patient's care team should be informed about the planned interventional procedure and given a chance to voice any input or concern.

Detailed history and physical examination

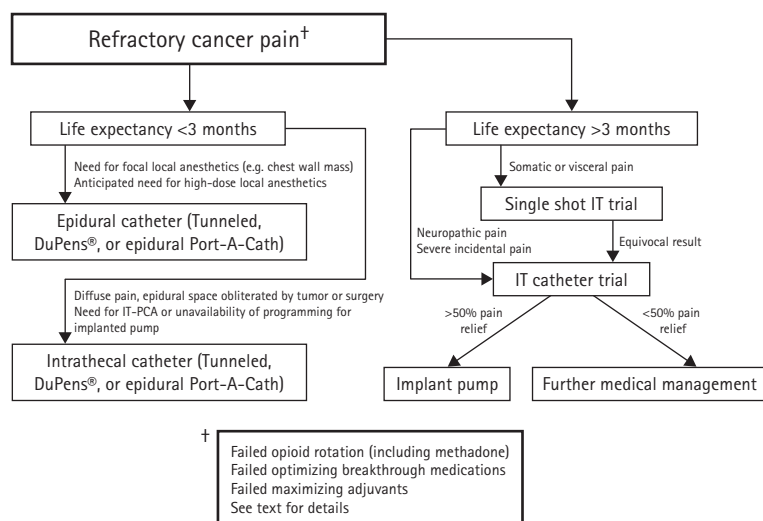
A thorough history and physical examination of the patient prior to the procedure is also critical. This entails a complete neurological evaluation. Interventional procedures for pain control generally involve placing needles and/or catheters near tissues such as nerves and other structures in central nervous system. The objective of intervention is to disrupt or modulate nociceptive pathways. Intrathecal infusion of opioids and local anesthetics will not only block pain transmission but at higher doses they may also reversibly block sensory and motor function. Consequently, it is important to have a thorough understanding of the patient's neurological and functional status before and after the procedure. Changes such as sensory and motor blockade are closely monitored after procedures, especially when high doses of local anesthetics are being used. Patients need to be fully informed about the use of high-dose local anesthetics as they may otherwise fear that they have become paralyzed if a motor block occurs.

Another important aspect of the pre-procedural evaluation is the assessment of overall symptom burden and psychological distress. If the overall symptom burden and/or magnitude of psychological distress is high, the result of the intervention aiming to decrease nociception may be disappointing in its seeming lack of overall effectiveness.

Delivery of intraspinal analgesics

Intraspinal delivery of opioids and other agents can be achieved by a variety of approaches, including epidural bolus, intermittent intrathecal injection, and continuous epidural and intrathecal infusions.[35] Continuous infusion via either the epidural or the intrathecal route requires the use of a catheter system and either external or implantable infusion pumps to deliver the analgesic medications. There is little consensus on when to use the intrathecal versus the epidural route of administration and when to use an implantable versus an external pump. With prolonged epidural infusions of greater than 6–9 months, complications such as catheter obstruction, fibrosis, and loss of analgesic efficacy have been observed, leading most clinicians to favor the intrathecal route for long-term intraspinal analgesic infusions.[36]

Many factors are considered in the decision whether to use an external pump system versus an implantable pump. Factors that are favorable of an external system include: a short life expectancy (<3 months), the need for frequent patient-controlled doses (such as with severe incident pain), the need for an epidural infusion (which generally requires infusion volumes which are too great for the implantable pump), the lack of reprogramming/refilling capabilities near the patient's home, payor constraints, as well as the ability of the patient and family to take care of an externalized catheter system.[37] We use a variety of catheters for our external systems including a tunneled Arrow Flex-Tip® catheter, the DuPen® epidural catheter, and Sims' Port-A-Cath® epidural system.

Factors that favor considering an implantable intrathecal pump include: a longer life expectancy (>3 months), access to pump refill/reprogramming capabilities, diffuse pain (e.g., widespread metastasis), and favorable response to an intrathecal trial. Our decision-making algorithm was recently published[37] and is also shown in Fig. 48.3. An economic analysis of an implantable versus externalized pump revealed the 3-month life expectancy to be the approximate


'break-even' point for the implanted pump to become more cost effective than the externalized pump system.[38,39]

The rate of flow of implanted infusion pump systems can be fixed (factory preset at 0.5 mL or 1.0 mL/day) or programmable. All implantable pumps come with a refillable drug reservoir. In addition, they all have an access port and a side port system that allows for direct injection of a drug into the implanted catheter system. FDA-approved fixed infusion pump systems include Codman's model 400, Medtronic's Isomed® and Arrow's M-3000. Changing the dose in a fixed rate pump requires the medication concentration be changed, mandating a pump refill each time the dose is adjusted.

Medtronic Inc. (Minneapolis, MN) has the only programmable pump on the market today. Medtronic's Synchromed I and II pumps can hold up to 20 mL and 40 mL of medication, respectively. They can be programmed to deliver a single bolus, time-specific boluses, or a complex regimen of continuous infusion of intrathecal analgesic. A function exists for a patient-controlled 'demand dose' via a remote control, but this has not been approved for use in the USA as of the time of writing. Although these fixed rate and programmable pumps can be used to deliver either epidural or intrathecal medications, they are more suited to intrathecal delivery. Epidural infusions usually require a significantly higher daily volume and thus are typically managed with an external pump system.[36,37]

Intraspinal analgesic trial

Once intraspinal analgesia has been decided on, an intrathecal trial must be accomplished. This trial is to demonstrate efficacy of the intraspinal medication in improving pain control, level of functioning, and overall quality of life. There is no standard for neuraxial trials, although numerous approaches have been advocated.[36,37,40,41] We do not trial patients undergoing catheter–external pump systems, as the

trial procedure and catheter 'implant' procedure are virtually identical. For consideration of intrathecal catheter–pump implantation, our preference is a single shot (one subarachnoid opioid or opioid/local anesthetic injection) trial in most cases. If the analgesia is equivocal or the patient has a severe incidental pain syndrome, a tunneled intrathecal catheter trial is done, usually with opioid/local anesthetic or opioid/clonidine combination. Also in some cases when we anticipate the need for local anesthetic combination therapy, an intrathecal catheter trial is helpful in adjusting and achieving the right opioid and local anesthetic mix prior to pump implantation. Criteria for successful intraspinal opioid trial are variable, with some effective indicators being: reduction in pain scores, improvement in function, and decreased opioid requirement as well as reduction in opioid-related side effects.[37]

Pump implantation surgery

Prior to surgery, patients are again evaluated for any change in medical as well as neurological status since the last preoperative clinic visit. The procedure may be done under general anesthesia or monitored anesthetic care (sedation plus local anesthesia). The usual surgical aseptic precautions must be observed during the entire surgical procedure, with the use of preoperative prophylactic antibiotics to minimize the chance of perioperative infection. Under guidance of a fluoroscope, a spinal catheter is placed up to a specific level for optimal analgesia. The pump is implanted in the lower quadrant of the abdomen via an 8 cm incision, which is made to allow placement of the pump into the subcutaneous tissues with connection of the pump and catheter (Fig. 48.4). The patient is observed overnight and generally discharged the next morning with instructions regarding follow-up care, pump refill date, safety precautions, and routine postoperative wound care. The patient is also instructed to keep in touch with the
Figure 48.4 *Surgical placement of the intraspinal infusion pump into the left lower quadrant of the abdomen. Courtesy of A Burton.*

clinic in the coming week as we titrate the pump medication regimen for optimal pain control as needed.

Efficacy of intraspinal opioids in cancer pain

Intrathecal delivery of opioids has been shown to reduce pain levels in patients with intractable cancer pain.[37*,42*,43*,44*,45***,46*,47**] A recent review of literature found that use of intrathecal delivery of morphine by an implanted infusion pump provided 'good to excellent' pain relief, accompanied by increased activity and improved quality of life in patients with intractable pain.[45***] Furthermore, the results of three recent studies of intrathecal therapy have demonstrated the effectiveness of this therapy in management of severe cancer pain.[37*,46*,47**] Two of these studies examined the effectiveness of intrathecal drug delivery systems on the management of continuous severe cancer pain.[37*,47*] The third study examined the effectiveness of intrathecal therapy for episodic or breakthrough pain.[46*]

Our group at MD Anderson Cancer Center reported the results of use of intraspinal analgesia in 87 of 4107 evaluated patients using the previously mentioned algorithm.[37*] These patients were highly refractory to medical management with mean oral morphine doses of 588 mg/day and baseline mean pain scores of 7.9. Retrospective evaluation of 8-week follow-up revealed improved pain control, decreased oral opioid intake, and decreased drowsiness and mental clouding. This study analyzed the effectiveness of intraspinal analgesia on pain reduction by comparing pain scores, oral opioid intake, and self-reported symptoms before and after the intraspinal intervention. After administration of intraspinal analgesia either via epidural or intrathecal route, there was a significant reduction in the proportion of patients in severe pain (pain scores 7–10 on

a numerical rating scale [NRS]) from 86 percent to 17 percent ($P < 0.001$). The patients' NRS scores decrease significantly from a mean ($\pm$ SD) of 7.9 $\pm$ 1.6 to 4.1 $\pm$ 2.3 ($P < 0.001$). Oral opioid intake decreased from 588 mg/day MEDD to 294 mg/day ($P < 0.001$). Self-reported drowsiness and mental clouding (range 0–10) also significantly decreased from 6.2 $\pm$ 3.0 and 5.4 $\pm$ 3.4 to 3.2 $\pm$ 3.0 and 3.1 $\pm$ 3.0, respectively ($P < 0.001$).

In a prospective, randomized, multicenter clinical trial, the use of implanted intrathecal drug delivery system was shown to improve pain control, reduce toxicities, and improve survival in cancer patients with refractory pain.[47] At study entry, all patients (N = 202) had unrelieved cancer pain, as indicated by their visual analog pain scores of $\geqslant 5$ on a 0–10 scale. Patients were randomized to receive either morphine via intrathecal delivery and comprehensive medical management according to the 1994 Agency for Health Care Policy and Research (AHCPR) cancer pain relief guidelines, or comprehensive medical management alone. At week 4 of follow-up, 60 of the 71 patients (84.5 percent) in the intrathecal delivery arm achieved clinical success, as indicated by $\geqslant 20$ percent reduction in visual analog scale pain scores or $\geqslant 20$ percent reduction in toxicity. In contrast, in the comprehensive medical management arm, only 51 of 72 patients (70.8 percent) achieved clinical success. Mean toxicity scores declined in the intrathecal delivery and comprehensive medical management only arm by 50 percent and 17 percent, respectively ($P = 0.004$). Further, the intrathecal delivery group had significant reduction in fatigue and depressed level of consciousness ($P < 0.05$). Moreover, slightly greater improvement in 6-month survival was seen in the intrathecal delivery group compared with the medical management only group (53.9 percent vs. 37.2 percent, $P = 0.06$).

In a third study, Rauck *et al.* evaluated intrathecal drug delivery systems in the management of episodic or breakthrough pain in a prospective, open label study.[46] In this study of 119 cancer patients with refractory cancer pain and/or uncontrollable side effects, better analgesia was achieved when the patients managed their pain with an implantable, patient-controlled intrathecal drug delivery system. Such a system allowed patients to self-administer a bolus dose of morphine sulfate on demand. The results showed that the mean numerical analog pain score significantly decreased from 6.1 to 4.2 at month 1 ($P < 0.01$, n = 99), and was maintained through month 7 ($P < 0.01$, n = 14) and month 13 ($P < 0.05$, n = 10). In addition, the morphine equivalent daily dose (MEDD) was significantly reduced throughout the study ($P < 0.01$). Overall success ($\geqslant 50$ percent reduction in numerical analog pain score, system opioid use, or severity of opioid side effects) was reported at month 1 at 83 percent and at month 4 at 91 percent of patients.

Clearly, in these three studies and many other studies, intraspinal administration of opioids and analgesics has been shown to play a significant role in controlling cancer

pain, reducing opioid-related toxicities, and even improving survival outcomes. Intraspinal analgesic therapy is an effective mode of pain control in cancer patients with difficult-to-control refractory pain.

Complications

Complications fall into two broad categories: device and drug related. Device-related complications include wound infection, catheter breakage/migration, catheter tip granuloma. There is a growing body of literature on granulomas at the catheter tip, which are being increasingly reported. The consensus is that this is related to highly concentrated medications, especially morphine, and the index of suspicion should be high in patients with a new pain in their back prompting magnetic resonance imaging (MRI) evaluation and appropriate management as outlined elsewhere.[48] Drug-related complications include dosing/programming errors, misfiling, and the spectrum of opioid-related side effects including nausea, sedation, urinary retention, pruritus, and respiratory depression. These side effects are generally less pronounced than with systemic opioids.[47]

NEUROSURGICAL ABLATIVE TECHNIQUES IN THE MANAGEMENT OF CANCER PAIN

The relative roles of ablative procedures are still controversial in neurosurgical pain management. Many of these ablative procedures have been available for 40–50 years yet, in many situations, had been replaced by newer augmentative procedures over the past 10 years. Pain relief from ablative procedures may be of a shorter duration than that resulting from stimulation, and may be accompanied by deafferentation pain.[49] More recently, however, older techniques for intracranial ablative procedures have been updated. With the use of improved stereotactic equipment and guidance by computed tomography (CT) and MRI, the accuracy of intracranial procedures has improved and the need for ventriculography largely eliminated. The procedures can be carried out under local anesthesia with light sedation and require only a twist drill hole, rather than a burr hole or a craniotomy.

Patients generally must have severe pain that is not relieved adequately by systemic medications, neuraxial analgesics, or simple neurolytic procedures. Although some of the procedures, such as thalamotomy and cingulotomy often have been used for pain of noncancer causes, these operations are still quite beneficial for patients with cancer.[50–54] As with long-term spinal infusions of morphine, it remains unclear whether delayed recurrence of pain represents extension of the underlying tumor to new anatomical areas or late failure of the procedure.[55,56]

Neurosurgical procedures are used for both nociceptive and neuropathic pain, but it appears that, with the exception of thalamotomy, nociceptive pain responds better to intracranial procedures, which also cover larger body areas. Neuropathic pain often responds better to spinal procedures that have more limited areas of coverage. In addition to logistical issues, choice of a specific operation also needs to take into consideration the type of pain, severity, location, and the primary cause of the painful sensation.

Techniques

Though neurosurgical approaches to lesion placement are fairly standard, the requisite tools have changed as technology has progressed. Originally, ablations were placed using open surgical techniques.[57,58] Air or contrast ventriculography for intracranial lesions was the traditional, accurate method for placing lesions at coordinates defined by the anterior commissure–posterior commissure (AC–PC) line.[59,60] General anesthesia was often required to perform the procedure, which could not adjust for interpatient variability in anatomy. Now, however, closed operations using stereotaxis under ventriculogram, and CT or MRI guidance have become dominant.

The use of CT and MRI for stereotactic guidance eliminates the need for ventriculography and also increases the surgeon's ability to correct for individual patient variation in anatomy.[61,62] For example, using MRI, the actual trajectory for the electrode placement can be planned in relation to other brain structures. Special angled slices, which correspond to the trajectory for the electrode placement, can be taken allowing the target site and the actual trajectory through various brain structures to be found on these slices. Computed tomography has a high resolution and accuracy but also has a more limited level of resolution, thus making direct observation of the target difficult.[63] Magnetic resonance imaging is especially useful in the identification of relevant anatomy but does suffer from a somewhat lower accuracy because of magnetic field inhomogeneity.[64,65] Although there are statistically significant differences between CT and MRI-derived coordinates, the actual discrepancies are small enough that the MRI can be used alone for target localization.[63] Since neither method is entirely exact, a variety of intraoperative procedures are often used to confirm lesion placement.[63] Such techniques include the use of 'reversible' lesions, allowing intraoperative testing of the area without causing permanent damage; low-frequency stimulation that aids determination of the function of the region surrounding the target; and single-unit microelectrode recording to ensure preservation of critical structures in the area.[63]

Radiosurgery, for example using the gamma knife, is being increasingly employed to create ablative lesions for treatment of chronic pain and functional disorders. This method is particularly useful for sites found deep within the brain.[1] Targets in the thalamus and the anterior limb of the internal capsule have been frequently reported.[66–68]

The radiosurgical technique for these pain-relieving lesions uses a similar technique to that for focused radiation (radiosurgery) of a brain tumor. Although radiosurgery is noninvasive to the brain, it is unclear to what extent the lesions become smaller, and what degree of pain relief can be expected at various time points after the radiation exposure.

Specific procedures

The following procedures either are currently being practiced or, based upon past reports, offer significant efficacy of relief with minimal morbidity. As seen from the descriptions that follow, some of these procedures treat specific pain areas such as the head or legs whereas others treat more generalized areas of pain. The various approaches have been divided into ablative and augmentative techniques and described within each group, beginning with the most commonly used technique first.

INTRACRANIAL ABLATIVE TECHNIQUES

Hypophysectomy

The mechanism by which lesions of the pituitary gland bring pain relief is unclear, although it is generally agreed that neither the limbic system nor areas controlling affective responses are manipulated. Current research supports three theories for hormonal, hypothalamic, and neurotransmitter release mechanisms. A postulated hormonal mechanism involves changes in a humoral substance in the CSF or hormonal changes via a direct neural mechanism.[69,70] Contrary to this proposal, it has been noted that pain relief occurs almost immediately without any regard for tumor regression. Relief can also occur in the thalamic pain regions and hormonally unresponsive tumors on a scale that could not be inferred given the degree of pituitary ablation experienced.[71–75] Still, very small amounts of tumor regression cannot be discounted.[76]

Modalities used to perform a hypophysectomy lend credence to the hypothalamic mechanism theory. A possible relation to the pain relief properties of the posteromedial hypothalamus can be observed, although the morphological effects of hypophysectomy, regardless of the technique used to create the lesions, center in the anterior hypothalamus, specifically in the supraoptic and paraventricular nuclei.[76,77] Projections from the paraventricular nucleus to the periaqueductal gray, rostral ventral medulla, and lamina I of dorsal horn have been noted, linking the area to crucial elements in the descending antinociceptive system.[78–81] Information indicating the particularly strong impact that pituitary ablations have on the paraventricular nucleus coupled with knowledge of anatomical connections between this area and antinociceptive regions of the brain suggests the role of endogenous neurotransmitters. It has been observed, however, that naloxone does not reverse

pain relief as it does with opioid-based relief. Although plasma concentrations of β-endorphin were elevated in one study, no changes have been found in CSF concentrations of met-enkephalin or β-endorphin.

Techniques for open surgery on the area include the transcranial hypophysectomy[82] and the open microsurgical hypophysectomy.[70,74,83,84] As technology has improved stereotactic methods, percutaneous stereotactic lesions are being created using radiofrequency thermal techniques, cryotherapy, or interstitial placement of radioactive seeds. The success of focused radiation therapy (e.g. gamma knife) on pituitary tumors has led to the use of this noninvasive modality to create similar lesions for pain relief.

Of these various techniques for hypophysectomy, stereotactic instillation of alcohol into the pituitary gland is one of the best-described and most common techniques at this time. Alcohol has been shown to pass to the floor of the third ventricle, hypophyseal portal vessels, and the hypothalamus.[76] The use of stereotaxy for chemical hypophysectomy enables an injection of alcohol volumes between 1 mL and 5 mL, a method first described in 1957.[85] Better results have been achieved using alcohol volumes extending to the upper volumes of this range that are clearly greater than the volume of the sella.[76]

After placing the patient under general anesthesia and securing the stereotactic frame, the surgeon locates the superoposterior part of the sella as the initial target. An 18 gauge, 15.24 cm (6 inch) spinal needle is introduced in a transnasal trajectory that passes through the floor of the sphenoid sinus. This needle is then replaced by a 20 gauge spinal needle directed through the sellar wall, with its progression observed by means of lateral X-ray fluoroscopy. Injection of 1–2 mL of alcohol in aliquots of 0.1 mL follows placement of the needle tip. After withdrawing the needle halfway to the floor of the sella, another 1–2 mL of alcohol is injected.[76] The needle is completely withdrawn after this last injection. Throughout the procedure, the eyes are monitored for compression of cranial nerves in the cavernous sinus as evidenced by changes in pupil size or movement of eyes from the midline. Other methods used to perform a hypophysectomy, such as stereotaxic radiofrequency hypophysectomy, stereotaxic cryohypophysectomy, and interstitial irradiation use standard stereotactic methods of intracranial operations.[54,73,86–88]

Hypophysectomy is generally recommended for patients with severe cancer pain such as metastatic breast or prostate carcinoma with diffuse areas of pain. It can also be effective for hormonally unresponsive tumors.[69,75,89–91] In two different series of greater than 100 patients each, chemical hypophysectomy appeared to provide significant pain relief. Excellent pain relief was reported in 45–65 percent of all patients and 75–85 percent of patients ceased using opioids. The mean postoperative survival time was 5 months, while the mean length of pain relief appeared to be 3 months. This length of pain relief was accomplished with one additional alcohol injection in 25–30 percent of patients and

with two additional injections in another 3–9 percent.[69,76,92] Of the patients treated with alcohol injections, those with breast or prostate carcinoma (50–75 percent of patients) appeared to have slightly better pain relief than those with other types of tumors.[76] Approximately 25 percent of patients had at least one significant exacerbation of pain after the procedure whereas a third of these patients had more than one exacerbation.[76]

Common complications included hormonal deficiency, such as diabetes insipidus, in 5–20 percent of patients, CSF leak in 1–10 percent of patients, and ocular nerve palsy or temporal field visual loss in 2–10 percent of patients.[76,93] Most of these changes were temporary.[76] Other problems associated with the procedure on a far less frequent basis were meningitis in 0.5–1 percent of patients, hypothalamic changes, headaches, and carotid artery damage in approximately 0.5 percent of patients.[93] Despite a reported 2–5 percent mortality, it seems likely that these numbers have been significantly lowered with the adoption of newer percutaneous and stereotactic methods.[89,93]

Thalamotomy

The thalamus is the termination site of the spinothalamic tract (lateral nucleus and central lateral nucleus of the medial thalamus), the pathway responsible for transmitting information about pain and temperature from the body to higher areas in the brain.[49] The lateral thalamus seems to be principally involved with sensory discrimination aspects of pain, while the medial thalamic nuclei has more to do with affective responses.[49] In the late 1930s and early 1940s, there were increasing reports of the use of thalamotomy in the treatment of patients with Parkinson disease. In his attempt to create a means to preserve involuntary movements through an open pallidotomy, Russell Meyers also based his work on these ideas. Using the effectiveness of pallidal lesions as corroborating evidence, investigators reasoned that lesions of their thalamic projections in the ventrolateral nucleus of the thalamus would also be effective.[94] Advances in human stereotaxic procedures have led to a resurgence in use of the thalamotomy.

Despite its development for noncancer pain, thalamotomy can be highly effective for and has been reported in the treatment of cancer pain.[51,94] Thalamotomy is generally considered for intermittent shooting and hyperpathic or allodynic pain and not considered very effective for steady, burning, or dysesthetic components of central or deafferentation pain.[94] The targets have been the basal thalamus, medial thalamus, and dorsomedian thalamus affecting extralemniscal fibers, and thalamic projections terminating in the intralaminar nucleus, centromedianus nucleus, and the frontal lobe.[95] One of the most effective sites appears to be the inferior posteromedial thalamus, containing the intralaminar, centromedianus, and parafascicularis nuclei, all of which might affect the paleospinothalamic tract.[96] More recent literature has proposed that the medial thalamus is related to the spinoreticular tract, the descending

passageway responsible for conducting impulses to many of the motor neurons.[49] Ablations of the lateral thalamus, particularly the ventrocaudal parvocellular nucleus, attempt to destroy the pain-receiving nucleus itself. Combination lesions, such as centromedianus and parafascicularis lesions with dorsomedial nucleus or the thalamic pulvinar lesions, might provide better long-term results.[96] Although lesion size is an important component of this type of operation, a standard does not truly exist because many surgeons have personal preferences. Specific cases may dictate a particular lesion size so as not to inflict damage on the surrounding areas.[94]

Currently, a thalamotomy includes the use of stereotactic methods, frame imaging, referencing, target location(s) selection, and careful introduction of the probe so that sensitive motor structures remain intact.[94] These operative steps are followed by physiological testing to confirm the site.[94] The interactive nature of these tests requires the use of local anesthesia to ensure patient cooperation. The testing site according to Tasker[94] should be approximately in the 15 mm sagittal plane or the tactile representation of the contralateral manual digits. A 5 cm (2 inch) diameter head shave and prep is made for the entry point.

Two types of physiological testing can be used to determine target accuracy. Macrostimulation requires nominal instrumentation with quick progression and total identification of the brain and the spectrum of structures at variable distances from the probe. The process can be executed simultaneously with deep brain recording using the same electrode. The microelectrode recording technique is capable of identifying a limited group of structures. Located on the arc of the stereotactic frame, the microelectrode extends from its protective tubing with the aid of a hydraulic microdrive.[94] Actual stimulation with the microelectrode occurs every 1.0 mm at 300 Hz, 100 mA, 0.1 ms, until responses occur below about 15 mA.[94] A bipolar concentric electrode, 1.1 mm in diameter with a 0.5 mm tip separated by a 0.5 mm ring, monitors the stimulation. In the medial thalamus, neurons that fire spontaneously in a burst fashion provide clear hallmarks of the region, whereas an absence of touch-responsive neurons signals the proximity to the ventrocaudal parvocellular nucleus in the lateral thalamus.[49] Both types of stimulation effect are used in order to minimize damage, procedural failure, and any morbidity resulting when a lesion is made in a position other than the anticipated anatomical target. A documented example of this can be seen in Nashold's work where he implanted electrodes as a testing method prior to performing a thalamotomy.[88] The implanted electrodes permitted an accurate direction for the placement of the thalamotomy electrode tip during the actual operation.[88]

Complications often depend on the problem necessitating the operation and include paresis, cognitive disorders, infection and mortality (although rare in nociceptive pain cases), seizures, speech disturbance, and other matters related to specific areas of disease. Both medial and lateral

lesions of the thalamus are moderately effective (approximately 60 percent pain relief) in dealing with cancer pain, but lateral thalamotomy carries with it higher rates of complication, nearly 32 percent.[49] In treatment of nociceptive pain, thalamotomy has been reported to produce transient loss of all contralateral sensory modalities after the operation and also pseudoparesis in many of the cases studied by Tasker; patients seemed to lose the appreciation of position and vibration sense due to the lesions in the ventrocaudal nucleus.[94] Though lesions do not seem to affect cognitive ability, studies have shown that left-sided lesions affect language and the dominance of the right ear in listening exercises (right ear advantage).[49] Enthusiasm for the use of thalamotomy, however, has waned over the past few years because of concerns of pain recurrence after 6–12 months. Due to this decreased efficacy and the significant risks, more recent reports have suggested that thalamic stimulation should be carried out before considering the creation of a lesion.[94]

Cingulotomy

Dating back to 1948, the method calling for the creation of lesions in the cingulate gyrus originated when Hugh Cairns at Oxford removed a portion of the anterior cingulate gyrus in an open operation.[58] The use of the open cingulotomy in the 1940s and 1950s produced significant improvements in psychiatric symptoms in most patients.[57] In 1962, Foltz first described the application of stereotaxy to bilateral anterior cingulate lesions for pain relief while Ballantine began to use ventriculogram-guided stereotaxy to create smaller lesions in the anterior cingulate gyrus. Although cingulotomy has most often has been applied to patients with affective disorders, there are numerous reports of its use for severe pain control.[50–52,97–100] The procedure has been quite successful in patients with cancer suffering from diffuse or multiply-located pain, but it has not been fully adopted because of neurosurgical stereotactic techniques required to perform the operation.[64,65,101]

With the availability of technology capable of guiding closed procedures, there is not any present role for open surgical techniques for cingulotomy. The specific target is the cingulate gyrus, 20–30 mm posterior to the anterior tip of the lateral ventricles. The target is 1.5 mm lateral to midline and 15 mm superior to the roof of the lateral ventricles.[102,103] The radiofrequency method is used more commonly, with each lesion being created at 75°C for 60–90 seconds. The result is a cylindrical lesion approximately 10–20 mm long and 5–7 mm in diameter, centered in each cingulate gyrus.

Although its exact role in pain transmission is unclear, the anterior cingulate cortex incorporates motor, affective, memory, and nociceptive functions, accounting for the various pathways connecting this area with the basal ganglia, frontal subsytems, and lateral frontal and parietal regions.[101,104] The involvement of the cingulate gyrus in emotional processes has led to the suggestion that the anterior cingulate cortex is most notable for its role in human

response to pain rather than sensitivity to pain stimuli.[104] Still, studies of cingulate gyrus lesions in laboratory animals have shown a reduction contralaterally in the response to pain, particularly noxious thermal stimuli.[101,105] The anterior cingulate cortex, particularly the posterior side of this region, has been shown to be particularly responsive to nociceptive signals from the thalamus.[105] A recent study indicates that the anterior section of this region is activated by attention-demanding tasks. Some patients studied a year after cingulotomy were seen to have executive and attentional deficits, particularly in the areas of focused and sustained attention.[104]

As many as 30 percent of patients were treated for severe chronic pain in the many reports of patients undergoing cingulotomy. Approximately 51 percent of these patients who were treated with intractable cancer pain had moderate, marked, or complete pain relief 3 months after the procedure. Like many ablative procedures, cingulotomy is more effective for patients with a shorter survival time.[64,65] The main complications resulting from cingulotomy using ventriculogram-guidance (in the treatment of psychiatric or pain symptoms) have been controllable seizures (9 percent incidence), transient mania (6 percent incidence), decreased memory (3 percent incidence), hemiplegia from intracerebral hematoma (0.3 percent incidence), and a low, but measurable, mortality (0.9 percent).[102,103,106] In neuropsychiatric examination, the only abnormalities noted were occasional difficulties in copying complex figures, performing two tapping tests, and successfully completing memory components of an organized serial learning test.[97,107,108] Present evidence suggests that changes in attention due to cingulate gyrus lesions do not significantly affect daily functioning and social behavior for patients with severe cancer pain.

Trigeminal tractotomy

The discovery that lesions in the descending trigeminal tract affected pain and temperature without diminishing touch sensation led to the study of this area and the adjacent nucleate caudalis as a target site for the ablative treatment of trigeminal neuralgia.[109] The caudalis nucleate lies on the surface of the medulla posterior to the dorsal spinocerebellar tract, lateral to the fasciculus cuneatus, and inferior to the restiform body.[110] It appears to act as a relay station for pain and temperature transmission from cranial nerves II, V, IX, and X so that destruction of its oral pole decreases neuron hyperexcitability and severs the ascending multisynaptic pathways for pain.[111]

Trigeminal tractotomy is used primarily for treatment of patients with head and neck cancer and with intractable pain in the distribution of the trigeminal nerve. For those patients whose pain is more diffuse in the head and neck, mesencephalotomy often is a more effective choice.[112] Although trigeminal tractotomy was originally used to treat trigeminal neuralgia and postherpetic neuralgia, it is not frequently used for these conditions because of the availability of other percutaneous and open operations. Newer

research indicates that, because the trigeminal, glosso-pharyngeal, and vagal nerves all meet at the spinobulbar juncture, ablative therapy in this region can also be used to treat vagoglossopharyngeal and geniculate neuralgias.[111] Other treatment options have higher rates of morbidity and mortality as well as more extreme complications.[111]

Both percutaneous and open surgical techniques have been described for this operation. A percutaneous technique has been reported with needle penetration at the C1–foramen magnum area under stereotactic guidance.[113,114] Use of CT technology in particular allows direct visualization of the target and generates measurements of the spinal cord that are patient specific.[111] An electrode with a 0.5–0.6 mm diameter is angled 30° cephalad and placed in the spinal cord, 6 mm lateral to the midline, to a depth of 4 mm. Under local anesthesia, electrical stimulation at 50 Hz should provide facial response to low voltage. Stimulation will be felt in contralateral body areas via the spinothalamic tract if placement is too ventral, whereas placement that is too dorsal will be felt in ipsilateral areas via the fasciulus cuneatus.

Based on the procedures described by Sjoqvist,[109] the open operation uses a prone position to remove bone unilaterally from the occiput and C1. After opening the dura, a lesion is created on the nucleus caudalis, 3–5 mm below the surface of the cervicomedullary junction, using a transverse knife. Located 4–8 mm inferior to the obex, the incision extends medially from the fasciculus cuneatus to the rootlets of the spinal accessory nerve. An oblique incision that is angled from superior to inferior as it is made from posterior to anterior minimizes the chance of accidentally injuring the restiform body. Extension of the lesion to include part of both the spinothalamic tract and the fasciulus is recommended for mouth coverage. The tractotomy is often combined with other nerve and/or root sections in the same area.

Limited published reports of the results of this procedure, either with open or percutaneous techniques, suggest that about 75–85 percent of patients with head and neck cancer have good pain relief. Postoperative sensory changes in the area of the pain accompanied by limited relief have been documented as well. Duration of efficacy appears to be months rather than years after the procedure.[110] In some cases, pain associated with the percutaneous operation may result in termination of the procedure before completion. Temporary complications consist of changes in ipsilateral arm coordination, contralateral leg sensation, and ipsilateral arm (rarely leg) proprioception. Less frequent complications include Horner syndrome, dysarthria, gait changes, and hiccups. Overall mortality has been estimated at 5–10 percent in patients with advanced cancer.

Mesencephalotomy

Mesencephalic tractotomy (mesencephalotomy), the surgical production of lesions in the midbrain, has been reported to provide significant pain relief in greater than 80 percent of cancer patients on both short-term and long-term (2–4 years)

follow-ups.[49] The longest duration of pain relief in cancer patients is in the extremities whereas pain in the chest and abdomen does not respond adequately.[115] The procedure is particularly effective in the treatment of head and neck cancer. A common target site is found by locating the spinothalamic tract (STT) and the spinoreticular tract (SRT), which are found 7–9 mm lateral to the midline and 4–7 mm lateral of the midline, respectively (carefully avoiding the medial lemniscus which is 9–12 mm lateral of the midline).[49] By disrupting the junction of the STT and the SRT, the lesions on the mesencephalon disrupt two nociceptive pathways.[49]

The target has been at the superior colliculus or inferior colliculus level although it appears that the inferior colliculus target provides a lower incidence of ocular problems but perhaps with lesser success (50–70 percent). In the studies carried out by Bosch, the target was identified based on intraoperative ventriculography with water-soluble medium using the frontal burr-hole route.[115] The usual stereotactic techniques are performed under general anesthesia to further standardize the procedure. The area of evoked pain is limited to a very small range (about 2–3 mm of target) and requires the use of a bipolar concentric electrode for extremely precise localized stimulation. Stimulation of the STT results in thermal or noxious sensation contralaterally, while stimulation of the media lemniscus results in temporary paresthesias of the contralateral side.[49]

The accuracy of the stereotactic trajectory to the rostral midbrain also reduces morbidity and other risks.[116] Because of neuropathic side effects, the operation should be limited to patients with short life expectancy and lateralized nociceptive pain. With a well-defined target, the operation can produce pain relief comparable to other pain relief operations like open anterior cordotomy, midline myelotomy, and dorsal root entry zone (DREZ) lesions.[115] The major side effect appear to be difficulties with ocular movement and binocular vision with mortality varying from 1 percent to 7 percent.[88,117] Postoperative dysesthesia has been reported in studies of the medial lemniscus after large mesencephalic lesions in patients with different types of pain.[116,118] These side effects have been reduced by using a smaller electrode, neural recording, and more precise electrical stimulation.[116]

The results of this operation vary due to the nature of the particular diseases. Although nociceptive pain is often sensitive to opioids, mesencephalic surgery is a successful and viable alternative.

Pulvinotomy

Pulvinotomy appears to be ideally suited to treatment of intractable cancer pain whose symptoms are similar to those indicated for cingulotomy, particularly in patients with survival times up to 18 months.[119] Kudo et al. first described lesions in the pulvinar of the thalamus for pain relief in 1966,[120] and by 1975, 30 patients had undergone this treatment. Exact mechanisms for pain relief have not

yet been ascertained, but research indicates that the oral and medial parts of the pulvinar are involved in pain appreciation.[121] Electrophysiological studies in cats have demonstrated that the pulvinar is involved in an indirect route for afferent stimuli.[82] From the pulvinar, afferent transmission connections have been traced to the temporal lobe and, from there, to the posterior sensory cortex.[122]

Typically, lesion placement has occurred only in the medial area or in both the medial and lateral areas of pulvinar. Concentration of the lesions in the hemisphere contralateral to the site of pain appears to be less effective than lesions positioned bilaterally.[86,96,118] The coordinates for pulvinar lesions have been 4 mm superior to the AP–PC line, 5 mm posterior to the posterior commissure, and lateral to the AP–PC line by either 10–11 mm for a medial target or 15–16 mm for a lateral target.[119] Lesions are created using ultrasonic probes, with a setting of 75 W and 2.5 megacycles for 30 seconds, at two to six separate sites, resulting in lesions 5–6 mm in diameter.[119] Currently, MRI-guided stereotaxis and radiofrequency thermal tools are also used to generate lesions in the pulvinar.

Moderate to excellent pain relief has been reported in as many as 25 percent of patients for periods ranging from 1 to 2.5 years.[119,122] When the lesions are extended backward to involve the pulvinar, the lesions, especially in the anterior pulvinar, have been found to be more effective than the centromedianus thalamotomy.[122] Extension of the lesions to a more posterior region of the pulvinar, particularly when coupled with thalamotomy lesions in the centromedianus and parafascicularis provides an increase in pain relief.[123] Preexisting pain is most affected by this operation and there is no reported loss of somatic sensation after the procedure.[96] Analysis of patients after pulvinotomy has shown no apparent changes in cognitive functions, although temporary changes in behavior, such as tendencies toward childishness, excessive excitability and euphoria, have all been observed.[124]

Hypothalamotomy

Lesions of the hypothalamus were reported initially for control of cancer pain in 1971, with 28 patients reported to have received the procedure for pain control between 1971 and 1982.[125,126] β-Endorphin concentrations in ventricular cerebrospinal fluid, believed to increase in response to nociceptive stimuli, elevate as a result of electrical stimulation of the target prior to actual ablation of the area and remain at a higher level for at least 2 days after the hypothalamotomy.[127] A postoperative degeneration of axon fibers occurs in regions found ipsilateral to the hypothalamus, including the nucleus ventrocaudalis parvocellularis of Hassler (Vcpc), nucleus parafascicularis, somatosensory cortices, pallidum, and the reticular formation but not in the dorsomedial nucleus of the thalamus.[128] Patients with cancer suffering from diffuse pain, particularly when an emotional or visceral component is present, are good candidates for the operation.[129]

Target sites had previously been localized 2 mm below the midpoint and 2 mm lateral to the lateral wall of the third ventricle, but more recent reports have suggested that a more posterior placement may provide greater pain control.[128] In one series, 15 of 21 hypothalamotomy procedures were bilateral with 'good' results reported in 62 percent of patients.[127,129] Hypothalamotomy does not seem to result in any significant complications; however, published reports are limited.

Combined procedures

As technology enables intracranial procedures to be performed with much more ease, combinations of these techniques should be increasingly used, with particular attention paid to those combinations already used to treat affective disorders. For instance, the use of cingulotomy and anterior capsulotomy, in which lesions are created in both the cingulate gyrus and the anterior limb of the internal capsule, is well reported within the realm of affective disorders. The same combination also has proved useful in the area of severe cancer-related pain, yielding better pain relief, including neuropathic pain, than cingulotomy alone.[130] Targets for thalamotomy also include the pulvinar as an additional target because of the increase in pain relief that this combination brings.[123] As experience and technological advances improve and become more accessible, it is hoped that interest in the research of combination therapy will result in more modalities that provide better long-term efficacy in pain control.

SPINAL ABLATIVE TECHNIQUES

Cordotomy

Until recently, intraspinal ablative procedures have been favored despite the variety of intracranial procedures available as the older spinal methods are 'rediscovered' by using newer percutaneous techniques and CT-guidance. Although its use appears to be decreasing as technological innovations focus more and more attention on intracranial ablative and intraspinal augmentative procedure, the most acknowledged intraspinal ablative procedure, cordotomy, is still a standard option. The aim of the operation is to disrupt the spinothalamic tract as it enters the medulla. However, the mechanism of action for this procedure has been suggested to affect more than just C-fibers because pain relief coincides with a lessened sensation of pinching skin and temperature cooling.[131]

In the percutaneous method, X-ray fluoroscopy is used to position a radiofrequency electrode needle at the level of the C1–2 interspace in the lateral spinothalamic tract as determined by the area of pain.[132] CT-guidance allows for better visualization and more accurate insertion of the electrodes into the spine. A cordotomy needle puncture is made in the side of the neck contralateral to the site of pain with the aid of a questioning stimulation in which the patient is asked about sensory changes and twitching. The open surgical technique for cordotomy is similar to the

percutaneous method except that it is often carried out with the patient seated in an upright position. In this procedure, the anterolateral surface of the spinal cord is viewed and an avascular area is found for the incision. The blade projects 6 mm through the cervical area and 4–5 mm in the thoracic area, and then cuts ventrally in order to transect the ventral quadrant but spare the medial funiculus. The open operation is currently considered the less effective surgical option because of the greater risks it entails in comparison with the percutaneous operation.

A patient's case must be exactly suited to the procedure for pain relief to be successfully achieved. Proper preoperative respiratory/pulmonary function is critical because mortality is almost always related to respiratory problems. The main complication during and after surgery is the possible loss of the sensation of temperature. Possible side effects of the percutaneous operation include contralateral limb weakness from lesioning too deep, transient Horner syndrome, respiratory problems, and burning postcordotomy dysesthetic syndromes. Postlesional dysesthesias and new pain either in the contralateral limb or above the level of the previous pain have been reported. Some patients also have been reported to experience low levels of analgesia due to the failure of the surgery or lack of adequate anatomical localization of target sites during the operation. A small group experienced new pain formation in a similar and/or different location, whereas others did not experience relief at all. In other words, the operation is fairly successful in achieving pain relief although many small impediments may hinder success along the way.

In the large series of Tasker,[133] long-term success with no pain was found in 33 percent of patients, and partial pain relief in 12 percent. Persistent pain was noted in 6 percent and a dysesthetic pain in 34 percent, whereas 2.6 percent required a repeat cordotomy for continued pain relief. Others, however, have found that absolute pain relief has decreased through postoperative time with only 37 percent having satisfactory analgesia even after 5–10 years.[134] Complications in the Tasker series included persistent paresis (2 percent), bladder dysfunction (2 percent), temporary respiratory failure (0.5 percent), and death (0.5 percent).

Midline myelotomy

First conceived by Armour in 1927 as a way of treating a patient with tabetic abdominal pain,[135] the midline myelotomy was first performed by Putnam in 1934.[136] Since its first use, the procedure has undergone many mechanical and functional adjustments for new applications. The procedure for midline myelotomy also has undergone adjustments as technologies have changed; it can now be performed with mechanical ablation, radiofrequency techniques, or carbon dioxide laser[137] to section midline fibers posterior to the central canal of the spinal cord.

The lesions are usually created at the lower thoracic spinal cord level although Gildenberg and Hirshberg[138] and others also have reported lesions at C1. The percentage of

patients reporting moderate to marked pain relief has been approximately 70 percent with only rare complications or side effects noted. This procedure is particularly effective for visceral lower body pain in patients with cancer in whom other procedures are inapplicable or unsuccessful. There is evidence for a tract in the anterior part of the medial borders of the posterior columns mediating both pelvic and more proximal epigastric visceral pain.[139–142] Research conducted with laboratory animals has shown that lesions in the dorsal column reduce responses to noxious colorectal pain stimulation by 60–80 percent, compared with the 20 percent reduction that results from lesioning the ventral posterolateral nucleus of the thalamus.[143] Orthograde and retrograde tracers have shown the presence of a postsynaptic pathway (separate from the spinothalamic tract) that ascends in the gray matter around the central canal to the nucleus gracilis.[144] From there, nociceptive stimuli are relayed to the ventral posterolateral nucleus of the thalamus using the medial lemniscus.[144] A study of cancer patients with visceral pain has confirmed that punctate midline myelotomy of the mid-thoracic spinal cord can reduce visceral pain and use of narcotics without changes in sensation or motor function.[144] In general, analgesia from hyperpathia and background pain has been obtained without sensory loss but with preserved ability to localize and discriminate between sharp and dull stimuli.[145]

A commissural myelotomy on the spinal cord aims to interrupt all decussating second-order spinothalamic fibers that are contributing to pain perception on both sides of the body through the posterior commissure of the spinal cord. Two methods are presently available: open and closed. The open operation requires an incision in the spinal cord down the exact midline between the two gracilis tracts and ventrally configured down until completely divided. This transection disconnects the two sides of the posterior half of the spinal cord so that they are now independent of each other and can no longer communicate dorsally. The closed operation involves placement of a radiofrequency electrode between the two gracilis tracts using CT guidance.

Although many different methods have been described over many decades, there continues to be a lack of knowledge about the myelotomy, particularly the mechanism of pain relief. Since the use of this procedure has been diminishing over the last 15 years, there have only been about 425 total cases reported throughout neurosurgical journals.[137,138,145–156]

AUGMENTATIVE PROCEDURES

Intraventricular infusion of opioids

Intraventricular infusion of opioids is one of the best-known intracranial augmentative procedures. The mechanism by which it regulates pain appears to involve supraspinal pathways for analgesia. This treatment option is normally among the last resort options for a patient's treatment.[157]

The opioid can be delivered by an implanted infusion pump placed subcutaneously in the anterior abdominal wall and connected by subcutaneous tubing to an implanted ventricular catheter. The length of action of the intraventricular injections appears to be significantly longer than with intraspinal delivery. Patients may be able to receive adequate relief with an implanted ventricular catheter connected to a subcutaneous Ommaya reservoir-type device with one to two injections per day.[158] Morphine sulfate is the usual agent and appears to provide a marked increase in potency as compared to intrathecal or epidural infusions, with daily morphine doses for intraventricular delivery ranging from 50 μg/day to 700 μg/day.[159–161]

Recent studies using sheep indicated that certain drugs, particularly lipophilic morphine-type drugs, have problems diffusing through the CSF pathways to reach distant receptors. Thus, the type of opioid must be carefully considered. Payne et al. used drugs like hydromorphone, morphine, methadone, naloxone, and then sucrose to test the spread of specific opioids in cerebrospinal fluid (CSF).[154] Morphine, hydromorphone, and sucrose were identified at approximately 90 minutes in the lumbar CSF after an intracerebroventricular (ICV) injection. Hydromorphone was located after 50 minutes. Methadone was never found in the CSF due to the fact that the ICV and intrathecal dosage of lipophilic opioids creates distinctly different CSF distributions from hydrophilic drugs, like morphine.[162]

Most significantly, it has been shown that there is a rapid spread of hydrophilic compounds in CSF after lumbar intrathecal injections. The hydrophilic nature of these compounds, however, does make it more difficult for them to attach to the desired receptors. The lipophilicity of the opioid determines the extent of diffusion and concentration in the brain after ICV administration.[162] Brain concentrations of the morphine persist for a few hours after injection although the drug is unevenly dispersed in the tissue. Since morphine is hydrophilic, the movement of the drug through the ventricles of the brain is more like passive diffusion than active transport. Fentanyl, sufentanil, and etorphine, the lipophilic opioids, are cleared in the CSF after one hour as they bind better to lipophilic receptors.[162]

This procedure appears to be best suited for head and neck cancer pain. Occasionally, it is used for patients with limited survival time (1–3 months) who develop a tolerance to intraspinal infusion of opioids despite an good initial response to the treatment. Several factors must be weighed for effective treatment with intraventricular morphine delivery via an Ommaya reservoir, such as the location of the pain, age of the patient and the history of opioid usage. The lower limbs benefit from lumbar subarachnoid administration of morphine, whereas craniofacial or diffuse pain was shown to be more responsive to the analgesic effect of ICV delivery.[163]

Seiwald and Kofler[164] have described in detail their experience with 20 patients (18 patients had cancer) treated with ICV morphine injections between 1990 and 1993.

Administration of morphine into the ventricle through a catheter-reservoir system was nondestructive and effectively relieved nociceptive pain.[164] They also found that lower doses were slower to bring about pain relief. Somatogenic pain was ameliorated in 95 percent of the patients; however, minimal effects were seen in the management of neurogenic pain.[164] The safety and side effects of the intraventricular injections or infusions are similar to intraspinal infusions with the exception of the increased risk of respiratory depression noted in the first 3 days of the intraventricular delivery.[158,160]

Deep brain stimulation

Interest in stimulation swelled in the late 1960s and early 1970s as the severe morbidity rates and limited scope of some early ablative procedures came to light.[165] In 1972, the first stimulation of periventricular and periaqueductal gray matter were performed in humans.[165] Particularly effective in those with chronic pain that activates the paleospinothalamic tract, deep brain stimulation is currently the most useful technique for central pain caused by spinal cord lesions as well as pain that is inadequately relieved with spinal cord or peripheral nerve stimulation.[165] The use of deep brain stimulation has also been reported in the relief of chronic pain of noncancer etiology.[166]

During this procedure, an electrode is implanted by placing the patient under local anesthesia while a burr hole is made 3 cm from the midline in the coronal structure. These burr holes are made easily with CT and MRI-guided stereotaxis because the technology enables accurate placement of the stimulating electrodes.[166] For this operation, the initial targets are either the periventricular gray/periaqueductal gray (PVG/PAG) area, the ventral posterior lateral thalamus, or the internal capsule.[166] To implant an electrode in the PVG/PAG, the exploring electrode tip is placed 10 mm posterior to the midpoint of the AC–PC line at a depth of 4–5 mm.[165] The internal capsule can be found using the atlas of Tasker and Emmers and test stimulation performed at the junction of the thalamus and internal capsule.[165]

In the PVG/PAG, stimulation sets off an endogenous opioid system, mediated primarily by β-endorphins, which inhibits noxious pain impulses.[165] Judging from failed trials with naloxone, the system in the thalamus and internal capsule does not involve opioids, although the mechanism of action is not precisely known.[165] The type of pain being experienced and the severity of the situation help in determining which target site will provide sufficient analgesia. Stimulation of the PVG/PAG is best suited to nociceptive pain, while stimulation of areas in and around the thalamus is thought to work better for neuropathic pain.[167] The small size of thalamic targets as well as the numbness that may result from implantation have led some surgeons to prefer the internal capsule to the lateral thalamus.[165] Many surgeons place electrodes temporarily in both areas and allow the patient to choose the location that best alleviates pain; others rely on intraoperative stimulation to determine

placement. After 4 days, routine tests of the apparatus determine the frequencies that generate pain relief. Several days to 3 months after implantation, a radiofrequency-receiving device can be attached so that the patient can freely use the device.[165]

In cancer pain, deep brain stimulation can accommodate patients with pain refractory to ablative procedures. This includes pain from diffuse bone metastases, midline or bilateral pain (especially of the lower body), brachial or lumbosacral plexopathy, and recurrent pain from head and neck cancer.[168] In a series of 31 patients with cancer pain who were treated with deep brain stimulation, 87 percent of the patients experienced satisfactory relief with 55 percent of these experiencing lasting relief until death.[168] In a trial of 68 patients over 15 years, 78 percent underwent internalization of their devices and 79 percent reported long-term relief.[167]

Complications are unavoidable because they are greatly influenced by the placement of the deep brain stimulator electrode. They occur less frequently when the electrode is placed in the PVG region than when it is placed in the PAG. The most reported complication in the Kumar study resulted from hardware malfunction, although 20–25 percent of patients involved in the study reported the development of migraine-type headaches.[167] One complication specific to PVG/PAG is the development of tolerance. It has been suggested that ramp stimulation (intermittent stimulation) and administration of L-tryptophan for a period of 2–3 weeks can diminish this occurrence.[165] Although individual variations can reduce the chance for successful analgesia as a result of deep brain stimulation, the possibility of effective pain relief is both promising and realistic for most patients.[166]

Key learning points

- The management of cancer pain is a complicated challenge, requiring a thorough understanding of the cancer disease process, the pain diagnosis, and the treatment modalities available to treat the painful condition.

- In addition to pain, the patient with cancer often presents with a constellation of symptoms arising from the cancer and the oncological treatment. Full utilization of all available treatment modalities should help to optimize the patient's pain control and quality of life.

- In selected patients, neuraxial intervention via epidural or intrathecal delivery system can help the physician and patient to achieve effective control of cancer pain, minimize opioid-related side effects, and thereby optimize quality of life.

- Over the past decade, the technology for and use of spinal procedures has remained fairly constant and as a result,

information is still not complete concerning the best application of many of these procedures. Most certainly, it should be emphasized that these techniques are applied only to patients with severe pain since many of the noninterventional options will suffice for pain that is minimal or mild in severity.

- Selection of a specific technique can be based upon expected survival time of the patient with cancer, pain location, and/or preference toward ablative or augmentative options.

- Despite the praise heaped by different clinical groups upon individual methods, information regarding the best modalities of treatment for specific pain syndromes is still lacking. This might be an indication that technology has outpaced our knowledge of the most effective application for each procedure.

- In the modern era, palliative care can and should make use of these modalities to become both 'high-touch' and 'high-tech', which need not be mutually exclusive concepts in the care of patients with cancer.

Topical administration of analgesics

ANDREAS KOPF, STEFFEN SCHMIDT, CHRISTOPH STEIN

INTRODUCTION

Systemic application of analgesics is the preferred route of drug administration to achieve pain control in malignant as well as nonmalignant pain. However, recent findings suggest a role for topical administration of analgesics as well as the use of local receptor systems. This can be achieved by a variety of application forms, e.g. creams, lotions, gels, patches, aerosols, and occlusion systems. They allow high local drug concentrations at the site of pain with low or absent adverse drug effects due to low systemic drug levels. By definition, topical analgesia targets a site immediately at the location of drug delivery whereas transdermal analgesia uses the skin merely as an alternative delivery route to achieve systemically active drug levels. Tissue affected by cancer may be more responsive to topical analgesia due to injury of skin or membrane integrity. Peripheral pain signaling is influenced by a number of excitatory and inhibitory mediators released by local tissue injury and inflammation. Neurotransmitter receptors are expressed and/or upregulated on sensory nerve endings, which may be targeted by topical analgesics. Inhibitory receptors which may be useful clinically include μ-, λ- and δ-opioid and cannabinoid receptors. An extensive review of this topic has been published recently.[1] A number of different drug classes have been administered topically (Table 49.1).

DRUG CLASSES

Opioids

Opioids are mostly used orally or parenterally. Lately the transdermal route has gained popularity for patients with and without cancer. Less frequently, opioids are administered

Table 49.1 *Drug classes which have been used for topical administration*

Drug class	Target
Opioids	μ-, κ- and δ-opioid receptors
Nonsteroidal anti-inflammatory drugs	Cyclooxygenase
Local anesthetics	Na channel
Menthol	TRPM8 receptor
Capsaicin	TRPV-1 receptor
Tetrahydrocannabinol	CB_2 receptor
Clonidine	α_2 receptor
Ketamine	NMDA receptor
Tricyclic antidepressants	Na channel, adenosine receptor

intranasally or intraorally to achieve high and reliable systemic drug concentrations, mostly in postoperative[2*] but also in cancer pain.[3*] Still, in some patients systemic side effects of opioids limit their use. Therefore using topical effects of opioids may help achieve analgesia and at the same time reduce systemic blood levels and side effects.

Opioid receptors have been identified outside the central nervous system in animals[4] and in humans.[5] They are expressed in the neuronal cell bodies in the dorsal root ganglia and then transported intraaxonally to peripheral sensory nerve terminals of C- and A-fibers.[6*] The presence of local inflammation and secretory stimulants (e.g. interleukin [IL]-1, corticotrophin-releasing hormone [CRH]) determines the migration of opioid-producing cells and opioid peptide release.[7] In certain pain situations where affected tissue may be approached externally (e.g. skin ulcers or oral mucositis) local opioid receptors may be used to achieve analgesia. μ-Agonists like morphine seem to be the most potent

at producing peripheral analgesia. Patients with ulcerating cancers may benefit not only from local analgesia but also from the local anti-inflammatory effects of opioids.[8,9]

While the therapeutic concept of local opioid analgesia is regularly used and well documented in the case of intraarticular application of morphine for perioperative analgesia,[10] there is scarce literature on local opioid analgesia in other locations like skin, bladder, or nerve plexus.[11*,12*,13] Only few studies have examined the effects of local opioid analgesia in cancer patients. Oral mucositis is a frequent complication of cytoreductive radio- or chemotherapy.[14] In particular, pain from oral mucositis remains a therapeutic challenge in patients with bone marrow transplantation.[15***] Ulcerations of the oral cavity are a consequence of the direct toxic effects to the epithelial layer, enhanced by cytokines[16] and local superinfections,[17] resulting in damage to the epithelial integrity.[18] The majority of patients with oral mucositis will depend on the World Health Organization (WHO) step III systemic analgesics to achieve pain reduction,[19**] usually for 10–20 days. Patient-controlled intravenous opioid analgesia is the first choice.[20] In radiochemotherapy-induced oral mucositis it has been shown that the topical administration of 15 mL of 0.2 percent morphine reduced pain intensity and duration, which might be interpreted as a local analgesic and/or anti-inflammatory opioid effect.[21**] In a similar study that used repeated applications of 200 µg fentanyl sufficient analgesia could not be achieved or a healing tendency of the oral mucosa.[22] To achieve local opioid analgesia and to avoid systemic uptake a less lipophilic substance like morphine may be more suitable. For example, it has been shown that less than 20 percent of (5 mg) morphine after being in the oral cavity for 10 minutes was absorbed systemically.[23]

Apart from intraoral local opioid analgesia there is a growing body of experimental and clinical evidence that opioids are also useful when applied topically to cutaneous ulcers. A number of case reports and case studies describe profound and long-acting analgesia with minimal adverse effects.[11,12*,24–28] In most cases morphine was used locally, usually in a commercially available gel formulation, and in some instances with an occlusion tape. One study evaluated the ability of morphine to penetrate intact skin and its subsequent systemic uptake.[29] The maximum calculated systemic bioavailability for morphine after topical application was 20 percent. In most patients absorption was negligible. It was concluded that topical morphine has local analgesic effects without considerable systemic absorption, with the possible exception of ulcers with a large surface. However, it has yet to be determined systematically how specific formulations and application techniques influence bioavailability and systemic uptake, which drugs are optimal and what is the potential for cutaneous side effects.

Nonsteroidal anti–inflammatory drugs

Nonsteroidal anti-inflammatory drugs are an integral part of the World Health Organization (WHO) analgesic ladder.

Due to their gastroenterological and renal toxicity they are often used with caution in the management of pain in palliative care patients. Selective inhibitors of cyclooxygenase (COX)-2 have the advantage of longer dosing intervals and do not need to be combined with gastroprotective agents. Nevertheless in many instances topical NSAID preparations would be welcome, since plasma concentrations following topical application are 15 percent lower than those after systemic application.[30***] Whether the possible increase in cardiovascular morbidity and mortality with COX-2 inhibitors is a real concern in the palliative care patient population is questionable, since only patients with long-term treatment seem to be at risk.[31**] Topical NSAIDs are typical over-the-counter medications which are widely advertised and used for acute and chronic pain, but usually not for cancer pain. A large number of formulations (cream, gel, ointment) are commercially available with varying drug delivery to the skin.[32,33***] Most studies examined patients with acute pain due to sports injuries or chronic pain in osteoarthritis.[34**] In contrast to the general belief that NSAID concentrations in tissues below the dermis are low, two meta-analyses concluded that topical NSAIDs are effective for a limited period of time in acute painful conditions[35***,36] and chronic conditions.[37,38***] The long-term use of topical NSAIDs in the treatment of osteoarthritis did not support efficacy.[39***] For the palliative care situation specific indications for topical NSAIDs are unknown. However, there are some situations when their application might be justified, e.g. to alleviate pain and inflammation at sites of cannulation,[40*] to reduce pain and discomfort from topical treatments in actinic keratoses[41*] or to control pain in acute herpetic neuralgia,[42**] a painful complication frequently seen in cancer patients. In the latter study 30 mL of ethyl-ether added to 1500 mg acetylsalicylic acid were applied locally onto the affected dermatome with beneficial effects on pain. No active drug concentrations could be detected in plasma after topical administration.[43] In a more recent study this effect could be reproduced using a topical aspirin-moisturizer solution.[44**]

Local anesthetics

Topical formulations of local anesthetics produce analgesia by blockade of sodium channels in cutaneous primary afferent neurons. Sodium channel blockade reduces impulse generation both in normal sensory neurons and in damaged sensory neurons with ectopic repetitive firing. Therefore, topical local anesthetics are effective in acute pain states as well as in chronic neuropathic pain states. Remarkably, in neuropathic pain states with altered expression, distribution and function of sodium channels along axons, pain relief is achieved with local anesthetic tissue concentrations far below those which totally block impulse conduction. Therefore, pain reduction in neuropathic pain states is possible without achieving anesthesia of the skin.[45]

Most evidence for pain relief through topical local anesthetics exists for lidocaine either as a eutectic mixture with prilocaine (EMLA®)[46***] or as a patch.

EMLA is used for alleviating pain resulting from invasive procedures. A variety of controlled studies have demonstrated analgesic effectiveness for procedures such as venipuncture,[47**,48,49] central venous port access[50*] or lumbar puncture,[51] especially in children with cancer. A minimal application time of 60 minutes with occlusion is necessary for optimal results. Invasive procedures therefore have to be prearranged. A new formulation with liposomal lidocaine seems to have a faster onset and could therefore be advantageous.[52] For the palliative care patient there is good evidence for efficacy of EMLA in reducing pain in venous leg ulcers.[53***] There is one case report of pain control with EMLA in a patient with rectal pain caused by a malignant mass.[54] Side effects are rare and include erythema or pruritus. Prilocaine-induced methemoglobinemia has been described primarily in infants but there are case reports of occurrence in adults.[55] Due to its short duration of action (2–4 hours) EMLA is normally not suitable for treatment of chronic pain conditions.

Lidocaine patches have been reported to be effective in the treatment of chronic neuropathic pain and are a valuable alternative or supplement to systemic neuropathic pain therapy. The coated lidocaine patch contains 5 percent lidocaine and is easy to apply. It has to be attached for 12 hours per day at the site of pain. Controlled studies showed pain reduction in patients with longstanding postherpetic neuralgia and mechanical allodynia.[56**,57*,58**] However, reduction of allodynia seems to be at least in part due to patch protection of the allodynic skin. Also, in patients with painful diabetic polyneuropathy,[59] complex regional pain syndrome (CRPS), postmastectomy syndrome or post-thoracotomy syndrome[60] pain relief can be achieved with the lidocaine patch. A recent controlled study reported significant reduction in pain and allodynia in patients with focal nonherpetic neuropathies.[61*] There have been no reports of serious side effects,[62] but local skin irritation can occur. In certain situations gel formulations of lidocaine may be useful without systemic adverse effects, e.g. in a 5 percent concentration for the treatment of postherpetic neuralgia[63**] or oral mucositis.[64]

Some years ago the local anesthetic n-butyl-p-aminobenzoate (BAB), also known as butamben, a highly lipid-soluble congener of benzocaine, was reintroduced into clinical practice for end-stage cancer patients. It was shown that (repeated) injections in the epidural space, at peripheral nerves, and at the celiac plexus resulted in a prolonged and profound analgesia without impairment of motor function.[65*,66*,67*] The prolonged period of effect was achieved without pathomorphological changes of nerve structures. More recently the ability of butamben to penetrate skin when applied locally was tested in an animal study,[68] In this study butamben was superior to lidocaine and displayed synergistic interactions with morphine.

Phytotherapeutics

Peppermint oil containing 10 percent menthol (the active ingredient) has been used successfully in a patient with neuropathic pain.[69] Also, itching may be relieved with menthol through its possible interaction with the TRPM8 receptor.[70,71] Arnica gel (combined with salicylate) may also be useful.[72,73*]

An interesting observation regarding traditional herbal medicine in India is the analgesic and anti-inflammatory effect of topical gall extract of *Quercus infectoria* Olivier (Fagaceae).[74] Commonly used externally for pain control and internally for its supposed anticancer potential but with only anecdotal evidence is noni (*Morinda citrifolia*), a traditional Polynesian medicinal plant.[75]

CAPSAICIN

Capsaicin is the active pungent ingredient in hot red chili pepper. Topically applied capsaicin interacts with nociceptive neurons in the skin via the vanilloid receptor (TRPV-1).[76] It causes an initial activation of neurons with release of substance P. This is perceived as burning or itching sensation with a flare response. After repeated application desensitization and hypalgesia occurs, probably due to depletion of substance P both peripherally and centrally.[77] Another potential mechanism for hypalgesia after repeated application is a direct neurotoxic effect on small diameter sensory afferents, resulting in degeneration of those fibers.[78]

Topical capsaicin was shown to achieve significant pain relief in the treatment of postherpetic neuralgia when used as a 0.075 percent cream three to four times daily for 8 weeks.[79**] A small controlled study reported pain reduction in postmastectomy syndrome.[80] A recently published systematic review[36] pooled data from six double blind, placebo controlled trials with analysis of capsaicin application for neuropathic pain. It revealed a moderate to poor efficacy of topically applied capsaicin 0.075 percent, and the NNT (number needed to treat) was 5.7. A different treatment approach using concentrations up to 10 percent was successfully tested in CRPS.[81] To tolerate this treatment, patients needed regional anesthesia, since pretreatment with topical EMLA failed to control pain induced by capsaicin above a concentration of 1 percent.[82*] In conclusion, topical capsaicin may be a valuable supplement for the treatment of neuropathic pain in a small number of patients unresponsive to or intolerant to other therapeutic approaches.

TETRAHYDROCANNABINOL

The effects of systemic tetrahydrocannabinol (THC) tend to be overestimated in palliative care.[83] Comparative levels of analgesia may be achieved with 'weak' opioids like 60 mg codeine.[84] Furthermore the antiemetic effect of ondansetron is superior to THC[85] and anorexia may be treated more effectively with megestrol.[86,87**] Intractable pruritus secondary to

cholestatic liver disease may be a new indication for THC.[88] Side effects such as sedation and vertigo limit the doses of THC used in clinical practice. The analgesic activity of cannabinoids is generally believed to be mediated via CB_1 and CB_2 receptors.[89,90] Interestingly, for certain situations in palliative care where injury of epidermis or mucosa is present, CB_2 receptors may play a particularly prominent role in the periphery.[91,92] In animals a local effect[93] and interaction with topical morphine antinociception[94] could be demonstrated. Local peripheral formulations of cannabinoid derivatives have not been tested yet.

Clonidine

α_2-Adrenergic agonists such as clonidine cause antinociception due to the inhibition of postsynaptic spinothalamic neurons and presynaptic primary sensory nerve terminals and due to a generalized attenuation of sympathetic efferent activity. Systemic, spinal, and supraspinal analgesic effects of clonidine have been reported.[95] Therapeutic utility for general pain management is confined to mild pain because of dose-limiting central side effects, e.g. sedation and hypotension.[96] Topical administration may be an alternative since α_2 receptors are expressed by nociceptive sensory neurons and are mediators of sympathetic afferent coupling.[97–100] Peripheral antinoceptive effects devoid of central side effects could be demonstrated in animals[101*] and in a human case report with clonidine ointment.[102] Clonidine is available as a patch for transdermal administration, but relief of symptoms has been ascribed to systemic action.[103**] Local intraarticular clonidine may enhance the effects of local anaesthetics[104] and opioids[105] when inflammation is present.

Ketamine

The analgesic and dissociative properties have made ketamine, the most prominent N-methyl-D-aspartate (NMDA) receptor antagonist with combined activity at opioid receptors, a frequently used anesthetic for minor surgery. However, its undesired psychomimetic effects do limit its use. Ketamine binds noncompetitively to NMDA receptors and to opioid receptors. NMDA receptors are seen to play a key role in spinal processing of neuroplasticity mainly by inhibiting the effects of excitatory amino acids like glutamate. The clinical use of NMDA receptor antagonists in palliative care remains anecdotal since clinical studies are rare and mostly case reports. Ketamine oral rinse was tested with some success in mucositis in one cancer patient.[106] Case reports on the efficacy of ketamine administered topically for pain in the palliative care setting[107] and different neuropathic pain states[108,109] have been published. Apart from the NMDA receptor antagonism other actions and interactions from ketamine may contribute to local analgesia.[110–112] The value of NMDA receptors in cancer pain remains to be defined.

Tricyclic antidepressants

Tricyclic antidepressants (TCAs) are the mainstay of treatment for neuropathic pain. In a variety of neuropathies of different origin systemically administered TCAs have the lowest NNT to produce pain relief. Their efficacy is only partial and can be limited by the occurrence of troublesome side effects.[113***] To limit side effects the topical application of amitriptyline and desipramine was studied in a rat model, demonstrating antinoceceptive properties.[114] According to studies with doxepin 5 percent[115] and 3.3 percent[116**] either a cream or gel formulation may be useful in both inflammatory and neuropathic pain. Additionally TCAs have been tested as a mouthwash in oral mucositis due to cancer or cancer therapy.[117]

Other approaches

Other approaches to topical analgesia have been tried, but without major practical significance for cancer pain and the palliative care situation. Experimental research has demonstrated modulatory effects on pain of the endogenous nucleoside adenosine and its analogs.[118,119] This is probably due to the activation of the antinociceptive adenosine A_1 receptor. Peripheral adenosine kinase inhibitors might produce a direct effect on pain by adenosine actions on the sensory nerve terminal via A_1 receptors and through effects on the inflammatory process via A_2 receptors. In rodents local application caused neurogenic edema.[120,121]

Since γ-aminobutyric acid A ($GABA_A$) receptors are present on afferent axons, peripherally acting GABA agonists may inhibit pain.[122] A recent study evaluated the analgesic potency of a mouthwash with clonazepam, which possesses a high affinity for the $GABA_A$ receptor.[123**] Without considerable systemic blood levels patients with clonazepam achieved significant pain reduction, an effect which might be used in cancer-related mucositis as well.

Neuraxial administration of cholinesterase inhibitors like neostigmine has been studied in different patient populations,[124] but there are no reports of topical administration, although peripheral muscarinic receptor activation results in sensory neuron desensitization.[125] The findings of a clinical study[126*] with iontophoretically applied topical vincristine in postherpetic neuralgia could not demonstrate a reduction in neuropathic pain in comparison with placebo.

Neuropeptide FF is an octapeptide present in the central nervous system with specific receptors in the human spinal cord. It is believed to modulate morphine-induced analgesia. A recent study[127] in rats reported the effects of an analog of neuropeptide FF on hyperalgesia and morphine-induced analgesia. Unfortunately these effects were weakest in neuropathic pain states. Peripheral modulatory influences of neuropeptides on pain signaling have been postulated but are poorly understood at present.

Table 49.2 *Possible useful indications for topical analgesics*

Topical analgesic	Possible useful indication
Morphine, fentanyl	Oral mucositis, ulcerating skin cancer
Acetylsalicylic acid	Skin lesions in (acute) herpes zoster
EMLA, 5% lidocaine, butamben	Skin ulcers, postherpetic neuralgia with allodynia
Menthol 10%	Itching with hyperbilirubinemia
Capsaicin ≥ 0.075%	Peripheral neuropathic pain, e.g., in HIV/AIDS
Ketamine	Oral mucositis, peripheral neuropathic pain
Doxepin 5%	Peripheral neuropathic pain, urethral hyperesthesia

Possible useful indications for topical analgesics are shown in Table 49.2.

Key learning points

- Topical analgesia targets local (e.g. cutaneous or subcutaneous) receptors and neurotransmitters to inhibit pain signaling.

- Due to reduced or absent systemic uptake side effects of analgesic substances are reduced.

- Local anesthetics and capsaicin are currently the most widely used topical analgesics.

- Especially opioids but also ketamine and cannabinoids are promising drugs for clinical studies and practice.

- Increasing understanding of the peripheral mechanisms of pain signaling holds the promise of future advancement of topical analgesia.

- Postherpetic neuralgia, regional allodynia, oral mucositis and exulcerating cancer are the current indications for topical analgesia with most satisfying results.

- Topical analgesia should be part of a multimodal approach to palliative symptom control whereever possible.

Pain and opioids in children

RICHARD D W HAIN, MARY DEVINS, ANGELA MISER

INTRODUCTION

The management of pain in the palliative care of children is somewhat different from that of adults. It also differs in approach from management of other types of acute and chronic pain in childhood. Where once opioids were thought to be highly dangerous drugs, often unsuitable for use in children, they have now taken their place as the mainstay of provision of good analgesia in the palliative phase.

The verb 'to palliate' means to relieve without curing. Palliative medicine was first recognized as a medical specialty in the UK in 1987. It has been defined as 'the study and management of patients with active progressive, far advanced disease for whom the prognosis is limited and the focus of care is on the quality of life'.[1] The World Health Organization (WHO) further elaborated on the multi-dimensional care inherent in this ideal, summarizing palliative care as 'the active total care of patients whose disease is not responsive to curative treatment. Control of pain, of other symptoms and of psychologic, social and spiritual problems is paramount. The goal of palliative care is the achievement of the best quality of life for patients and their families'.[2]

Palliative medicine in children was initially defined in 1997 by the Royal College of Paediatrics and Child Health working with the Association of Children with Life-limiting or Threatening conditions and their families (ACT).[3,4] The basic principle remains the same as for adults; palliative care for children and young people with life-limiting conditions is described as 'an active and total approach to care embracing physical, emotional, social and spiritual elements. It focuses on enhancement of quality of life for the child and support for the family, and includes the management of distressing symptoms, provision of respite care through death and bereavement'. Life-limiting conditions are those for which there is no hope of cure and from which children will eventually die, though often years or even decades after diagnosis. For many the progress of the disease is such that they become increasingly dependent on others. Because an end to life is imminent or anticipated in the foreseeable future, care and interventions may sometimes differ from those chosen in acute care, where therapy is aimed at reversing a disease process. They may even differ from chronic care, where optimal management of long-term conditions is the goal.

Opioids often play a central role in analgesic management in palliative care. They are commonly divided into weak and strong opioids, and they have no 'ceiling effect'. The dose can be escalated as required to achieve adequate analgesia. Occasionally this is limited by increasing toxicity, in which case an alternative may be equally effective with fewer adverse effects. Such a limitation is more likely with weak opioids. Strong opioids are the predominant analgesics used in palliative care, and this chapter is limited to aspects of their use in treating pain in children with life-limiting conditions. Their use in neonates, and in management of acute postoperative pain or for sickle crisis, will not be addressed here. The interested reader is referred to the extensive published literature on these topics.

Historically, the approach taken by physicians to using major opioids in their patients has been an illustration of the human tendency to place more faith in myth than in evidence. We are particularly prone to believe myths that appear to carry the authority of scientific research. For decades it was believed that opioids were highly addictive drugs whose therapeutic potential was trivial compared with their threat to society. The fear of prescribing morphine,

now often termed 'morphophobia', has been and perhaps remains the single greatest threat to the comfort of patients with moderate to severe pain.

Children are especially vulnerable to undertreatment of their pain. In caring for a child, the instinct of adults may be to adopt a precautionary approach. The belief that morphine is a highly dangerous drug, however ill supported by evidence, is enough to cause many pediatricians to hesitate before prescribing it. Other myths have developed to justify such an approach. These include the traditional notion that children are physiologically less capable of feeling pain,[5] or that they can and should 'tolerate discomfort well'.[6] Provided that basic prescribing principles are observed throughout, morphine and other strong opioids are very safe in the management of moderate to severe pain. The risks of adverse effects and addiction in adult palliative care are small[7] and there is no evidence that children differ in this regard.[8]

MAJOR OPIOIDS IN PALLIATIVE MEDICINE IN CHILDREN

Measuring pain in children

Pain is one of the most prevalent and distressing symptoms experienced by children with life-limiting conditions, and is rightly given high priority by the WHO.[9] For the dying child, accurate assessment of pain is often difficult and it is frequently necessary to review the effectiveness of therapy. Furthermore, many children with life-limiting illnesses are unable to verbalize their symptoms and will instead communicate their discomfort nonverbally. A great deal of work on the development of age-appropriate scales for measuring pain has been published.[10,11] Choosing a pain assessment scale suitable for day-to-day clinical use is important. However, it can be problematic. There are multiple tools available and this reflects the fact that none is ideal. Also, the measurement of pain in cognitively impaired children remains a challenge.[12] Whatever tool is chosen, it must remain part of the cycle of assessment, intervention, and review or reassessment.

The place of morphine in pain control

In attempting to address misunderstandings about opioids, the WHO developed an analgesic ladder[2,9,13] (Fig. 50.1). This provides a rational, simple, stepwise approach to pain, in which simple analgesics comprise the first rung, weak (minor) opioids such as codeine the second, and strong (major) opioids such as morphine the third. Analgesia on a higher rung of the ladder is introduced only if the previous one becomes ineffective.

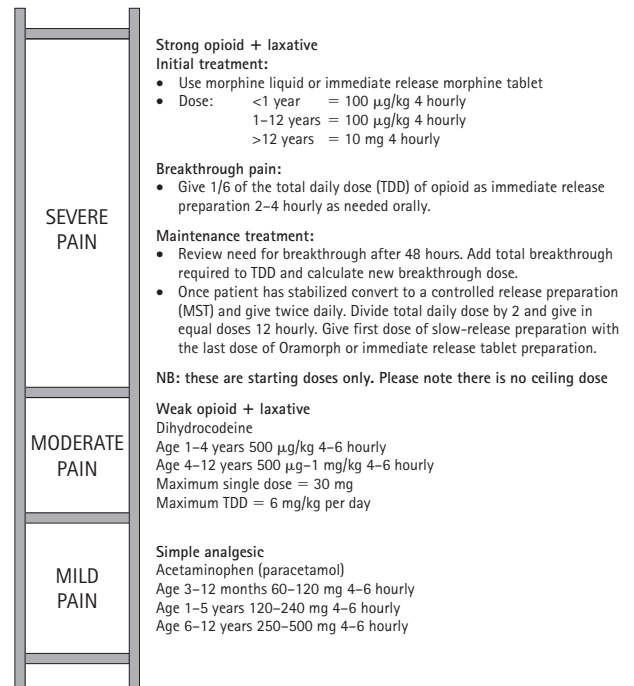
This 3-step approach has to be taken in conjunction with a number of other principles. First, at each stage, adjuvant analgesics appropriate to the nature of pain should be


Figure 50.1 An example of the World Health Organization pain ladder approach to pain relief. At each 'rung' appropriate analgesics should be considered (for example, radiation for metastatic bone pain, nonsteroidal anti-inflammatory drugs for musculoskeletal pain, antidepressants or anticonvulsants for neuropathic pain).

introduced. It is particularly important to identify features of neuropathic or bone pain. Second, there is no place for strong opioids to be given only pro re nata; if a strong opioid is required it should always be given on a regular schedule by the clock. The prescription of a regular dose of strong opioid should always be accompanied by a breakthrough dose that should be a fixed fraction of the total daily requirement. The total dose should be reviewed every 48 hours, with increases in the regular dose being indicated if more than two breakthrough doses per day have been required during any 48-hour period. Third, the oral route is always preferred unless there is a contraindication (for example, cytotoxic-induced mucositis).

Notwithstanding these general principles, a child suddenly presenting with severe pain may need a strong opioid from the outset, often parenterally and in frequent doses, until pain control is achieved.

PHARMACOKINETICS OF MORPHINE IN CHILDREN

Morphine remains the most frequently prescribed strong opioid in children and is the one about which most is known. It is the archetype strong opioid. Here we will consider opioids in children by examining the characteristics of morphine first, and then other strong opioids insofar as they differ in indication or in pharmacology from morphine itself.

Morphine appears to be well absorbed from the child's gastrointestinal tract.[14,15] The oral to parenteral potency is

approximately 50 percent; in other words, to achieve the same effect, an oral dose of morphine should be twice that given intravenously or subcutaneously. There is extensive biotransformation in the liver to a number of compounds, of which the two most important are morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G).[15,16] Both are more soluble in water than the parent compound. Morphine-3-glucuronide is quantitatively the most important but has little or no affinity for the μ-opioid receptor and no analgesic activity.[17,18] There is some evidence to suggest that it may contribute to some of the adverse effects of morphine, particularly neuroexcitability[18] though this is hard to explain. The 6-glucuronide on the other hand, has a high affinity for μ-opioid receptors[19] and is a powerful analgesic[20,21] with an effectiveness that exceeds that of morphine. The capacity to form both glucuronides is present from an early stage in fetal development[22] and there is some evidence that it increases over the first 12 months of life.[23,24]

The distribution of morphine and M6G seems to be similar in children and adults.[15,16] Clearance of the glucuronides is almost entirely renal and much of the parent compound is also excreted in the urine. The clearance of morphine and M6G in children appears to exceed that in adults.[15,16,23,25] This may be due to both better renal clearance and faster glucuronidation in children. To have a therapeutic effect, morphine and M6G must cross the blood–brain barrier to have access to receptors in the brain. Both morphine and M6G can penetrate into the cerebrospinal fluid of children. There is no evidence to suggest that outside infancy this happens more easily in children than in adults,[16] making it unlikely that children are any more sensitive to centrally mediated effects of opioids, such as respiratory depression.[26,27]

Morphine is the only major opioid whose pharmacokinetics have been extensively studied in children. The results have often been inconsistent. Some studies suggest that the volume of distribution per kilogram in children is much the same as adults, but that clearance and half-life are shorter.[15,16] The ratio of glucuronides to morphine may be higher in children than in adults.[15] Kinetics in the infant under 12 months of age is very different, with rather lower clearance particularly in neonates under 2 weeks of age.[28–30] One study, which concluded that clearance appeared to reach adult levels by 2 years of age,[25] did not exclude the possibility that it may then improve further before declining to adult levels at puberty.

There is anecdotal evidence to support the use in children of a smaller opioid dosage interval than in adults, particularly in the use of slow-release morphine and fentanyl patches. The slow-release formulations of morphine seem to result in a less sustained serum concentration in children than in adults and it is common in practice for children to require slow-release preparations of morphine to be given 8 hourly, rather than the recommended 12 hourly. Such a difference has not been shown in immediate release preparations of morphine, but this may be because when the appropriate breakthrough-dosing interval of 2–4 hours is used the difference does not have time to manifest.

CLINICAL USE AND ADVERSE EFFECTS OF MORPHINE IN CHILDREN

Typical guidelines for management of pediatric pain are shown in Figure 50.1. The adverse effect profile in children may be slightly different from that in adults. It is distinctly unusual in clinical practice for a child to complain of nausea as a result of opioid therapy, and prophylactic antiemetics are not usually indicated. On the other hand, constipation is very common, and laxatives should always be started at the time as prescribing a strong opioid. The mechanism of opioid-induced constipation is a reduction in bowel motility. To overcome this requires a stimulant laxative such as senna. Lactulose, which enjoys a prominent role in the management of constipation in children in the UK, is not an appropriate laxative for opioid-induced constipation. It is not primarily a stimulant. Furthermore, the breakdown products of lactulose cause flatulence, abdominal distension, and colic.[31,32] Where a softener is required, magnesium hydroxide is effective. Co-danthrusate, a combination of sodium docusate and dantron conveniently combines a softener and a stimulant laxative. It is currently licensed only for use in palliative care.[31,32]

Another adverse effect that seems to occur more commonly in children is urinary retention. The mechanism is not clear; it could be due to direct stimulation of opioid receptors in the smooth muscle of the internal sphincter, or else antimuscarinic activity. This uncomfortable complication is an indication to consider an alternative major opioid.

Alternative major opioids in children

Alternative opioids (Table 50.1) should probably only be considered in children when there is a good reason to abandon morphine. There are several potential reasons, and it is helpful to consider the alternative opioids that are available in terms of the advantages they confer over morphine. Of all the steps in the WHO pain ladder, the final major opioid step offers the greatest variety to choose from. Large numbers of opioids and synthetic or semisynthetic opioids are available. Many offer dubious advantage over morphine itself and do not have the benefit of its long track record and predictable clinical effectiveness.[35*,36*] Others, however, offer real benefits to the individual patient who has specific difficulties using morphine.

DIAMORPHINE

Diamorphine is currently thought to act in precisely the same way as morphine itself. The major difference is simply that it is more easily soluble in water. It has a role where a child requires a parenteral dose of morphine that cannot be dissolved in a convenient volume of fluid. Many units

Table 50.1 *Dose equivalents of major opioids commonly used in children, and their potential advantages over morphine*

Opioid	Advantage over morphine	Relative potency compared with oral morphine (approx)
Diamorphine (PO)	More soluble (when given parenterally)	1.5
Fentanyl (patch)	Patch formulation Less constipation[33] Less itch* Less retention*	100
Methadone (PO)	Anti-neuropathic activity[34]	Variable
Hydromorphone (PO)	None	5
Pethidine (PO)	None	0.125
Tramadol (PO)	None	0.25
Oxycodone (PO)	None	1.5–2

*Anecdotal information not based on trial.
PO, per oral.

have made diamorphine their standard parenteral opioid while retaining morphine as their standard oral opioid. Diamorphine is slightly more potent than morphine, approximately two-thirds of the dose is needed to give the same effect. To have the same effect as an oral dose of morphine, a parenteral dose of diamorphine should therefore be one-third of the dose.

FENTANYL

Fentanyl is a synthetic opioid which may offer a number of advantages over morphine itself for some children.[35*,36*] It does not appear to accumulate to the same degree when renal clearance is impaired,[37,38] it may cause less constipation than morphine,[33*] and does not seem to cause urinary retention. Perhaps most importantly from the child's perspective is that it is available as a transdermal patch, which can avoid the need for a subcutaneous or intravenous syringe driver in children needing prolonged major opioid therapy at home. The smallest patch size currently available, which delivers 25 μg/h of fentanyl, is rather too high a starting dose for many children. Fentanyl, being a completely different molecule from morphine, may also be effective when tolerance has developed to morphine or diamorphine. Fentanyl is often used in children as second-line strong opioid after morphine or diamorphine.[39]

HYDROMORPHONE

Hydromorphone is approximately five times more potent than morphine[40,41] and can therefore offer an alternative solution to the problem of solubility of large parenteral doses of opioid. It is metabolized in a similar way to morphine[42] and probably confers little advantage over diamorphine where the latter is available. Its main role is in

countries where diamorphine is not yet freely available for prescription, usually because of unfounded fears of heroin addiction.

METHADONE

Despite anecdotal reports of its safe use even in outpatients, there is little published experience of methadone in children.[43,44] This is a pity; potentially methadone has an important role in the management of pediatric pain. Methadone combines the effects of an opioid with those of an NMDA (*N*-methyl-D-aspartate) antagonist.[34] This gives it a potentially major role in the management of neuropathic pain, such as when following thoracotomy, amputation, or nerve damage due to compression by a tumor.[45–49] More research is required into the use of methadone in children before it can be recommended. It has an unusual distribution curve which can result in toxicity many hours or even days after the drug is commenced.[50,51]

OTHER OPIOIDS

Buprenorphine

There is anecdotal evidence that buprenorphine is effective and well tolerated in children, but this has yet to be substantiated in clinical trials. Potentially it has a valuable role in managing pain in pediatric palliative medicine, as it has the advantage over morphine of a transdermal matrix formulation that can be divided to enable small doses to be given. Evidence in adults also suggests constipation is relatively rare.[52*,53*] It may therefore have a particular role in children with neurological disorders such as cerebral palsy or metabolic conditions, where long-term weak opioid therapy is often needed but patients are susceptible to constipation and the enteral route for medications may be difficult. Clinical experience suggests that in children buprenorphine may be more nauseating than other opioids, but again this has yet to be confirmed in studies.

Pethidine

Nowadays, pethidine has little role in pediatric pain relief. It is considerably less potent than morphine (see Table 50.1). Enteral absorption is erratic.[54,55] The major toxicities of pethidine are in the brain, where accumulation of its metabolites causes convulsions.[56–59] Its one advantage over morphine is that it causes less constriction of the sphincter of Oddi, and proved biliary colic is perhaps its only – rare – indication in children.

Oxycodone

Although oxycodone is a κ as well as a μ agonist, its properties are similar to those of morphine.[60,61] Its oral

bioavailability is about 75 percent and like morphine it is biotransformed in the liver to a potent analgesic metabolite (oxymorphone). Again like morphine, the onset of action for oral oxycodone is 20–30 minutes and its duration of action is around 4–6 hours. Its clearance is impaired in renal failure. There is little experience of the use of oxycodone in pediatric palliative medicine, but it appears safe and effective in acute pain.[62] The risk of ventilatory depression may be higher than with morphine.[63] In general, there is little evidence that oxycodone offers significant advantage over morphine in children. Its role in pediatric palliative care, if any, remains unclear. It seems little different from morphine.

Tramadol

Tramadol is a weak opioid but its analgesic strength is augmented by an additional effect in inhibiting monoamine neurotransmitter reuptake.[64] Nevertheless its potency is only one-fifth to one-tenth that of morphine and it is probably best considered a weak or intermediate opioid. Its bioavailability is about 75 percent, and its onset and duration of action are similar to morphine. Its clearance is significantly impaired in liver dysfunction. Tramadol has a potency intermediate between codeine and morphine. It is more nauseating than oxycodone[65] and, like pethidine, can induce seizures.[66,67] Most research in children has been in the perioperative or postoperative context rather than the palliative. Like morphine, any effects on respiratory depression appear clinically insignificant.[68]

EPISODIC AND BREAKTHROUGH PAIN

Breakthrough pain has been defined as 'a transitory exacerbation of pain superimposed on a background of persistent but usually well controlled pain'.[69] The difficulty in managing episodic pain is that a dose of analgesic adequate for pain at its worst is often toxic when pain is at its least. Extra doses of morphine may be ineffective for severe episodic pain, since the time taken for it to reach effective serum levels means the pain has often subsided before it can work.

Pain may be episodic for three reasons. The dose of regular medication may be too small, resulting in intermittent breakthrough pain. The solution is to review the regular medication. The cause for pain may be episodic. For example, pain from a dislocated hip in cerebral palsy, or from bony metastasis in cancer can be provoked by movement (incident pain). Identifying, anticipating and where possible avoiding the provoking factors are the mainstays of treatment. Finally, the pain may simply be of an episodic nature, for example intestinal colic or muscle spasm. This is a situation in which adjuvant therapy such as anticholinergics or muscle relaxants may be helpful.

Because these causes for breakthrough pain are closely related, the definitions are often confused and incidence is therefore difficult to estimate.[70] The prevalence and characteristics of episodic and breakthrough pains have been evaluated. Patients report a wide variety of types of pain that can break through their regular analgesia, and similarly variable events that could precipitate it.[71] See also Chapter 54 (Episodic pain).

CHOOSING THE MOST APPROPRIATE ROUTE

The oral route is usually best for children. However, not all patients are able to swallow tablets or capsules. This is particularly true of children with neurodegenerative conditions, though many may have alternative enteral routes such as gastrostomy. Patients who are experiencing nausea and vomiting may simply be unable to tolerate oral medication. A range of alternative routes is available.

Transdermal patch

Fentanyl and buprenorphine are available as a self-adhesive patch.[35,36] The usual interval between changes of patch is 72 hours but a significant minority of patients may need the patch to be changed every 48 hours. It is important that adequate breakthrough medication continues to be made available, usually as immediate-release oral morphine or transmucosal fentanyl.[72]

Subcutaneous infusion

The subcutaneous route is often overlooked in the management of children. Portable syringe drivers, which are battery operated, are a convenient method for administering many drugs through subcutaneous infusion (CSCI). This approach combines the advantages of intravenous infusion (consistent delivery, easy titration, and potential for simultaneous administration of multiple drugs) with simplicity. Subcutaneous syringe drivers can be sited by nurses and can be managed at home with little medical or nursing input. Adverse effects can include local irritation at the site but this is usually easily managed by rotation through different sites.

Patient–controlled analgesia

Patient-controlled analgesia is an effective means of delivering postoperative pain relief. A modification of patient-controlled analgesia in children is nurse-controlled analgesia. This approach requires interpretation by an adult of a child's pain experience and risks delays to drug administration or even overruling of a child's reports of pain.

Continuous intravenous infusion

Where a child already has an indwelling central line, the intravenous route may be preferred.[73] This again permits constant plasma concentration, although this advantage is sometimes offset by difficulties maintaining the line. Multiple peripheral cannulation for intravenous infusion is not usually appropriate in the palliative phase since the subcutaneous route is at least equally effective and much easier to set up and maintain at home or in the hospice.

Rectal route

Many children will find rectal administration of medications unacceptable and this route should probably be discouraged nowadays, although it can provide rapid absorption and avoids the need for injection. The rectal route is contraindicated in children with neutropenia or thrombocytopenia. Relatively few strong opioids are available in rectal formulations. They include oxycodone, morphine,[74] and hydromorphone.

Transmucosal routes

Many strong opioids can be absorbed directly from the nasal or oral mucosa and can therefore be given via the buccal or intranasal route. This approach is particularly widespread among those working in children's hospices, where facilities for immediate intravenous or subcutaneous infusion may not immediately be available. The transmucosal route avoids first-pass metabolism, which may influence the effectiveness of opioids that are extensively metabolized in the liver.

OPIOID ROTATION OR SUBSTITUTION

It is likely that in some children tolerance to strong opioid analgesia can occur even in a therapeutic setting. The solution to this is usually simply to increase the dose of the major opioid. Rarely, such increases are constrained by dose-limiting toxicity such as neuroexcitability. One solution is to change to an alternative strong opioid of a different class.[39,75] A patient who has developed tolerance to the analgesic effects of morphine may well be less tolerant to those of fentanyl, for example. This phenomenon is termed 'incomplete cross-tolerance'. When substituting one opioid for another, the dose can and should be reduced, because tolerance to the analgesic effect of the new opioid will be incomplete. A corresponding reduction in toxicity will occur. The dose reduction is conventionally 25 percent.

Thus, a child who is toxic but not pain free on 1000 mg oral morphine per day can receive instead a fentanyl dose

equivalent to only 750 mg oral morphine, and yet enjoy better analgesia and less toxicity. This is further helped by the fact that tolerance to the adverse effects of opioids often occurs more rapidly than tolerance to the beneficial effects. It is probable that there is little advantage in changing drugs within a class, for example substituting diamorphine for morphine, since cross-tolerance is not likely to be incomplete.

CONCLUSION

Clinical evidence is accumulating that strong opioids can be used safely and effectively in children with moderate to severe pain. They should be used as part of a rational approach to the diagnosis, assessment, and management of pain (Box 50.1, Fig. 50.2). The WHO pain ladder gives a straightforward structure to such an approach and is recommended to all those who wish to approach the management of a child with pain.

The evolution of clinical expertise and experience has been paralleled and supported by an expansion of the

---

Box 50.1 Using opioids effectively: principles of good pain management in children

Do not be afraid of strong opioids in children – the risks of serious toxicity or addiction are vanishingly small when they are used therapeutically and rationally. Always:

- use a rational approach to diagnose pain and its cause

- use a rational approach to manage pain (use pain ladder)

- balance benefit of any diagnostic or therapeutic approach with burden to patient or family

- use the simplest approach that is effective (e.g. oral route where possible)

- use appropriate adjuvants at each 'rung'

- prescribe stimulant laxatives when major opioid is started

Avoid:

- intramuscular route

- strong opioids 'prn' except as breakthrough

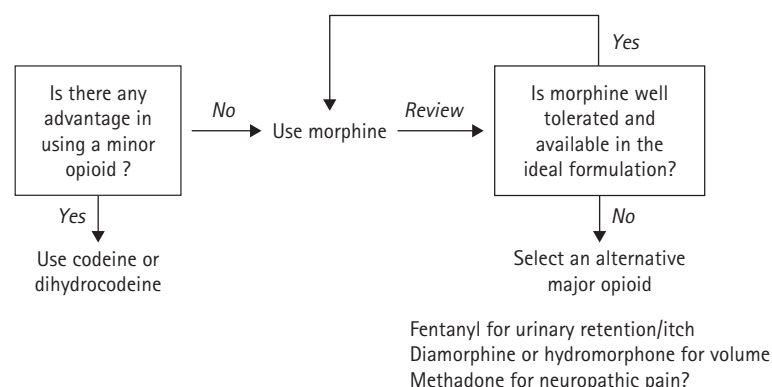
- novel opioids unless they are a genuine improvement on morphine


Figure 50.2 *A logical approach to the use of opioids in children. Until and unless evidence accumulates to suggest that another major opioid is more effective, less toxic, or cheaper (or ideally all of these), oral morphine should usually remain first line.*

research evidence base. This seems to show that, where children differ from adults in their handling of morphine, the result is that morphine is cleared more rapidly. It is plausible that this may make them more resilient than adults to its effects. More research is needed, as in so many other areas of pediatric clinical pharmacology. Important research areas include the clinical use of methadone and buprenorphine in children, and clarifying the dose–response relation of this important but often ill-understood class of analgesics in children.

Key learning points

- Children differ from adults in the pathophysiology and the pharmacology of pain management.

- Children experience pain at least as intensely as adults, but may not be able to express or quantify it verbally.

- After the first year of life, children may require higher doses of opioids than adults (relative to size) to obtain the same degree of analgesia. This may be because they clear some opioids more quickly. More research is needed.

- Pharmacokinetics in the neonatal period is very different from other periods in childhood, and in particular renal clearance is slower.

- The range of causes for pain in pediatric palliative medicine is wide, reflecting a great variety of life-limiting conditions other than cancer.

- Despite these differences, basic principles of pain management in adults can often be extrapolated to children, albeit with caution.

- Management of pain in children requires a combination of expertise in pediatrics and in symptom control. Where specialist pediatric palliative medicine is not available, close cooperation between pediatric and palliative medicine teams is essential.

Pain in older people

WENDY M STEIN

INTRODUCTION

Young patients fear new or increasing pain as a sign of impending death, whereas their older counterparts most fear that pain will reflect declining functional status and a loss of independence. In older patients where pain is often chronic, pain loses its diagnostic significance and degenerates instead into chronic depression as their world begins to revolve solely around unremitting pain. In advanced disease, unrelieved pain may actually shorten life,[1] and certainly limits the time spent in activities consistent with quality of life. Despite advances in understanding of the mechanisms of pain, improvements in drug delivery systems and increasing educational requirements of physicians already in practice as well as those in training, a substantial number of patients are in pain, particularly those from special populations like older people. These people remain vastly underrepresented in drug studies, when often they are the very population ultimately targeted for the product's use. Insurance carriers are more apt to fund high-tech surgical or anesthesia interventions as opposed to ongoing medication or physical therapy. Older patients often do not volunteer pain as a problem at an outpatient visit when presenting with multiple other medical problems, feeling that pain is a natural part of aging. Older patients have a greater potential for drug–drug and drug–disease interactions due to changes in pharmacokinetics with aging and thus present a greater treatment challenge.

Despite these obstacles, pain can be successfully assessed and treated in the older patient, and when done so successfully fulfills the mission of geriatric care to improve function

as the patient defines it. The purpose then of this chapter is to outline those issues unique to pain assessment and treatment in the older person. As this textbook is quite comprehensive in nature, this chapter will not review information already presented, but rather seek to supply the practitioner with a framework with which to competently approach the older person in pain.

DEFINITION AND EPIDEMIOLOGY

The International Association for the Study of Pain defines pain as an 'unpleasant sensory and emotional experience'.[2] Sensation and transmission is mitigated against the backdrop of previous pain experiences which are often far richer than for their younger counterparts. The multifactorial nature of pain separates it from many of the other syndromes commonly observed in geriatric medicine. Like dementia and incontinence, pain occurs with increasing prevalence as an individual ages, but should never be considered a normal or necessary part of the aging process. As many patients consider pain a natural sequela of aging, they will not volunteer clinical information unless specifically queried.

Exact estimates of pain in older cohorts are not known, particularly in those community dwelling elders over age 75. In most studies significant pain is defined as pain severe enough to prompt a patient to take medication several times a week or daily or to impair functional status. Studies have suggested that the prevalence of significant pain in

community-dwelling elders may range from 25 percent to 56 percent,[3] and in nursing home residents from 45 percent to 80 percent.[4] The most common causes are related to musculoskeletal sources such as arthritis or chronic back pain. A Harris poll in 1997 found that 18 percent of older persons surveyed took analgesic medication several times a week or daily, and of this group, more than 70 percent each self-reported taking prescription and over-the-counter medications for their pain.[5] This finding is of particular concern as anti-inflammatory related complications are one of the most common reasons why older persons are admitted to acute care hospitals. As these medications can be purchased without prescription, they are often not reported to physicians at office or home visits. It is not unusual for an older person to have explored every option available to him or her before reaching the physician's office with a pain complaint.

Pain should be classified by physiological mechanism thus allowing the clinician to focus treatment interventions appropriately. Nociceptive pain arises from stimulation from nociceptors and is divided between somatic and visceral sources of pain. Somatic pain such as tendonitis commonly arises from injury to a specific tissue, joint or tendon. Pain can be localized to the injured area and is often described as aching pain. This type of pain responds well to common analgesic medications and topical interventions as well as physical therapy. Visceral pain arising from an organ may be dull, constant or sharp but may be referred to a site distant from the involved organ. Visceral pain may require surgical intervention depending on the cause and may require analgesics for moderate to severe pain. Neuropathic pain such as postherpetic neuralgia or diabetic neuropathy is generated from aberrant nerve signals in the periphery or central nervous system. Neuropathic pain is distinctly different from the nociceptive sources of pain; although traditional analgesics may 'take the edge off' the pain, adjuvant medications or invasive interventions are often needed to effectively treat these syndromes. Patients will often describe this type of pain as burning, shooting, electric, or shocklike. The patient's self-description will often lead the clinician to the most appropriate intervention more quickly than diagnostic testing, and without the waiting time required to obtain test results so that relief can be initiated almost immediately.

PAIN ASSESSMENT

The Joint Commission on Accreditation of Hospitals (JCAHO) now stipulates that pain assessment should be initiated upon admission to every healthcare setting, but wisely leaves it to that setting to determine how that should be best accomplished. In the acute care hospital, this provides the opportunity to identify pain and order any necessary consultations or studies prior to discharge, thus minimizing lengthy trips back and forth to the hospital. Subsequent pain assessments should be performed in the outpatient office setting and upon initial admission to the assisted living, nursing home, or subacute care unit after acute illness, with each change in level of care or with each pain intervention, and finally as part of the Minimum Data Set (MDS). The greatest challenge at each of these step points is transfer of key information and treatment plans.

Pain assessment may present unique challenges in the older person. The population of older persons living in some kind of community care setting is rising rapidly. The long-term care environment may pose difficulties in obtaining diagnostic testing and evaluation. In-house laboratories, radiology or other resources for the accurate and timely evaluation of patients are uncommon. Expert consultants from neurology, palliative medicine, anesthesia, physiatry, and psychiatry are usually unwilling to travel from the acute care environment. This often results in residents being transported to distant facilities for evaluation of active problems and for scheduled state-of-the-art diagnostic evaluations. From the older person's perspective this means missed meals and medications as well as hours waiting at the diagnostic center for studies, and the potential for iatrogenic illness (complications due to invasive diagnostic requirements such as radiographic dye), or increased musculoskeletal discomfort incurred while lying on hard surfaces without premedication for prolonged time periods in order to procure diagnostic information. The key question in geriatric palliative medicine, or geriatric primary care for that matter, is always will the findings change the plan of care enough to make the burden of procuring the information worthwhile?

A second significant challenge is the meaning of pain to an older person. It is uncommon for older people to have only one pain complaint, and since musculoskeletal sources of pain (arthritis) are prevalent in this population along with other pain types occurring with high prevalence (vasculitis, neuropathy, etc.), often pain goes unreported as it is assumed to be a natural part of aging. Although like dementia and incontinence, pain increases in prevalence with aging it should never be assumed to be a natural or requisite part of aging. In addition, the provider should listen carefully for terms other than pain which may be suggestive such as discomfort, or indications of depression which may be related to chronic unremitting pain.[6]

Initial pain assessments for the older person should always start with complete histories and physical examinations, including careful neurological and musculoskeletal assessments, and include history of trauma and previously used pharmacological and nonpharmacological approaches as well as indications of their success or failure (see Fig. 51.1).[7] Information concerning the length of time a particular intervention was used is as important as information regarding what specific interventions were used as often drugs have not been given adequate clinical trials or at adequate dose levels.

If medication review is done on an outpatient visit asking the patient to 'brown bag' anything she or he puts in

their mouth or on their body for symptoms, illness, or discomfort is helpful as often older patients are apt not to count anything not prescribed by a provider as medicine. If this is done at a home visit asking the patient to 'show me the pills' until the patient runs out of places is helpful. It is not uncommon to find medications from several physicians as well as medications which are many years outdated, some of which could be toxic if taken, especially outdated antibiotics. Older patients will commonly hold on to unused portions of prescriptions because of the cost and in some cases the sacrifices they may have had to make to purchase a prescription. This exercise is a wonderful opportunity to discuss appropriate storage and use of medications, as well as finding out about other treating physicians. In addition, older patients are often unaware of the potential for interactions among prescriptions and over-the-counter medications or alternative/complementary therapies.

Common medication side effects such as nausea or sedation in the first 48–72 hours with an opioid need to be carefully separated from allergies likely to lead to anaphylaxis which are obviously a true medical concern. All major active diagnoses should be outlined and addressed to ensure that all chronic and currently symptomatic problems will be treated appropriately. Any diagnoses which are no longer active should be removed, allowing the clinician to streamline the medication list and decrease the potential for drug–drug interactions.

In addition, the assessment of the older person should also include some measure of mental status such as the Folstein Mini-Mental State Examination (MMSE),[8] a screen for depression such as the Geriatric Depression Scale (GDS), and a review of activities of daily living (ADLs) and instrumental activities of daily living (IADLs),[9] as well as the impact of pain on daily function. Although some research with limited numbers of subjects has not disclosed statistically significant relations between pain intensity and standard geriatric measures of function, this should not deter the use of these instruments with individual patients as a measurement of progress or worsening of underlying burden of disease. Pain often interferes with what patients perceive as overall function, however the usual geriatric measures of function may not be sensitive or specific enough to identify fine changes. Improving function means less assistance required with ADLs and thus less staff or caregiver involvement over time. Also, a patient delirious with pain, or sleep deprived secondary to pain is unlikely to score well on a MMSE but should improve significantly with effective pain management. Many of these measures are routinely collected on long-term care residents at the time of admission and subsequently updated at monthly, quarterly and annual physician visits, and therefore readily available. Care plans need to be developed for any abnormalities found on screening with scheduled visits at intervals to check on progress or new symptoms such as increased constipation. Functional status may also assist in providing an outcome measure for improvement of pain in follow-up visits.

Due to the high rate of dementing illness in this population, particularly in those over age 80, it is important on the initial assessment to identify significant others or caregivers. Unfortunately many older persons may be living in the community without close family and may be relying on close friends as 'the keepers of the med box', to refill prescriptions, fill out pain diaries, and get them to physician appointments. This fact is important to identify as often the 'caregiver' is as functionally impaired as the patient, and without this individual the patient may be unable to remain independently in the community.

There are many standardized pain assessment tools, both unidimensional and multidimensional. The key to pain assessment tools is which tool works best for a particular individual, and can be used with multiple providers of varying skill levels on different occasions with reliable results. The 'gold standard' of the multidimensional tools is the McGill Pain Questionnaire.[10–12] However, as with most multidimensional scales it is extremely burdensome for the older person in pain and not apt to be completed at multiple visits in a reliable fashion. Additionally, this tool is not easily adaptable to ill or incapacitated individuals and has been used primarily in the outpatient setting as the standard against which newer tools have been tested. The Geriatric Pain Measure is one such tool which includes multiple domains, consists of 24 items, and showed significant validity and reliability in older persons with multiple medical problems.[13] Unidimensional tools consist of a single item which gauges pain intensity.[14–16] If different pain scales are attempted upon admission to determine which may be best used with that patient, information concerning the most successful scale with *that patient* should be documented clearly in the record, and communicated to each member of the interdisciplinary team for continuity. The Initial Geriatric Pain Assessment Form (see Fig. 51.1)[7] as first developed and published includes gait and balance; bowel function should be added as well. It is imperative to pick up any potential problems in these key areas before adding any medications which could result in, or exacerbate, complications such as impactions or falls and fractures.

Key components of the pain evaluation should be performed initially and repeated on a consistent and continual basis, and include pain location, intensity using both a numerical scale and a patient-generated list of descriptors, and a review of alleviating and exacerbating factors. Often patients have extremely useful nonpharmacologic interventions which in an institutional environment (hospital, SNF) require a physician's order. Potential influences on sleep and mood need to be elicited. There are changes which occur in sleep patterns with 'normal' aging such as increased sleep latency and decreased REM sleep, which often prompt older patients to use medications inappropriately such as sleeping medications or diphenhydramine, both of which carry with them increased risk of falls. When these changes are coupled with unrelieved pain, sleep is often vastly disturbed by the time a patient reaches their provider.

These items can be incorporated into a pain diary, the patient record, kept at the bedside or with the nursing medication administration record (MAR) for easy acquisition. Entries should be accompanied by dates and times in order to assist in correlating pain entries with administration times of medications or nonpharmacologic interventions. Assessments should be obtained as often as needed while patients continue to require aggressive titration of medications, and at least once every shift in an acute or long-term care setting. Although more frequent assessments may be desirable, it is often difficult to obtain assessments more than once per nursing shift in a long-term care facility.

Chronic pain may present very differently in the older person than their younger counterpart. Acute pain commonly presents with autonomic discharge leading to elevations in pulse, temperature, blood pressure, or respiratory rate. Patients may have changes in facial expression, fidgeting, or changes in posture or mood. Patients with chronic pain may not exhibit any of these signs or symptoms, and thus the assessment of pain is all the more challenging.

Depression and pain are often inextricably bound together and so depression when present needs to be identified and treated aggressively in order to successfully manage the patient's total pain. Cohen-Mansfield and Marx[17] performed a study of 408 nursing home residents and demonstrated that depressed residents were more likely to have pain regardless of the presence of cognitive impairment.[17] Parmalee et al.'s 1991 study of 598 nursing home and congregate housing residents also showed a significant association of pain with depression.[18] Those meeting Diagnostic and Statistical Manual (DSM)-IIIR criteria for major depression reported both more intense pain and a greater number of localized pain complaints than did those with minor or no depression in this study. Although no causal mechanisms were established, the authors suggested that older patients with significant depression might be more sensitive to pain caused by a preexisting physical disorder.[18]

PAIN IN THE COGNITIVELY IMPAIRED

This section will address the most challenging assessment problems clinicians face which include alterations of cognitive status such as delirium and dementia, and vision and hearing impairments which may further complicate the assessment of pain in the cognitively impaired. Although delirium has been specifically identified in a large number of patients with cancer,[19] these challenges predominantly involve older people; therefore, this section will focus primarily on research and clinical suggestions developed for this rapidly growing section of the population.

Cognitive impairment or altered mental state has been defined as 'a change in the patient's usual premorbid state of mind'.[8] This may include delirium and dementia as well as alterations in emotions and behaviors. The most critical task is to establish the patient's premorbid mental status, and the nature and association of any clinical changes which may have occurred. Changes in mental status may occur in as many as 20–30 percent of medical inpatients and 50–90 percent of nursing home residents,[20] and significantly impact upon an individual's ability to participate actively in symptom assessment.

Delirium

Delirium has also been called 'acute confusional state' and clinicians have often colloquially referred to this state as 'temporary brain failure'. Delirium is best defined as 'an organic mental syndrome featuring global cognitive impairment, disturbances of attention, reduced level of consciousness, increased or reduced psycho-motor activity, and disorganized sleep–wake cycle'.[21] Symptoms include restlessness, anxiety, difficulty in thinking coherently, insomnia, disturbing dreams as well as fleeting hallucinations. Age greater than 65, chronic cerebral disease and brain damage are the main predisposing factors for delirium. Psychological stress, sleep loss and sensory deprivation and overload can all facilitate and maintain delirium. DELIRIUMS is a mnemonic offered as a way to remember the causes of delirium.[20]

D – alludes to drugs which can include a number of drugs, especially those with anticholinergic properties, as well as drug overdose or withdrawal

E – stands for emotional causes such as agitated depression or mania

L – includes low oxygenation as is found in cardiac ischemia, chronic pulmonary disease, congestive heart failure or pulmonary embolism

I – represents infection of any sort, and typically in hospitalized older patients includes pneumonia or urosepsis

R – refers to retention of urine or feces

I – represents ictal states

U – stands for undernutrition as well as dehydration which occur commonly in community-dwelling as well as institutionalized older people

M – includes metabolic causes such as organ failure or specifically, hypo- or hyperthyroidism

S – raises the possibilities of stroke or subdural hematoma.

All of these possible causes need to be considered when entertaining the diagnosis of delirium.

The aging of America

The population over the age of 60 in the USA is expected to increase by 69 percent by the year 2020, and those over 85 represent the most rapidly growing subsegment of this population.[22] There have been substantial scientific and technological breakthroughs in the field of medicine, all of which

have contributed to the growth of an older, chronically ill population. Prevalence rates of dementia, and specifically Alzheimer disease, rise exponentially after age 65. Rates of Alzheimer disease have ranged as high as 50 percent in those over the age of 90.[22]

Dementia

Dementia has been defined as 'a syndrome characterized by a decline in multiple cognitive functions occurring in clear consciousness'.[23] Dementia has been documented in 10–15 percent of older surgical patients, one-third of older medical inpatients, and more than 50 percent of nursing home residents.[23] The more than 50 causes of dementia include primary dementia with no other signs, dementia with signs of vascular disease, dementia with evidence of chronic infection, secondary dementia with signs of an underlying neurological condition such as is seen in neoplasm and movement disorders as well as motor neuron disease or multiple sclerosis. Dementia may also follow diffuse brain trauma as well as occur with endocrine disorders and vitamin deficiencies, toxic disorders, psychiatric disorders such as chronic schizophrenia or pseudodementia, as well as other conditions largely affecting adolescents or young adults such as Wilson disease, tuberous sclerosis, progressive myoclonic epilepsy, and the metabolic storage diseases.

For convenience, dementia may be divided up into cortical causes such as Alzheimer disease, Jakob–Creutzfeldt disease, Pick disease, and stroke, and subcortical causes. Cortical causes feature prominent amnesia, aphasia, apraxia, agnosia, and in Alzheimer disease specifically, preservation of fine motor movement until late in the illness.[23] Subcortical causes include Parkinson disease, Huntington disease, and hydrocephalus. The latter characteristically exhibit amnesia, slowness of thought, apathy and lack of initiative in all aspects of cognitive function, and early disorders of movement.[23]

The issue of potentially reversible dementias has received much attention in the medical literature. These include drugs, depression, hypothyroidism, B$_{12}$ deficiency, sensory impairment, normal pressure hydrocephalus, tumor, subdural hematoma, infection, and anemia.[20] The chief concern in identifying these phenomena is in limiting further deleterious consequences, not in the potential to reverse the cognitive impairment that has already occurred.

Delirium versus dementia

It is vital to differentiate between delirium and dementia. Both conditions may also occur simultaneously. Rates of delirium have ranged as high as 50 percent in hospitalized patients with previously diagnosed dementia.[20] Delirium favors an acute onset lasting days to weeks in its subacute phase, fluctuating over time leading to disrupted sleep–wake cycle and waxing and waning level of consciousness. Ability to attend to task is impaired as well as orientation. Autonomic changes are common and electroencephalograms (EEGs) show diffuse slow waves. Language may be incoherent and the patient may be fearful and agitated.

Dementia is usually insidious in onset, excluding vascular dementia which follows a stepwise connection. Symptoms tend to be persistent and stable over time with a normalized sleep–wake cycle and normal level of consciousness in a particular patient. Ability to attend to task is not affected, but orientation is impaired and aphasia and apathy are quite common. Autonomic changes are unusual and EEGs, if anything, will show a mild slowing.

The impact of sensory impairment

Uncompensated sensory impairment can impact upon functional decline, social isolation, depression, falls, and accidents, leading to increased patient frustration and resentment. Visual and auditory impairments are the two sensory losses which most often complicate both symptom assessment and management.

Senile miosis, decreased amplitudes of accommodation of the lens (presbyopia), and age-related changes in color vision occur with normal aging. Cataracts, glaucoma, age-related macular degeneration and diabetic retinopathy represent the four most common causes of blindness in older persons and affect 9 percent of adults 65–74 years old. The incidence rises to greater than 50 percent in those over 75 years old.[24]

Hearing loss is the third most commonly reported chronic problem in those over age 65.[25] In nursing homes, prevalence statistics for hearing loss range between 50 and 100 percent with prevalence rising with advancing age.[26] In the Framingham Heart Study cohorts, although 41 percent of those over age 65 had some level of hearing impairment, only 10 percent of these individuals had tried hearing aids.[26] This is a significant problem among older people which can seriously impede the clinician's ability to conduct meaningful symptom assessment. Hearing impairment can be broken down into the conductive type (cerumen impaction, middle ear disease and otosclerosis), sensorineural disease (cranial nerve VIII damage from noise, cochlear damage, ototoxic drugs such as gentamicin, presbycusis, trauma, infection, and acoustic neuroma), mixed and central hearing loss which itself affects 50 percent of those aged 51–91 years.[26]

Studies of pain in the cognitively impaired

Of all the symptoms seen in individuals at the end of life, pain is the single symptom which has been most well studied in the cognitively impaired. In a study designed to assess physicians' detection of pain among geriatric nursing home residents, Sengstaken and King[27] found that 66 percent of those able to communicate were identified as having pain by

chart review as well as patient interview. Only 34 percent of these patients, however, had pain identified by their treating physicians. When the noncommunicative residents were compared to those able to communicate, the physicians were found to have identified pain less frequently in those who were noncommunicative. There were no differences between these groups in regard to demographic or medical diagnoses other than dementia, so one might expect that they would be equally likely to suffer pain, although the treating physicians identified chronic pain more than twice as frequently in those who were able to communicate. Parmalee et al.[28] studied self-reported pain in 758 nursing home and congregate housing older people with mild to moderate levels of cognitive impairment as defined by the Blessed Memory Information Concentration Test. This study showed that, in general, pain complaints decreased with increasing levels of cognitive impairment. Markedly impaired subjects reported less intense pain, and a smaller number of pain complaints than those who had intact cognition or mild impairment. However, when cognitively impaired individuals reported pain, their pain complaints were no less valid.

Ferrell et al.[29] examined the problem of pain in nursing homes and explored the usefulness of currently existing pain scales for cognitively impaired residents utilizing a patient base drawn from 10 different community nursing homes. Their study population consisted of patients with moderate to severe degrees of cognitive impairment (mean 12.1 ± 7.9 on the MMSE) and scales included the McGill Present Pain Intensity Subscale (0 to 5 with word anchors) the Rand Coop Chart (cartoon figures with word anchors), the Memorial Pain Card Subscale, and a verbal 0 to 10 scale in enlarged format and with adequate amounts of light and hearing augmentation. Although only 32 percent of patients could complete all five scales presented, 83 percent of these individuals with significant degrees of cognitive impairment could complete at least one of the existing scales presented. This finding validated the utility of attempting to utilize established pain assessment tools in communicative, cognitively impaired older people. The study participants were quite good at communicating how intense their pain was at a particular moment, but were unable to convey the intensity of pain at a past point in time.

Studies of pain in noncommunicative cognitively impaired

Multiple attempts have been and are being made to use pediatric instruments, and specifically those developed for neonates, with noncommunicative cognitively impaired older people. There are some fundamental issues to address when using pediatric assessment tools in older patients. First, pediatric tools have been developed to measure acute, and often specifically procedure-related pain; in cognitively impaired older patients clinicians are often evaluating chronic, or acute on chronic pain, which might be expected

to present differently. In acute pain, the observer might expect to see changes in facial expression, vocalization, increased muscle tension and autonomic discharge resulting in alterations of heart rate, blood pressure and respiratory rate. Although in chronic pain states such as arthritis, which is highly prevalent in both community-dwelling and institutionalized older people, clinicians may witness vocalizations and increased muscle tension, chronic pain may more likely present as primary depression or change in baseline mental status. Second, infants have no wealth of pain memory to influence their pain interpretation, and so existing knowledge cannot attach any meaning to induced pain. It is currently unknown whether cognitively impaired older people retain this ability.

There are fewer studies published on pain assessment in noncommunicative cognitively impaired older people; those that currently exist include relatively small numbers of subjects. Marzinski[30] reviewed 60 patients living in a dementia unit, 43 percent of whom had potentially painful conditions on the basis of chart review. Only three of these patients received routinely scheduled analgesics. However, one of the most interesting findings of this study was the nursing staff could quickly identify what amounted to normative behavior for a particular patient. Once deviations were identified, they were noted and acted upon.

The Assessment of Discomfort in Dementia (ADD) Protocol was designed by Kovach et al.[31] to more accurately assess discomfort, more accurately treat pain, and decrease use of psychotropic medications. This program focused first on educating the nursing staff who best knew the patients to identify even subtle changes in behavior which may represent abnormal versus normal behaviors for a particular patient, to perform basic physical examination and chart review looking for new findings. They were then taught a protocol of nondrug soothing interventions once abnormal behaviors were identified. Only last did this protocol go on to physician ordered as needed analgesics and if successful, the physician was notified and medication for pain ordered on a routine basis. A convenience sample of 104 residents with dementia were drawn from the 32 participating facilities. Utilization of the ADD protocol resulted in increased use of scheduled analgesics and nonpharmacological soothing interventions. Difficulties in this setting involved limited time, challenges getting staff sufficiently educated, and resistance to change. Staff reported that the main benefits were increased sense of residents' discomfort and improved pain and physical assessments.

The Pain Assessment in Advanced Dementia (PAINAD) Scale developed by Warden et al.[32] is a 0–10 scale that allows a caregiver or proxy to rate a patient's pain from 0 to 2 in terms of breathing, negative vocalization, facial expression, body language, and consolability, and was found to be reliable and valid in the nonverbal cognitively impaired population. This tool is also particularly useful for professionals using 0–10 scales with their verbal patients as it simplifies intensity; however, we do not know whether increasing

scores are associated with higher levels of pain as this tool is a compilation of scores in five separate areas and thus cannot be directly compared to VAS-type intensity scores.

RECOMMENDATIONS FOR PAIN ASSESSMENT AND MANAGEMENT

In order to accommodate for sight and hearing impairment, it is recommended that extra time be given for the patient to assimilate questions. Large print visual cues, adequate ambient light, and ensuring that hearing aids or pocket amplification devices and refractive lenses are in place are vital. Limited attention span may necessitate performing symptom assessments in portions over time. Subjective responses or descriptions must carry equal weight with fixed answers to standardized tools. In the case of pain, multiple tools should be presented upon initial assessment if standardized instruments are being utilized. Whichever tool is most clinically useful with a particular patient should be carefully recorded in the chart and this information communicated to other members of the interdisciplinary team. This procedure will ensure that each subsequent assessment is performed exactly the same regardless of the team member involved. As cognitively impaired older people are often able to report on pain at the time of but not previous to pain assessment, pain assessment should be conducted more frequently than would be necessary with a cognitively intact patient.[33]

In the case of the noncommunicative cognitively impaired the single most important sign is deviation from what is baseline or 'normal' behavior for that particular individual. When this occurs, a careful bedside examination should be undertaken with laboratory studies consistent with the patient and family's wishes. Examination should focus particularly on occult sources or atypical presentations of infection in older people such as pneumonia or urinary tract infections. The aid of nursing staff should be enlisted to exclude alterations in sleeping, eating or elimination as the source of change in behavior. Chart review should exclude medication changes as an etiology. After all of these have been carefully undertaken, there may be a role for a well defined empirical trial of short acting pain medication with consistent and continual reassessment.[33]

PAIN TREATMENT

Pain treatment may present several unique challenges in the older population. The World Health Organization (WHO) three-step ladder approach to pain based on pain intensity[34,35] is as applicable in the older population as in the young with certain caveats. The ladder assumes that the patient will enter the protocol based on their current pain, i.e. a patient with severe pain does not have to go through steps 1 and 2 first. Pain relief should be provided even while the patient is in the diagnostic phase of their work-up. Finally, if pain ratchets up from mild to severe the step 2 medications can be skipped. Or if it is recognized that the patient is presenting with advanced disease, it makes more sense to go from step 1 drugs to low-dose step 3 drugs with appropriate adjuvants along the way.

Aging is associated with an increased fat to lean body mass combined with decreased hepatic and renal clearance of medications that may lead to slower breakdown of medications in general, and specifically of potentially harmful metabolites. For example, meperidine and propoxyphene both have potentially harmful active metabolites which may accumulate and cause central nervous system hyperexcitability.[36]

Almost every over-the-counter pharmaceutical product available is compounded with acetaminophen or aspirin. The step 2 medications most commonly ordered for pain also contain these common ingredients. Although there are general guidelines for the acute use (7–14 days) of acetaminophen of no more than 4 g/day in a younger patient and no more than 3 g/day in an older patient, no chronic dosing guidelines have ever been released. The prevalence of both drug–drug and drug–disease interactions are higher in this population and may result in worsened cognitive status, orthostatic hypotension, and the potential for falls. It is important to remember that older patients are often already at increased risk of constipation secondary to decreased activity, decreased fluid intake, and multiple concomitant medications, and so should be started on an aggressive bowel regimen as soon as any potentially constipating medications (opioids, tricyclics, anticholinergics) are started. The high prevalence of laxative dependence in this age group may require starting with the patient's daily laxative requirement and titrating over this amount to effect as needed. Side effects should be anticipated and appropriate measures taken to avoid them, particularly constipation, with thorough follow-up on subsequent visits. And finally, nonsteroidal anti-inflammatory drug (NSAID) use is more problematic because of increased frequencies of gastric and renal toxicities in this age group.[37] The frail older person over 85 years has the highest risk of both silent bleeds and fatal bleeds.[38] The newer cyclooxygenase 2 (COX-2) agents, although specifically formulated to decrease the risk of gastrointestinal side effects, may still carry some risk of gastric irritation, as well as the usual renal and central nervous system toxicities, and did not turn out to be the anticipated panacea. General recommendations remain regarding the cautious use of NSAIDs in this population and then coupled with misoprostol[39] or proton pump inhibitors. However, as there are no generally accepted published guidelines for clinical follow-up in this population, the usual advice to start low, go slow, and use only for as long as absolutely necessary pertains.

Older people may be more sensitive to the analgesic effects of opioids with a higher peak effect and longer duration of action secondary to decreased elimination.[40,41] This does not mean, however, that pain in older patients should

not be as aggressively treated as in younger patients. In fact, unlike acetaminophen and NSAIDs, opioids are the only drugs which can be taken for years with no threat of end-organ toxicity. Patients and their caregivers need to be educated regarding the expected side effects of nausea and sedation associated with opioids in the first 24–72 hours so that the patient continues to take the medication and not assume she or he has developed a drug allergy. Education regarding the concept of dependence which occurs with chronic opioid use, as it does with β blockers, needs to be separated from the concepts of tolerance and addiction.

The clinician should anticipate a higher peak effect and longer drug half-life because of slower clearance and dose accordingly. For these reasons, drugs like meperidine and propoxyphene should be avoided; extremely extended duration and particularly potent drugs like levorphanol, methadone and sustained release fentanyl should be considered only in special circumstances and for opioid-tolerant patients only. Methadone has gained increased attention as it is inexpensive and is the only opioid to date that has also demonstrated N-methyl-D-aspartate receptor activity which is often helpful in recalcitrant nerve pain. However, methadone is extremely long-acting and thus difficult to titrate, particularly in the institutional setting. Nonpharmacological and pharmacological measures should be used concomitantly to act synergistically and to decrease the incidence of drug–drug interactions and side effects.

Neuropathic pain is often the most challenging pain to treat in older persons. Traditionally tricyclics were used, however in a multiarm study Max and colleagues found no greater benefit in less anticholinergic drugs such as desipramine than with amitriptyline.[42] It is most likely that tricyclics work through the norepinephrine-mediated downward inhibitory pain pathway. The serotonin-mediated antidepressants have not been found to be beneficial adjuvants in neuropathic pain. Gabapentin was used in two large multicenter, randomized, double blind, placebo controlled clinical trials and found to be effective in the treatment of diabetic neuropathy and postherpetic neuralgia.[43,44] The main side effect was sedation necessitating low initial doses and very gradual dose increases to a therapeutic range of 1000–1600 mg/day. Other drugs for neuropathic pain have included valproic acid and intravenous lidocaine.

ROUTES OF ADMINISTRATION AND DELIVERY

Whenever possible the least invasive route of medication delivery should be employed to maximize patient and caregiver independence and limit risk. Because of the increased risk of side effects, short acting medications should be started first, titrated to comfort and then converted to long acting medications with an appropriate amount of medication prescribed for breakthrough pain. Whenever possible, only one drug should be titrated at a time in order to more accurately identify side effects and limit stopping whole regimens. Pharmacokinetic realities should be respected, i.e. medications which should reasonably last 4–6 hours and may in this population last 6–8 hours should be ordered that way to avoid overshooting the mark and risking oversedation or worse. Unfortunately clinicians need to keep medication costs uppermost in their minds when prescribing. Older patients are often unable to pay for needed medications on fixed incomes. Insurers are more apt to cover an invasive procedure or medication pump rental costing thousands of dollars than medications or physical therapy if needed on an ongoing basis. And finally, there may indeed be a role for consultation with an anesthesiologist who is trained in the special needs and anatomical concerns of older people.[45]

TOPICALS AND ADJUVANTS

Topical therapy has attracted significant attention due to patient acceptability, increased sense of control, and limited untoward side effects. Capsaicin is extracted from hot chili peppers, and when applied faithfully multiple times every day depletes the supply of substance P from the terminus of unmyelinated C fibers.[46] The patient needs to adhere to a treatment regimen and endure the initial skin irritation and burning before the onset of anesthesia which must then be maintained. Breaks in treatment regimen require restarting capsaicin and waiting for therapeutic effect. This product has best been used as an adjuvant to drug therapy and rarely as sole therapy.

EMLA® (Eutectic Mixture of Lidocaine and Prilocaine anesthetics) was initially developed for temporary analgesia in pediatric patients. The cream is applied thickly to a specific area 1–1.5 hours before a scheduled procedure such as a planned dose of ceftriaxone (Rocephin), venepuncture or intravenous stick, covered with a plastic membrane to keep it in place, then the area is prepped as usual. Analgesia is effective but temporary necessitating additional applications for longer pain relief. Although intended for procedure-related analgesia, some clinicians have evolved protocols involving EMLA or lidocaine gel with morphine for various pain problems to decrease dose-related side effects of pain medications or in some cases as sole therapy.

In response to the early success with EMLA, researchers developed the 5 percent lidocaine patch. Rowbotham et al.[47] studied 35 adults (mean age 75 years) with a diagnosis of postherpetic neuralgia in a four session, random order, double blind, vehicle controlled study. Up to three patches were applied to the patient's most painful area, 12 hours on, 12 hours off. The lidocaine patch was superior to both no-treatment and vehicle patches, without systemic side effects, and was well tolerated. New roles for this product continue to be developed, with varying application schedules, and in different pain presentations. Originally developed as an

adjuvant to medications as a strategy to cut down dose, it is now used in patients who wish to avoid any oral medications, or as an adjunct in patients with either inadequate response to customary treatment, or in whom higher doses would inflict intolerable side-effects.

Older patients often benefit greatly from the use of non-pharmacological interventions. The use of heat, cold, massage, distraction and relaxation techniques can be routinely integrated with appropriately prescribed medicines, and while waiting for doses of breakthrough medications to take effect. These augment, not replace, medication and can help give the patient and caregivers a sense of participation in the therapeutic process. Often patients have been using some of these techniques successfully prior to admission to acute care hospitals or long-term care facilities, and integrating these with the total care plan after admission can improve outcome; however, it is vital that these be listed on the initial assessment as in institutional settings these nonpharmacological interventions require physicians' orders. Alternatively, techniques which might have been difficult for an older person to utilize alone at home on an ongoing basis can be provided in the long-term care facility with assistance from nursing and restorative personnel. Physical therapy, restorative services and activities personnel, all of whom are available in the long-term care, can be part of the plan of care to integrate nonpharmacological therapies. Restorative nursing assistants after an initial assessment by a physical therapist can continue helpful therapies without extending limited resources under Medicare Part B in the USA. These therapies can strengthen deconditioned and sore muscles, helping to decrease overall fall risk, improve pain related to problems affecting posture and gait, decrease muscle spasm from overcompensation from pain associated with compression fracture, and use helpful modalities such as ultrasound, hydrotherapy or paraffin.

Older patients have historically been less interested in cognitive modalities. Cognitive interventions are made all the more complex by sensory or cognitive impairments. Many older patients have been socialized by traditional Western medicine into thinking about pills as the only solution to medical conditions or problems, and so are more likely to welcome what they perceive as a 'quick fix' approach. Many cognitive modalities require instruction and reinforcement by an expert, and finally are usually not reimbursed by insurers. Acupuncture and chiropractic have become increasingly more accepted practices and in some cases even covered by insurers. In their review of alternative medicine in older Americans, Foster et al.[48] questioned 2055 adults, of whom 311 were aged 65 and older about their use of 20 alternative medicine therapies in the previous 12 months. Thirty percent of people aged 65 and older used at least one alternative treatment in the last year compared with 46 percent of those less than 65. The two most commonly used modalities were chiropractic and herbs.

Alternative and complementary therapies hold great promise as adjuvants in pain management in older persons.

They have become increasingly acceptable, increase patient and caregiver autonomy, decrease side effect profiles by potentially working synergistically with traditionally pharmaceutical agents, and often have multisymptom use. These therapies may require a special practitioner, however, are limited or uncovered by most insurance carriers, and require a prescription in an institutional setting. Finally, some of these therapies may be positively or negatively affected by sensory or cognitive impairments. There currently are few studies involving these therapies, partly because of difficulties creating 'sham' control arms, and specifically few if any in older people especially those over age 75. More research needs to be done in this necessary area to answer these basic questions.

PAIN IN THE LONG–TERM CARE ENVIRONMENT

The assessment and treatment of pain in the long-term care environment continues to present several unique and challenging problems. Increasingly, studies are focusing on the large number of older people with important pain problems in long-term care.[49–51] The inclusion of pain as an area of clinical research interest in the minimum data set (MDS) has generated interest in this problem and will provide an ongoing data stream for continued study. Researchers are attempting to establish reliability and validity data of standardized assessment tools previously validated in younger populations, and utilizing both traditional and novel assessment tools in the cognitively impaired. Assessment strategies in the noncommunicative cognitively impaired resident are being developed in tandem with unique clinical protocols focusing on the role of the primary care nurse who best knows that patient to decipher 'normal' from 'abnormal' behavior.

The application of available pharmacological interventions poses greater challenges because of the higher incidence of drug–drug and drug–disease interactions as well as side effects in older people; this picture is in turn complicated by the decreased hepatic metabolism and renal clearance present in many older patients. The long-term care environment has limited resources which can present logistical concerns for both diagnosis and treatment, but can also positively limit overly invasive or extensive modalities which may not in the end positively alter treatment and may pose iatrogenic concerns of their own. This section will explore these issues and offer suggestions for the appropriate assessment and management of pain in the resident in long-term care.

ISSUES RELATIVE TO CARE IN THE LONG–TERM CARE ENVIRONMENT

A significant proportion of individuals over the age of 65 now make their home in some part of the long-term care community, whether these individuals are recovering from acute illness and able to return home, admitted for long

stays, or in the last 6 months of life.[20] By the year 2030, it is anticipated that in the USA, the number of persons over 65 will double to over 60 million, with the greatest increase in those frail elders over age 85.[20] Nursing home beds are expected to double over the next 30 years to keep up with this boom, and may exceed 5 million by the year 2040.[20]

Long-term care is growing rapidly, and the quality of care provided in a nursing home affects a significant proportion of our older population. By necessity, the older person is looking for more diverse choices, and there is often a considerable range in available finances to spend for care. To that end, the term long-term care now also includes a variety of different care settings such as senior apartments, RCFEs (residential care facilities for the elderly) or in some areas of the USA board and care, and assisted living homes, as well as specialized units within each of these care settings for individuals with dementia.

As the acuity level of the acute care hospital has risen with the boom in technology, patients are apt to be released to long-term care with much higher care needs. Traditional rehabilitation units require the patient to be able to tolerate at least 3 hours per day of therapy to qualify for admission. Many older patients after an acute event cannot meet this requirement but can make therapeutic gains and thus began the development of subacute care units or transitional care units. The older stroke patient who would have remained in the hospital a decade ago, now is sent out to subacute care in a nursing home. The typical nursing home resident of the 1960s would today more likely be placed in an assisted living or residential care facility. Nursing homes are less and less composed of homogeneous populations; most nursing homes have populations of residents admitted near end of life, those with lengths of stay ranging from 6 months to years, patients admitted for rehabilitation after an acute hospital stay, and those in their last years of life lacking adequate community or family support to remain at home.[20] With tighter budgets and higher enforced federal and state requirements, it becomes an even greater challenge to provide individualized resident-focused care to all of these individuals.

One of the first successful legal cases involving inadequate pain management involved a nursing home resident with end-stage prostate cancer whose plan of care clearly delineated an adequate pain treatment plan, but whose plan of care was not followed.[52] Including pain within the scope of the MDS and as a quality indicator, and the initiation of JCAHO guidelines to have pain assessed in every healthcare site including long-term care, have also resulted in more appropriate recognition of, and treatment for, pain in long-term residents. Under or untreated pain is no longer acceptable regardless of the setting.

PAIN PREVALENCE IN LONG–TERM CARE

Estimates of pain prevalence specifically among nursing home residents vary widely with some estimates as high as 45–80 percent,[4] whereas in the community-dwelling older population estimates range between 25 percent and 50 percent.[5] The occurrence of concomitant sensory impairments, dementia and disability make assessing and managing pain a challenge in the long-term setting.

One of the earliest studies in the long-term care population involved 97 patients from a 311-bed long-term care multilevel facility.[51] Existence of pain problems and their management in addition to functional status, depression, and cognitive impairment were obtained from chart review and patient interview. Seventy-one percent of these patients had at least one pain complaint, of which 34 percent described continuous pain. Of the 43 subjects with intermittent pain, 51 percent had pain on a daily basis. Types of pain varied widely, although the majority involved musculoskeletal sources. The most striking finding was that only 15 percent had received pain medications within the previous 24 hours despite the fact that 84 percent had physician orders for pain medications. There were moderately strong correlations between pain and activity attendance. There was little statistical correlation between pain and depression scale, MMSE, and ADL scales although individuals often reported functional impairments with pain. Of greatest clinical significance was that the subjects reported substantial impairments in both their activities of daily living and quality of life due to pain. If we are to believe the patient report as the single best measure of the intensity and impact of pain,[14,53–55] then perhaps the patient's report of the effect of pain on their life is the most vital measure of all.

Arthritis is the single most common musculoskeletal source of pain in those over age 65. The prevalence of arthritis alone in nursing homes has been identified as between 23 percent and 24 percent.[56] In a study of 629 nursing home residents in the greater Boston area,[56] 23.3 percent had some form of arthritis. Even controlling for age, the residents with arthritis more often reported requiring assistance at least some of the time for six of eight functional task items, and using more assistive devices. The implication is that these residents would also likely need greater assistance from caregivers. Those with arthritis had higher visual analog scale scores (76.25 ± 31.75) than those without arthritis (51.93 ± 30.67).

In addition to the pains which likewise affect younger patients, there are also a number of problems occurring with higher prevalence in older patients such as polymyalgia rheumatica, angina, atherosclerotic vascular disease, temporal arteritis, cancer, herpes zoster, and peripheral neuropathies; and it is likely for an older patient to have two or more sources of pain. Therefore, it is vital that the provider assess each pain separately and continue to do so on an ongoing basis in order to treat the older person's total pain problem adequately. Pain in the older long-term care resident can significantly impact healthcare and quality of life concerns.

Pain occurs with approximately a 75 percent prevalence rate in cancer patients,[57] and undertreatment particularly of

older patients has been fairly well described in various settings;[58–60] many of these patients may at some point in the disease trajectory require long-term care. As the incidence of most cancers increases with advancing age with rare exceptions, this amounts to a significant number of older individuals experiencing cancer pain. Despite the inclusion of other nonmalignant end-stage conditions such as renal failure, dementia, congestive heart failure and others, the majority of patients requiring hospice care continue to be admitted with cancer diagnoses.[61] Many hospice patients either are admitted already in long-term care or ultimately require nursing home admission as their illness worsens either temporarily or long term; in some areas hospices are establishing inpatient hospice units within or adjoining to existing nursing homes. Some long-term care facilities are even acquiring their own licenses for inpatient hospice care. Previously the hospice advised the nursing home in the area of pain assessment and management. With the advent of JCAHO, AMDA (American Medical Directors' Association), AGS (American Geriatrics Society), and other guidelines on pain and its management, and the increasing use of long-term care as a core clinical training site, long-term care facilities now have the potential to demonstrate clinical expertise in this area. The establishment of multiple guidelines which include the assessment and treatment of nonmalignant as well as malignant pain has led to a greater acceptance of the imperative to treat regardless of the pain etiology.[14,34,53–55]

CHALLENGES TO OVERCOME IN THE NURSING HOME

Although pain management in general has improved significantly over the last decade, there are many concerns unique to the long-term care environment that make pain assessment and management particularly challenging. These include systems barriers intrinsic to the nursing home care setting, physiological barriers to pain management in older persons, and research and educational barriers which interfere with effective clinical care.

Nursing homes lack the extensive diagnostic, nursing, and pharmacy resources present in higher acuity settings. Until the advent of the recent JCAHO, AGS, AMDA guidelines, the institution-wide commitment to pain assessment and management was not a long-term care priority. Whereas patients or caregivers can administer 'as needed' or prn doses in the home environment, the ability to respond to this request is severely hampered in long-term care by the significant number of planned medications required for each patient. Nursing home residents have on average seven to nine or more routine medications; in most states, regulations require that the medication be distributed within 1 hour before or 1 hour after the scheduled time period to get that medication to a resident, observed and properly recorded. It is therefore not unusual for patients to sometimes ask family members to provide acetaminophen or other pain relievers handy for self dosing in lieu of requesting 'as needed' medications, resulting in potentially harmful situations. A useful exercise when making a home visit to a long-term care resident is asking permission to look in the bedside stand. It is not unusual to find almost any prescription or over-the-counter medication. In addition, interventions such as hot or cold packs which family members may have provided at home with good effect, require physician orders in long-term care. Each medication or laboratory test ordered also requires an accompanying diagnosis; medications in the five quality indicator categories (sedatives, anxiolytics, 'others' including mood stabilizers, antidepressants, and antipsychotics) also require the terminology 'AEB' (as exhibited by) with appropriate symptoms which the nursing staff can then flowsheet and track. The intent of this requirement is to have staff use a nondrug intervention and gauge its effectiveness before a medication in these categories is given. Pain adjuvants (valproate, gabapentin, tricyclics, etc.) given specifically for this purpose should be so labeled and would not require psychiatric tracking language.

Often long-term care residents have multiple medical problems and many potential sources of pain. Memory and sensory impairments, and increased sensitivity to adverse drug reactions are among the physiological barriers often encountered in the older population. Lack of family understanding of the goals of treatment, the difference between physical dependence and addiction, and often family inability to be present and involved during physician rounds in the nursing home may hinder communication and thus the provision of optimal pain management.

Educational and attitudinal barriers may exist among staff, families and patients as well. There are still misconceptions about changes in pain tolerance with aging, or that medications suitable for young patients cannot be used safely in older people, despite available evidence to the contrary even in cognitively impaired populations. And finally, many regulatory and policy barriers also exist, including the use of increasingly restricted formularies, and difficulty in obtaining opioid drugs in states where multiple copy prescriptions are required. The identification of potential barriers to pain management is an integral component of improving pain management in long-term care. With improved institutional commitment to optimal pain relief many of these barriers can be reduced or eliminated.

NURSING HOMES AS UNIQUE ENVIRONMENTS

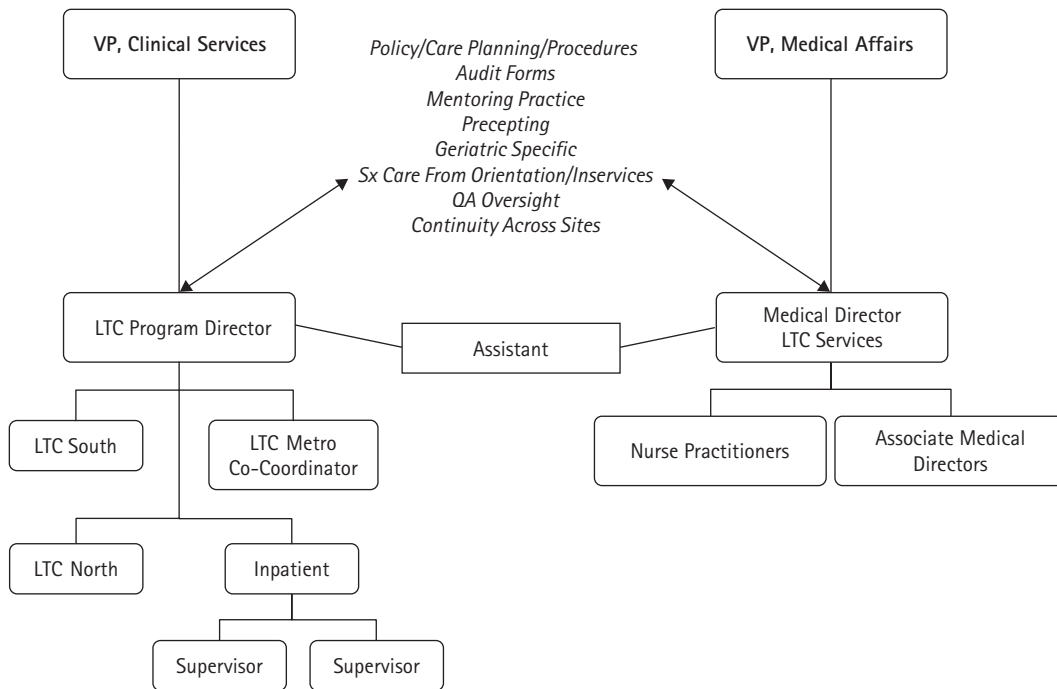
Nursing homes are unique as evidenced by their interdisciplinary approach to care planning and provision. Team-based care is not only encouraged but required by state and federal and where applicable JCAHO rules and regulations, and is at least, therefore, indirectly reimbursed. Each resident's


Figure 51.2   *Organization, responsibilities, and relationships between the interdisciplinary team members and nursing home residents with pain problems. LTC, long-term care; QA, quality assurance. plan of care is required to be reviewed by an interdisciplinary team composed of nursing, social service, appropriate therapies, dietary, medical, and pharmacy services. Care plans are developed using a problem-oriented approach and revised every 30–90 days depending on the patient's acuity level. Pain management, like most areas of palliative care, is best accomplished by an interdisciplinary approach and thus adapts particularly well to the nursing home milieu. Figure 51.2 illustrates the organization, responsibilities, and relationships between the interdisciplinary team members and nursing home residents with pain problems. In community nursing homes, the administrator and nursing home board of directors/owner(s) have the ultimate responsibility for establishing and maintaining the function of the interdisciplinary team. Moreover, it is the administrator and ownership who are ultimately responsible for compliance with state and federal guidelines, regulatory issues, and the total quality of care provided in the facility. The individual healthcare team members each provide their particular expertise and share responsibility for pain management. They develop living care plans and work toward a common goal of pain management for individual patients based on the frequent and appropriate assessment of the resident's pain. Using this framework the team is usually successful in assisting the resident in reaching important goals including restoration and maintenance of function as the resident defines it, preservation of autonomy, delaying

the progression of chronic medical problems, and ensuring quality of life.

QUALITY OF LIFE AND OUTCOME MEASURES

Quality of life involves many dimensions. Some of the domains of quality of life frequently cited by investigators include physical concerns, functional ability, family well being, spirituality, social functioning, treatment satisfaction, financial concerns, future orientation, sexuality, intimacy, and occupational functioning. Most patients and clinicians agree that pain and its management substantially improve quality of life. An individual incapacitated by pain will not participate in rehabilitative or restorative therapy because of increased pain with movement, resulting in further deconditioning and isolation which limit the individual's ability to participate in social activities and interpersonal relationships. Patients with chronic pain may lose their sense of purpose and hope for the future when all they experience is unremitting pain and often present with chronic depression. Life stops focusing around activities and people that bring joy and meaning to their life and instead revolves around unremitting pain. Residents who have entered some part of the long-term care trajectory have already experienced multiple losses associated with aging and chronic disease. Unremitting pain only worsens this sense of loss.

Several investigators have developed instruments for the assessment of quality of life as an outcome measure for pain management but the role of these instruments in clinical practice remains uncertain. For example, it has been observed that although pain may improve dramatically, it may be overshadowed by other issues confounding the assessment of overall quality of life. In an era of ever increasing quantity of life, the quality of that life should demand equal attention.

Key learning points

- Pain assessment and treatment in the older person continues to offer considerable challenges. Multiple studies indicate a high prevalence of pain which is often poorly managed in both the cognitively intact and cognitively impaired.

- A variety of barriers to pain management have been identified that can be overcome with appropriate educational interventions and correction of common misconceptions concerning pain in this population.

- Clearly to date, no research has definitively shown changes in pain perception with the aging process.[62–65] Additional research still remains to be done to more accurately identify and treat pain in this population, particularly in the case of the cognitively impaired resident.

- The validity and reliability of standard pain assessment tools need to be better defined, and new pain tools developed which are specific to this population.

- Drugs with milder side effect profiles are desperately needed, and as new drugs are developed more studies need to be done in every segment of the older population particularly in those over 80 years of age.

- Nonpharmacological strategies including exercise programs, and physical methods of pain control need to be scientifically evaluated in this population.

- These challenges will require practical clinical solutions that take into account the physiological barriers to pain management in long-term care residents, the pharmacokinetic changes which occur with normal aging, as well as the limited resources and logistical issues often encountered in various care settings where older persons often reside.

Neuropathic pain

MARCO LACERENZA, FABIO FORMAGLIO, LIA TELONI, PAOLO MARCHETTINI

INTRODUCTION

Diagnosing and treating neuropathic pain remains a major challenge for neurologists, oncologists, and pain specialists. Major advances in clinical and experimental research in the past decade(s) have shed light on the multiple types of neuropathic pain; it is now recognized that the same clinical condition may have diverse pathophysiological mechanisms.[1] The International Association for the Study of Pain[2] defines neurogenic pain as 'Pain initiated or caused by a primary lesion or dysfunction or transitory perturbation in the peripheral or central nervous system'. Neuropathic pain is a subentity where 'transitory perturbation' is omitted. The inclusion of 'dysfunction' in the definition of neuropathic pain raises confusion, because it allows improper labeling of nociceptive and psychogenic conditions as neurogenic/neuropathic. To clarify and simplify the definition of neuropathic pain, we proposed[3] amending the definition to 'pain due to primary lesion of the peripheral or central nervous system', a concept now approved by recognized pain experts.[4,5]

Neuropathic pain originates from diseases or trauma to the peripheral or central nervous system, and exhibits an acute or chronic temporal profile, the latter being by far more common and disabling. Pain and related neuropathic symptoms and signs may fluctuate according to the temporal evolution of the painful disease, mood and anxiety of the patient, and even weather conditions (trigeminal neuralgia).

Neuropathic pain can be spontaneous (stimulus-independent pain) with an episodic or continuous temporal profile. Episodic paroxysms are typical of trigeminal and glossopharyngeal neuralgias, but other pains in neuropathy may appear as isolated attacks or attacks of increasing intensity superimposed on continuous pain. Spontaneous symptoms are described as uncommon tactile and thermal sensations associated with numbness, tingling, pins and needles, burning, shooting, or electric shocklike sensation. In addition, the common aching pain, attributable to the nociceptive component, may be part of the clinical picture of painful peripheral neuropathies and a frequent complaint in patients with central pain due to multiple sclerosis[6] and syringomyelia.[7]

Neuropathic pain may also be evoked. The evoking stimulus may cause massive activation of ectopic sensory discharges by acting on mechanosensitive neural pathways. The maneuvers evoking the latter are improperly called clinical signs and classically referred to by their eponyms (Lhermitte, Lasègue, and Spurling are widely known). Pain may also be evoked by direct stimulation of cutaneous nerve endings (stimulus-dependent pain) unchaining a sequence of spontaneous attacks, such as trigger point activation of tic douloureux, or remaining time locked within the original stimulus, however, with exaggeratedly intense or distorted quality. Dysesthesia, hyperalgesia, and allodynia are the terms applied to define aberrant evoked sensory phenomena. Such aberrant sensations appear following a lesion in the peripheral or central nervous system; obviously similar symptoms originating from anatomically different sites and causes are likely to have different pathophysiology. Sensitization of nociceptors, ectopic activity, and multiplication of impulses are probable peripheral mechanisms of dysesthesia and hyperalgesia.[8] Disinhibition of the spinothalamic pathway and, again, ectopic activity, are likely central mechanisms, although the evidence in humans is still weak. It is at least recognized that central pain and pain evoked by central stimuli require abnormal spinothalamic function.[9*,10*] Allodynia is a more complex condition. By definition the term implies a painful perception evoked by stimuli (mechanical or thermal) of intensity below nociceptor threshold. Therefore allodynia is widely viewed as the clinical 'sign' of central sensitization.[1] However, nociceptor threshold is

remarkably lower than pain threshold, the pain perception requiring temporal and spatial summation of nociceptive impulses to overcome the endogenous inhibitory state. Thus, what common experience would reasonably define as stimulus of painless intensity might be sufficient to activate nociceptors.[11] Hyperactivity and multiplication of discharges in peripheral nociceptive afferents may well give rise to allodynia. Novel recordings from nociceptors in patients with allodynia due to painful neuropathies provide objective evidence for this peripheral explanation.[12]

When considering the somato-topical organization of the peripheral and central nervous systems, all neuropathic pains are perceived to occur within the innervation territory of the damaged structure. A thorough exploration of the neuroanatomical distribution of pain and sensory alteration using a pain drawing completed by the patient aids the diagnosis[3] that otherwise relies on the medical history and bedside examination. The evaluation aims at correlating sensory, motor, and autonomic signs with the anatomical localization of the lesion based on a careful history.

Autonomic signs may be a direct consequence of the nerve injury or a consequence of spinal/supraspinal reflex to nociceptive input, and care should be taken to distinguish between these phenomena.[13] Clinical neurophysiological tests such as electromyography, nerve conduction studies, evoked potentials, infrared telethermography, and quantitative mechanical and thermal threshold tests supplement the clinical diagnosis allowing definition of nerve fibers or central sensory pathways involved.

NEUROPATHIC PAIN SYNDROMES IN PATIENTS WITH CANCER

In the final stages of the disease 80 percent of cancer patients complain of pain,[14] and a neurological complication is frequently heralded by pain.[15*] Direct activity of the tumor causes nerve trunk, nerve plexus or radiculospinal compression; among the indirect consequences are paraneoplastic polyneuropathies, ischemic mononeuropathy, and postherpetic neuralgia. In the early clinical phase, compression or invasion of the peripheral or central nervous system by tumor generates a nociceptive pain due to stimulation of the perineurium or the meninges. This nerve-trunk pain[16] or meningeal pain, responds well to drugs effective against nociceptive pain, such as nonsteroidal anti-inflammatory drugs (NSAIDs) or opioids. In the following phase, when the axonal membranes get damaged, typical neuropathic symptoms enter the clinical picture. Two clinical studies tried identifying the different types of pain in cancer patients and found that 5 percent and 10 percent had pure neuropathic pain, 64 percent and 49 percent had nociceptive pain, 31 percent and 41 percent had mixed pain. Overall, 36 percent of pains in one study[17*] and 51 percent in the other study[18**] had a neuropathic component. A multicenter survey of IASP Task Force on Cancer Pain reporting in 1999, found neuropathic mechanisms in 39.7 percent of 1095 patients from 24 countries.[19*]

Neuropathic pain syndromes due to direct or indirect activity of the tumor

Classic trigeminal neuralgia is among the presenting symptoms of malignancies of middle and posterior cranial fossae.[20*] Most commonly, bone or meningeal invasion causes constant deep aching pain overlapping with paroxysmal electric shocklike trigeminal pain. With the progression of the illness, neuropathic pain becomes continuous. Spontaneous deep burning sensation combined with sensory loss and other focal neurological signs appear following axonal loss. A progressively worsening pain in the territory of the trigeminal or other cranial sensory nerves, coupled with evolving neurological signs or symptoms is almost pathognomonic of head/neck tumors.

The intercostal nerve syndrome, caused by metastatic spread into a rib, is a common example of syndromes caused by peripheral nerve compression and infiltration by the evolving cancer. A period of deep aching pain in the chest precedes the appearance of a continuous burning pain with superimposed episodes of segmentally distributed, shooting pain. Later, positive and negative sensory symptoms combine and worsen progressively, culminating in the fracture of the rib.

Plexopathies

Nerve plexus lesions in cancer frequently lead to pain with a neuropathic component. The nerve injury can be caused by direct invasion by the primary tumor, dissemination via lymph nodes, postradiation therapy or surgery. Cervical plexus involvement is witnessed in primary or metastatic head or neck tumors, resulting from invasion or compression from the growing mass or from surgical and/or radiation treatment. The neuropathic pain syndrome reflects the anatomical distribution of the damaged nerve fibers. Pain and sensory symptoms can arise from the lesser and greater occipital nerves territories in the occipital region, the preauricular area supplied by the greater auricular nerve, and the anterior part of the neck and shoulder innervated by the transverse cutaneous and supraclavicular nerves, and may also project to the jaw.[21*] A combination of nociceptive and neuropathic pains with positive and negative sensory symptoms in multiple nerves territories is the rule in patients with postsurgery and postradiation syndromes.

Brachial plexopathy is a frequent neurological complication in patient with cancer and occurs in lymphoma and breast and lung carcinoma. Pain usually precedes focal neurological signs, even up to 9 months; it is the most common symptom in 85 percent of patients.[22*] Lower plexus invasion is by far the most common, as in Pancoast syndrome due to apical lung cancer. An aching pain in the shoulder,

subscapular area and upper back may appear some months before a burning pain in the armpit. Clinical examination usually reveals sensory loss in the intercostobrachial nerve territory, of which patients are frequently unaware. In the early phase, an X-ray of the chest often has normal findings and only computed tomography (CT) or magnetic resonance imaging (MRI) of the chest reveals the neoplasm.[23] The advanced clinical picture includes Horner syndrome (Fig. 52.1) and focal weakness, atrophy, sensory loss in the hand and severe electromyographic-electroneurographic abnormalities in the C7, C8, and T1 root distribution. Involvement of the upper plexus (C4, C5, C6 roots) by metastatic breast carcinoma and lymphoma is less frequent. Pain is localized in the shoulder girdle, worsened by neck movement, and projected to the radial side of the hand with tingling, sensory loss, burning and shooting sensations. The combination of Lhermitte sign, Horner syndrome, and pan-plexopathy strongly suggests epidural extension, which can be occur even in the absence of bony erosion in patients with lymphoma.[22*]

Painful lumbosacral plexopathy (LSP), and its complications, is a most disabling condition in cancer. Pelvic tumors and metastatic malignancies almost always cause pain in the buttocks and/or legs following lumbosacral plexus invasion.[24*] The insidious onset of an aching and cramping nociceptive pain, provoked by perineural invasion and activation of nociceptors in the nervi nervorum, typically precedes neuropathic pain. In Jaeckle and coworkers' series of 85 patients with proved LSP, causalgic pain was present in 8 percent. They described three types of pain: local pain (85 percent), radicular pain (85 percent) and referred pain (44 percent), which was associated with an upper plexopathy (L1–L4) in about a third of the cases, a lower plexopathy (L4–S1) in half of the cases, and a pan-plexopathy in less than a fifth. The anatomical distribution of weakness and sensory symptoms and signs, usually appearing after the pain, does not always correlate with CT imaging – the examination usually reveals wider invasion.[24*] Presence of pain and neurological signs of LSP with normal findings on CT of the abdomen and pelvis calls for a differential diagnosis of meningeal carcinomatosis, epidural cord compression, and cauda equina compression.

Radiculopathies and myelopathies

Painful radiculopathies in patients with cancer are usually related to direct compression or invasion of nerve roots by vertebral and paraspinal cancers or leptomeningeal metastases. There can be nociceptive focal and neuropathic pain projected along the distribution of the damaged root. When multifocal radiculopathies are associated with headache and changes in mental status, the clinical picture is highly suggestive of leptomeningeal metastases.[25] The clinical picture of myelopathy is often preceded by local nociceptive pain due to invasion of vertebral body or epidural space and
Figure 52.1   *(a) This 72-year-old woman developed aching pain in the left shoulder followed by projected burning pain in the left upper limb 4 months prior to examination. The neurological evaluation revealed Horner syndrome and signs of left lower brachial plexus involvement. (b) Telethermography revealed straightforward thermal asymmetry of the face, the left side warmer being than the right due to sympathetic denervation. (c) Computed tomography of the pulmonary apex disclosed a Pancoast tumor on the left side.*

then neuropathic pain of radicular origin. When the compression extends to the dorsal column of the spinal cord, generating focal demyelination, the presence of Lhermitte sign confirms the onset of clinical myelopathy.

Rarely, in case of advanced myelopathy, neuropathic pain originates from compression/invasion of spinothalamic pathways. The pain is usually unilateral, a few myelomeres below the affected level – extended down to the foot or with a patchy distribution, associated with tingling and allodynias, mainly due to cold and spontaneous thermal sensations.

POSTHERPETIC NEURALGIA

Postherpetic neuralgia is a painful radiculopathy following herpes zoster infection usually in the mid-thoracic dermatomes and in the ophthalmic branch of the trigeminal nerve. It is more common in altered immune states, e.g. in older people and in patients with cancer (mainly leukemia and lymphomas), and it has been shown that the site of the primary tumor correlates with the site of subsequent herpes zoster infection.[26*] Neuropathic pain can be spontaneous with deep aching, burning and shooting components, or stimulus dependent with allodynia and/or hyperalgesia.[27]

Polyneuropathies

Peripheral paraneoplastic neuropathies, due to either indirect cancer activity or the immune reaction against the cancer, may be painful. Altogether, these are a rare complication of cancer and an accurate diagnosis is crucial: sometimes it may uncover the tumor. Paraneoplastic sensory neuronopathy is a disabling condition presenting with neuropathic pain and progressive sensory loss in the limbs, trunk, and face. Burning pain and shooting sensations are present and associated with asymmetrically distributed numbness and tingling. Symptoms usually appear before, by weeks or months, the diagnosis of tumor, which most frequently is a small-cell lung cancer or less frequently a breast carcinoma. Given the high specificity (99.8 percent) and sensitivity (82 percent) of anti-Hu antibodies,[28] in patients with no evidence of cancer a CT study of the chest should be done.

Although paraneoplastic sensory neuropathy is related to an inflammatory, probably immune-mediated lesion of sensory neurons, usually it does not respond to plasma exchange, intravenous immunoglobulin, or immunosuppressants but to early treatment of the tumor.[29] Early symptomatic treatment of neuropathic pain is mandatory. Among other painful paraneoplastic disorders affecting the peripheral nervous system is the Guillain–Barré syndrome, which sometimes can be heralded by radicular pains, and a nonsystemic vasculitic neuropathy. This subacute and progressive condition can be associated with small-cell lung cancer and lymphomas and involves sensory and motor fibers in a symmetric or asymmetric fashion. Early diagnosis of paraneoplastic vasculitis encourages combined treatment with steroids and cyclophosphamide, with better results than steroids alone.[30] Severe local pain can be related to the inflammatory biochemical cascade that leads to

activation/sensitization of nervi nervorum, followed by ischemia and consequent axonal damage and neuropathic pain along the anatomical distribution of the damaged nerve.

Table 52.1 summarizes the neuropathic pain syndromes in the patient with cancer along with their etiology.

IATROGENIC NEUROPATHIC PAIN IN CANCER

Bleuler in 1924 introduced the term 'iatrogenic' to define any disorder 'generated or caused by medicine or medical doctors'. Longer survival times and more aggressive surgical and medical treatment of cancer have led to an increase in iatrogenic painful conditions. Iatrogenic neuropathic pain in cancer patients may arise as a consequence of radiotherapy, chemotherapy, or surgical nerve lesions.[31] Pain in malignancies is often associated with cancer recurrence. The appearance of a novel painful condition deserves extensive examination aimed at early diagnosis of the cause of the pain. Informing the patient that the pain is iatrogenic and not a direct consequence of the tumor reduces their anxiety and results in a favorable response to specific treatment.

Neuropathic pain as a consequence of radiotherapy

Radiation may provoke painful myelopathy or peripheral nerve lesions. High-dose radiotherapy close to the spine causes transient or, less frequently, delayed progressive myelopathy that occasionally has the features of a central pain syndrome.[32*,33*] Sometimes the presenting complaint of a post-radiation myeloradiculopathy is the Lhermitte sign.[34*] Painful brachial plexopathy is the most common post radiotherapy syndrome. The nerve injury may be direct or indirect, i.e. infarction of the brachial plexus due to thrombosis of the subclavian artery and its branches.[35*] High-voltage radiation may cause acute painful but reversible brachial plexopathy.[36*] A delayed, but usually not painful, brachial plexopathy due to radiation fibrosis may develop several months after radiotherapy, with tingling and large fiber sensory loss within the upper plexus distribution.[37] In contrast, recurrent cancer with invasion of the peripheral nerves is often severely painful with neuropathic and nociceptive pains. Electromyographic studies help in differentiating the two conditions, with radiation being associated with myokymias more often than tumor invasion.[38]

Lumbosacral plexopathy, which is rarely painful, may also follow radiotherapy as a late delayed complication.[39] However, pelvic pain and lower extremity paralysis are described as an acute complication, occurring up to 10 weeks following completion of radiation therapy for cervical cancer.[40*]

Table 52.1   *Neuropathic pain in patients with cancer*

	Clinical syndrome	Etiology
Nerve compression/invasion	Trigeminal neuralgia	Middle and posterior cranial fossa tumors, base of skull metastases
	Glossopharyngeal neuralgia	Jugular foramen invasion, leptomeningeal metastases
	Intercostal neuralgia	Primary or metastatic lung, pleural, rib cancer
Direct effects of cancer		
	Postauricular neuralgia	
Cervical ⎫	Preauricular neuralgia	Primary head and neck cancer and cervical lymph node metastases
⎬ compression/invasion plexopathies	Anterior part of the neck neuralgia	
Brachial ⎪	Upper brachial plexus neuralgia	Lymphoma and cervical lymph node metastases from breast and lung cancer
	Pancoast syndrome	Breast metastases and lung cancer
Lumbosacral ⎭	Upper lumbar (L1–L4) neuralgia	Primary cancer: colorectal, genitourinary and sarcoma, lymphoma
	Lower lumbar (L5–S1) neuralgia	Metastatic cancer: colorectal, breast, lymphoma, genitourinary,
	Sacrococcygeal neuralgia	melanoma, lung, gastric
Compression/invasion of nerve root	Unilateral pain in the cervical and lumbosacral radicular territories	Vertebral cancer Paraspinal invasion
	Frequently bilateral distribution in the thoracic dermatomes	Epidural invasion Leptomeningeal dissemination
Compression/invasion of spinal cord	Rarely, central pain with Brown-Séquard syndrome	Primary and metastatic cancer
Compression/invasion of thalamocortical projections	Rarely, central pain with thalamic syndrome	Primary and metastatic cancer
Indirect effects of cancer		
Paraneoplastic neuropathies	Sensory ganglionopathy	Small cell lung, ovary, colon, and breast carcinomas
	Guillain–Barré syndrome	
	Nonsystemic vasculitis	Small cell lung cancer, lymphoma
	Brachial plexopathy	
Acute herpes zoster Postherpetic neuralgia	Frequently in the thoracic dermatomes, ophthalmic branch of the trigeminal nerve and in previously irradiated dermatomes	Leukemia, lymphomas, post irradiation
Nerve entrapment due to lymphedema	Brachial plexopathy	Post mastectomy
Ischemic neuropathy/ies	Painful mono/multiple neuropathy	Thrombosis, compression/invasion of small arteries
Cerebral hemorrhage	Central pain with thalamic syndrome	Primary and metastatic cancer
Iatrogenic neuropathic pain in cancer		
Postsurgical nerve lesion	Post neck surgery syndrome	Neck dissection
	Intercostobrachial neuralgia	Mastectomy
	Intercostal neuralgia	Thoracotomy
	Post-thoracotomy pain	Thoracotomy
	Phantom pain	Limb, breast, rectal amputation
	Stump pain	
Postradiation neuropathies	Painful brachial plexopathy acute and delayed, rarely painful lumbosacral plexopathy	Radiotherapy
Postradiation myelopathy	Central pain with Brown-Séquard syndrome	
Painful polyneuropathy associated with chemotherapy	Distal ascending pain and sensory symptoms	Platinum compounds, vincristine, taxanes, and their combination

Neuropathic pain as a consequence of chemotherapy

Peripheral polyneuropathy is a common complication of chemotherapy. Neuropathic pain and sensory symptoms are often the limiting factor in chemotherapy with cisplatin, vincristine, and the taxanes. The severity of nerve damage is directly proportional to drug dosage.[41–43] Patients with preexisting neuropathy due to diabetes mellitus, alcohol, hereditary neuropathies, paraneoplastic neuropathy, or earlier treatment with neurotoxic chemotherapy are thought to be more vulnerable to developing chemotherapy-induced peripheral neuropathy.[44] Ascending distal paresthesias and dysesthesias together with burning pain and allodynia to cold or mechanical stimuli in a glove and stocking distribution often appear after chemotherapy. The mechanisms producing the nerve injury, and in particular neuropathic pain and sensory symptoms, are not clear.

A common mechanism has been proposed for the toxicity of cisplatin, vincristine, and taxol.[45] Vincristine therapy provokes a predominantly sensory, sometimes autonomic subacute neuropathy in almost all patients. Cisplatinum neuropathy becomes clinically evident with cumulative dosages of the drug, nerve deterioration continuing months after drug withdrawal.[46*] The widely used paclitaxel is known to provoke neuropathic pain and sensory dysfunctions that mostly affect the hands and feet, and is related to a myelinated fiber neuropathy preferentially affecting the largest fibers (with sparing of C fibers).[45]

Brachial and lumbosacral plexopathy may also be related to chemotherapy. Chemotherapy administration through the subclavian or iliac artery may cause an acute painful brachial or lumbosacral plexopathy, which is sometimes irreversible. This is probably due to direct damage to small vessels and thrombosis, which leads to infarction of the nerve plexus.[47*]

Postsurgical neuropathies

Postinjury neuralgia is a relatively rare event compared with the large number of nerve injuries provoked by surgical trauma, perioperative ischemia, compression, and delayed scar entrapment. Although reliable clinical data are lacking, the incidence of painful neuralgia following peripheral nerve injury seems to be about 2.5–5 percent of the injuries.[48]

Post–neck surgery syndrome

Neck and nuchal pain may arise as a consequence of cutaneous nerve lesions provoked by surgical interventions for primary or metastatic head or neck tumor. Pain affects almost 50 percent of patients, sometimes weeks after neck dissection.[49*] According to the aggressiveness of tumor and the timing and location of the surgery, the pain may have nociceptive and neuropathic components. In half of the patients the pain subsides in a few months, whereas in the other half it lasts for years.[49*] In studies reporting on pain following neck surgery, 8 percent of patients complained of shoulder and arm pain, increasing to around 30 percent after a 1-year period.[49*,50,51] Only 2 percent of the patients reported this pain as 'severe',[49*] but most of them judged it to be debilitating.[51] Shoulder pain and disability were shown to be proportional to the surgical extension; they seem to be reduced in modified radical neck dissection and selective neck dissection compared with standard radical neck dissection.[52*] Therefore it is likely that the surgical technique influences the pain occurrence.

Pain following breast cancer surgery

More than 50 percent of patients have chronic pain syndromes after breast cancer surgery.[53] Acute postoperative pain has both nociceptive and neuropathic components, whereas persistent pain has predominantly a neuropathic origin. A recent, validated classification of neuropathic pain following breast cancer surgery has identified four classes: phantom breast pain, intercostobrachial neuralgia, neuroma pain, and other nerve injury pain.[53] In another study pain occurrence correlated significantly with the surgical extension: infrequent in lumpectomy but involving up to 72 percent of patients who underwent axillary lymph node dissection.[54*] In these cases, pain appearance was positively associated with the number of lymph nodes removed.[54*] Pain seems to be less frequent when careful surgical techniques are used, or when surgeons perform more interventions, as in hospitals experienced in breast surgery.[55*]

Post–thoracotomy pain

One year after thoracic surgery up to 61 percent of the patients report post-thoracotomy pain. Chronic pain development is directly related to the degree of postoperative pain severity.[56*] This pain may be due to intercostal nerve lesions, or to brachial plexus traction. Transaxillary rib resection is one of the causes of brachial plexopathy.[57] Persistent chest pain may also be due to complete intercostal nerve transection, sometimes followed by painful neuroma. Seventy percent of patients undergoing thoracotomy report severe pain (usually subsiding after 2 months time) with a neuropathic component. Progressive pain, worsening over weeks or months, and recurrence of chest pain following a pain-free period are significant negative prognostic symptoms, suspicious for cancer recurrence.[58*]

THERAPY

Treatment for neuropathic pain at the end of life differs from the management of chronic nonmalignant pain. In

palliative care relief of pain is the priority while preservation of functionality becomes a secondary issue. Therefore, the overall side effects, and in particular the sedative effects of opioids and adjuvant drugs may become acceptable, providing the drugs offer adequate pain control. The current recommendation of care is to follow the World Health Organization (WHO) ladder, choosing an analgesic regimen on the basis of pain intensity, and adding adjuvant drugs in selected pain syndromes.[17*,59*] Adjuvants analgesic mechanisms are often complementary to opioids. Well-established guidelines recommend a combination of opioids and adjuvant drug to improve the analgesic regimen of patients with neuropathic cancer pain.[17*,60]

Nerve trunk pain, i.e. the nociceptive component of neuropathic pain syndromes caused by compression, invasion or acute nerve ischemia, is treatable with NSAIDs, steroids, and eventually opioids.[14] Conversely, in the experience of most clinicians, neuropathic pain of the deafferentation type responds poorly to NSAIDs.

For a long time opioids were considered barely effective in neuropathic pain. However, in the past few years several retrospective reports on long-term therapy for neuropathic pain related to nonmalignant diseases and cancer have supported opioid efficacy and low risk of addiction and tolerance.[18*,61*] Since then, several clinical studies have supported the use of opioids in the treatment of peripheral neuropathic pain.[61,62**,63**,64**,65**] However, the evidence for their efficacy with regard to central pain is weak.[66**] Some opioids are potentially more effective than others in neuropathic pain due to their pharmacological properties: methadone[67,68**] and propoxyphene have weak N-methyl-D-aspartate (NMDA) receptor antagonism, and tramadol[69**] has noradrenergic/serotonergic activity. However, comparative studies of opioids in neuropathic pain syndromes are still lacking.

Anticonvulsants, other channel blockers, and antidepressants, commonly referred to as adjuvant drugs, are considered effective treatment for neuropathic pain.[70***,71***,72***] Gabapentin is an anticonvulsant structurally related to γ-aminobutyric acid (GABA) and binds the $\alpha_2\delta$ subunits of voltage-gated calcium channels with well-documented efficacy in peripheral neuropathic pain related to diabetic neuropathy and postherpetic neuralgia.[73**,74**,75**] Gabapentin added to opioids in cancer patients with neuropathic pain reduced pain in one study,[76*] but it had a limited effect in a larger patient population investigated by the same group.[77**] Pregabalin modulates the $\alpha_2\delta$ subunits of voltage-gated calcium channels with better kinetics properties compared to gabapentin; its efficacy in neuropathic pain due diabetic polyneuropathy and postherpetic neuralgia is also well documented.[78**,79**] Carbamazepine is an old anticonvulsant that unselectively blocks sodium channels. It is still considered the gold standard treatment for trigeminal neuralgia.[80**] In older clinical studies proved efficacy of carbamazepine was shown in painful diabetic neuropathy[81**] although with a higher incidence of side effects compared with the newer anticonvulsants. Its analog oxcarbazepine is also effective in trigeminal neuralgia[82*] and in painful diabetic polyneuropathy, with a better tolerability profile.[83**] Lamotrigine is an antiepileptic agent that stabilizes the neural membrane, blocking voltage-sensitive sodium channels and inhibiting presynaptic release of glutamate. Its analgesic efficacy has been shown in trigeminal neuralgia,[84**] post-stroke central pain[85**] and human immunodeficiency virus (HIV)-related polyneuropathy.[86**]

Tricyclic antidepressants (TCAs) were the mainstay of neuropathic pain therapy before the introduction of the new anticonvulsants.[87***] Among these drugs, amitriptyline and imipramine are the most commonly prescribed TCAs in neuropathic pain. Amitriptyline reduces pain in diabetic neuropathy[88**] and central post-stroke pain.[89**] Randomized trials of selective serotonin reuptake inhibitors have shown inconstant efficacy in neuropathic pain.[72***] The noradrenergic/serotonergic reuptake inhibitor venlafaxine seems a promising drug, because at high doses it has shown analgesic efficacy in peripheral neuropathic pain.[90*,91**] Bupropion, a second-generation non-TCA antidepressant, has demonstrated efficacy and good tolerability in a single double-blind randomized trial on different types of peripheral neuropathic pain.[92**] A lidocaine patch decreases pain and allodynia in postherpetic neuralgia.[93**] Intravenous lidocaine[62**] and parenteral ketamine[94**] quickly, although only transiently, reduce pain and may help control episodic neuropathic pain unresponsive to conventional analgesics.

Neuromodulation with spinal drug delivery is a recognized treatment for patients with severe refractory pain and life expectancy of at least 6 months.[95,96*] The most commonly used drugs in neuraxial analgesia are morphine, bupivacaine, clonidine, and ketamine. Recently intrathecal ziconotide, an N-type calcium-channel blocker derived from a sea-snail peptide, has shown statistically significant analgesic efficacy in advanced cancer and acquired immune deficiency syndrome (AIDS) patients with intractable pain.[97**] On the other hand, a lack of cost–benefit efficacy and concomitant poor long-term prognosis precludes electrical spinal cord stimulation.[98]

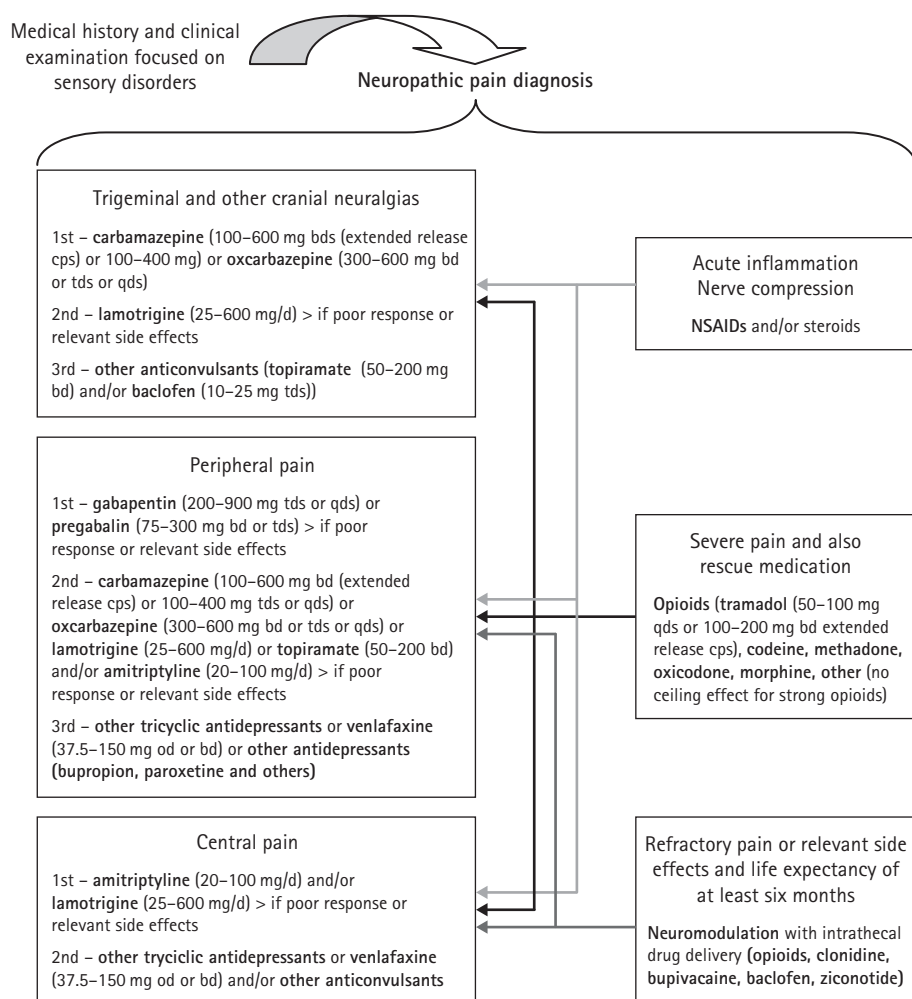
As a general rule, for treating the neuropathic component of a pain, the initial approach could be based on gabapentin or pregabalin (particularly for peripheral pain), alternatively on amitriptyline or lamotrigine (also effective in central pain), given 'round the clock' in a regular fashion with an appropriate titration dose. Other anticonvulsants or antidepressants might be considered as second step in poorly responsive patients. Opioids, and sometimes NSAIDs and steroids, may be used as rescue medication for treating episodes of incident or worsening pain, or may be available on an 'as needed' basis, or added at regular times in the presence of pain of mixed origin or severe intensity. Figure 52.2 summarizes our standard approach to treating neuropathic pain in palliative care patients.


Figure 52.2 *Management of neuropathic pain in palliative care patients. *Based on the clinical practice at the authors' center. This management protocol is not fully supported by randomized clinical trials. bds, twice daily; tds, thrice daily; qds four times daily, od, once daily; d, day.*

In conclusion, we emphasize the need to identify the cause of the pain, unravel its neuropathic nature and possibly hypothesize or search for the mechanisms. A thorough investigation might lead to a more specific treatment, which even in the palliative stages could be relevant for improving the patient's autonomy, cognition, and dignity.

Key learning points

- Neuropathic pain is not a single entity but encompasses a variety of different, complex clinical pictures with diverse pathophysiological mechanisms.

- Neuropathic pain is frequently present in cancer patients either in isolation or combined with nociceptive pain (mixed pain).

- Direct and indirect activity of cancer cause different neuropathic pain syndromes depending on the anatomy

and the pathophysiology of the injured part of the nervous system.

- The number of cancer patients with neuropathic pain of iatrogenic origin is increasing due to longer survival times and the more aggressive surgical and medical treatment.

- Radiotherapy, chemotherapy, and surgery may cause multiple painful neuropathic syndromes.

- A thorough evaluation of the patient's pain informs the most appropriate treatment and enhances the patient's ability to cope.

- Treatment of neuropathic pain is moving out of the empirical era to an evidence-based scientific approach. Novel adjuvant compounds have become available for neuropathic pain, supported by clinical studies on their efficacy and tolerability.

- Improved understanding of neuropathic pain pathophysiology is steering clinical research and patient management.

Bone pain

YOKO TARUMI

INTRODUCTION

The disease-related event that has the most significant impact on quality of life for patients with malignant disease is cancer-induced pain.[1] Bone metastases are most commonly associated with cancers of the breast, prostate, lung, kidney, and with multiple myeloma (Table 53.1). Approximately 40–70 percent of patients with bone metastases will develop skeletal complications (skeletal-related events [SRE]) at some point during the course of their disease, most commonly bone pain, pathological fractures, hypercalcemia and spinal cord compression.[11,**12**,13] Malignant bone pain is the most common source of pain in patients with malignant disease.[14,15*] At its onset, malignant bone pain can be intermittent, but it progresses rapidly into continuous pain (background pain) that is exacerbated by episodes of spontaneous aggravation of pain or movement-induced (incident) pain. Patients with established chronic malignant bone pain syndrome who show perception of severe pain to normally nonpainful activity or stimulation such as coughing, turning in bed, gentle touching, or gentle limb movements have developed mechanical allodynia and hyperalgesia.[16–18] Pain management in this population is particularly important to maintain function, especially in patients with primary malignancy of breast and prostate, and multiple myeloma whose may have a long life expectancy after the diagnosis of metastatic bone disease.

PATHOPHYSIOLOGY OF MALIGNANT BONE PAIN: WHY IS TUMOR–INDUCED BONE DESTRUCTION PAINFUL?

Not all the bone metastases are painful. Although the most common presenting symptom of metastatic disease to the bone is pain, 30–50 percent of patients have asymptomatic bone metastases found during staging studies for primary tumors.[19] On the other hand, in the animal model of bone cancer, pain-related behavior is present before any significant bone destruction is evident.[20]

Animal model of malignant bone pain

In the past, malignant bone pain was understood to be due to vascular occlusion, compression of the bone or peripheral nerve, or mechanical instability. Since 1999, an animal model of malignant bone disease has been established, which shares key features with human malignant bone pain with

Table 53.1 *Incidence of bone metastases and life expectancy after diagnosis*

Type of cancer	Frequency	Life expectancy
Prostate cancer	75–100%[2,4]	53 months without visceral metastases and 30 months with visceral metastases[3]
Breast cancer	80%[2]	34 (1–90) months[2,5]
Multiple myeloma	95–100%[2]	20 months[2]
Nonsmall and small cell lung cancer	30–40%[2]	<1 year[6**]
Renal cell cancer	35%[7]	1–2 years[8***]
Bladder cancer	22%[9*]	1–2 years[10]

progressive bone destruction leading to a pathological fracture, accompanying progressive limping, guarding, spontaneous flinching and vocalization on palpation, reduced movement secondary to hyperalgesia, and allodynia, while, at the same time, the animal remains well with good weight gain.[16,21,22] The level of pain behaviors observed correlated with the extent of disease-induced osteolysis.[17,18] The response to systemic opioids in the mouse model was similar to that found in humans, which showed reduced attenuation with morphine compared with the model with inflammatory pain.[23]

Neurochemical alterations

In the animal malignant bone pain model, three significant and specific neurochemical alterations in the spinal cord are observed:

1 Expression of the prohyperalgesic peptide dynorphin (an opioid family relating to maintenance of chronic pain.[24]
2 Increased neuronal activity.
3 Increased number of astrocytes (the most numerous type of glial cell in the central nervous system).[16]

These neurochemical findings were correlated with the degree of bone destruction.[16–18,20] In the neurochemical studies measures of pain have been compared in mice or rats with inflammatory pain, neuropathic pain, and malignant bone pain; the findings indicated that bone pain results in a unique neurochemical pain state: a condition that differs clearly from inflammatory pain or neuropathic pain.[18,25]

Tumor–nociceptor interface

In malignant bone pain expression, multiple types of tumor-associated cells including immune-system cells such as macrophages, neutrophils and T cells, secrete factors such as prostaglandins, multiple cytokines, and endothelin (a peptide activating nociceptors, inflammation, and angiogenesis). These factors are thought to play an important role in exciting or sensitizing the peripheral and central nervous system through continuous nociceptive activation, resulting in the release of neurotransmitters such as calcitonin gene-related peptide (CGRP), glutamine, histamine, and substance P (a neurotransmitter, synthesized and transported to the C-fiber after painful stimuli, potential mediator of hyperalgesia).[26] Bone has rich sensory and sympathetic fiber innervations involving mineralized bone and periosteum.[27,28] The stimulation of sensory afferent nerves endings located in the bone cortex, periosteum, and surrounding soft tissue are ultimately involved in pain transmission.[28]

Osteoclast and malignant bone pain

Although the mechanisms of malignant pain are largely unknown, data from clinical trials with bisphosphonates and analysis of bone metabolism in patients with bone metastases suggest that cancer-induced bone resorption is linked to malignant bone pain.[2,3,11,29,30**,31**,32**] It is now understood that the osteoclast plays the major role in the resorption of bone instead of the cancer cell itself. Cancer cells produce and secrete a variety of cytokines and growth factors such as transforming growth factor β (TGFβ and parathyroid hormone-related protein (PTHrP) that recruit osteoclast precursors and activate mature osteoclasts[33] (Fig. 53.1). Osteoclasts are derived from myelo-monocytic precursors and destroy bone by forming an acidic extracellular compartment at sites of bone resorption.[16,34] Many primary afferent neurons that innervate the periosteum have been shown to express acid-sensing ion channels.[35]

Osteoprotegerin as bone resorption 'regulator'

Macrophage colony-stimulating factor and the receptor activator of nuclear factor κB-ligand (RANKL) and its receptor system are important components of osteoclastogenesis.[34] RANKL is produced by osteoblasts and stromal cells, and osteoclast precursors express RANK. RANKL stimulates recruitment, differentiation, and activation of osteoclasts.[34] Osteoprotegerin (OPG) is a 'decoy' receptor that competes with RANK for RANKL, and thus modulates the effects of RANKL.[36,37] Although OPG has been shown to decrease pain behaviors in animal models of malignant bone pain, it is still being developed for use in cancer patients.[17,20,26] Although an animal model of malignant bone pain treated with OPG halted progression and stabilized bone destruction, the pain behavior or neuromechanical measure of pain did not improve.[17,20] Osteoprotegerin has also been shown to increase bone mineral density and bone volume, which are associated with a decrease in active osteoclast number in women with osteoporosis and patients with multiple myeloma.[38**,39]

ASSESSMENT

Diagnosis of malignant bone pain can usually be made by history and physical examination. The clinician should enquire about the onset, quality, intensity, location, radiation of the pain, factors that exacerbate or alleviate the pain, and other systemic symptoms such as bowel and urinary problems, and functional problems. Malignant bone pain syndrome consists of a triad of background pain, spontaneous pain, and movement-induced (incident) pain[15,40] (Table 53.2). Patients often describe a sudden flare of their pain which keeps them from moving freely, resulting in disability (see Chapter 54, page 505).

Besides the general physical examination, a musculoskeletal and neurological examination should be completed focusing on palpable tenderness in the skeletal system and neurological deficits/alterations. Patients who have back

Table 53.2   *Triad of clinical signs of malignant bone pain*

Sign	Characteristic features
Background pain	Constant dull ache Increase in intensity over time
Spontaneous pain	Intermittent episodes of intense pain without trigger
Movement-induced (incident) pain	Intermittent episodes of intense pain upon movement/weight bearing

pain with or without weakness of the limbs, paresthesias, sensory change, or bladder or bowel impairment should be carefully assessed for potential spinal cord compression and cauda equina syndrome (see Chapter 88, page 817). The differential diagnosis of bone pain includes degenerative disease due to osteoporosis in older women with a history of malignancy (such as breast cancer) who may present with acute back pain due to collapsed vertebrae, or Paget disease of bone in older men with a history of prostate cancer with sclerotic radiographic changes in the pelvis. In all

cases, it is important to emphasize that the imaging tests should be interpreted in conjunction with the clinical picture, information from measurement of biochemical markers of bone metabolism and serum tumor markers when appropriate. Tables 53.3 and 53.4 provide summaries of the use of diagnostic modalities.

Bone consists of 85 percent dense cortical bone composed of minerals, and 15 percent porous and spongy trabecular bone composed of collagens which encompasses the marrow component. Most of the red marrow is located in axial bones, such as vertebrae, pelvis, proximal femora, while fat marrow is located in appendicular bones.

Plain radiography

On X-rays, bone metastases may appear as areas of absent density or absent trabecular structure which represents osteolytic lesions. Osteoblastic lesions may appear as increased density and sclerotic lesions or rims. X-ray is specific to confirm symptomatic lesions or suspicious lesions on bone scintigraphy (bone scan). It is also useful for

Table 53.3 *Comparison of bone structure and various bone imaging modalities*

	Cortical bone	Trabecular bone	Bone marrow	Tumors	Bone metabolism	Tumor glucose metabolism
X-ray (plain radiography)	√	√				
Computed tomography	√	√	√	√		
Magnetic resonance imaging			√√	√√		
Bone scan					√	
Positron emission tomography						√

Table 53.4 *Comparison of diagnostic sensitivity/specificity and advantages/disadvantages*

	Sensitivity	Specificity	Advantages	Disadvantage
X-ray (plain radiography)	Low	Not available	Assessment of risk for pathologic fracture Less expensive Detects structural changes	Delayed appearance
Computed tomography	High	High	Evaluates cortical and trabecular bone	Relatively expensive
Magnetic resonance imaging	High	High	Evaluates spinal cord compression and soft tissue	Expensive
Bone scan	Varies	Low	Detects new lesions Reasonable screening tool	Low specificity
Positron emission tomography	Varies	High	Detects new marrow lesions	Very expensive

assessing patients at high risk for pathological fractures, for example, persistent pain on weight bearing, which may guide planning for prophylactic management surgically or nonsurgically. However, because 30–75 percent of normal bone mineral content must be lost before osteolytic lesions in the vertebrae become apparent on X-ray, metastatic lesions may not appear on X-ray for several months.[41] A recent systematic review suggests that the diagnostic sensitivity of X-ray is 44–50 percent, which is less sensitive than bone scan for detecting initial bone metastases.[42***]

X-ray may be used as the primary investigation for bone malignancies with pure lytic disease such as multiple myeloma in which bone scintigraphy (bone scan) is falsely negative in up to 50 percent of lesions.[43*,44] Pure lytic disease can also occur in other tumor types when there are rapidly growing lytic lesions.[44]

Bone scan

Bone scan, unlike X-ray, is highly sensitive for the detection of bone metastasis but lacks specificity.[45] In their systematic review, Hamaoka *et al.* reported that its diagnostic sensitivity ranges from 62 percent to 100 percent and specificity from 78 percent to 100 percent.[42***] A bone scan commonly shows abnormality where there is osteoblastic activity; it may be negative in purely lytic lesions, such as in multiple myeloma, or in rapidly progressive disease which allows little chance for new bone formation (cold spots).[44] However, it may be positive in osteoarthritis, infections, trauma, and

Paget disease.[45] Therefore, the advantage of bone scan is not for diagnosis but rather for screening, as it is widely available and can produce rapid whole-body images at a reasonable cost.[42***] Despite the usefulness of bone scan, other imaging modalities such as X-ray, CT (computed tomography), or MRI (magnetic resonance imaging) may be performed to characterize lesions further.

The 'flare' phenomenon, which may be misinterpreted as disease progression, has been reported in prostate cancer or breast cancer patients who show escalation of activity or new lesions on bone scan due to their repair process during the first 3 months of treatment. However, after 6 months, the activity associated with the flare gradually decreases.[41,46] It is important to note that determining the final response of bone metastases to oncological treatment solely on the basis of changes in bone scan is not appropriate.[42***]

Computed tomography or magnetic resonance imaging

Computed tomography with bone window setting offers superior skeletal detail, including bone marrow, because of its ability to distinguish among materials of different densities.[41,46] A systematic review suggests that its diagnostic sensitivity of bone metastases ranges from 71 percent to 100 percent.[42***] Metastases in the marrow can be detected on CT before bone destruction becomes evident.[47]

Magnetic resonance imaging can provide detailed information of the bone and bone marrow, and has better

contrast resolution than CT for visualizing soft tissue and spinal cord, especially when spinal cord involvement is suspected.[46] The diagnostic sensitivity and specificity of skeletal MRI have been reported as 82–100 percent and 73–100 percent, respectively, in a systemic review.[42***] In one retrospective survey of 100 patients, 47 percent had therapy changes associated with MRI findings.[48*] In this survey, 40 out of 78 patients who had symptoms such as back pain, weakness, paresthesia, or sphincter dysfunction had MRI-associated change in further therapy, whereas 7 out 22 patients without spinal symptoms detected on bone scintigraphy had a change in further therapy.[48*] MRI results influenced the addition or modification of radiation therapy treatment in 33 percent of the patients suspected of metastatic disease to the spine.[48*] Clinically asymptomatic presentations of spinal cord compression are not uncommon. A poor correlation between the site of vertebral body metastases and extent of epidural disease has been emphasized.[49*]

Occasionally, despite the presence of pain, no abnormalities are detected in X-ray or bone scan,[50*] and MRI may have a role in this setting. In a survey of 734 vertebral lesions, 255 were of an intertrabecular pattern; these intertrabecular lesions were detected by only 7.1 percent of radiographs and 4.5 percent of bone scans, but were demonstrated by all MRI scans.[51*]

Positron emission tomography

Positron emission tomography (PET), which visualizes the uptake of a positron-emitting radioactive form of biochemicals by tissues to trace the metabolism of the natural form of that chemical through imaging, may have role in early detection of soft tissue or bone metastases. Although high in sensitivity and specificity, its high cost, relative lack of availability, and additional time required for scanning are disadvantages.[42***] In the palliative care setting, the significance of this modality would be limited.

Biochemical markers

Markers of bone remodeling in metastatic bone disease may be useful tools when considering the cost of repeated imaging studies and possible radiation exposures. Markers of bone resorption could play a variety of roles in the management of metastatic bone disease.[41] For example, they could be indicated to identify patients at risk of developing skeletal complications or patients who may or may not benefit from bisphosphonate therapy.[41,52,53*,54] Some studies suggest that markers may predict the rate of bone loss, the risk of disease progression, and the potential for fracture in patients with lytic bone disease.[41,55*] It also has been suggested that the newer bone-specific markers may be sensitive enough to provide early diagnosis of bone metastases. However, the currently available evidence does not allow

final conclusions in regard to the accuracy and clinical validity of any of these indices in the primary diagnosis of bone metastases. As regards the monitoring of anticancer therapy, markers of bone resorption such as the pyridinium crosslinks, N- and C-terminal crosslinked telopeptide of type I collagen, react promptly and profoundly to bisphosphonate, hormonal, or chemical treatments. However, there have been no controlled studies on the usefulness of bone markers in monitoring of clinical symptoms of malignant bone disease.[56]

CURRENT THERAPEUTIC OPTIONS FOR MANAGEMENT OF MALIGNANT BONE PAIN

Goal of management

Once the etiology of pain has been determined, it is important that the patient and care-providers, including family members, have shared expectations and goals of the management of pain. The treatment modalities may be influenced by the individual situation, such as life expectancy, function prior to the pain experience, disease status, comorbidities, and availability of the modalities.

Table 53.5 shows the available therapies for management of malignant bone pain.

Opioid analgesics and episodic pain

Opioid analgesics are widely available and often effective; therefore they should be commenced and optimized as promptly as possible, before any other modalities are considered. Clinicians should be aware that patients may experience multifocal malignant bone pain besides other types of pain such as visceral or neuropathic pain.[15,57] Goals for the management of pain should include immediate relief of pain, restoration and maintenance of function, and prevention of complications.[58]

There is no single opioid analgesic that is preferable for malignant bone pain. The dosage should be individualized accordingly (see Chapters 44 and 45, pages 380 and 390, respectively). One of the challenges in the management of malignant bone pain with opioid analgesics is the management of spontaneous flares of pain and movement-induced (incident) pain, which may be categorized as episodic pain.[59] Because background pain can often easily be controlled by opioid analgesics, higher dosing of opioids to manage primarily the incidental component may lead to opioid toxicity. Anticipatory rescue (breakthrough) analgesics may be used prior to the activity for movement-induced pain (see Chapter 54, page 505). Newer, highly liposoluble opioids such as transmucosal fentanyl were developed particularly for management of episodic pain;[60*,61**,62*] however, this preparation is not widely available worldwide at present.

Table 53.5 *Therapies available for management of malignant bone pain*

Therapy (cost)	Mechanism	Effect	Onset	Adverse events
Opioids (relatively low cost)	μ-Opioid receptor agonism	Analgesia	Immediate	Side effects through multiple opioid receptors (See Chapter 45)
NSAIDs (relatively low cost)	COX-1 + 2 synthesis inhibitor	Analgesia + anti-inflammatory	Immediate to days	GI ulceration, interstitial nephritis, bleeding, etc.
Corticosteroids (low cost)	Inhibit eicosanoids, cytokines and substance P release	Analgesia + anti-inflammatory	Immediate to days	Psychosis, infection, proximal myopathy, edema
Bisphosphonates (high cost)	Inhibit osteoclasts activity; induce apoptosis of osteoclasts	Suppression of osteoclasts + some analgesia	Days to weeks	GI toxicity, 'flulike symptoms, electrolyte imbalances
Radiation (very high cost)	Cause apoptosis of osteoclasts + control release of cytokines	Tumor shrinkage + analgesia	Weeks	Fatigue, variety of local adverse effects (nausea, diarrhea, skin reaction, etc.)
Systemic radioisotope (very high cost)	Destruction of tumor cells	Tumor shrinkage + analgesia	Weeks	Leukocytopenia, thrombocytopenia
Surgery (very high cost)	Stabilization of unstable skeletal system	Prevention of further fracture	Immediate to days	Postsurgical complications

COX, cyclooxygenase; GI, gastrointestinal; NSAIDs, nonsteroidal anti-inflammatory drugs.

Nonsteroidal anti–inflammatory drugs

A recently reported systematic review found that the efficacy of nonsteroidal anti-inflammatory drugs (NSAIDs) in cancer pain control, especially for bone pain management, is inconclusive. Analysis is limited due to the short duration and the heterogeneity of studies.[63***] Overall, the long-term advantage/efficacy and safety of NSAIDs in bone pain management with or without opioid analgesics have not been established. Prostaglandins, which are released by tumor cells as well as through nociceptor activation from peripheral terminals of sensory fibers, are involved in the sensitization and/or direct excitation of nociceptors.[64,65] Cyclooxygenase 2 (COX-2) enzyme, which is one of two isomers involved in prostaglandin synthesis, is expressed only under inflammatory conditions, and is also expressed by cancer cells and tumor-associated macrophages. COX-2 has also been associated with angiogenesis and tumor growth.[66] Newer and more selective COX-2 inhibitors than celecoxib or rofecoxib showed efficacy in both background and movement-induced malignant bone pain in an animal model, in addition to reducing tumor burden and inducing osteoclast destruction.[67,68]

Corticosteroids

Corticosteroids play an extensive role as an adjuvant analgesic in malignant bone pain. However, there is little evidence to indicate the ideal type of corticosteroid and treatment regimen (dose, duration, etc.). Corticosteroids,

as inhibitors of adrenal androgen synthesis, are used as third-line hormonal therapy in prostate cancer in combination with mitoxantrone. Corticosteroids attenuate bone pain by inhibiting synthesis of eicosanoids, cytokines, substance P, and sprouting of sensory nerve fibres.[69,70**,71**,72] In multiple myeloma without prior treatment, high-dose dexamethasone alone or combined with thalidomide seemed to improve lytic bone lesions; however, analgesic effect was not included in the endpoint of these studies.[73**,74**,75**] Dexamethasone is commonly used due to its long-acting efficacy and absent mineralocorticoid effect. As breast cancer, prostate cancer, and multiple myeloma patients' life expectancies are relatively long, an extended period of high-dose corticosteroids should be avoided, in view of adverse effects such as proximal myopathy, which aggravates immobility, immunosuppression, and avascular necrosis.[76] Although little supporting evidence exists, the use of a nonfluorinated steroids such as methyl prednisone may delay the development of proximal myopathy.[77]

Calcitonin

Calcitonin is a hormone produced in the thyroid gland. It has a hypocalcemic action that is due primarily to the inhibition of osteoclastic bone resorption, and secondarily by action on the kidneys that results in increased urinary excretion of calcium and phosphorus. A recent systematic review suggested a nonsignificant effect of calcitonin on analgesia, reduction of analgesic consumption, control of skeletal complications, and improvement in quality of life

or survival in the malignant bone pain setting. Although statistically nonsignificant, a greater number of adverse effects (facial brushing, subcutaneous pain) were observed in the calcitonin group.[78***]

Bisphosphonates

Bisphosphonates have been recognized as an effective treatment option for hypercalcemia of malignancy due to their strong affinity for the hydroxyapatite crystal of the bone. Preclinical research has recognized that bisphosphonates inhibit the formation of osteoclasts, interfere with signaling between osteoclasts and osteoblasts (see Fig. 53.1), induce apoptosis (programmed cell death) in osteoclasts, and show disease-modifying and antinociceptive effects.[21,79,80] Newer bisphosphonates such as ibandronate and zoledronic acid show 10 000 to 100 000-fold greater potency in inhibiting osteoclast-mediated bone resorption than older agents such as clodronate or pamidronate.[81]

A systematic review supports the efficacy of bisphosphonates in providing some pain relief for bone metastases.[82***] In a total of 3682 subjects included, the number needed to treat to achieve 50 percent pain relief at 4 weeks was 11, falling to 7 at 12 weeks.[82***] However the superiority in analgesic efficacy of one agent for different primary neoplasms cannot be established due to lack of direct comparisons between bisphosphonates. Another important finding is that there is insufficient evidence to recommend bisphosphonates for immediate pain relief or as first-line therapy. Thus, bisphosphonates should be considered where analgesics and/or radiotherapy are inadequate for the management of painful bone metastases.[82***]

A number of large controlled, longitudinal, disease-specific studies have been reported since the last systematic review, primarily for breast cancer,[83**,84**,85**] prostate cancer,[86**,87**,88**,89**,90**] and multiple myeloma,[91**,92**] regarding the efficacy of different bisphosphonates for reducing SRE. However, there are still unanswered questions, such as in which primary disease, which bisphosphonate, when to start and stop therapy, especially in longer survivors, and what is the role of the therapy in the absence of symptoms.

External beam radiation therapy

External beam radiotherapy continues to be a mainstay in the palliative treatment of malignant bone pain of all primary types. A systematic review supported the efficacy in pain relief by radiotherapeutic intervention in both localized or multifocal bone metastases, with 25 percent of patients experiencing complete pain relief at one month, and 41 percent of patients experiencing at least 50 percent pain relief.[93***] Single or multiple fractions did not produce different outcomes in pain management, and the number needed to treat to achieve complete relief at 1 month (compared with an assumed natural history of 1 in 100 patients

whose pain resolved without treatment) was 4.2.[93***] Although one of the largest studies suggested that complete pain relief was achieved within 4 weeks and lasted for 12 weeks (median), no pooled estimates of the speed of onset of relief or its duration could be obtained.[93***] The description of adverse effects was poor over all.[93***]

Another systematic review suggested no difference between single-fraction and multifraction radiotherapy arms in overall rates of partial pain relief (60 percent and 59 percent, respectively) and complete pain relief in patients with any primary site, but mainly prostate, breast, and lung.[94***] A higher re-treatment rate was seen in the single-fraction arm than the multifraction arm (odds ratio 3.44).[94***] Three percent of patients in the single-fraction arm developed pathological fractures compared with 1.6 percent patients in multifraction arm (odds ratio 1.82).[94***] The incidence of spinal compression was similar for both arms.[94***] Single-fraction radiotherapy may have a significant role in the palliative setting.

The mechanism of action of radiotherapy in the relief of pain is not well-defined. The speed of onset and pain relief over the first 14 days appears to be independent of tumor type when based on retrospective subgroup analysis.[95*] Roughly 50 percent of patients record an improvement within 2 weeks, and another 10–20 percent within 4 weeks, although those with lung cancer appear to have a lower prospect of pain relief.[95*,96*] These observations led to the hypothesis that tumor shrinkage may not be an essential requirement for pain relief.[97*] This may indicate the possibility that radiosensitive host cells, including macrophages and osteoclasts, which respond to low doses of ionizing radiation by apoptosis, may be therapeutic targets. Recent data suggest that the response to radiotherapy may reduce osteoclast activity.[98*]

For treatment of generalized bone pain, hemibody irradiation may alleviate pain, although serious adverse effects such as bone marrow suppression and radiation pneumonitis limit its application.

Radioisotopes

Radioisotopes, which concentrate in sites of bone metabolism due to malignant tumor activity, produce similar analgesic results to external-beam radiotherapy for management of multifocal malignant bone pain.[93***] Strontium-89, samarium-153, phosphorus-32 and lexidronam (Quadramet) have been found to be effective and are widely available.[99**,100*,101**] There is no evidence suggesting that one particular kind of radioisotope is more effective than the others in management of malignant bone pain.[102] A systemic review suggested a small effect of radioisotopes on pain control for 1–6-month period without available evidence for long-term effects (12 months) in management of metastatic bone pain.[103***] A high incidence of leukocytopenia (relative risk 4.56) in association with radioisotope therapy was

found.[103***] A recently evaluated 'bone consolidation approach', which is the combination of a systemic chemotherapy regimen (doxorubicin) followed by Metastron (strontium-89), seemed promising for reduction of SRE as well as survival benefit in patients with metastatic prostate cancer.[104]

Radioisotopes may have a role in recurrent pain sites after maximum dose of external beam radiotherapy. However, the timing of administration with respect to chemotherapy and radiotherapy is important. A rapid fall in leukocyte or platelet count may be contraindications. The presence of disseminated intravascular coagulation is also a contraindication for this therapy.[105*] Radioisotopes should not be considered as an alternative option to external beam radiotherapy for an existing or impending pathological fracture and spinal cord compression since it would not provide sufficient radiation to soft tissues.[106]

Orthopedic surgery

Pathological fractures of bones will generally not heal by themselves because of excessive osteolytic activity in the area of the metastasis. These fractures may contribute to the development of pneumonia, pressure ulcers, urinary tract infections, thromboembolism, and caregiver burden due to extremely limited functional status. In fractured bone, internal fixation or endoprosthetic reconstruction provides superior relief of pain and restoration of function, compared with nonoperative treatment of most pathological fractures.[107] An expected survival of only weeks to months is not necessarily a contraindication to surgery.[108]

In painful bone metastases without fracture, the first prospective, consecutive series of pilot studies to evaluate surgical treatment did not find a clear benefit to quality of life for patients with advanced skeletal metastases.[109*] The complications associated with these procedures include spinal cord compression, urinary retention, ileus, intractable pain, and pulmonary compromise due to osteolytic fractures.[110*,111*] Postoperative radiotherapy generally is recommended after surgical fixation of pathological fractures, stabilization of impending fractures, decompression of the spinal cord, or stabilization of the spine. Postoperative therapy has been associated with a decrease in the need for second surgical procedures and improved functional status in patients with previously unirradiated long bone and acetabular lesions.[112*] Treatment generally is started within 2–4 weeks of surgery.

Kyphoplasty

Kyphoplasty is a new technique evolving from vertebroplasty, which combines injection of polymethylmethacrylate to strengthen a vertebra with balloon angioplasty.[113*] This technique was developed after vertebroplasty, which showed a high incidence of complications especially epidural leakage of cement outside of vertebral bodies. This procedure

may lead to early and sustained clinical improvement in pain and function through timely intervention of effective skeletal reconstruction for those suffering from ongoing osteolytic destruction of vertebral bodies with minimum complication.[114,115*] Further controlled study will be warranted for clinical implication in the setting of metastatic bone disease.

Percutaneous image–guided radiofrequency ablation

A small study of consecutive patients examining the efficacy of percutaneous image-guided radiofrequency ablation using multiple needles for patients with painful osteolytic metastasis suggests that this therapy may have a role in reducing malignant bone pain, reducing the amount of opioid requirement, and preventing the painful consequence of disease progression.[116*] The possible mechanisms of action include destroying tumor cells and decreasing the production of cytokines and tumor factors involved in bone nerve sensitization and osteoclastic activity.[116*]

CONCLUSION

Identification of the multiple mechanisms responsible for production of distinct pain syndromes and their molecular components as well as identification of clinical malignant bone pain syndrome has been a major contribution in further advancement in management of malignant bone pain. Mechanism-based therapies are under development that target specific components of bone cancer pain. However, there are still unanswered questions regarding currently available treatment modalities, such as: How should we integrate the use of each treatment modality with our understanding of the heterogeneity of malignancies and individual factors?, and How should we determine the cost-benefit consequences?

Key learning points

- Recent evidence from the basic sciences supports that malignant bone pain is a distinctive pain state compared with inflammatory or neuropathic pain.

- Diagnosis of malignant bone pain should include a thorough history and physical examination, particularly musculoskeletal and neurological examination, in conjunction with information from imaging tests.

- Bone pain accompanied by progressive neurological symptoms or signs of pathological fracture may need to be assessed and treated urgently.

- Opioid analgesics, possibly in conjunction with NSAIDs or corticosteroids, may be considered as first-line therapy for malignant bone pain management because of their rapid onset of action.

- Limited evidence supports the analgesic efficacy of currently available treatment modalities, such as bisphosphonates and external beam radiotherapy for malignant bone pain.

- Further research into new mechanism-based therapy in malignant bone pain and integration of currently available treatment modalities is warranted.

Episodic pain

SHIRLEY H BUSH

INTRODUCTION

The intensity of cancer pain commonly fluctuates over time and challenges usual cancer pain management using the World Health Organization (WHO) analgesic 'ladder'. It is an important clinical problem, often significantly impacting on a patient's quality of life, and can be difficult to assess and predict. A bewildering array of terminology and definitions has been used to describe this heterogeneous phenomenon but the lack of a standardized worldwide definition has led to difficulty in comparisons of reported prevalence and management.

Background to terminology and definitions

In 1989, the Edmonton staging system for cancer pain defined 'incidental pain' as 'pain aggravated suddenly as a result of movements, swallowing, defecation or urination'.[1] Portenoy and Hagen developed a working definition for 'breakthrough pain' in 1990, for a prospective survey of cancer pain patients.[2] Breakthrough pain was defined as 'a transitory increase in pain to greater than moderate intensity, which occurred on a baseline pain of moderate intensity or less'. Opioid use was not included in the working definition, but evaluated patients had been on relatively stable doses of opioids for two consecutive days. Breakthrough pain required controlled background pain for this definition.[3] It has been felt that breakthrough pain cannot be assessed in patients with uncontrolled pain.[4] Breakthrough pain has also been defined as pain that 'breaks through' the regular doses of an analgesic schedule.[5] This includes 'end-of-dose failure', where pain worsens before the next scheduled dose of opioid.

The term 'incident pain' is frequently used to describe pain induced by movement.[6] The definition is often broadened to define pain due to, or exacerbated by a specific inducing event (action) or activity.[7,8] McQuay and Jadad classified 'incident pain' into two subtypes. The first was pain on movement that included walking, turning, lifting, coughing, and deep breathing. The other subtype was intermittent pain not related to activity or movement.[9] 'Incident pain' has also been used to represent pain with a volitional precipitant, i.e. induced by the patient's voluntary actions, which should be predictable.[2,10]

Other terms that have been used include 'pain in motion'[11*] and 'transitory pain'.[12] In an international survey of 58 clinicians from 24 countries, where breakthrough pain was defined as an episode of 'pain flare', there was a large variation in the rates of breakthrough pain identification, suggesting that the concept of breakthrough pain varies geographically.[13]

'Episodic pain' is the term agreed on by an expert working group of the European Association for Palliative Care, in December 2000, as it translates better into different languages.[14] 'Episodic pain' is a transitory exacerbation of pain that changes with time. It can occur with controlled or uncontrolled baseline pain (Fig. 54.1). In the absence of significant baseline pain, it can be further differentiated into movement-related (incident) episodic pain, which is usually due to bone metastases, and nonmovement-related episodic pain. The working group also recognized pains which are volitional and not induced by a specific movement, e.g. swallowing in presence of mucositis or touch if hyperesthesia, and nonvolitional pains, e.g. sneezing, coughing, laughing or myoclonus. Spontaneous pains are independent of movement or volition, e.g. neuropathic pain.
Figure 54.1   *(a,b) Episodic pain (EP) crescendos. VRS, verbal rating scale.*

From these assorted definitions, episodic pain can be more usefully classified into three subtypes: activity and movement-related, spontaneous and end-of-dose failure.

ETIOLOGY OF EPISODIC PAIN

As with cancer pain etiology, episodic pain may be caused by the cancer or by the cancer treatment. Episodic pain may also be related to the cancer or debility, or be due to a concurrent disorder.

EPISODIC PAIN MECHANISMS

Episodic pain, like cancer pain, is categorized according to different anatomical and pathophysiological pain mechanisms.[15] The mechanistic categories are: nociceptive, comprising superficial somatic, deep somatic and visceral pains, and neuropathic pains. Episodic pain may have a different pathophysiology to the baseline pain.

PREVALENCE AND CHARACTERISTICS OF EPISODIC PAIN

The prevalence of episodic pain differs enormously depending on the definition and survey instrument used and the population sampled. Reported prevalence has been as low as 19 percent[16*] to around 90 percent.[17–19] Many studies report prevalence in the range of 40–70 percent.[2,3,12,20,21*] Internationally, prevalence has been found to vary according to region with a reported prevalence of 80.1 percent from English-speaking countries, 69.4 percent from North

and Western Europe, 54.8 percent from South America, and only 45.9 percent from Asia.[22]

Episodic pain commonly occurs a median 4–6 times/day, although the range can markedly vary, as in the reported case of a patient with a rib fracture and cough experiencing episodic pain every minute.[2] Box 54.1 gives the mean time for pain to peak and the mean duration, although the upper limit of the range can be as long as 2 or even 4 hours. Most cases of episodic pain are exacerbations of the baseline pain, but they can be a worsening of a different pain. A minority of patients experience more than one type of episodic pain.

Box 54.1   Features of typical episodic pain

- Mean time to peak – 3 minutes
- Mean duration – 15–30 minutes

The onset of episodic pain is often unpredictable, despite 20–40 percent being movement-related and 13–30 percent classified as end-of-dose failure.[3,18,21*] Neuropathic episodic pain is significantly briefer and more frequent than nociceptive episodic pain.[12,18]

REGARDING THE IMPACT OF EPISODIC PAIN

Patients with episodic pain tend to have higher pain scores and more intense baseline pain than patients without episodic pain. The presence of episodic pain significantly impacts on walking and causes functional interference on the Brief Pain Inventory, manifesting as increased levels of depression and anxiety.[3,21*,22] Episodic pain often interferes with sleep and impairs quality of life by restricting social

and general activities. Cancer patients with episodic pain are more likely to have endured increased medical costs, due to pain-related hospitalization and physician visits.[23]

Movement-related episodic pain, which is commonly due to metastatic bone disease, is relatively resistant to treatment with analgesics.[21*,24*] The presence of bone metastases had a significant impact for patients attending a multidisciplinary pain clinic in Denmark as only 6 percent of these patients became pain free 'in motion' after pain treatment.[11*] In a prospective multicenter assessment of the Edmonton clinical staging system, patients with 'incidental pain' were less likely to respond well to any analgesic treatment.[25]

MANAGEMENT OF EPISODIC PAIN

For the appropriate management of episodic pain, a multi-modality approach is needed while maintaining a holistic framework. Ongoing explanation with the patient and family is essential for professional care.

Assessment of episodic pain

A detailed assessment of the patient and the episodic pain(s) experienced should include episodic pain characteristics and mechanisms, in addition to those of the baseline pain, and a psychosocial evaluation. The Breakthrough Pain Questionnaire was designed to characterize breakthrough pain.[2] It should be noted that the assessment algorithm used in the 1999 survey had not been validated.[3]

Primary therapies to treat the underlying cause

Oncological interventions may be appropriate, depending on the patient's condition and anticipated prognosis. Radiotherapy is effective at reducing pain from painful bone metastases (see Chaper 91). Single and multiple fractionation schedules have been used with similar efficacy.[26***] For extensive bone metastatic disease causing pain, hemibody irradiation has been used. There is some evidence that radioisotopes, e.g. strontium-89, relieve pain over 1–6 months, but with a risk of leukopenia and thrombocytopenia.[27***] Bisphosphonates have been shown to be effective in reducing pain due to bone metastases (see Chapter 53).[28***]

There may be a role for chemotherapy or hormone therapy in responsive disease. Surgery may also be used palliatively after an assessment of benefits and attendant risks, e.g. stabilization of a pathological fracture, or prophylactically for a femur at risk of fracture. Percutaneous vertebroplasty has been shown to reduce pain and improve mobility in patients with fractured spinal metastases, who have failed radiation.[29*] Some cases of bowel obstruction may be remediable with surgery, thus eliminating episodic pain due to colic.

Optimizing the analgesic regimen

Implementation of the principles of the WHO 'ladder' should optimize the treatment of baseline pain. Episodic pain regularly improves as often baseline pain has been poorly controlled. However, it is important not to over-sedate the patient by increasing baseline opioid analgesia levels excessively in pursuit of around-the-clock control of episodic pain crescendos, as the pain signal will often diminish with rest or time (Fig. 54.2a). If opioid side effects are excessive, then opioid substitution or 'switching' should be considered (see Chapter 45). Another strategy to decrease sedation from opioids is the addition of methylphenidate.[16*] Increasing the opioid dose or reducing the interval between opioid doses can manage end-of-dose failure. For example, a few patients require 12-hourly modified release morphine to be given every 8 hours or transdermal fentanyl patches changed every 48 hours, rather than the usual 72 hours.

Depending on the pain mechanism, the use of non-opioid analgesic regimens may also improve baseline analgesia. Anti-inflammatory agents, such as nonsteroidal anti-inflammatory drugs (NSAIDs) and short-term use of steroids like dexamethasone, are indicated for pain due to bone metastases, mucosal or skin lesions. They also provide relief for pain originating from organ capsules, such as liver capsule inflammation, and from mesothelial membranes (pleura and peritoneum). Steroids also have an analgesic effect on neuropathic pain by reducing edema around peripheral nerves. The regular use of adjuvants for neuropathic pain, including tricyclic antidepressants, anticonvulsants and antiarrhythmics, should diminish episodic pain from this mechanism. Patients with either multiple bone metastases and severe movement-related episodic pain, mucositis or neuropathic pain have responded to ketamine, an N-methyl-D-aspartate (NMDA) receptor antagonist, given as a 'burst' subcutaneous infusion for 3–5 days.[30*]

Other drugs used for episodic pain include antispasmodics, e.g. hyoscine butylbromide for bowel spasm, oxybutynin for bladder spasm, and diazepam or baclofen for muscle spasm.

Using 'rescue' analgesia for episodic pain

A 'rescue' dose of analgesia should be administered when needed to 'top-up' baseline analgesia, either in anticipation of a predicted episodic pain or at the onset of an episodic pain. Frequently, a patient will have concluded that their prescribed oral 'rescue' dose is pointless, as their episodic pain will have resolved long before the onset of the extra pain relief. Often an opioid is used, but sometimes an NSAID is prescribed. Properties of an ideal 'rescue' analgesic include:

● quick absorption with rapid onset of analgesia and early peak effect

(a)

(b)
Figure 54.2   *Drug management of episodic pain (EP). (a) Increasing the baseline analgesia to meet the peaks of episodic pain, leading to oversedation. (b) Rescue doses of analgesia – schematic representation. OTFC, oral transmucosal fentanyl citrate; PCINA, patient-controlled intranasal analgesia.*

- a short duration of action, but long enough to treat the episodic pain event
- minimal side effects
- a good safety profile.

The drug should target the implicated pain mechanism. The ideal 'rescue' analgesic would be responsive to the peaks and troughs of episodic pain with a rapid on/off effect to counter a fluctuating pain trajectory over a short period of time, analogous to the current 'gold standard' of intravenous patient controlled analgesia (PCA). It should also be easy to self-administer, available for both inpatients and those in the community and should not be expensive. The choice of drug for the 'rescue' dose and the route used will also be influenced by the accessibility of opioids and their formulations in different countries.

Routes of administration of opioid 'rescue' analgesia for episodic pain

See Table 54.1 and Figure 54.2b.

ORAL ROUTE

For patients on an oral regularly scheduled morphine regimen for baseline pain, it has been recommended that the 'rescue' dose be equivalent to the 4-hourly dose of morphine, i.e. 16 percent of the 24-hour dose.[31] Other clinicians suggest 5–10 percent. More recent studies suggest that an individual's 'rescue' dose should be found by titration.[32*]

Table 54.1   *Comparing the efficacy of different routes of administration of opioids*

Route	Average time for onset of analgesia	Average duration of analgesic effect
Intravenous, e.g. morphine	5 minutes	1–2 hours
Oral transmucosal/ intranasal, e.g. fentanyl series	5–15 minutes	1–2 hours
Subcutaneous, e.g. morphine	10–15 minutes	3–4 hours
Oral, as immediate (normal) release, e.g. morphine	30 minutes	4 hours

The immediate (normal) release formulation of morphine has a mean T_{max} (time at which maximum concentration is reached) of 1 hour.[33***] Analgesia then lasts about 4 hours, indicating that the time taken for onset of analgesia and its duration are usually too prolonged for the majority of episodic pain events.

INTRAVENOUS ROUTE

Pain relief should begin within 5 minutes of intravenous (IV) administration, and last for 1–2 hours.[34] On using a fixed ratio of IV morphine, given by bolus injection, pain intensity of episodic pain has been reported to be reduced

by more than 50 percent within a mean of 16.6 minutes.[35*] Patients have had their uncontrolled bone pain successfully and safely managed at home by skilled and accessible staff, using a PCA pump and either the IV or subcutaneous route.[36*]

SUBCUTANEOUS ROUTE

Following a subcutaneous injection of opioid, analgesia begins within 10–15 minutes and lasts for 3–4 hours.[34] Mean time to pain relief with subcutaneous morphine for episodic pain is 17 minutes.[20]

ORAL AND NASAL TRANSMUCOSAL ROUTES

These routes have the advantage of bypassing the first-pass effect of the liver. The nasal and oral mucosae are highly vascular areas enabling rapid absorption and superior bioavailability for those drugs with suitable physicochemical properties.[37,38] Drugs meeting these requirements are lipophilic, with a high permeability coefficient, and potent. The properties of the fentanyl series of drugs make them the best of the available opioids for transmucosal administration. Sublingual administration of fentanyl citrate,[39] sufentanil[40] and alfentanil[41] have been reported. Volumes of fluid greater than 1–2 mL have been found to be problematic, due to reflex swallowing. Buprenorphine can be given sublingually, but sublingual absorption of morphine is poor due to low lipid solubility and over 90 percent ionization.[42]

There are a multitude of published studies on oral transmucosal fentanyl citrate (OTFC). OTFC is a compressed, sweetened lozenge with an artificial berry flavor, attached to a plastic applicator. It is available in six dose strengths but is relatively expensive. A unit should be consumed slowly over 15 minutes by rubbing it across the oral, particularly buccal, mucosa. The units must be kept out of the reach of children and correctly discarded. Randomized, double blinded trials have shown significantly better pain relief compared with placebo or immediate (normal) release morphine.[32*,43**] In an open label study of OTFC, the average time for onset of pain relief was 9.5 minutes.[44*] The T_{max} of a 15 μg/kg dose is 22 minutes with the effect lasting 1–2 hours. The overall bioavailability of OTFC is 50 percent, with 25 percent from rapid oromucosal absorption and 25 percent from slower gastrointestinal absorption, after swallowing the remaining dose.[45] It has been found that there is no fixed relationship between the total daily dose of scheduled opioid and dose of OTFC required for the episodic pain,[46*,32*] so individual dose titration of this formulation is mandatory. Common adverse effects are somnolence, nausea, and dizziness.

The fentanyl series of drugs have also been administered by intranasal spray.[40,47*,48*] The T_{max} for their intranasal single dose administration in healthy volunteers is 5–10 minutes, with bioavailabilities of 65–78 percent.[37] The maximum volume for one nostril in a single administration is 150–200 μL. The use of a patient-controlled intranasal analgesia (PCINA) device mimics the efficacy of IV PCA.[48*] Morphine has been administered intranasally using chitosan to enhance penetration.[49*] In a pediatric population with clinical fractures, a nasal diamorphine spray provided a quicker onset of pain relief compared with intramuscular morphine.[50**] Adverse effects of nasal administration are mainly related to the opioid used, as opposed to the route itself.

Other drugs used for episodic pain

Intermittent subcutaneous midazolam has been used for the temporary sedation of patients with pathological hip fractures and severe episodic pain.[51] Subanesthetic ketamine, in a subcutaneous bolus dose of 20–40 mg, is often used before predictable movement-related episodic pain, such as difficult dressing changes or repositioning of a patient with a fractured long bone. It may be combined with a bolus injection of midazolam.[52] The utilization of intranasal ketamine for episodic pain appears promising following evidence from a recent placebo controlled, crossover trial in 20 patients with chronic pain.[53**]

Nonpharmacological approaches

There are a variety of contributing pain-relieving factors, including rest, repositioning, movement, heat, massage, relaxation, or diversion.[12,19] Referral to physiotherapy and occupational therapy is beneficial for patients with movement-related episodic pain. Orthotic devices, bracing or aids may be necessary, in addition to lifestyle modification.

Interventional approaches

For patients with resistant episodic pain, anesthetic or neurosurgical intervention may be required. Techniques used include: peripheral nerve or neurolytic blocks, spinal (intrathecal or epidural) analgesia, and percutaneous or open cordotomy.

FUTURE DIRECTIONS

Uniform worldwide and precise definitions of episodic pain are needed for consistency in characterization and to enable direct comparisons of trial data and management. Validated instruments to measure pain intensity over short periods of time are warranted. Further studies should investigate the appropriate dosing and titration of 'rescue' analgesia. 'Flexible' drugs are needed as 'rescue' analgesics, being responsive to changes in the pain intensity/time profile.

Studies should examine and refine the most appropriate management of the different episodic pain mechanisms.

Key learning points

- Episodic pain challenges the WHO 'ladder' for pain management.

- Current terminology and definitions are confusing.

- Prevalence is in the range of 40–70 percent.

- It is typically characterized by both rapid onset and brief duration.

- The parenteral and transmucosal routes are the most efficacious for 'rescue' analgesia, for drugs with appropriate pharmacodynamic properties.

Somatization and pain expression

MARILU P BERRY, DIANE M NOVY

INTRODUCTION

In most clinical settings, the term somatization is loosely thought to be the presence of any physical complaints without a recognized organic basis. If a patient has a physical symptom or symptoms that have no apparent physiological cause, this may be viewed as the conversion of mental distress into physical symptoms. However, this clinical impression does not meet all of the strictly formulated inclusion criteria of a true somatization disorder.

DIFFERENTIAL DIAGNOSES OF SOMATIZATION

Somatization disorder is one of a group of disorders known as somatoform disorders. The Diagnostic and Statistic Manual of Mental Disorders (DSM)-IV[1] defines somatoform disorders as a group of specific disorders or problems characterized by persistent bodily symptoms or concerns that cannot be fully accounted for by a diagnosable disease. Hypochondriasis, for example, is the persistent, unfounded worry or conviction, despite adequate medical assurance to the contrary, that one has a serious medical illness. Body dysmorphic disorder involves preoccupation with an imagined or exaggerated physical defect. Conversion disorder is characterized by medically unexplained deficits or alterations of motor or sensory function. Somatization is a chronic condition consisting of multiple and specific categories of medically unexplained physical complaints that occur over a prolonged period of time. Pain disorder involves the persistence of medically unexplained pain symptoms. In each of these somatoform disorders, the physical symptoms are not under voluntary control and often coexist with anxiety or depression or both.[1,2*,3*] Somatoform disorders are widespread and largely unsolved problems that involve physical and psychological components.[4]

Somatoform disorders are distinguished from factitious disorder and malingering by the intentional production of symptoms in the latter two. Factitious disorder, as defined by the DSM-IV, is the *intentional* production or feigning of symptoms to assume the sick role. In malingering, the motivation for producing the symptoms is an external incentive such as economic gain or avoiding legal responsibility. This intentional 'faking' for secondary gain differs from somatization and its typically unconscious nature. Alternatively, some patients may consciously amplify their existing symptoms as a 'cry for help', and this not uncommon amplification of symptoms may accompany somatization and/or other psychiatric diagnoses.

In the medical literature, the term functional somatic syndrome refers to several syndromes in which the symptoms and subsequent suffering and disability are not fully explained by demonstrable tissue abnormality.[5] These syndromes include irritable bowel syndrome, fibromyalgia, chronic fatigue syndrome, multiple chemical sensitivity, chronic whiplash, and tension headache. These patients express symptoms such as gastrointestinal symptoms and fatigue in addition to pain. Individuals with functional somatic syndromes have higher rates of somatization, somatoform disorders, anxiety, and depression.[5]

PREVALENCE OF SOMATIZATION

In actuality, most patients in medical settings, including pain clinics and centers, do not meet the strict criteria of

somatization as defined by the DSM-IV. However, when the overarching group of somatoform disorders is loosely defined as a medically unexplained symptom or symptoms, prevalence rates are quite high. For example, the prevalence is as high as 80 percent in primary care settings.[6*] In a secondary care orthopedic clinic, more than 50 percent of patients seen with chronic low-back pain had multiple unexplained symptoms, and 34 percent had pain diagrams that were believed to be incompatible with an organic cause.[7*] Among patients with chronic noncancer pain, the prevalence of multiple medically unexplained symptoms ranges from 0 percent to 53 percent.[8] In a recent comparison study on patients with chronic noncancer pain and patients with cancer pain, prevalence rates for having at least one somatic symptom that was in excess or unrelated to disease or side effects of medication were as high as 80 percent in both groups.[9*,10*] Some of the commonly reported symptoms of those patients with noncancer and cancer pain that could not be fully explained by existing medical information and physical examination include pain in arms and legs, fatigue, backache, pain in multiple sites, tingling or numbness, weakness of body, pain in joints, and sleep problems.

Because these comparison studies[9*,10*] had the patients' physicians rate the degree to which they thought the patient-reported symptoms were medically unexplainable, a broader understanding of patients' somatic symptoms was possible. Physicians noted that many patient-reported somatic symptoms could not be clearly differentiated between medically explainable and unexplainable. Hence, these symptoms were considered indeterminate. The overall findings from these studies were of complex profiles of somatic symptoms that are mostly medically explainable or indeterminate and only partially medically unexplainable. Therefore, the authors concluded that it would be difficult to assign a specific somatoform disorder diagnosis to most of the patients in these studies. Further, the authors noted that even those somatic symptoms that were rated as highly unexplained medically could not automatically be considered to be of psychological origin.[11*] They also pointed out that patients in pain are likely to be sleep-deprived and depleted of energy, which influences their experience and reporting of symptoms.[12*,13]

DEFINING MEDICALLY UNEXPLAINED SYMPTOMS

The pain literature provides other competing explanations for medically unexplained symptoms. Explanations with inconsistent and weak support include: the 'pain-prone personality' perspective; the pain as a variant of an affective disorder perspective; and the functional relation between secondary gain and disability in patients with chronic pain.[8] A more tenable explanation is that unexplained or indeterminate somatic symptoms among patients with pain may

be related to a sensitizing effect to physiological events that heighten bodily awareness.[14] Several researchers have found that patients with chronic pain blur certain experiences, including affective distress, and interpret them in terms of pain.[15] Another viable explanation is that cultural factors and medical and social institutions that focus on physical symptoms rather than the accompanying psychological distress may also be responsible for heightening the perception of physical problems.[15] Finally, work by Geisser and colleagues[16*] supports Field's neurobiological model of pain in which the patient's tendency to focus on somatic symptoms activates pain facilitation neurons. These neurons, in turn, are believed to sharpen the perception of the stimulus. The current theory for the majority of patients with chronic pain is that unexplained somatic symptoms are related to both pain and negative mood states.[17]

Indeed, pain and negative mood states are considered part of the multidimensional nature of chronic pain syndromes. Other relevant dimensions are behavioral and cognitive. There is wide acceptance that individuals with chronic pain may exhibit symptoms including negative mood states (depression, anxiety, anger), behavioral changes (inactivity, pain behaviors), and maladaptive beliefs and thoughts about pain, in addition to the somatic pain complaints. This multifaceted expression of pain is supported by clinical evidence for a multiplicity of treatments for chronic pain.[18]

Several possible reasons have been offered to explain the connection between negative mood states and somatic complaints. One possibility is that negative mood may contribute directly to bodily dysfunction and symptoms or more indirectly by causing changes in habit patterns and behavior, thus increasing vulnerability. Another possibility is that negative mood state may be associated with bodily arousal that then may be appraised as symptoms of various kinds. Third, negative mood state may affect the interpretation of physical changes as symptoms.[19*]

RELATION BETWEEN SOMATIC SYMPTOMS AND MOOD

Empirical evidence supports the relationship between somatic symptoms, which definitely include pain, and negative mood states in patients with pain. For example, with chronic cancer pain, data reported by Berry and Novy and colleagues[9*,10*] show scores on anxiety, depression, and somatization, as rated on the Brief Symptom Inventory (BSI)-18, approximately one standard deviation above the norm for the BSI oncology normative sample.[20] Using these illness-specific norms, the anxiety, depression, and somatic symptoms of patients with cancer seem to be greater among those who have pain. The difference may be because the participants in the normative sample were not being treated for pain, *per se*, and pain is known to be associated with greater psychological dysfunction.[3*,12*] In Zimmerman's[21*]

study of cancer patients with and without pain, the data showed that somatization, hostility, anxiety, and depression were more problematic for patients with pain.

The relation between somatic symptoms and negative mood states has also been demonstrated in patients with chronic noncancer pain. In Berry and Novy and colleagues'[9*,10*] studies, the sample of patients with chronic noncancer pain had *t* score means approximately one standard deviation above the community norms for anxiety, depression, and somatization.[10*] This increase over community norms may be related to patients' experience of pain which is known to impact many different emotions, all of them negative.[22,23] Berry *et al.* and Novy *et al.* also found strong relations between their somatic symptom checklist and negative mood states among their sample of patients with cancer and noncancer pain.[9*,10*] Taken together, the conclusion of these studies is a rejection of a reductionist explanation (real body pain versus a psychological problem) of somatic and negative mood states, particularly for most of patients who have complex profiles of medical problems, pain, and negative mood states.

It appears that many somatic symptoms cannot be fully explained by the extent of organic pathology alone. The frequency of this occurrence and physician endorsement of the indeterminate basis of somatic symptoms in the Berry and Novy and colleagues' studies[9*,10*] should lessen the negative connotations that often are associated with somatoform symptoms and the possibility of any one of the somatoform disorder diagnoses.

SIGNIFICANCE OF SOMATIC SYMPTOMS

As the data presented here suggest, and as most healthcare professionals who work with patients with chronic non-cancer or cancer pain know, unexplained symptoms do not necessarily indicate a psychiatric or somatoform diagnosis. The presence of unexplainable somatic symptoms is common in this population. To the frustration of physicians and patients alike, diagnostic and radiographic studies do not always reveal the cause of all of the underlying problems. Once healthcare providers give patients a somatoform disorder or other psychiatric diagnosis, that label often serves to invalidate patients' physical symptoms and prevent them from having credibility in the future.

However, there still is the tendency of some physicians to question the credibility of patients' reports of somatic symptoms when medical evidence does not support their presence. At those times, some physicians may think that negative mood states or other psychological symptoms are the cause of the unexplained somatic symptoms. Regretfully, those physicians have little appreciation for the potential interaction among sensory/physical, affective, behavioral, and cognitive components of patients' problems. Another regrettable situation is created by failure to gather patients'

extensive medical and psychosocial histories and repeatedly pursuing organic causes of unexplained somatic symptoms by tests, procedures, medications, and operations. In such cases, the dollar cost of strictly organic work-ups and treatments are exceeded only by the potential for iatrogenic harm in patients with and without chronic pain.[24,25**]

Patients with a somatic focus typically have a history of repeated hospitalizations and surgeries, see many physicians for consultation and work-up, take many medications, and resist psychological explanations for their symptoms. Because of this overutilization of the healthcare system, one important aspect of management is to have a heightened threshold for instituting aggressive diagnostic and treatment procedures.[26] It is important to note that the physician must rule out treatable medical problems but balance this with caution to avoid repeating unnecessary tests and procedures that reinforce the focus on the symptoms, cause added expense, and may be damaging to the patient in other ways. Taking the suggestions of Barsky and Borus[5] and Purcell[27*] together, we present management guidelines in Box 55.1. When working with this type of patient, it is important to avoid statements such as 'It is all in your head' and 'The symptom does not exist' that could harm the working relationship and cause the patient to feel defensive.

Box 55.1 Management guidelines for somatization

- Rule out diagnosable medical disease

- Assess for psychiatric disorders

- Build a collaborative relationship with the patient

- Establish that improved function is the goal for treatment

- Provide limited reassurance

- Refer for cognitive behavioral therapy

- Provide a caring physician attitude

- Refer patient to a support system such as a support group

Detection rates for anxiety, depression, and other psychological distress and appropriateness of referral to support services tend to be different across noncancer and cancer pain groups. The literature reports evidence of low detection and referral for psychological problems in oncology settings.[28*,29*] Although patients with chronic nonmalignant pain often are referred for multidisciplinary assessment and treatment, those with cancer pain are not. The findings of Berry *et al.* and Novy *et al.* highlight the importance of routine screening for psychological distress in

cancer pain groups so that there will be improved detection and more appropriate referrals.[9*,29*]

SUMMARY

In summary, prevalence rates for a medically unexplained symptom or symptoms in pain populations range from 0 percent to 80 percent, and unexplainable somatic symptoms remain a frustrating phenomenon for many healthcare providers and patients alike. Research supports a connection between number of somatic symptoms experienced and negative mood states, although many patients with a complex presentation of somatic symptoms are mistakenly written off as having purely psychogenic pain. Improved assessment and management of these complex cases is needed so as not to err on the sides of over- or underutilization of healthcare services. Both medical and psychological screening and treatment are needed with this patient group, and various nonpharmacological techniques are suggested for the management of this type of patient. Further research is needed in somatoform disorders to better understand the mind–body connection.

Key learning points

- Somatization is loosely, and incorrectly, thought to be the mere presence of a medically unexplained symptom or symptoms.

- Prevalence rates for an unexplained symptom or symptoms in pain populations range from 0 percent to 80 percent.

- Research supports a connection between somatization and negative mood states.

- In both patients with cancer pain and with noncancer pain, somatization, anxiety, and depression were higher than in patients without pain.

- Unexplained symptoms do not necessarily indicate a psychiatric or somatoform diagnosis.

- Physicians should rule out diagnosable medical disease but with caution to avoid unnecessary testing and procedures.

- Management should include assessment for psychological problems and appropriate referral as needed for cognitive behavioral treatment.

Pain in patients with alcohol and drug dependence

STEVEN D PASSIK, KENNETH L KIRSH

INTRODUCTION

Substance abuse and addiction are difficult problems both theoretically and clinically in the arena of pain management and palliative care.[1***] Patients with histories of alcohol and substance dependence are seen often by palliative care specialists, as well as those with the less obvious aberrant drug-taking behaviors sometimes in evidence in the treatment of patients without formal psychiatric histories of substance use disorders. An example of this is when a patient with advanced disease and pain is unilaterally escalating drug doses, using medications to treat other symptoms or when prescriptions are being mishandled. The clinician therefore is challenged to understand such happenings and plan interventions accordingly. Once these aberrant behaviors are identified the clinician must decide on a course of action that is fair and in the best interests of the patient as well as his or her own career. Thus, the problem of alcoholism, chemical dependence and drug abuse spans a continuum from formal psychiatric disorders to problematic behaviors in the absence of these disorders.

PREVALENCE

Nearly one-third of the US population has used illicit drugs and an estimated 6–15 percent have a substance use disorder of some type.[2–4*] As a result of this high prevalence, and the association between drug abuse and life-threatening diseases, problems related to abuse and addiction are encountered commonly in palliative care settings.[5*] In diverse patient populations with progressive life-threatening diseases, a remote or current history of drug abuse presents a constellation of physical and psychosocial issues that carry a stigma that can both complicate the management of the underlying disease and undermine palliative therapies. Clearly, the interface between the therapeutic use of potentially abusable drugs and the abuse of these drugs is complex and must be understood to optimize palliative care.

Substance abuse appears to be less frequent among palliative care patients than the prevalence of substance use disorders in society at large, in general medical populations, and in emergency medical departments.[2–4*,6] This relatively low prevalence was also reported in the Psychiatric Collaborative Oncology Group study, which assessed psychiatric diagnoses in ambulatory cancer patients from several tertiary care hospitals.[7*] Following structured clinical interviews, less than 5 percent of 215 cancer patients met the Diagnostic and Statistical Manual for Mental Disorders (DSM)-III criteria for a substance use disorder.[8*] Thus, the problem reflects a minority of patients, but one that can only be adequately and successfully treated when their addiction problems are noted by staff and the patient's special needs can be addressed.[9,10*]

CURRENT DEFINITIONS OF ABUSE AND ADDICTION

The pharmacological phenomena of tolerance and physical dependence are commonly confused with abuse and

addiction. All the definitions applied to medical patients have been developed from addict populations without medical illness, as well as sociocultural considerations, which may lead to mixed messages in the clinical setting. The clarification of this terminology is an essential step in improving the diagnosis and management of substance abuse in the palliative care setting.

Tolerance, a pharmacological property defined by the need for increasing doses to maintain effects, has been a particular concern during opioid therapy.[11,12] Clinicians and patients both commonly express concerns that tolerance to analgesic effects may compromise the benefits of therapy and lead to the requirement for progressively higher, and ultimately unsustainable, doses. Additionally, the development of tolerance to the reinforcing effects of opioids, and the consequent need to increase doses to regain these effects, has been speculated to be an important element in the pathogenesis of addiction.[13]

Notwithstanding these concerns, extensive clinical experience with opioid drugs in the medical context has not confirmed that tolerance causes substantial problems.[14–16] Although tolerance to a variety of opioid effects can be reliably observed in animal models,[17**] and tolerance to nonanalgesic effects, such as respiratory depression and cognitive impairment,[9*] occurs routinely in the clinical setting, analgesic tolerance does not appear to routinely interfere with the clinical efficacy of opioid drugs. Most patients can attain stable doses associated with a favorable balance between analgesia and side effects for prolonged periods. Dose escalation, when it is required, usually heralds the appearance of a progressive painful lesion.[18–24*] Unlike tolerance to the side effects of the opioids, clinically meaningful analgesic tolerance appears to be a rare phenomenon, and is rarely the cause for dose escalation.

Physical dependence is defined solely by the occurrence of a withdrawal syndrome following abrupt dose reduction or administration of an antagonist.[11,12,25*] Neither the dose nor duration of administration required to produce clinically significant physical dependence in humans is known. Most practitioners assume that the potential for withdrawal exists after opioids have been administered repeatedly for only a few days.

There is great confusion among clinicians about the differences between physical dependence and addiction. Physical dependence, like tolerance, has been suggested to be a component of addiction, and the avoidance of withdrawal has been postulated to create behavioral contingencies that reinforce drug-seeking behavior.[13,26–28] These speculations, however, are not supported by experience acquired during opioid therapy for chronic pain. Physical dependence does not preclude the uncomplicated discontinuation of opioids during multidisciplinary pain management of nonmalignant pain, and opioid therapy is routinely stopped without difficulty in the cancer patients whose pain disappears following effective antineoplastic therapy.[29] Indirect evidence for a fundamental distinction between physical dependence

and addiction is even provided by animal models of opioid self-administration, which have demonstrated that persistent drug-taking behavior can be maintained in the absence of physical dependence.[30**]

CONCERNS OVER CURRENT DEFINITIONS

These definitions of tolerance and physical dependence highlight deficiencies in the nomenclature applied to substance abuse. The terms 'addiction' and 'addict' are particularly troublesome and are often inappropriately applied to describe both aberrant drug use and phenomena related to tolerance or physical dependence. Clinicians and patients may use the word 'addicted' to describe compulsive drug taking in one patient and nothing more than the possibility for withdrawal in another. It is not surprising, therefore, that patients, families and staff become very concerned about the outcome of opioid treatment when this term is applied, and which often leads to misperceptions of this mode of therapy for all involved.[31]

The accurate assessment of drug-related behaviors in patients with advanced medical disease usually requires detailed information about the role of the drug in the patient's life. The existence of mild mental clouding or the time spent out of bed may be less meaningful than other outcomes, such as noncompliance with primary therapy related to drug use, or behaviors that jeopardize relationships with physicians, other healthcare providers or family members.

AN ALTERNATIVE APPROACH FOR DEFINING ABUSE AND ADDICTION IN THE MEDICALLY ILL

Previous definitions that include phenomena related to physical dependence or tolerance cannot be the model terminology for medically ill populations who receive potentially abusable drugs for legitimate medical purposes. A more appropriate model definition of addiction notes that it is a chronic disorder characterized by 'the compulsive use of a substance resulting in physical, psychological or social harm to the user and continued use despite that harm'.[32] This definition appropriately emphasizes that addiction is, fundamentally, a psychological and behavioral syndrome. Any appropriate definition of addiction must include the concepts of loss of control over drug use, compulsive drug use, and continued use despite harm.

The spectrum of aberrant drug–taking behavior

If drug-taking behavior in a medical patient can be characterized as aberrant, a differential diagnosis for this behavior can be explored. A true addiction is only one of several

possible explanations. Of the behaviors likely to represent true addiction, some recent research suggests that multiple unsanctioned dose escalations and obtaining opioids from multiple prescribers may have some specific relevance.[33] If the problem is not addiction, the challenging diagnosis of pseudo-addiction must be considered if the patient is reporting distress associated with unrelieved symptoms. Behaviors such as aggressively complaining about the need for higher doses, or occasional unilateral drug escalations may be signs that the patient's pain is under-medicated. Also, impulsive drug and alcohol use may indicate the existence of another psychiatric disorder, which may have therapeutic implications. For example, patients with borderline personality disorder can express fear and rage through aberrant drug taking and behave impulsively and self destructively during pain therapy.[34] Similarly, patients who self-medicate psychiatric conditions such as anxiety, panic, depression or even periodic dysphoria and loneliness can present as aberrant drug takers. In such instances careful diagnosis and treatment of these additional problems can at times obviate the need for such self-medication.[35] Other rule-outs for addiction include mild encephalopathy and criminal intent through diversion or sale of medications.

In assessing the differential diagnosis for drug-related behavior, it is useful to consider the degree of aberrancy. The less aberrant behaviors (such as aggressively complaining about the need for medications) are more likely to reflect untreated distress of some type, rather than addiction-related concerns. Conversely, the more aberrant behaviors (such as injection of an oral formulation) are more likely to reflect true addiction. Although empirical studies are needed to validate this conceptualization, it may be a useful model when evaluating aberrant behaviors.

Empirical validation of the aberrant drug–taking concept

The spectrum of aberrant drug-taking has been used as a heuristic to guide the assessment of problematic drug-taking in several recent studies. The studies performed to date all involve small samples, though they have shown the utility of the spectrum concept as an assessment tool yielding important implications for clinicians.

The first study examined the relationship between aberrant drug-taking behaviors and compliance in patients with a history of substance abuse receiving chronic opioid therapy for nonmalignant pain. Dunbar and Katz examined outcomes and drug-taking in a sample of 20 patients with diverse histories of drug abuse during a year of chronic opioid therapy.[36] During the study, 11 patients were compliant with the drug regimen and 9 were not. The authors examined patient characteristics and aberrant drug-taking behaviors that differentiated the two groups. The patients who did not abuse the therapy were current abusers of alcohol only (or had remote histories of polysubstance abuse), were in a solid drug-free recovery as evidenced by participation in 12-step programs, and had good social support. The patients who abused the therapy were polysubstance abusers, were not participating in 12-step programs and had poor social support. The specific behaviors that were recorded more frequently by those who abused the therapy were unscheduled visits and multiple phone calls to the clinic, unsanctioned dose escalations and obtaining opioids from more than one source.

A second study examined the relationship between aberrant drug-taking and the presence or absence of a psychiatric diagnosis of substance use disorder in pain patients. Compton and colleagues studied 56 patients seeking pain treatment in a multidisciplinary pain program who were referred for 'problematic drug-taking.'[37*] The patients all underwent structured psychiatric interviews and the sample was divided between those qualifying and not qualifying for psychiatric diagnoses of substance use disorders. The authors then examined the subjects' reports of aberrant drug-taking behaviors on a structured interview assessment. Those with a substance use disorder were more likely to have engaged in unsanctioned dose escalations, received opioids from multiple sources and had lost of control of their prescribed medications.

Passik and researchers examined the self-reports of aberrant drug-taking attitudes and behaviors in samples of cancer (n = 52) and acquired immune deficiency syndrome (AIDS) (n = 111) patients with a questionnaire designed for the purposes of the study.[31*] Reports of past drug use and abuse were more frequent than present reports in both groups. Current aberrant drug-related behaviors were seldom reported. Attitude items, however, revealed that patients would consider engaging in aberrant behaviors, or would possibly excuse them in others, if pain or symptom management were inadequate. Overall, patients greatly overestimated the risk of addiction in pain treatment. Experience with this questionnaire suggests that patients with both cancer and AIDS respond in a forthcoming fashion to drug-taking behavior questions and describe attitudes and behaviors which may be highly relevant to the diagnosis and management of substance use disorders.

Such studies will help us to better understand the particular diagnostic meanings of the various behaviors so that clinicians may recognize which are the true 'red flags' in a given population. Far too often anecdotal accounts shape the way clinicians view these behaviors. Some behaviors are regarded almost universally as aberrant despite limited systematic data to suggest that this is the case. Consider for example the patient who requests a specific pain medication, or a specific route or dose. Such behavior often reflects a patient who is knowledgeable about what works for him or her but is almost always greeted with suspicion on the part of practitioners. Other behaviors may be found to be common in nonaddicts, and although they seem aberrant based upon their face value, they may have little predictive value for true addiction.

ADDICTION IN PATIENTS WITH DRUG ABUSE HISTORY VERSUS THOSE WITHOUT

It is interesting to explore the differences inherent in populations of patients with and without histories of drug abuse or addiction. The following discussion highlights the known differences while also highlighting the fact that we have a long way to go regarding true understanding of the effects of prior abuse and addiction on current treatments for oncology patients.

Abuse and addiction in patients without prior drug abuse

An extensive worldwide experience in the long-term management of cancer pain with opioid drugs has demonstrated that opioid administration in cancer patients with no prior history of substance abuse is only rarely associated with the development of significant abuse or addiction.[26,38–49*] Indeed, concerns about addiction in this population are now characterized by an interesting paradox: Although the lay public and inexperienced clinicians still fear the development of addiction when opioids are used to treat cancer pain, specialists in cancer pain and palliative care widely believe that the major problem related to addiction is not the phenomenon itself, but rather the persistent undertreatment of pain driven by inappropriate fear that it will occur.

The traditional view of long-term opioid therapy is negative and early surveys of addicts, which noted that a relatively large proportion began their addiction as medical patients administered opioid drugs for pain, provided some indirect support for this perspective.[50–52*] The most influential of these surveys recorded a history of medical opioid use for pain in 27 percent of white male addicts and 1.2 percent of black male addicts.[52*]

Surveys of addict populations, however, do not provide a valid measure of the addiction liability associated with chronic opioid therapy in populations without known abuse. Prospective patient surveys are needed to define this risk accurately. One project evaluated 11 882 inpatients who had no prior history of addiction and were administered an opioid while hospitalized; only four cases of addiction could be identified subsequently.[53*] A national survey of burn centers could find no cases of addiction in a sample of more than 10 000 patients without prior drug abuse history who were administered opioids for pain, and a survey of a large headache clinic identified opioid abuse in only three of 2369 patients admitted for treatment, most of whom had access to opioids.[54–55*]

Other data suggest that the typical patient with chronic pain is sufficiently different from the addict without painful disease that the risk of addiction during therapy for pain is likely to be low. For example, surveys of cancer patients and

postoperative patients indicate that euphoria, a phenomenon believed to be common during the abuse of opioids, is extremely uncommon following administration of an opioid for pain; dysphoria is observed more typically, especially in those who receive meperidine.[56*] Although the psychiatric comorbidity identified in addict populations could be an effect, rather than a cause, of the aberrant drug-taking, the association suggests the existence of psychological risk factors for addiction. The likelihood of genetically determined risk factors for addiction also has been suggested by a twin study that demonstrated a significant concordance rate for aberrant drug-related behaviors.[57*]

Favorable surveys of pain patients are not definitive, of course, and there are conflicting data collected by multidisciplinary pain management programs that suggest a high prevalence of abuse behaviors among the patients referred to this setting.[58–66*] The latter surveys, however, are subject to an important selection bias, and this bias, combined with other methodological concerns, limit the generalizability of these data to the large and heterogeneous populations with chronic nonmalignant pain.[67*]

The inaccurate perception that opioid therapy inherently yields a relatively high likelihood of addiction has encouraged assumptions that are not supportable in populations without a prior history of substance abuse. For example, agonist–antagonist opioid analgesics are less likely to be abused by addicts than pure μ agonist opioids, and, consequently, some clinicians view the agonist–antagonist drugs as safer in terms of addiction liability. There is no evidence for this conclusion in populations without drug abuse histories, and the extensive experience with long-term opioid therapy for cancer pain and chronic nonmalignant pain has relied on the pure μ agonists.[22–24*,68–70*] Similarly, there is a common perception that short-acting oral opioids and opioids delivered by the parenteral route carry a relatively greater risk of addiction because of the rapid delivery of the drug. Again, these perceptions derive from observations in the healthy addict population and are not relevant to the treatment of pain in medical patients with no prior history of substance abuse.

Risk of abuse and addiction in populations with current or remote drug abuse

There is very little information about the risk of abuse or addiction during, or after, the therapeutic administration of a potentially abusable drug to patients with a current or remote history of abuse or addiction. Anecdotal reports suggest that successful long-term opioid therapy in patients with cancer pain or chronic nonmalignant pain is possible, particularly if the history of abuse or addiction is remote.[36*,71*,72*] Indeed, one study showed that patients with AIDS-related pain were able to be successfully treated with morphine whether or not they were substance users or nonusers. In fact, the major difference found was that

substance users required considerably more morphine to reach stable pain control.[73*] However, a modicum of caution should be employed. For example, although there is no empirical evidence that the use of short-acting drugs or the parenteral route is more likely to lead to problematic drug-related behaviors than other therapeutic approaches, it may be prudent to avoid such therapies in patients with histories of substance abuse.

CLINICAL MANAGEMENT

Out-of-control aberrant drug-taking among palliative care patients (with or without a prior history of substance abuse) represents a serious and complex clinical occurrence. Perhaps the more difficult situations involve the patient who is actively abusing illicit or prescription drugs or alcohol concomitantly with medical therapies. The following guidelines can be useful whether the patient is an active drug abuser, has a history of substance abuse, or is not complying with the therapeutic regimen.

Multidisciplinary approach

A multidisciplinary team approach is recommended for the management of substance abuse in the palliative care setting. Mental health professionals with specialization in the addiction field can be instrumental helping palliative care team members develop strategies for management and patient treatment compliance, though often such professionals are not readily available. Providing care to these patients can lead to feelings of anger and frustration among staff. Such feelings can unintentionally compromise the level of patient care surrounding the patient's pain management and contribute to feelings of isolation and alienation by the patient. A structured multidisciplinary approach can be effective in helping the staff better understand the patient's needs and develop effective strategies for controlling pain and aberrant drug use simultaneously. Staff meetings can be helpful in establishing treatment goals, facilitating compliance, and coordinating the multidisciplinary team.

Assessment

The first member of the medical team to suspect problematic drug taking or a history of drug abuse should alert the patient's palliative care team, thus beginning the multidisciplinary assessment and management process.[74***] A physician should assess the potential of withdrawal or other pressing concerns and begin involving other staff (i.e. social work and/or psychiatry) to begin planning management strategies. Obtaining as detailed as possible a history of duration, frequency, and desired effect of drug use is crucial. Frequently, clinicians avoid asking patients about substance abuse out of fear that they will anger the patient or that they are incorrect in their suspicion of abuse. However, such approaches will likely contribute to continued problems with treatment compliance and frustration among staff. Empathic and truthful communication is always the best approach. The use of a careful, graduated interview approach can be instrumental in slowly introducing the assessment of drug use. This approach entails starting the assessment interview with broad questions about the role of drugs (e.g. nicotine, caffeine) in the patient's life and gradually becoming more specific in focus to include illicit drugs. Such an approach is helpful in reducing the denial and resistance that the patient may express. This interviewing style also assists in the detection of coexisting psychiatric disorders that may be present. Comorbid psychiatric disorders can significantly contribute to aberrant drug-taking behavior. Anxiety, personality disorders, and mood disorders are the most commonly encountered.[75–76] The assessment and treatment of comorbid psychiatric disorders can greatly enhance management strategies and reduce the risk of relapse. The patient's desired effects from illicit drugs can often be a clue to comorbid psychiatric disorders (i.e. drinking to quell panic symptoms).

Development of a multidisciplinary treatment plan

Drug abuse is often a chronic, progressive disorder. Therefore, the development of clear treatment goals is essential for the management of drug abuse. Team members should not expect a complete remission of the patient's substance use problems. The distress of coping with a life-threatening illness and the availability of prescription drugs for symptom control can make complete abstinence an unrealistic goal.[77] Rather, a harm reduction approach should be employed that aims to enhance social support, maximize treatment compliance, and contain harm done through episodic relapse. The following guidelines are recommended for the management of patients with a substance disorder.

1 The clinician should first establish a relationship based on empathic listening and accept the patient's report of distress.
2 It is important to utilize nonopioid and behavioral interventions when possible, but not as substitutes for appropriate pain management.
3 The team should consider tolerance, route of administration and duration of action when prescribing medications for pain and symptom management. Preexisting tolerance should be taken into account for patients who are actively abusing drugs or are being maintained on methadone maintenance programs. Failure to realize any existing tolerance can result in undermedication and contribute to the patient's attempts to self-medicate.
4 The team should consider using longer-acting drugs (e.g. fentanyl patch, and sustained-release opioids).

The longer duration and slow onset may help to reduce aberrant drug-taking behaviors when compared to the rapid onset and increased frequency of dosage associated with short-acting drugs. Finally, the team should make plans to frequently reassess the adequacy of pain and symptom control, as well as compliance via use of urine drug screens and any other forms of monitoring.[78*]

Patients in recovery

Pain management with patients in recovery presents a unique challenge. Depending on the structure of the recovery program (e.g. Alcoholics Anonymous, methadone maintenance programs), a patient may fear ostracism from the program's members or may have an increased fear regarding susceptibility to re-addiction. The first choice should be to explore nonopioid therapies with these patients, which may require referral to a pain center.[79] Alternative therapies may include the use of nonsteroidal anti-inflammatory drugs, anticonvulsants (for neuropathic components), bio-feedback, electrical stimulation, neuroblative techniques, acupuncture, or behavioral management. If the pain condition is so severe that opioids are required, care must be taken to structure their use with opioid management contracts, random urine toxicology screens, and occasional pill counts. If possible, attempts should be made to include the patient's recovery program sponsor to garner their cooperation and aid in successful monitoring of the condition.

The patient with advanced disease

Managing addiction problems in patients with advanced cancer is labor intensive and can be extremely time-consuming. This begs the question as to why a clinician should even bother to address such a complex health concern in the patient with advanced disease. In fact, many clinicians might opt to overlook a patient's use of illicit substances or alcohol entirely, viewing these behaviors as a last source of pleasure for the patient. However, addiction has a deleterious impact on palliative care efforts. Proper addiction management plays an important part in the success of palliative efforts to reduce suffering and increase quality of life. Complete abstinence may not be a realistic outcome, but reduction in use can certainly have positive effects for the patient.[80]

CONCLUSION

Although the most prudent actions on the part of clinicians cannot obviate the risk of all aberrant drug-related behavior, clinicians must recognize that virtually any drug that acts on the central nervous system can be abused. The effective management of patients with pain who engage in aberrant drug-related behavior necessitates a comprehensive approach that recognizes the biologic, chemical, social,

and psychiatric aspects of substance abuse and addiction, and provides practical means to manage risk, treat pain effectively and assure patient safety. An accepted nomenclature for abuse and addiction, and an operational approach to the assessment of patients with medical illness, are prerequisite to an accurate definition of risk in populations with and without histories of substance abuse.

Key learning points

- Substance abuse and addiction are difficult challenges in practice and theory when addressing pain management issues in palliative care patients.

- Traditional definitions for defining addiction (i.e. those focusing on tolerance and physical dependence) are subpar for application in the medically ill population. Rather, a focus on use despite harm is a better approach for identifying patients at risk.

- It is important to embrace an understanding of aberrant drug taking as a spectrum of behaviors that can be viewed as potentially problematic by prescribers.

- The use of opioid analgesics in patients without a history of addiction is very unlikely to create a problem unless the patient has genetic, social, and familial vulnerabilities, and a predisposition toward addiction. In essence, we do not 'create addicts' simply by prescribing opioids.

- Managing patients with known alcohol or other drug dependence creates a complex clinical management challenge that is best addressed through a multidisciplinary team approach.

Pathophysiology of cachexia/anorexia syndrome

EGIDIO DEL FABBRO, EDUARDO BRUERA

INTRODUCTION

The cachexia/anorexia syndrome is a common, debilitating condition characterized by involuntary weight loss, weakness, and poor appetite in up to 80 percent[1] of patients with advanced cancer. Cachexia is commonly found in patients with chronic illnesses such as acquired immune deficiency syndrome (AIDS), chronic obstructive pulmonary disease (COPD), congestive heart failure (CHF), renal failure, liver failure, rheumatological disorders, tuberculosis (TB), and malaria. The pathophysiology of cachexia and even the response to treatment modalities may be quite similar in these seemingly disparate illnesses. The syndrome is distressing for both patients and families.[2] It decreases the quality of life, compromises the sense of body integrity, self-confidence, and attractiveness,[3] and is a marker for poor prognosis.[4**] This chapter describes the interactions between the disease and host, which may lead to increased resting energy expenditure, the loss of both lean muscle mass and fat through lipolysis and proteolysis, and the neurohormonal dysregulation of compensatory mechanisms such as appetite.

Certain tumors, such as pancreatic (83 percent) and gastric (83 percent) cancers, are more likely to cause weight loss,[5**] whereas others, such as lung (57–61 percent), colon (54 percent), prostate (56 percent) and breast (36 percent) cancers, are less likely to cause weight loss. Hematological tumors other than unfavorable non-Hodgkin (36 percent) are unlikely to produce cachexia. Although there is limited evidence of an association between weight loss and the extent of the cancer, some studies have demonstrated an increased weight loss in those patients with more than one organ involved. The metabolic effects of tumor factors produced by the genetic expression of the individual cancer are more important than the extent of metastases or the size of the primary tumor.

PRIMARY VERSUS SECONDARY CACHEXIA

In patients with advanced cancer primary metabolic cachexia should be distinguished from secondary cachexia or starvation. Secondary cachexia occurs when there is impaired oral intake, impaired gastrointestinal absorption, or loss of nutrients. This may be due to taste abnormalities, dysphagia, delirium, dementia, mucositis, constipation, diarrhea, chronic nausea, clinical depression, or bowel obstruction. Patients with advanced cancer typically have early satiety due to decreased gastric motility, an enlarged liver or spleen, an intraabdominal mass, or severe constipation. The pathophysiology and treatment of primary and secondary cachexia are different, yet both may be present in a particular patient (Fig. 57.1). However, there is evidence of some shared mechanisms for primary cachexia and secondary cachexia. Cytokines not only play a significant role in primary cachexia, but they also appear to affect gastric motility[6] and small bowel absorption.[7]

DEFINITION

Cancer cachexia has been defined as 'a wasting syndrome involving muscle and fat directly caused by tumor factors, or indirectly caused by an aberrant host response to tumor presence'.[8] Cachexia is characterized by involuntary weight loss. As little as 5 percent weight loss over a 4–6-month period is associated with increased mortality in patients with human immunodeficiency virus (HIV) infection.[9,10**] Lung cancer patients with a pretreatment weight loss of >5 percent have a poorer prognosis[11**] and a greater risk for treatment toxicity.[12**] Measurement of body mass index (BMI) may not be useful as the prevalence of obesity has

increased and patients are now more likely to have a much higher pre-illness weight. Fluid retention (ascites, pleural effusions) may also mask significant weight loss. The severity of anorexia, which often accompanies cachexia, can be measured by a numerical scale (usually >3/10), however, there is no specific threshold or duration of loss of appetite to define anorexia.

Other parameters which are consistent with the diagnosis are increased resting energy expenditure as measured by indirect calorimetry, decreased lean muscle mass and fat as demonstrated by anthropometric testing and bioelectrical impedance. Commonly available laboratory tests such as albumin, and C-reactive protein (CRP) may provide correlation with weight loss and also prognosis.[13**]

MECHANISMS OF CACHEXIA (FIG. 57.2)

Nutrition and metabolic abnormalities

Patients with chronic illnesses such as rheumatoid arthritis, COPD, CHF, and advanced cancer often experience weight loss despite an intact gastrointestinal tract and 'sufficient' nutritional intake. These patients may still benefit from nutrition support if there is a significant starvation or secondary cachexia component. In contrast with starvation where the patient undergoes adaptation to reduce energy expenditure, conserve protein, and use fatty acids and ketones as an energy source, in primary cachexia there is

accelerated catabolism despite declining energy intake, as well as normal or increased resting energy expenditure, mobilization of protein and lipid stores and augmented gluconeogenesis (Table 57.1).

Primary cachexia is not simply a nutrition deficit caused by the combination of increased energy consumption by the tumor and decreased caloric intake due to the action of tumor-related factors on the satiety center. Past attempts at increasing nutrition intake with aggressive nutritional therapies failed to reverse the cachexia/anorexia syndrome and did not improve clinical outcomes such as survival or tumor response.[14***] Performance status or symptom control did not improve[15**] with dietary counseling, and invasive artificial nutrition had a negative impact on quality of life[16] and a higher rate of complications[17**] compared with oral intake. High caloric oral nutritional therapy was also unsuccessful in COPD[18*] patients with cachexia and relative anorexia. Despite the general poor response, the support of food intake should not be neglected as shown in one prospective randomized trial[19**] which added nutritional intervention to existing pharmacological treatment and found significant benefit in weight gain, function, and survival.

In contrast with starvation, where more than 75 percent of weight loss is from body fat, studies of cancer patients have found approximately equal losses of fat and body-cell mass, particularly skeletal muscle.[20,21*] With the introduction of retroviral therapy, patients with HIV rarely experience the catastrophic weight loss which was common in the past, however, the loss of lean body mass is still common.[22*] Investigation of changes in body composition on longitudinal follow-up of up to 5 years[23*] reveals that weight loss in cancer patients on anti-inflammatories appears to be predominantly from loss of body fat, primarily from the trunk and then leg tissue and arm tissue, respectively. Lean mass is predominantly lost from arm tissue. There may be a gender difference in cancer cachexia, with increased muscle loss in males.[24*] In patients with moderate-to-severe COPD[25] fat free mass is an independent predictor of mortality irrespective of fat mass.

Metabolic abnormalities include increased resting energy expenditure (with reduced physical activity level and total energy expenditure) and are more likely to be found in certain tumor types[26] and even in some tumors without evidence of[27] metastatic disease. Similar abnormalities are found in CHF, rheumatoid arthritis,[28] and kidney failure.[29] The increased resting energy expenditure may represent an increase in futile metabolic cycles such as the Cori cycle (which converts the large amount of lactate produced by the tumor back into glucose in the liver) or may be due to an increased expression and activity of mitochondrial uncoupling proteins,[30] which are involved in the control of energy metabolism and cause increased thermogenesis and blood flow of brown adipose tissue in cachectic states. Tumor necrosis factor (TNF) is able to increase gene expression[31] of uncoupling proteins and can also induce uncoupling in the mitochondria[32] of rats, however, muscle samples from cachectic pancreatic cancer patients demonstrated increased mRNA for ubiquitin but not uncoupling proteins.[33] Inhibition of fatty acid synthase (and therefore fatty acids) has been shown to decrease food intake in mice by decreased expression of neuropeptide Y, which is probably mediated by increased levels of malonyl coenzyme A (proposed to act as a signal of the availability of physiological fuels).[34] Progressive cachexia is also associated with other metabolic abnormalities including relative glucose intolerance, insulin resistance and gluconeogenesis.[35]

Tumor and host factors

CYTOKINES

Cytokines may be produced by the tumor or by the host and include TNF-α, interleukin (IL)-1, IL-6, and interferon-γ. Cytokines are also elevated in other conditions characterized by a chronic inflammatory response, such as TB, malaria,[36] rheumatoid arthritis, and COPD. Patients with CHF and cachexia have significantly elevated levels of cytokines (TNF-α, IL-6, soluble TNF-receptor-1) compared with noncachectic patients.[37**] Proinflammatory cytokines such as TNF-α, IL-6 and IL-1β promote weight loss, anorexia, and protein and fat breakdown. They increase the levels of cortisone and glucagon, and increase insulin resistance and decrease insulin levels. Furthermore, cytokines increase the resting energy expenditure in humans and animals and promote the acute phase response by the liver (characterized by the synthesis of acute phase proteins, such as CRP, fibrinogen, and α₁-antitrypsin).

TNF-α modulates the activity of glucose-sensitive neurons in the hypothalamus[38] and stimulates prostaglandin E_2 (PGE_2) synthesis, which induces the release of anorectic corticotropin releasing factor (CRF).[39] Administration of a TNF inhibitor to anorectic rats results in improved food intake and body weight.[40] In COPD patients hypoxemia appears to be associated with activation of TNF-α and may be a contributing factor to weight loss.[41] However, in humans with cancer cachexia, serum levels of TNF-α do not appear to

correlate directly with appetite and weight loss[42] and some animal experiments suggest that administration of cytokines may induce an acute phase response without causing weight loss. By itself, TNF may not be able to cause muscle wasting and would require the synergistic effect of a combination of cytokines.[43] In myotubes and mouse muscle, the combination of TNF-α and interferon-γ strongly reduces myosin expression through an RNA-dependent mechanism[44] via the transcription factor nuclear factor kappa B (NF-κB).[45] In addition, loss of myosin was found to be caused by a second mechanism, the activation of the ubiquitin-dependent proteasome pathway. Ultimately, the preferential loss of the myosin-heavy chain protein relative to actin, tropomyosin and troponin may alter the ratio between thick and thin filaments, possibly inducing atrophy to restore balance in the formation of a functional contractile lattice.[46]

Proteasomal degradation of intracellular skeletal muscle proteins via the ubiquitin–proteasome pathway involves enzymes which bind (E3) to the protein substrate, and conjugate (E1) and transfer (E2) ubiquitin. Activation of this pathway is important in the mediation of muscle atrophy in a number of disease models including renal failure,[47] diabetes, and heart failure. Experimentally, the genetic deletion[48] of muscle-specific E3 ligases protects against muscle[49] atrophy following denervation and disuse. The expression of ubiquitin ligase E3 alpha-II is increased by proinflammatory cytokines and accelerates ubiquitin conjugation to endogenous cellular proteins.[50] Ubiquitin–proteasome-dependent proteolysis is probably the predominant mechanism of muscle protein loss, but there is evidence that several other regulatory mechanisms may be important as well.[51]

The role of NF-κB in the activation of the transcription of genes is well established, and it also functions in promoting cell growth. It is activated by TNF, muscle disuse[52] and IL-1, and leads to the production of a host of related proteins including cytokines and acute phase response proteins as well as regulators of apoptosis. Activation of the NF-κB pathway of skeletal muscle in mice induces serious skeletal muscle atrophy[53] and is characterized by increased catabolism via the ubiquitin–proteasome pathway. Genetic inactivation of NF-κB has been shown to prevent atrophy whereas a pharmacological blocker sodium salicylate partially suppressed the atrophy. Although activation of NF-κB in skeletal muscle may be an appropriate response during periods of starvation, providing amino acids for energy, in pathological conditions, such as cancer, it may have catastrophic consequences. Activation of NF-κB has been demonstrated in the skeletal muscle of COPD patients with low body weight,[54] adding support for the role of NF-κB as a potential molecular mechanism leading to cachexia.

Another important proinflammatory cytokine, IL-6, does not consistently induce weight loss when administered alone to animals, but a review of trials using monoclonal antibody to IL-6 showed a decrease in CRP and cachexia.[55] High mobility group box 1 is a ubiquitous protein present in the nuclei and cytoplasm of nearly all cell types and causes anorexia and weight loss when administered to normal animals.[56] Other growth factors which have been demonstrated to produce cachexia in animal models include ciliary neurotrophic factor and leukemia inhibitory factor. Their importance in human cachexia is yet to be determined. Some cytokines, in contrast, may have an anabolic effect. Myosin heavy chain accretion in human skeletal myogenic cultures has been shown to be stimulated by IL-15,[57] and when administered to tumor-bearing rats, IL-15 partly inhibits skeletal muscle wasting.[58]

PROTEOLYSIS–INDUCING FACTOR

Proteolysis-inducing factor (PIF) is a sulfated glycoprotein, tumor-derived product whose biological effect is mediated by its sulfated oligosaccharide chains.[30] It is detectable in the urine of 80 percent of patients with pancreatic cancer, and these patients have a significantly greater rate of weight loss than those in whom PIF is undetectable.[59] A longitudinal study also demonstrated that over time patients who were positive for PIF experienced weight loss whereas those with a negative test gained weight.[60] A correlation has also been reported between PIF expression in gastrointestinal tumors, its detection in urine, and weight loss.[61] Human melanoma cells produce PIF and induce cachexia and depletion of lean muscle mass in nude mice.[62] Mouse skeletal muscle and in vitro murine myotubes show an increased activity and expression of the ubiquitin–proteasome proteolytic pathway when treated with PIF.[63] Proteasome inhibitors attenuated the enhanced degradation of myofibrillar proteins. The expression of the ubiquitin–proteasome pathway in skeletal muscle and PIF-induced proteolysis appears to be mediated via NF-κB,[64] therefore agents capable of inhibiting NF-κB activation may be able to prevent muscle degradation; PIF activates NFκB, resulting in increased IL-6 and IL-8 production and to a lesser degree CRP, as well as inducing the signal transducers and activators of transcription pathway (STAT3),[65] which are involved in the induction of acute phase protein response. Recently, tumor xenografts engineered to overexpress human PIF did not induce cachexia in mice.[66] The reason for this unexpected result is not clear.

Lipolytic factors

Cancer patients with weight loss show urinary excretion of a lipid-mobilizing factor (LMF),[67] which is characterized by its ability to stimulate lipolysis in isolated murine epididymal adipocytes. This bioactivity was not detected in the urine of patients without weight loss. When LMF or Zn-α_2-glycoprotein (ZAG) is administered to mice or to human adipocytes, lipid is mobilized and glycerol and 3-hydroxybutyrate is increased.[68] When LMF is administered to murine myoblasts there appears to be an increase in protein synthesis and a decrease in protein catabolism.[69] More recent work has demonstrated that ZAG/LMF is produced locally by adipocytes and is upregulated in cachexia.[70] ZAG

also induces uncoupling protein expression in skeletal muscle and adipose tissue.[71] Eicosapentaenoic acid (EPA) attenuates body weight loss in mice and downregulates ZAG expression in adipose tissue, whereas dexamethasone-stimulated lipolysis is attenuated by anti-ZAG antibody; EPA may preserve adipose tissue in cachectic mice by downregulation of ZAG expression through interference with glucocorticoid signaling.[72] Natriuretic peptides, known to play a key role in blood pressure and volume homeostasis, have been found to promote lipolysis in human fat cells[73] and lipid mobilization, and therefore may have a potential role in cardiac cachexia.

NEUROHORMONAL MECHANISMS

Neurohormonal mechanisms are an important compensatory means by which caloric intake is increased in response to hormonal signals of energy balance. Before examining the abnormalities documented in the cachectic/anorexic state, a summary of the normal physiology may be helpful to understand the process.

PHYSIOLOGY

Evidence suggests that reciprocal circadian rhythms in two peripheral hormones, anorexigenic leptin from adipocytes and orexigenic ghrelin from the stomach, are major afferent signals for the activation of the appetite regulating network in the hypothalamus.[74] Another hormone, cholecystokinin, released from the proximal small intestine, signals postprandial satiety and has been shown to inhibit the orexigenic effect of peripheral ghrelin[75] while mobilizing gastric leptin and increasing plasma leptin levels.[76] However, the recent discovery that the precursor preproghrelin produces obestatin in addition to ghrelin in rats is further demonstration of the complexity of the 'gut–brain' axis. Obestatin[77] appears to decrease food intake, weight gain, gastric emptying, and jejunal motility. The hypothalamic melanocortin system is also an important regulator of caloric intake via proopiomelanocortin neurons that produce and release α-melanocyte-stimulating hormone (MSH) which binds to melanocortin receptors (MC3-R and MC4-R) resulting in decreased food intake. Leptin may increase the potency of the anorexigenic effects of α-MSH by enzymatic N-acetylation.[78] In mice, leptin has been shown to play an inhibiting role in an alternative orexigenic pathway involving the endocannabinoid receptor CB-1 and the endogenous agonists anandamide and 2-arachidonyl-glycerol.[79]

Agouti-related peptide (AgRP) is an endogenous antagonist which binds to MC3-R and MC4-R thereby inhibiting the effect of anorexigenic melanocortin peptides. The expression of AgRP is stimulated by fasting and inhibited by leptin and cytokines. Other hormones which increase feeding include melanin concentrating hormone (MCH), opioid peptides, orexin, and galanin. Those peptides that decrease food intake include corticotropin releasing factor (CRF), urocortin, bombesin, glucagons and cocaine and amphetamine-regulated transcript. When there is reduced

energy intake there is an increase in the number and amplitude of episodic ghrelin discharges. Leptin is secreted in a pulsatile manner similar to ghrelin, but in contrast decreased caloric intake diminishes the amplitude of the pulse.[80] Gastric ghrelin crossing the blood–brain barrier and locally produced hypothalamic ghrelin causes a release of orexigenic neuropeptide Y, AgRP, and increased appetite.[81] Another hormone which may play a role is peptide YY (PYY), which is secreted in the ileum and crosses the blood–brain barrier to reduce food intake by binding to the inhibitory neuropeptide Y2 receptor (NPY Y2) in the hypothalamus.[82,83]

Metabolism of sugars and fats has an established role in regulating feeding. The infusion of glucose[84] or ketones[85] inhibits feeding via vagal afferent signaling, and the inhibition of glucose or fatty acid oxidation stimulates caloric intake.

PATHOPHYSIOLOGY (FIG. 57.3)

Patients with cachexia and lung cancer have elevated plasma levels of ghrelin.[86] Compared with cancer patients without cachexia, those who have cancer-induced cachexia have significantly higher active ghrelin levels and the active to total ghrelin ratio is also increased. Because appetite is not increased in patients with cachexia despite high ghrelin levels, cachexia may be a state of ghrelin resistance.[87] In a long-term follow-up of cancer patients, survival and body fat were predicted by insulin, ghrelin, and leptin levels.[88] In patients with CHF, the plasma levels of ghrelin are significantly higher in cachectic than in noncachectic patients, possibly as a compensatory mechanism for the catabolic state.[89] Ghrelin appears to counteract the elevated sympathetic activity and high norepinephrine levels in COPD patients with cachexia[90] and probably has a similar role in CHF.

In uremia-associated cachexia and in children with renal failure leptin levels are elevated. Uremia-associated cachexia is attenuated mice deficient in leptin receptor and in MC-4R-deficient mice or those who had the antagonist AgRP administered.[91] This suggests a major role for the leptin–melanocortin pathway in this form of cachexia. In patients with COPD, leptin and ghrelin levels are lower[92] than in healthy controls but leptin appears to increase significantly in patients experiencing acute exacerbations.[93] In experimental models leptin does not appear to play a significant role in cancer cachexia, and in humans with cancer the leptin levels are low and inversely proportional to cytokines such as IL-6. In patients with TB and HIV plasma leptin concentrations are not associated with loss of appetite or wasting.[94] In HIV-negative TB patients there was no significant difference in leptin (corrected for energy balance) and muscle mass at baseline and after 1 month and 6 months of treatment.[95]

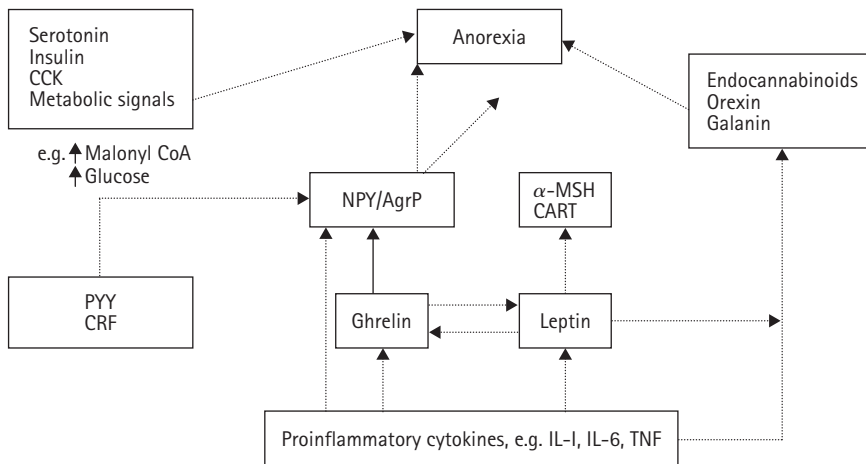
Despite the decreased fat stores in cancer patients, the levels of leptin may be inappropriately low, possibly due to inhibition by chronically high growth hormone levels and low insulin levels.[96] Some studies have found no significant


Figure 57.3 *Mechanisms of anoexia (via blood and neural signalling). .... inhibition; _____ stimulation, PVY, peptide YY, AgRP, Agouti–related protein (hypothalamus); CCK, cholecystokinin; TNF, tumor necrosis factor; CART, cocaine and amphetamine regulated transcript; NPY, neuropeptide Y (hypothalamus); MSH, melanocyte-stimulating hormone; IL, interleukin.*

difference in terms of insulin resistance in patients with cachectic or noncachectic cancer,[97] but increased peripheral resistance to insulin mediated by TNF-α[98] has been implicated in the development of cachexia in CHF and rheumatoid arthritis. When human oral squamous cell carcinoma cells are inoculated into mice, they produce weight loss but no compensatory hyperphagia. Corticotropin-releasing hormone mRNA is increased[99] in these mice and this is thought to inhibit NPY-induced feeding. Peptide YY levels have been found to be similar in patients with cachexia and those without, suggesting that it is unlikely to play an important role in cancer-induced cachexia.[87] The hormone orexin reverses cholecystokinin-induced loss of appetite in mice,[100] but its role in humans is unclear.

Proinflammatory cytokines are known to have anorexic effects and may interact with the neurohormonal system to cause decreased caloric intake. Proinflammatory cytokines (IL-1, IL-6, TNF-α) are believed to activate the melanocortin system by an unknown mechanism that leads to anorexia.[101] The mechanism of action of IL-1 may include the stimulation of leptin receptors, which decrease NPY[102] production and increase MSH, thereby reducing appetite. Interleukin-1 also increases hypothalamic levels of CRH[103] and serotonin.[104] Serotonin is found to be elevated in cachectic rats compared with controls.[105] In addition, IL-1 increases cholecystokinin levels and delays gastric emptying. However, in an experiment, an IL-1 receptor antagonist was not able to reverse the cachexia syndrome in animals.[106]

It seems likely that the failure of compensatory mechanisms to increase appetite is due to elevated levels of cytokines and disease products, which either decrease sensitivity to orexigenic hormones or inhibit hunger by direct stimulation of or increased sensitivity to anorexigenic peptides.

Anabolic hormone abnormalities

Cachexia has been associated with low testosterone levels in patients with pancreatic[107] cancer and in patients with lung cancer.[108] Long-term treatment with opioids may be another important factor which produces hypogonadism[109] in patients with cancer. Up to one third of COPD patients have hypogonadism (which may be aggravated by corticosteroids[110]), however this is not necessarily associated with weight loss or muscle weakness when compared to eugonadal COPD patients.[111] When compared to normal controls, hypogonadic nonsteroid-using COPD patients with normal arterial oxygen have decreased quadriceps muscle strength.[112] Also, patients with COPD and reduced mid thigh muscle cross-sectional area have significantly lower levels of dihydroepiandrosterone sulfate (DHEAS) when compared to healthy subjects.[113] Decreased testosterone is present in up to 50 percent of HIV patients and is highly correlated with loss of lean muscle mass, increased GH levels and decreased Insulin-like growth factor (IGF-I).[114] This suggests that a combination of GH resistance and androgen deficiency may play a role in the weight loss. Hypoandrogenemia is also found in HIV-infected women[115] and is associated with advanced disease state and weight loss. IGF-I induces hypertrophy of human myotubes in vitro and an increase in myosin heavy chain content,[116] and it is decreased in cachectic colorectal patients probably as a result of GH resistance.[117] There is also evidence that angiotensin II downregulates IGF-I in skeletal muscle, leading to proteolysis and wasting.[118] In CHF, local IGF-I expression is reduced in the presence of normal serum levels of IGF-I (this correlates with decreased muscle fiber cross-sectional area and inversely with local expression of IL-1beta.).[119]

Autonomic nervous system

Clinical manifestations of autonomic dysfunction are well described in patients with advanced cancer,[120*] rheumatoid arthritis, HIV disease, CHF, and COPD.[121] Whether the gastrointestinal (chronic nausea, early satiety, anorexia, pseudo-bowel obstruction) and cardiovascular (postural hypotension, fixed heart rate) manifestations represent the same underlying mechanism is unknown. In the patient with advanced cancer and autonomic neuropathy, vagal

nerve dysfunction may not only result in gastroparesis but may also lead to dysregulation of neurohormonal feeding signals and immune homeostasis, thereby contributing to the anorexia/cachexia syndrome.

Humoral and neural signals for satiety and hunger can be conveyed via the vagus nerve and may be the major pathway conveying ghrelin's starvation signals to the brain.[122] Ghrelin appears to suppress vagal afferent discharges when administered intravenously[123] to rats, whereas cholecystokinin and another anorectic peptide, PYY,[124] increase discharges and transmit a satiety signal to the nucleus tractus solitarius. Conversely, the electrical activity of efferent fibers of the vagus nerve is stimulated by ghrelin resulting in increased gastric acid secretion and motility. Ghrelin contributes to an anabolic state by stimulating growth hormone release via vagal afferents[125] (the growth hormone-releasing effect of ghrelin appears to be more potent than that of the growth hormone-releasing hormone[126]) and it also decreases fat utilization through growth hormone-independent mechanisms.[127] Decreased sensitivity to ghrelin and dysfunctional signaling by other peptides may cause abnormal regulation of satiety/hunger by the vagus. Abnormalities of the autonomic nervous system may be linked to a loss of circadian variation of leptin levels[83] in cachectic COPD patients, which in turn may lead to alteration of the afferent signaling to the hypothalamus.

In humans, stimulation of the vagus nerve may be associated with marked peripheral increases in pro and anti-inflammatory cytokines.[128] Efferent signals in the vagus nerve in response to peripheral inflammation provide a direct mechanism for neural regulation of the immune response that is reflexive and rapid. Proinflammatory cytokines are decreased,[129] as is NF-κB[130] via the release of acetylcholine in the vicinity of macrophages.[131] In rats with cancer anorexia, vagotomy markedly attenuates tumor-induced declines in food intake, suggesting that afferent neural signals also play an important role.[132]

Autonomic remodeling of the host by HIV has been proposed as a contributor to the immunodeficiency and cachexia in these patients.[133] Patients with cardiac cachexia exhibit severely impaired autonomic reflex control compared with noncachectic patients[134] and have higher norepinephrine and epinephrine levels. Experiments in rats indicate that angiotensin II stimulates lipolysis in subcutaneous and visceral adipocytes by sympathetic activation and β-adrenergic receptor stimulation. The nonselective blockade of β-adrenergic and angiotensin II receptors markedly attenuated the rise of norepinephrine.[135]

CONCLUSION

The cachexia/anorexia syndrome is a cascade of events that is initiated by the interaction between host and disease, and is caused by multiple interrelated mechanisms, which include the secretion of tumor products and cytokines, neuroendocrine abnormalities, autonomic failure, diminished calorie intake, muscle proteolysis, lipolysis, and the inability to accrue lean muscle mass or fat. This complex syndrome is not likely to be managed by a single treatment modality, but rather by the simultaneous institution of several nonpharmacological and pharmacological therapies.

Key learning points

- Inflammation, sympathetic activation, and hormonal abnormalities are mechanisms of cachexia that are common to a variety of diseases.

- Primary cachexia is characterized by increased proteolysis and increased acute phase protein production.

- Secondary cachexia or starvation is characterized by insufficient calories and utilization of fat as an energy source in order to conserve protein.

- Cytokines are important mediators of proteolysis, lipolysis, neurohormonal activation and anorexia.

- Dysregulation of hypothalamic hormones (e.g. neuropeptide Y, the melanocortin system) and peripherally secreted hormones (e.g. ghrelin, leptin, cholecystokinin, insulin) contribute to loss of appetite.

- Degradation of protein via the ubiquitin–proteasome pathway and decreased expression of myosin result in the loss of lean muscle.

- Successful management of cachexia/anorexia will require treatments targeted at multiple pathways.

Overview of the management of the anorexia/weight loss syndrome

CARA BONDLY, AMINAH JATOI

OVERVIEW AND DEFINITIONS

The anorexia/weight loss syndrome occurs in patients with a variety of illnesses, including cancer, acquired immune deficiency syndrome (AIDS), and congestive heart failure. The cancer anorexia/weight loss syndrome is particularly devastating and is characterized by loss of appetite and weight, and functional decline, which occurs as a result of tissue wasting, in particular, muscle wasting. This syndrome affects approximately two-thirds of patients who die from advanced cancer.[1]

Weight loss of 10 percent is a well-accepted diagnostic criterion for severe malnutrition. However, among patients with cancer, previous studies have clearly shown that the anorexia/weight loss syndrome can be invoked if an involuntary weight loss of even 6 percent has occurred. This degree of weight loss has been observed in conjunction with incurable cancer, progressive debility, and a decline in performance status.[2]

From a clinical standpoint, the assessment of nutritional status is often viewed as multifaceted, if not cumbersome. A variety of approaches are utilized, and these span anything from a quick hands-off assessment shortly after entering a patient's room to a detailed modeling of nutritional parameters into a single risk assessment to an elaborate assessment of body composition that includes measurement of total body potassium, ingestion and sampling of tritiated water, and dual X-ray absorptiometry. All these approaches have their merits. However, we believe that the most clinically useful, practical, and validated measurement is patient-reported weight loss. As discussed above, weight loss of 6 percent or greater over the preceding 6 months predicts a poor prognosis among cancer patients, and everyone will agree that it is relatively simple to acquire.

The anorexia/weight loss syndrome is distressing to patients and their families; in their eyes, the patient is 'starving'. Walsh et al. interviewed 1000 patients with advanced cancer referred to a palliative care program. Anorexia was tied for third, superseded only by pain and fatigue, as the most prevalent and bothersome symptom experienced by these patients.[3] Some of the distress associated with this symptom may be derived specifically from loss of appetite, but, at the same time, this decline in oral intake brings with it tremendous turmoil for the patient and family. This fear of 'starvation', as noted above, provides an extra emotional burden in the setting of an incurable, refractory malignancy.

Although these patients are not starving (Table 58.1), the anorexia/weight loss syndrome does portend an unfavorable prognosis in patients with cancer as well as in patients with human immunodeficiency virus (HIV) infection and congestive heart failure. In the cancer setting, Dewys et al. formally analyzed the impact of weight loss on prognosis. They retrospectively evaluated 3047 patients from 12 different Eastern Cooperative Oncology Group clinical trials.

Table 58.1 *Cancer anorexia/weight loss versus starvation*

Cancer anorexia/weight loss	Starvation
Loss of fat and lean tissue	Loss of fat
No hunger	Hunger
Resting energy expenditure sometimes increased	Drop in resting energy expenditure
Specific mediators have been implicated	Specific mediators not as well implicated

Patient-reported weight loss of more than 5 percent over the preceding 6 months predicted early mortality independently of tumor stage, histology, and patient performance status. This weight loss was also associated with a trend toward lower chemotherapy response rates.[4] Similarly, Anker *et al.* demonstrated a much worse prognosis among congestive heart failure patients who had lost weight compared with those who had maintained their weight. Both groups of patients had similar degrees of left ventricular dysfunction.[5] Finally, in HIV-infected patients, weight loss has been associated with increased mortality,[6–12] accelerated disease progression,[12] and impairment of strength and functional status.[13] Thus, in several disease states, involuntary weight loss clearly predicts a shortened survival (Fig. 58.1).

There are multiple readily observable clinical factors that contribute to involuntary weight loss in patients with chronic diseases such as cancer, HIV, or congestive heart failure. In cancer patients, the systemic and local effects of the tumor and side effects from anticancer treatments all contribute, whereas fatigue, anxiety, depression, and pain appear also to contribute to the weight loss. These patients face many challenges in maintaining adequate caloric intake, including difficulty swallowing due to obstructing tumors or nerve compromise, mucositis, dry mouth, odor sensitivity, taste changes, diarrhea, constipation, and nausea and vomiting. Changes in the capacity to recognize and taste sweetness in foods occur in over a third of cancer patients. Bitterness, sourness, and saltiness are less frequently affected.[14,15] Multiple theories have been proposed regarding this change in taste, including zinc deficiency, alterations in brain neuropeptides, and opioid peptides.[16–18] Alterations have also been described in the gastrointestinal tract of weight-losing patients, and these almost certainly play a role in the weight loss of these patients. Early satiety is seen in weight-losing cancer patients even without direct tumor involvement of the gastrointestinal tract. Proinflammatory cytokines such

as interleukin (IL)-1β and central corticotropin-releasing factor have been implicated in early satiety.[19,20] Central corticotropin-releasing factor may also induce delayed gastric emptying and gastric stasis, ultimately resulting in early satiety.[18,21,22]

PATHOPHYSIOLOGY

The anorexia/weight loss syndrome is a complex metabolic derangement that includes anorexia, early satiety, weakness, and anemia, as well as weight loss. Patients experience inadequate energy intake, possibly increased resting energy expenditure, and abnormalities induced by proinflammatory cytokines.[23] Bruera *et al.* demonstrated that weight-losing cancer patients consumed 3200 kJ (800 calories) per day less than patients without weight loss.[24] This observation is important because it shows that weight loss occurs not only as a result of inappropriately spent energy sources but also as a result of diminished energy intake. At the same time, however, multiple studies have shown that provision of increased energy through increased oral nutritional support does not result in weight gain.[25,26] In the anorexia/weight loss syndrome, unlike starvation, loss of skeletal muscle in relation to adipose tissue is accelerated. In contrast, starvation results in preferential consumption of fat rather than glucose as the primary fuel, perhaps in an effort to spare lean body mass.[27]

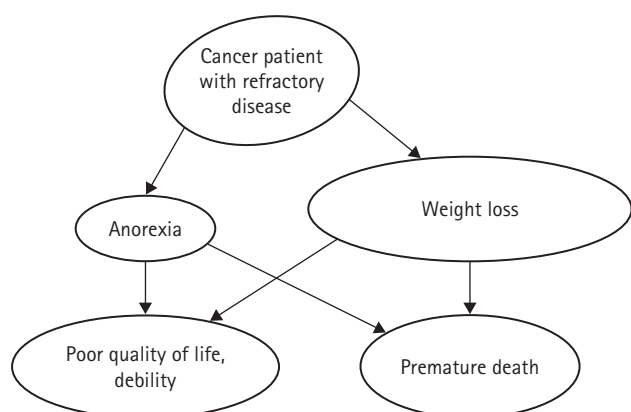
The exact pathophysiology of the cancer anorexia/weight loss syndrome has not yet been clearly defined, but the development of this syndrome is associated with multiple hormonal and metabolic alterations. Leptin is a hormone secreted by adipose tissue in response to changes in weight. Levels of circulating leptin decline as weight loss occurs and, through complex feedback mechanisms, stimulates food intake in healthy people.[2] In weight-losing cancer patients, however, the leptin system appears to be dysregulated; studies are inconsistent on whether weight loss is truly associated with a drop in serum leptin.[28] In addition to leptin, several cytokines have also been implicated as mediators of weight loss and anorexia. These include tumor necrosis factor α (TNFα), IL-1, IL-6, and interferon γ (IFNγ). High levels of serum TNFα, IL-1β, and IL-6 have been found in some patients with cancer. When elevated levels of these cytokines are present they seem to correlate with the progression of the tumor.[29–31] However, a recent North Central Cancer Group study has questioned the role of serum cytokines and hypothesized instead that cytokines in the peripheral blood mononuclear cells may be more reflective of what occurs at the tissue level.[32] Several studies have also shown that administration of these cytokines to healthy patients reduces food intake and reproduces the features of anorexia/weight loss syndrome.[17,27–33] Hypermetabolism, which is defined as an elevation in the resting energy expenditure, is sometimes a feature of this syndrome. Some studies suggest that this


Figure 58.1 *The anorexia/weight loss syndrome is associated with diminished survival and quality of life.*

occasional phenomenon may be caused by induction of the mitochondrial uncoupling protein in muscle and adipose tissue. The induction of this protein may be due to cytokine activation. Ultimately, these mechanisms lead to increased heat production and muscle wasting.[17,34]

A variety of changes in nutrient metabolism have also been described in weight-losing patients (Box 58.1). Glucose metabolism is altered in weight-losing cancer patients. Lactate is produced in excess quantities by many solid tumors and is converted back to glucose via the Cori cycle in the liver.[35,36] This cycle of producing glucose from lactate uses ATP in a highly inefficient manner. Possibly this process contributes to the increased resting energy expenditure mentioned above. In one study, a 40 percent increase in hepatic glucose production was observed in weight-losing cancer patients.[35–37] Changes in lipid metabolism have also been described in patients with the cancer anorexia/weight loss syndrome. These include increased lipid mobilization, decreased lipogenesis, and decreased activity of lipoprotein lipase, which is responsible for clearance of triglyceride from plasma.[18,35,36] A lipid mobilizing factor has also been isolated.[27,36,38,39] Studies in animal models have suggested that lipid mobilizing factor may contribute to loss of body fat and increased resting energy expenditure.[39]

Box 58.1 Mediators of the cancer anorexia/weight loss syndrome

- TNFα
- IL-1β
- IL-6
- 'Cancer cachectic factor'
- Lipid-mobilizing factor
- Leptin (possibly)
- IFNγ

Along with the changes in glucose and lipid metabolism, changes in protein metabolism have also been documented in weight-losing cancer patients. During starvation, glucose utilization by the brain is replaced by use of ketone bodies derived from fat. This process decreases the amino acid driven gluconeogenesis by the liver. In weight-losing cancer patients, however, amino acids are not spared and lean body mass is depleted.[2] Skeletal muscle biopsies from patients with cancer have demonstrated both increased rates of protein synthesis and increased rates of protein degradation.[40,41] The cancer cachectic factor is a 24 kDa proteoglycan that has recently been implicated as a mediator in cancer-associated weight loss. Utilizing a rodent model, Todorov et al.[42] found that direct injection of this 'cancer cachectic factor' into the body results in weight loss. In contrast, if an antibody to the 'cancer cachectic factor' is administered 24 hours before the injection, this same wasting effect is not observed. Providing provocative clinical data, these investigators found that this proteoglycan is highly specific for weight loss in patients with cancer as opposed to weight loss from trauma or sepsis or the mere presence of cancer with no weight loss.

In general, the pathophysiology of the cancer anorexia/weight loss syndrome continues to be studied, and much of what is described above still requires further investigation. Nonetheless, the available data clearly point to pathophysiological mechanisms that are markedly different from those observed in classic starvation. Thus, the most important point of the above discussion is that caloric repletion is not the answer to managing this syndrome and that other approaches, such as counseling patients on prognosis and, on occasion, pharmacological manipulation of the appetite, should be considered.

THERAPEUTIC OPTIONS

Treatment of the anorexia/weight loss syndrome has led to only modest improvements in clinical outcome. In the cancer anorexia/weight loss syndrome treating the underlying malignancy appears to reverse at least some aspects of the syndrome. Geels et al. examined 300 patients who were receiving chemotherapy for breast cancer, a relatively chemotherapy-sensitive solid tumor. Patients completed questionnaires that included an assessment of appetite, and a direct relation between tumor response and improvement in appetite was observed. Specifically, 82 percent of patients with a complete or partial response to chemotherapy also reported an improvement in appetite.[43] To our knowledge, no major studies have examined weight or body composition in cancer survivors or in patients whose cancer responds dramatically to cancer therapy to assess what sort of changes in weight or eating patterns occur in these settings. However, the above data suggest that at least some aspects of the cancer anorexia/weight loss syndrome can be reversed with chemotherapy.

Caloric supplementation

Intuitively, and at a first glance, caloric supplementation seems to be the ideal approach for managing weight loss in patients with the cancer anorexia/weight loss syndrome. This strategy, however, has shown to be beneficial in only a few, specific situations, particularly in the cancer setting. Indeed, it is our contention that, by definition, patients who benefit from nutritional supplementation do not truly have the cancer anorexia/weight loss syndrome. Cancer patients who do sometimes benefit from nutritional support include those with perioperative cancer, those who have undergone stem cell or bone marrow transplantation,

and those who are receiving radiation for head and neck cancer. The unifying theme behind all these situations is that these patients all appear to have potentially curable malignancies or a high likelihood of long-term tumor response.

In contrast, in patients with advanced, incurable, metastatic disease, no benefit has been derived from parenteral or enteral nutritional support. McGeer *et al.* published a meta-analysis showing no benefit with parenteral nutrition in cancer patients receiving chemotherapy. In fact in this meta-analysis, patients receiving parenteral nutrition experienced higher rates of infectious complications compared with patients receiving no parenteral nutrition.[44] Similarly, Ovesen *et al.* found that among cancer patients receiving chemotherapy, dietary counseling did lead to increased caloric intake but that this increased caloric intake did not result in improved survival, tumor response rates, or quality of life.[26] With regard to patients with congestive heart failure, there have been no large controlled studies of nutritional strategies in the management of cardiac-associated anorexia/weight loss. However, in patients with clinically stable congestive heart failure and no evidence of severe malnutrition, nutritional support alone has not been shown to carry a significant effect on clinical status.[45]

Unlike studies in cancer and congestive heart failure patients, studies of total parenteral nutrition in HIV-infected patients with severe wasting have shown significant improvement in weight. The patients receiving total parenteral nutrition experienced an 8 kg weight increase compared with a 3 kg weight loss in patients receiving no parenteral nutrition.[46] The effects of total parenteral nutrition on lean body mass were greatest in HIV-infected patients with documented malabsorption compared with patients with active secondary infections.[47]

Is there ever a situation among patients with incurable, metastatic cancer where nutritional support, such as total parenteral nutrition, appears to benefit patients? As emphasized above, we believe that this approach is outside the standard of care for most patients with cancer. However, case reports and small series suggest that occasionally these patients may benefit from total parenteral nutrition. Certainly, selection bias may result in publication of the most favorable outcomes. Recently, the Mayo Clinic published a report on a 20-year retrospective experience with total parenteral nutrition in this group of patients.[48] Overall, the use of total parenteral nutrition at this institution was quite conservative; only 52 patients with incurable cancer, or 15 percent of all patients treated at home received this intervention. Although most patients did poorly, 16 did live for one year or longer, presumably as a result of the total parenteral nutrition. In an attempt to tease out predictive factors in order to provide guidance on who might benefit from total parenteral nutrition from a practice perspective, no such predictive factor emerged. Thus the conclusion of this study was that clinical discretion – in the setting of a multidisciplinary approach and after indepth

discussions with the patient and family members – should guide management when this nonstandard approach is considered.

In cancer, the limited role of increased caloric intake emphasizes the need to discuss goals and realistic expectations of any intervention for patients suffering from the anorexia/weight loss syndrome. First, the healthcare provider should determine who actually is most bothered by the decreased oral intake and weight loss. Is it the patient or the family? Often, family members, and not the patient, are more distressed by these signs and symptoms. Family members often feel tremendous guilt over their inability to convince their loved ones to increase their oral intake and thereby presumably stop ongoing weight loss. Their attempts to encourage oral intake can become a source of frustrating disagreement between patients and their families. Second, frank discussions with patients and their family members regarding the fact that simple increased oral intake of food is unlikely to prolong life or improve quality of life in terminally ill cancer patients often relieves this source of anxiety. Studies of patients near the end of life indicate that they usually do not feel hunger and dehydration even in the absence of nutritional or fluid supplementation.[49] These findings should be explicitly conveyed to family members. Therefore, patients should base the use of pharmacological measures to improve appetite, as discussed below, on their own wishes for appetite improvement rather than on the guilt and frustration of family members. Third, it is important to point out to patients and family members symptoms such as loss of appetite and weight often occur at the end of life. The major role of dietary counseling in this setting is to provide education that the cancer anorexia/weight loss syndrome is common, out of the patient's control, and not representative of lack of volition on the part of the patient.

Pharmacological interventions

When the decision is made to initiate pharmacological treatment for the cancer anorexia/weight loss syndrome, progestational agents or glucocorticoids are reasonable options. These two classes of agents are the only ones that have been shown in multiple, placebo controlled, randomized trials to stimulate appetite.

PROGESTATIONAL AGENTS

Progestational agents used in the management of this syndrome include megestrol acetate and medroxyprogesterone acetate. Megestrol acetate is a synthetic, orally active derivative of naturally occurring progesterone. Medroxyprogesterone acetate is also be available as an injectable, depot formulation, although, to our knowledge, the depot formulation has not been used extensively for appetite stimulation. Multiple studies suggest that progestational agents improve appetite in patients with advanced cancer and

anorexia. Some have speculated that this effect is exerted partially by downregulation of IL-6, although some studies refute this mechanism of action. Approximately 15 published, placebo controlled trials in cancer patients have evaluated the appetite-stimulating effects of megestrol acetate. Thirteen of these studies demonstrated that megestrol acetate improved appetite.[50] For example, in a North Central Cancer Treatment Group trial, Loprinzi et al. examined 133 cancer patients in a placebo controlled trial and found that those who received megestrol acetate at 800 mg/day manifested both an increase in appetite and an increase in nonfluid weight.[51]

A recent meta-analysis by Pascual Lopez et al. included 26 studies published between 1990 and 1999 investigating the effectiveness of megestrol acetate in the treatment of anorexia/weight loss syndrome in comparison with placebo and other drugs used in the treatment of cachexia. All together, 3368 patients were included in the meta-analysis. Eighty-six percent of patients had cancer, 11 percent had HIV, and 2 percent had other illnesses (failure to round up apparently precluded summing to 100%), including cystic fibrosis in 12 children and a wide range of other diseases in the geriatric population. In general, the study revealed an increase in appetite and weight gain with megestrol acetate. Results regarding quality of life were somewhat less clear cut. However, when the Karnofsky performance index was used as surrogate marker for quality of life the overall results were in favor of megestrol.[52]

Megestrol acetate has been shown to have a dose-related benefit starting at doses of 160 mg. The optimal dosage is generally considered 800 mg/day, and increasing the dose beyond this level provides no further benefit.[53] It is generally recommended that patients start at 160 mg/day and titrate upward according to clinical response.[2] However, the clinician may choose to start at 800 mg/day if a rapid clinical decline is anticipated, and the option of gradual titration is thought to be unavailable.

Progestational agents are reasonably well tolerated for the most part. However, adverse effects of both megestrol acetate and medroxyprogesterone include thromboembolic phenomena, breakthrough uterine bleeding, peripheral edema, hyperglycemia, hypertension, adrenal suppression, and adrenal insufficiency.[2] The risk of thromboembolic events with the use of megestrol acetate is minimal. In Pascual Lopez et al.'s meta-analysis, the only statistically significant adverse effect observed in patients receiving megestrol acetate versus placebo was edema with a relative risk of 1.67.[52] However, a history of thromboembolism remains a definite contraindication to initiating megestrol acetate for the anorexia/weight loss syndrome, as the risk: benefit ratio is too great. Whereas use of progestational agents for the anorexia/weight loss syndrome in cancer or HIV patients may provide benefit, their use in weight-losing congestive heart failure has not been extensively studied. Progestational agents promote fluid retention and may therefore lead to deleterious side effects in this particular patient group. In general, their use in congestive heart failure patients is not routinely recommended.

GLUCOCORTICOIDS

In addition to progestational agents, corticosteroids have been extensively studied as a treatment approach for the anorexia/weight loss syndrome. These agents are thought to exert their effects through suppression of inflammatory mediators and possibly through a direct effect on appetite centers in the hypothalamus.[54] Moertel et al. published the first placebo controlled trial investigating the effectiveness of corticosteroids in the cancer anorexia/weight loss syndrome. This study included 116 patients with advanced gastrointestinal malignancies. At 4 weeks, 55 percent of patients in the corticosteroid group reported an improvement in appetite compared with 26 percent in the placebo group.[55] Multiple subsequent studies have demonstrated similar results with corticosteroids in the treatment of cancer-associated anorexia.

Which are better: corticosteroids or progestational agents? In a North Central Cancer Treatment Group study, Loprinzi et al. answered this question by a randomized controlled trial in 475 weight-losing and/or anorexic cancer patients. Patients were randomly assigned to receive megestrol acetate 800 mg daily versus dexamethasone 0.75 mg four times daily versus the androgen fluoxymesterone. Fluoxymesterone did not provide favorable results. However, the key point of this trial was that, at the doses studied, megestrol acetate and dexamethasone provided equivalent orexigenic effects. Toxicity was different in these two effective arms. Myopathy was more frequent in the dexamethasone group: 6 percent and 18 percent in the megestrol acetate and dexamethasone groups, respectively. Other adverse effects that were seen more commonly in the dexamethasone group included cushingoid changes (1 percent vs. 6 percent) and peptic ulcer disease (0 percent vs. 3 percent). Twenty-five percent of megestrol acetate-treated patients and 36 percent of dexamethasone-treated patients discontinued therapy because of either their wishes and/or toxicity.[56]

Based on these findings, corticosteroids are generally reserved for patients in whom megestrol acetate is contraindicated, such as in those with thromboembolism. Patients with a limited life expectancy and therefore likely to receive only short-term benefits may prefer corticosteroids.[54] For other patients who do not fall into these categories, progestational agents may be viewed as a more favorable choice.

INEFFECTIVE OR RELATIVELY INEFFECTIVE AGENTS

Other pharmacological agents have been proposed as possible treatments for the cancer anorexia/weight loss syndrome. The list of agents that have not proved as effective

in large randomized, comparative trials is extensive (see Box 58.2) and includes fluoxymesterone (as discussed above).

Box 58.2 What does not work

- Dronabinol

- Cyproheptadine

- Pentoxifylline

- Hydrazine sulfate

- Dietary counseling as a single intervention

- Eicosapentaenoic acid

OTHER PROMISING AGENTS

Other agents appear more promising and merit further study (Box 58.3). First, in cancer patients, melatonin appears promising. This is a pineal gland hormone that has been demonstrated to decrease the level of circulating TNFα. In one study, the addition of melatonin to chemotherapy for lung cancer resulted in improved response and survival rates and a reduced incidence of myelosuppression, neuropathy, and weight loss in the group treated with melatonin compared with the control group.[57] Although promising, this finding needs to be confirmed in larger trials. Second, thalidomide is another promising agent that may work in the treatment of cancer anorexia/weight loss syndrome by means of TNFα inhibition. Bruera *et al.* observed in their study that the majority of cancer patients who were at the end of life, reported an overall improved sense of wellbeing with this agent.[58] Third, phase III testing of the androgen

- Adenosine triphosphate

- Melatonin

- Creatine

---

oxandrolone has been recently completed following promising pilot data. The results of this larger trial are eagerly awaited. Finally, the North Central Cancer Treatment Group is currently testing other agents including TNFα inhibitors (etanercept and infliximab) and creatine. Preliminary results are anticipated in 2007.

In AIDS patients, modest doses of thalidomide have been associated with a significant improvement in wellbeing and weight gain.[59] There is now accumulating evidence that the combination of aggressive nutritional counseling, appetite stimulants, progressive strength training, and anabolic hormones can reverse weight loss and increase lean body mass. This approach requires further study, but at this point appears promising. The first goals of therapy for these patients should be treatment of any secondary infections and optimization of antiretroviral therapy.[60] Nutritional strategies employed in these patients with some success include total parenteral nutrition, β-hydroxy-β-methylbutyrate, and high-quality oral proteins including whey protein supplements. Improvement in weight has been shown with the use of megestrol acetate. Physiological testosterone administration in hypogonadal men with AIDS wasting has been shown to result in sustained improvement in lean body mass. Another agent associated with improvement in lean body mass in HIV patients is growth hormone.[61] Again, further study of all these approaches appears to be indicated.

Multiple drugs have been investigated as potential treatments for the anorexia/weight loss syndrome in the setting of congestive heart failure. Freeman *et al.* suggested that fish oil supplementation reduces circulating levels of IL-1 and improves cachexia in dogs.[61] Specific anticytokine therapies have been tested in this patient population. Etanercept, an anti-TNFα antibody, was studied in a large scale trial. Unfortunately, the trial was stopped early based on unfavorable preliminary results.[62] There are preliminary data that the angiotensin inhibitor enalapril can prevent development of weight loss in congestive heart failure patients although definitive evidence is lacking.[63] Hryniewicz *et al.* reported promising results with the use of β blocker therapy in patients with anorexia/weight loss and congestive heart failure. In this study, 27 patients with baseline anorexia/weight loss were treated with carvedilol or long-acting metoprolol. Compared with a similar control group, the patients treated with β blocker therapy demonstrated a significantly greater weight gain.[64] Anecdotal evidence has been reported supporting the use of short-term, high-dose growth hormone therapy in cardiac anorexia/weight loss patients. Two case reports of three 'cachectic' patients stated that there were profound increases in muscle mass and strength without significant side effects.[65,66] The use of anabolic steroids has also been proposed as a treatment option for patients with cardiac anorexia/weight loss, but the side effects of these medications often limit their usefulness in this patient population. Interestingly, treatment with left ventricular assist devices provides little benefit with regard to weight gain in this patient population.[67]

Key learning points

- Anorexia and weight loss are devastating aspects of a syndrome that complicates several chronic diseases.

- When present, the anorexia/weight loss syndrome is not only psychologically difficult for patients and their families but portends a worse outcome.

- The goals of nutritional/pharmacological management of this syndrome vary for individual patients depending on their underlying disease, but the approach is primarily palliative in nature.

- Aggressive nutritional support, particularly with total parenteral nutrition, is beneficial in only a few well-defined circumstances.

- Pharmacological interventions that are considered reasonable, particularly in patients with advanced cancer or HIV, include progestational agents or corticosteroids.

- Management of the cancer anorexia/weight loss syndrome is challenging because this syndrome represents a set of complex metabolic aberrations, but the exact pathophysiology remains unclear.

- Certainly, the most pressing issues surrounding this syndrome center around its etiology and finding effective means to palliate associated symptoms, improve quality of life, and prolong survival.

- Future research should focus on gaining a better grasp on pathophysiology for purposes of eventually developing better therapies.

Nausea/vomiting

SEBASTIANO MERCADANTE

INTRODUCTION

Nausea and vomiting are demeaning, reduce patients' quality of life, and affect compliance with therapy. Nausea occurs both at an early stage and in the advanced stage of cancer disease. The frequency reported in literature varies according to the setting: primary tumor, concurrent treatment, stage and life expectancy, different evaluation tools or study design, and sex. For example, nausea and vomiting occur more frequently in women, probably due to cancer type and increased sensitivity to drugs.[1]

Thus it is reasonable to distinguish two forms of nausea and vomiting: that associated with chemotherapy and other oncological treatments, and the chronic multifactorial nausea and vomiting, commonly observed in advanced cancer or associated with progressive diseases. Other than in cancer patients, patients with progressive neurological diseases such as central nervous diseases, peripheral nervous diseases, dysfunction of neuromuscular junction, and muscle diseases, may also develop nausea and vomiting with different mechanisms.[2]

DEFINITIONS

Accurate use of terminology and an understanding of the symptom experience are essential for reliable, valid assessment and measurement. Three components of vomiting are recognized: nausea, retching, and emesis. Nausea is an unpleasant sensation of the need to vomit and is associated with autonomic symptoms, including pallor, cold sweats, tachycardia, and diarrhea. It may occur without retching or vomiting. It is not clear if nausea and vomiting represent different points along the spectrum of outputs from the vomiting center, or if they are related, but independent, phenomena. Nausea, differently from vomiting and retching, which are objective and definitive signs, arises from subjective components and dimensions unique to the individual.

While nausea is an expression of autonomic stimulation, characterized by a decrease in gastric tone and peristalsis and associated with an increase in the tone of duodenum, retching and vomiting are mediated by somatic nerves. Retching is an attempt to vomit without bringing anything up. It is characterized by a spasmodic movement of the diaphragm and abdominal musculature with the glottis closed, and denotes the labored rhythmic respiratory activity that frequently precedes emesis. The vomiting act involves forceful contraction of the abdominal wall musculature, contraction of pylorus and antrum, a raised gastric cardia, diminished lower esophageal sphincter pressure, and esophageal dilatation. Intestinal contents are commonly present in vomited material, implying a possible reverse peristalsis. Hypersalivation and cardiac rhythm disturbances are frequent associated phenomena.[3] Although the neural pathways that mediate nausea are not known, evidence suggests that they are the same pathways that mediate vomiting.[4] It may be that mild activation leads to nausea, whereas more intense activation leads to retching or vomiting.

PATHOPHYSIOLOGY AND CAUSES OF NAUSEA AND VOMITING

The distress resulting from these symptoms may escalate over time with the continuing symptom experience, regardless of the frequency, duration, and severity. Although people may experience seemingly identical symptoms, the cause of

the symptoms and each person's response to the symptoms may vary, so that an accurate assessment of the individual's symptoms and recognition of the possible causes forms the basis for customized treatments.

Vomiting involves a complex set of activities that suggests a central neurological control by a vomiting center. Stimulation of the dorsal portion of the lateral reticular formation in the vicinity of the fasciculus solitarius produces vomiting. This vomiting center is anatomically adjacent to the medullary centers that control respiration and salivation. The emetic pattern generator is in the third ventricle, close to the area postrema, but lying fully within the blood–brain barrier. It contains D_2-receptors, histaminic (H_1) receptors, muscarinic-cholinergic receptors, serotonin (5-hydroxytryptamine [5-HT] 2 and 3) receptors, which are emetogenic, and μ_2-opioid receptors, which are antiemetic at this location. Intracranial lesions are an important cause of nausea and vomiting. The increased intracranial pressure compresses and stimulates the emetic center on the floor of the fourth ventricle. Circumscribed lesions – vascular lesions, neoplasm, or local inflammatory lesions of the brain – may directly affect the emetic center or its afferent pathways. The emetic center may also be stimulated through ventricular dilatation without increased intracranial pressure, as in low-pressure hydrocephalus. Infectious diseases of the central nervous system may also produce vomiting.[2]

Psychological or emotional factors may also contribute to the generation of nausea at this level, where there is a group of motor nuclei, including the nucleus ambiguous, ventral and dorsal respiratory groups, and the dorsal motor nucleus of the vagus.

A chemoreceptor trigger zone (CTZ), sensitive to chemical stimuli, lies in the floor of the fourth ventricle in the brain stem and is able to stimulate the vomiting center. This area is outside the blood–brain barrier and is bathed in the systemic circulation. The CTZ contains emetic receptors for dopamine (D_2), serotonin (5-HT_3), acetylcholine (ACHr), and opioids (μ_2), which when stimulated provide input for the vomiting center sited in the third ventricle. High plasma concentrations of emetogenic substances, such as calcium ions, urea, morphine, and digoxin may stimulate dopamine receptors in this area. Anorexia, dehydration, weight loss, abnormal metabolites, and toxins produced by associated infections may also contribute. Moreover, it also receives input from the vestibular apparatus and the vagus (see Box 59.1). The deeper layers of the area postrema are partly formed of the nucleus tractus solitarius, which predominantly contains 5-HT receptors and is considered the main central connection of the vagus. Visceral afferent impulses arising from the gastrointestinal tract may reach the medullary vomiting center by way of the vagus, without traversing the CTZ.[1,5]

Vomiting is an integrated somatovisceral process. The central emetic pattern generator coordinates emetic processes, receiving and integrating input from various sources. The efferent pathways are mainly somatic, involving the vagus

<div style="border:1px solid black; padding:10px">

nerve, the phrenic nerves, and the spinal nerves. Changes in tone and mobility of the stomach during vomiting are likely mediated by visceral efferent neurons. Once the vomiting center has been sufficiently stimulated, the vomiting reflex is initiated. The person takes a deep breath which is held, the glottis closes to avoid aspiration of vomitus, the soft palate elevates to close off the nasal passage, and finally the diaphragm and abdominal muscles contract. As a consequence intraabdominal pressure squeezes the stomach between the two sets of muscles, and the gastrointestinal sphincter relaxes, allowing the expulsion of gastric contents.[3]

RECEPTORS AND NEUROTRANSMITTERS

Different neuromediators are implicated in the genesis of gastrointestinal symptoms, including dopamine, serotonin (via 5-HT_3 receptors), histamine, norepinephrine, GABA, acetylcholine, and enkephalin.[6] The CTZ is also implicated in delaying the reflex of gastric emptying, and production of taste aversion, which could contribute to vomiting. Acoustic neuroma, bone metastases at the base of the skull, brain tumors, or metastases affecting the vestibular apparatus are possible other causes of vestibular stimulation of H_1 receptors and muscarinic cholinergic receptors. In addition to the direct afferent pathways from the gastrointestinal tract to the vomiting center, the anatomical region of the area postrema receives emetic impulses from the pharynx, heart, peritoneum, mesenteric vasculature, and bile ducts. Impulses from these peripheral receptors are also transmitted directly to the vomiting center.

Drugs, particularly aspirin and opioids, directly stimulate the vestibular apparatus, which in turn provides input to the vomiting centre. Receptors in the gastrointestinal tract play an equally important part in the pathogenesis and treatment of nausea and vomiting, particularly 5-HT_3, 5-HT_4, and D_2 receptors. Activation of D_2 receptors produces gastroparesis. Vagus receptors include 5-HT_3 receptors, which are emetogenic, and 5-HT_4 receptors, which enhance

5-HT, 5-hydroxytryptamine.

the propulsion, resulting in a prokinetic effect. This effect is mediated by the cholinergic myenteric plexus, so that it could be inhibited by anticholinergics. Various stimuli, notably bowel distension and inflammation, may produce massive release of 5-HT from enterochromaffin cells contained in the bowel wall. Slowed gastric emptying and constipation, frequently observed in patients progressively immobilized and anorectic, may activate the same process. The activation of these peripheral receptors leads to the stimulation of the vomiting center via vagal and sympathetic afferents. There are also corticobulbar afferents to the vomiting center that mediate vomiting in response to some smells, sights, and tastes, and may play a role in psychogenic vomiting. Stress, anxiety, and nausea from any cause induce delayed gastric emptying via peripheral dopaminergic receptors on the myenteric plexus interneurons. Therefore, nausea and vomiting are influenced by a complex network of central and peripheral factors which interact with each other. The receptor site affinities of principal antiemetics are listed in Table 59.1.

SPECIFIC CONDITIONS ASSOCIATED WITH VOMITING

Chemotherapy–induced nausea and vomiting

Although chemotherapy and radiation may no longer be indicated for curative reasons in patients with advanced disease, they may provide symptom palliation. Chemotherapy-induced nausea and vomiting is one the most feared effects of cancer treatment. There are five levels of emetic potential of chemotherapeutic agents, and preemptive treatment with antiemetics is mandatory for the highest levels.[7] Neurotransmitters, such as dopamine, acetylcholine, histamine, and serotonin are involved in the emetogenic pathways stimulated by chemotherapy and radiation. It has been suggested that chemotherapy causes release of serotonin from enterochromaffin cells of the gastrointestinal tract, which then stimulate emesis via both the vagus and greater splanchnic

nerve as well as stimulating the area postrema of the brain, which is rich in serotonin receptors. Thus, serotonin receptors, both central and peripheral, are particularly important in the pathophysiology of acute emesis and drugs that inhibit this group of receptors are the cornerstone of the prevention and treatment of chemotherapy-related nausea and vomiting. Contributing factors include emetogenic potential of the chemotherapy drug combination, dosages, route, time of day, and length of administration, other therapies, anxiety, previous episodes, sex, and age.[8]

Anticipatory nausea and vomiting

This phenomenon occurs on the day or some hours before the expected chemotherapy, and often symptoms present in particular conditions, such as talking or thinking about the treatment. It affects a third of patients attending for chemotherapy. A psychological mechanism of association is probable, and is strongly related to the intensity of adverse effects associated with the previous chemotherapy, and the number of treatments received. Younger age, expectation, and motion sickness are well recognized risk factors for developing anticipatory nausea and vomiting, probably due to the higher doses used and anxiety.[9]

Disorders affecting the central nervous system

Different neurological diseases may produce a disturbance in central control of gut motility, resulting in gastrointestinal syndromes, such as vomiting or intestinal pseudo-obstruction with or without gastric stasis (Table 59.2).

Lesions of various origin of the spinal cord, above T5, may isolate the spinal sympathetic control from the influence of high centers. This results in a delayed gastric emptying and delay in duodenal progression. In the early period, severe gastric stasis and dilatation, and ileus are commonly present. In cases of long-term loss of function, patients who develop

Table 59.2 *Nervous system diseases associated with nausea and vomiting[2]*

Disease group	Mechanisms
Central nervous system	
Cerebral and brainstem disorders	
Multiple sclerosis	Gastroparesis
Parkinson disease	Gastrointestinal dysmotility
Cerebral masses	Compression of vomiting center
Spinal cord disorders	
Amyotrophic lateral sclerosis	Gastric atony, ileus
Poliomyelitis	Gastric atony, ileus
Autonomic dysfunction, gastric atony	Esophageal dysfunction
Peripheral nervous system	
Alcohol-related gastroparesis	Gastritis (acute), neuropathy – impaired esophageal peristalsis
Myenteric plexus dysfunction	Pseudo-obstruction
(Chagas disease, Hirschsprung disease, achalasia, ganglioneuromatosis)	
Neuromuscular junction	
Myasthenia gravis	Oropharyngeal incoordination
Muscle disease	
Myotonic dystrophy	Dysphagia, gastric atony, pseudo-obstruction
Dermatomiositis-polymyositis	Dysphagia, gastric atony, pseudo-obstruction
Oculopharyngeal muscular dystrophy	Dysphagia
Duchenne muscular dystrophy	Dysphagia, pseudo-obstruction
Familiar visceral neuropathy	Dysphagia, pseudo-obstruction

quadriplegia are more likely to have gut complications than those with paraplegia. The incidence of gastroesophageal reflux is increased and gastric emptying impaired. Chronic constipation may worsen the clinical picture possibly facilitating the development of nausea and vomiting. Neuropathies are frequently encountered in patients with cancer.[2]

Autonomic failure

Autonomic failure is more common in patients with poor performance status often associated with anorexia-cachexia syndrome. The mechanisms remain unclear and appear to be multifactorial – tumor invasion of nervous tissue, malnutrition, damage from chemotherapy or radiotherapy, drugs, preexisting disease – and could be considered a sort of paraneoplastic syndrome, producing gastroparesis.[10]

Other disorders may affect the extrinsic gastrointestinal innervation. There is evidence that vagal autonomic neuropathy may be responsible for gastric motor disturbances in diabetic patients with gastroparesis. It is well known that the motility disorder involves not only the stomach, but also the upper small bowel. This has been commonly attributed to gastric motor dysfunction with delayed gastric emptying. Peripheral neuropathy, manifestations of autonomic neuropathy, with bladder dysfunction, sweat disorder, orthostatic hypotension, impotence, nephropathy, and retinopathy are frequently found, as gastroparesis is commonly reported in patients with longstanding, insulin-dependent poorly controlled diabetes.[11] Neurological diseases, such as dystrophia

myotonica and progressive muscular dystrophy, amyloidosis, collagen vascular diseases, and autoimmune neurological diseases may affect parietal structures of the gastrointestinal tract, inducing motility dysfunction, which can precipitate nausea and vomiting.[2] Radiation injury is another important cause of gastrointestinal dysmotility. Early vomiting is probably due to direct mucosal injury, whereas late vomiting and gastrointestinal stasis may be related to radiation-induced inflammation or strictures.[3,11]

Metabolic disorders

Significant gastrointestinal disturbances may be associated with thyroid and parathyroid disorders. Intestinal pseudo-obstruction may develop both in hyperthyroidism and hypothyroidism. The role of gastrointestinal hormones in disorders of upper intestinal motility remains unclear.[5]

Drug-induced nausea and vomiting

Many drugs commonly cause nausea and vomiting. Adrenergic agents, such as β agonists, generally delay gastric emptying, whereas β blockers enhance gastric emptying. Clonidine, an α_2 agonist, may induce nausea and vomiting. Anticholinergic agents, such as some tricyclic antidepressants, inhibit contractile activity and delay gastric emptying.

Dopamine agonists, opioids, digitalis, and chemotherapeutic agents such as cisplatin remain the major offenders.

Opioids have central and peripheral actions. Centrally, they may stimulate the emetic center via D_2 receptors of the CTZ, richly distributed in the area prostrema. In addition, they induce a relevant delay in gastric emptying and a delay in intestinal transit. The narcotic bowel syndrome is characterized by a picture similar to pseudo-obstruction. Non-steroidal anti-inflammatory drugs (NSAIDs) may induce nausea and vomiting by damaging gastric mucosa and activating peripheral ascending impulses. A central effect of alcohol on the CTZ has been recognized, other than the well known consequence of damage to the gastric mucosa.

ASSESSMENT AND DIAGNOSIS

Like pain, nausea is a subjective experience and presents all of the problems inherent in measuring pain. Nausea is usually assessed by visual analog or numerical scales.[12] Vomiting can be objectively recorded as events in a manner reminiscent of the methodology used to study antiemesis related to chemotherapy.

Many factors should be considered when choosing antiemetic treatment. History, examination, and review of the ongoing drug regimen are generally helpful in finding the cause of gastrointestinal symptoms in the neurological population. A multitude of medications, including opioids, digoxin, antibiotics, imidazoles, and cytotoxics can cause nausea and vomiting by acting on the CTZ, whereas NSAIDs, iron supplements, antibiotics, and tranexamic acid may damage gastric mucosa. Opioids, tricyclics, phenothiazines, and anticholinergics induce gastric stasis. Finally, selective serotonin reuptake inhibitors and cytotoxic drugs may induce 5-HT$_3$ receptor stimulation. Uncontrolled pain *per se* may be a cause of nausea and vomiting.

In patients with neurological diseases such as diabetic neuropathy, or with advanced cancer, autonomic failure occurs with gastroparesis, nausea, vomiting, and constipation. Movement-related nausea with vomiting suggests either vestibular dysfunction or mesenteric traction. Nausea increasing with head motion, with tinnitus, decreased hearing, or skull tenderness is suggestive of vestibular involvement due to drug toxicity and local lesions. Presence of vertigo may be helpful in distinguishing the two conditions. Candidal infection may produce pharyngeal irritation, activating the afferent arm of the vomiting circuit via the vagus nerve and should be suspected in patients taking steroids.

Emesis produced with cough occurs at the end or during a coughing paroxysm and is associated with chronic pulmonary disease, esophageal fistulas, and brain metastases. Morning vomiting, sometime projectile, associated with cognitive changes or neurological deficits may be due to brain tumors or secondaries. Papilledema may be a possible associated sign. Neck stiffness and headache may be signs of underlying meningitis. Computed tomography (CT) or magnetic resonance imaging (MRI) can confirm the diagnosis. Nausea produced by hyperglycemia or hypercalcemia is associated with polyuria and polydipsia. Patients treated for prolonged periods with steroids for chronic neurological disease may develop Addison disease after abrupt suspension of medication.

Vomiting that occurs in relation to meals is frequently of diagnostic importance. Patients with gastric outlet obstruction or gastric atony often will complain of vomiting several hours after eating. In contrast, patients who vomit as a result of viral gastroenteritis or psychogenic causes are usually symptomatic in the immediate postprandial period. Appropriate screening tests include a biochemistry profile consisting of electrolytes, blood urea nitrogen, creatinine, glucose, albumin and calcium. In patients taking digoxin or anticonvulsants the plasma drug levels should be considered. A pattern of infrequent large-volume vomitus which relieves nausea suggests a partial bowel obstruction. Abdominal examination and an abdominal X-ray are helpful to screen for situations involving sub-obstruction. Abdominal CT and ultrasound may be required to complete the investigation. Emotional experience may trigger psychogenic vomiting.

TREATMENT

Long periods or repeated episodes of vomiting can lead to dehydration. To avoid this, it is important to replace fluids lost through vomiting. In some circumstances it is necessary to administer fluids and drugs by the parenteral route, either subcutaneously or intravenously. Treating any identifiable cause of nausea and vomiting is the first step. Reversible causes include hypercalcemia, hyperglycemia, hypocortisolism, hyponatremia, uremia, obstipation, and increased intracranial pressure. Bisphosphonates for hypercalcemia and dexamethasone for intracranial tumors are the first-line treatments in these specific conditions. Identifiable offending drugs should be stopped. A calm and reassuring environment may be useful, avoiding exposure to foods precipitating nausea. Control of malodor from decubitus ulcers is mandatory. Behavioral techniques, relaxation exercises, and benzodiazepines may be helpful for anticipatory nausea.

Generally, widely accepted management guidelines are not available, except for the treatment of nausea and vomiting associated with chemotherapy. The use of the modern antiemetic regimens based on combinations of drugs has dramatically reduced the incidence, which was reported to be about 80 percent in the past decades. The fact that different agents cause nausea and vomiting by different mechanisms prompted researchers to develop regimens with multiple drug with different mechanisms of action.[13***] Although the mechanism considered to play the predominant role in the induction of nausea and vomiting is the activation of the CTZ, gastrointestinal stimulation or damage,

vestibular and cortical mechanisms, or alterations of taste and smell, may equally contribute in different ways in producing these symptoms. As discussed earlier in the chapter chemotherapeutic agents interact with the CTZ to release various transmitters, such as dopamine, histamine, serotonin, and neurokinin, largely represented in this area.

The pharmacological treatment of nausea and vomiting in the palliative care setting usually involves established drugs. Many classes of medication have been used as antiemetics. If vomiting prevents drug absorption a nonoral route should be used at first. Patients should be reevaluated at regular intervals to optimize the dose or to switch drugs. The choice of medication depends upon drug receptor selectivity and drug interactions, as patients are frequently receiving several medications that potentially interact with or antagonize the antiemetics. The afferent pathway involved and the group of antiemetics that antagonize the involved neuroreceptors are key factors that influence the choice of the first drug, i.e. a mechanistic approach should be the basis for choosing first-line antiemetic drugs. The sites and possible receptor mechanisms of the principal antiemetic drugs are listed in Table 59.1.

An important principle is to use combinations of antiemetics with different modes of action,[14,15] primarily based on starting with a metoclopramide regimen.[10] On the other hand, antiemetics may have specific adverse effects in patients with neurological diseases. Moreover, anticholinergic medications may antagonize the prokinetic effects of drugs acting via the cholinergic system in the myenteric plexus.[1,6,16,17]

In a recent systematic review of the efficacy of antiemetics in the treatment of nausea in patients with terminal cancer, uncontrolled studies had high response rates (75–93 percent) to standard regimens, whereas randomized controlled trials reported much lower response rates (23–36 percent for nausea, 18–52 percent for vomiting), regardless of an empirical or a more selective clinical approach.[18***]

Metoclopramide

Metoclopramide, in addition to its recognized dopamine antagonist action, also acts as a weak serotonin antagonist and can stimulate gastrointestinal motility by increasing acetylcholine release, which explains the potential for central adverse effects, such as extrapyramidal reactions. Metoclopramide, usually combined with steroids, appears to be as effective as the 'setrons' (see below) in preventing delayed emesis, and is cheaper than specific antiserotonin agents.

Metoclopramide enhances the transit of the contents of the gastrointestinal tract as far as the jejunum, speeding gastric emptying, and decreasing small intestinal transit time, probably by increasing cholinergic activity through the activation of $5-HT_4$ receptors. In high doses metoclopramide also has $5-HT_3$ receptor antagonist activity. Domperidone,

a D_2 antagonist that poorly crosses the blood–brain barrier, acts primarily on gastric D_2 receptors and D_2 receptors in the CTZ, which are outside the blood–brain barrier, facilitating gastric motor activity and emptying.[1,4] Although in same studies the efficacy was similar to that observed with placebo,[19**] metoclopramide in doses of 60 mg daily was quite effective in a cancer population with chronic nausea. Three percent of patients required other antiemetics because of extrapyramidal side effects.[20*] Controlled-release metoclopramide 40 mg every 12 hours, significantly reduced nausea without producing the pertinent adverse effects in patients with a history of cancer-associated dyspepsia syndrome.[21**] Metoclopramide use confers an increased risk for the initiation of treatment generally reserved for the management of Parkinson disease in patients with drug-induced parkinsonian symptoms.[22*]

Setron family

As mentioned above, serotonin receptors, both central and peripheral, are particularly important in the pathophysiology of acute emesis and drugs that target this group of receptors underpin the prevention and treatment of chemotherapy-related nausea and vomiting. The role of the $5-HT_3$ receptor was recognized during the evaluation of the mechanism of high-dose metoclopramide, which unlike other D_2 receptor antagonists, has a good capacity to reduce the emesis induced by cisplatin administration.

Several $5-HT_3$ antagonists are commercially available, including ondansetron, granisetron, tropisetron, and dolasetron. Many randomized controlled trials have demonstrated that these agents have equivalent antiemetic activity and safety at the recommended doses, despite differences in structure and pharmacokinetic profiles,[3] both orally and intravenously, due to their good bioavailability following oral administration. These drugs are well tolerated, and central adverse effects are not commonly observed with serotonin antagonists. The effect of the setrons on the serotonin-mediated emetic pathways may lend itself to the management of chronic nausea. Ondansetron, a selective $5-HT_3$ antagonist, has been used in palliative care setting in patients not responding to conventional treatments. In 9 of 16 patients with advanced human immunodeficiency disease, the treatment was effective and well tolerated.[23*] However, in a controlled study the efficacy of ondansetron at relatively large doses was similar to that reported with placebo.[19**] Tropisetron-containing combinations or tropisetron as a single agent are much more effective in the control of emesis in patients with advanced cancer than the conventional antiemetic combination of chlorpromazine plus dexamethasone.[24**] Not being antidopaminergic, setrons are potentially useful when the risk of extrapyramidal reactions is high, such as in children or elderly people who have neurological diseases with an extrapyramidal component. They appear to have no effect on motion sickness.[1]

Phenothiazines and butyrophenones

Phenothiazines and butyrophenones belong to the class of D_2 antagonists. Haloperidol has a relatively narrow spectrum and is a potent D_2 antagonist with negligible anticholinergic activity, so that it produces less sedation than phenothiazines but greater extrapyramidal reactions.[1,16]

Phenothiazines, including prochlorpromazine, promethazine, and chlorpromazine, possess a broader spectrum of activity with dopaminergic, cholinergic, and histamine receptor antagonism. Hypotension, sedation, decreased salivary flow are the main adverse effects. Central and hemo-dynamic adverse effects are more likely with major tranquilizers. Levomepromazine is a phenothiazine closely related chemically to chlorpromazine. Its proved analgesic properties make it unique among the phenothiazines. It is efficacious and generally nonsedative in doses of 5–12.5 mg/day. It is a potent antagonist at 5-HT$_2$, H$_1$, D$_2$, and α_1-receptors.[25*]

Anticholinergics

Hyoscine is a naturally occurring compound which competitively inhibits the action of acetylcholine and other muscarinic agonists. The primary indication of hyoscine is motor sickness and labyrinthic disturbances. It is also indicated for reducing intestinal secretions in patients with inoperable bowel obstruction. Unlike the other antimuscarinic agents, hyoscine produces central nervous system depression in therapeutic doses – manifesting as drowsiness, euphoria, amnesia, disorientation, restlessness, and hallucinations.[1]

Antihistamines

Cyclizine is effective in nausea associated with motion sickness, pharyngeal stimulation, bowel obstruction, and increased intracranial pressure. Drowsiness and antimuscarinic effects are the main adverse effects.[1,5,16]

Neurokinin–1 receptor antagonists

These substances inhibit the effects of substance P on the nucleus tractus solitarius. In early clinical trials, the neurokinin-1 receptor antagonist aprepitant was shown to improve the protection provided by the best available therapy, including a 5-HT$_3$ receptor antagonist and dexamethasone, against chemotherapy-induced nausea and vomiting over multiple cycles of cisplatin-based chemotherapy.[26**]

Cisapride

This drug acts on acetylcholine receptors in the myenteric plexus of the gut, improving gastroduodenal and pyloroduodenal coordination. It also affects colonic transit. As it is not a dopamine antagonist, and has no central nervous system penetration, it does not cause the central adverse effects of many other antiemetic drugs and can be extremely useful in most neurological patients with gastrointestinal disorders resulting in nausea vomiting. Its prokinetic effect is not limited to the upper bowel but extends throughout the gastrointestinal tract. The enhancement of gastric motor activity by prokinetics may reduce afferent activity in the vagus nerve and so diminish the stimulus to nausea and vomiting from visceral sensation (for example, distension).[1,3]

Steroids

Dexamethasone has synergistic or additive antiemetic effects combined with setrons, metoclopramide, or phenothiazines. The mechanism remains unknown. The antiemetic actions of dexamethasone are not well characterized, except for use in the treatment of nausea and vomiting due to increased intracranial pressure. Adverse effects include glucose intolerance, myopathy, osteopenia, and infections.[1,5]

Dronabinol

Cannabinoids appear to be of low antiemetic efficacy and adverse effects may occur. The mechanism of the antiemetic effect of cannabinoids is unknown. It has been hypothesized that an indirect inhibition of the vomiting center in the medulla occurs as a result of binding to opioid receptors in the forebrain. Dronabinol has been used in diffuse metastatic disease in the gastrointestinal tract mucosa for intractable nausea and vomiting unresponsive to conventional antiemetics.[27*]

Olanzapine

Olanzapine, an atypical antipsychotic, possesses a unique neurotransmitter binding profile that is similar to methotrimeprazine. It has been shown to relieve nausea in some patients with advanced cancer who fail to respond to the usual antiemetics.[28*] Olanzapine has been also used to reduce the incidence of delayed emesis in patients receiving moderate to highly emetogenic chemotherapy and is well tolerated.[29*,30*]

Key learning points

- Nausea and vomiting are frequent symptoms reported by cancer patients. Several causes are recognized, including curative and symptomatic treatments, as well as disease itself.

- Different and complex systems are involved in the mechanisms producing these symptoms.

- Except for chemotherapy-induced vomiting, no clear guidelines have been produced for the remaining conditions, particularly in advanced-stage disease, when multiple factors may play a role in producing or exacerbating nausea and vomiting.

- Different classes of antiemetics or their combinations are usually chosen according to the supposed mechanism with variable efficacy.

- The need for controlled studies is justified by the finding that uncontrolled studies show high response rates whereas randomized controlled studies have shown lower response rates.

Constipation and diarrhea

EDUARDO BRUERA, NADA FADUL

INTRODUCTION

Constipation and diarrhea are common and distressing symptoms in palliative care patients. In some patients these symptoms occur together, and others alternate between episodes of diarrhea and constipation. However, in the majority of cases, the patient presents with one manifestation or the other according to the clinical situation. During the trajectory of illness of patients with cancer or acquired immunodeficiency syndrome (AIDS), there will be episodes of chronic constipation related to opioid medications, decreased oral intake, immobility or autonomic failure; and episodes of diarrhea related to antibiotic therapy and chemotherapy-induced mucositis. For educational purposes, this chapter discusses the assessment and management of constipation and diarrhea independently. However, in clinical practice, the syndromes frequently occur in a less independent fashion.

CONSTIPATION

Definition

Constipation is a common symptom in the palliative care population. It affects more than 50 percent of the patients in a palliative care unit or hospice. This might actually underestimate the problem since many of these patients are already on stool softeners and/or laxatives. Constipation is a clinical syndrome, rather than a symptom. It is defined as infrequent or difficult defecation with reduced number of bowel movements, which may or may not be abnormally hard, with increased difficulty or discomfort.[1] Because of the variability of normal bowel movement pattern from one patient to another, it is difficult to find an objective measure of constipation. The Rome criteria are often used to define constipation (Box 60.1).[2] Constipation is inadequately assessed and is underdiagnosed in the palliative care settings, even though it has been found to cause greater distress than pain in this patient population.[3**] Untreated constipation may progress to obstipation, which may potentially lead to life threatening complications associated with bowel obstruction.[4**]

Box 60.1 Definition of constipation according to the Rome criteria

The presence of two or more of the following symptoms for a period of at least three months:

- Straining at least 25 percent of the time

- Hard stools at least 25 percent of the time

- Incomplete evacuation at least 25 percent of the time

- Two or fewer bowel movements per week

Pathophysiology

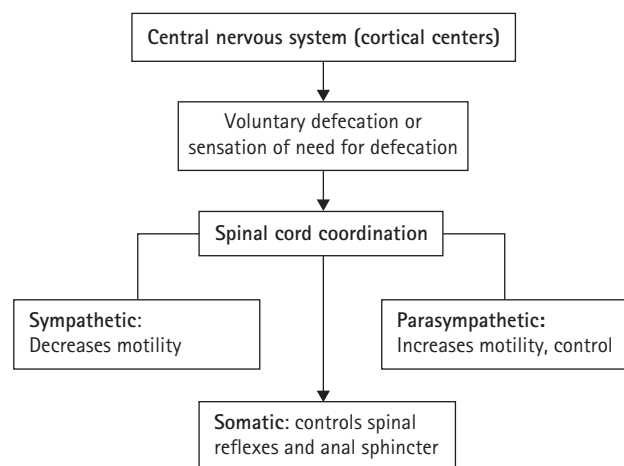
Normal bowel function requires the coordination of motility, mucosal transport, and defecation reflexes. Motility of the small intestine, colon, and sphincteric regions is controlled by myogenic characteristics, central nervous system mechanisms, the activity of the peripheral autonomic nervous system (sympathetic and parasympathetic systems, and circulating gastrointestinal hormones [Fig. 60.1]).[2]


Figure 60.1 *Neurological control of bowel motility.*

Gut smooth muscle is innervated by extrinsic nerves that relay information to and from the extraintestinal ganglia, the spinal cord, and the central nervous system, and by intrinsic nerves within the intestinal wall. The vagus nerve provides parasympathetic supply to the ascending colon and proximal half of the transverse colon, and the reminder of the large intestine is supplied by parasympathetic fibers from the second, third, and fourth sacral segments.[5] The external anal sphincter and pelvic floor muscles receive sacral spinal input from the pudendal nerves. Sympathetic fibers innervate the proximal part of the large intestine though the superior mesenteric plexus, and the distal part of the large intestine through the inferior mesenteric and superior hypogastric plexuses. Sympathetic innervation generally inhibits excitatory cholinergic transmission in the myenteric plexus of both the small intestine and colon.[6,7] The functional significance of these pathways is exemplified by the long inhibitory intestinal reflexes that decrease motility through neural arcs involving the prevertebral ganglia. Conversely, sympathectomy either has no effect on bowel function or may unmask colonic propulsion.

Colonic propulsion and defecation appear to be coordinated by a spinal center that is modulated by excitatory and inhibitory influences from the brain.[8] Patients with neurological lesions involving the cauda equina or lower spinal cord have all the neurological abnormalities observed after section of the pelvic nerves, but in addition the external anal sphincter contractions are weak or absent and may not occur in response to rectal distension, increase intraabdominal pressure, and anal stimulation.[8] These types of lesion produce constipation associated with hypomotility, colonic dilation, decreased rectal tone and sensation, stasis of the distal colon, and impaired defecation.[9,10] Patients with lesions involving the high spinal cord are often constipated, probably because they are unable to perceive the presence of feces in the rectum. However, colonic reflexes are intact and sphincter pressure is often normal and defecation

can often be triggered by digital stimulation of the anal canal.[11] Although the motor response of the sigmoid colon after a meal is reduced in persons with high spinal injuries, responses to pharmacological stimuli are normal. Colonic motility can also be abnormal in patients with pontine, hypothalamic, or cortical lesions.[8] The myenteric plexus provides the major intrinsic innervation to the small intestine and colon, although the submucous plexus may play a minor role in some reflexes. These two groups of nerve cells integrate the motor and secretory activities of the gastrointestinal tract.[12] The number of intrinsic neurons greatly exceeds the number of vagal, pelvic, or splanchnic fibers. The human enteric nervous system contains 10–100 million neurons versus 2000 efferent fibers in the vagus; thus, intrinsic nerves direct most motor activities, whereas extrinsic innervation provides a modulatory function.

A number of neurotransmitters participate in extrinsic neural control of small intestinal and colonic motor function. Peptidergic fibers containing somatostatin, substance P, cholecystokinin (CCK), neuropeptide Y (NPY), encephalin, and other transmitters are present in the vagus and splanchnic nerves.

Assessment

HISTORY

Because of interindividual variability of the normal elimination pattern, constipation in an individual patient should be defined according to that patient's experience. It is helpful to use the patient's prior stool pattern and regularity as a basis for comparison. It is also important to determine when was the last time the patient had a bowel movement and what were the characteristics of the bowel movement, whether straining was necessary or whether there was pain on defecation. If the patient has an urge to move the bowel but is unable to, this might suggest rectal obstruction or impaction of stool. In contrast, if the patient has lost the urge to move the bowel, this suggests a spinal cord problem causing neurogenic bowel dysfunction. Patients with impaired mobility are predisposed to constipation partly because of difficulty accessing the toilet or commode.

It is also important to determine whether there are other associated symptoms, because these might indicate development of complications or they could be atypical presentation of constipation (Box 60.2). Severely constipated patients can complain of diarrhea and continue to pass fecal material.[13] Patient can also complain of variable abdominal or rectal pain, which is colicky in nature. Unexplained nausea or vomiting should prompt investigations to rule out constipation.[14] Fecal impaction is well-recognized cause of urinary retention in elderly patients. Certain medications can predispose to constipation (Box 60.3) and it is essential to obtain a thorough history of prescription as well as over-the-counter medications and whether the patient is using laxatives along with these medications.[1]

Box 60.2 Symptoms associated with constipation

- Flatulence
- Abdominal pain
- Nausea and/or vomiting
- Pseudodiarrhea (see section on diarrhea)
- Urinary retention
- Abdominal distension
- Anorexia
- Mental status change and delirium

Box 60.3 Drugs commonly associated with constipation in palliative care patients

- Opioids
- Anticholinergic (antispasmodics, antidepressants and phenothiazines)
- Haloperidol
- Anticonvulsants
- Iron
- Calcium-channel blockers
- Vinca alkaloids
- Aluminum (antacids)
- Calcium
- Barium sulfate
- Ganglionic blockers
- 5-Hydroxytryptamine (5-HT$_3$) blockers
- Diuretics
- Antihypertensives

PHYSICAL EXAMINATION

Abdominal examination may reveal distension, tenderness, firmness, or the presence of fecal mass, particularly in the descending colon. Several features can help distinguish between a fecal mass and a tumor. Fecal masses usually indent with deep palpation and can have a crepituslike feeling because of the presence of entrapped gas. Over time the fecal mass will move.[9] Auscultation can detect high-pitched, hyperactive sounds, which are characteristic of intestinal obstruction, or loss of bowel sounds, which signifies ileus.

Digital rectal examination is essential in the assessment of constipation. It may reveal stenosis, fissure, scarring,

rectal tumor, hemorrhoids, or rectal prolapse. It can aid in the diagnosis and management of fecal impaction by removal of the impacted feces to facilitate bowel movement. An empty rectal vault may indicate proximal impaction or obstruction. Perineal sensation should be assessed, and reflex contraction of the anal canal after pinprick of the perianal area (anal wink) also can be used to test neurological function of the perineal areas.[10] The actual stool can be examined: small hard pellets suggest slow colonic transit time; ribbonlike stool suggests bowel stenosis or the presence of hemorrhoids. The presence of blood or mucus is suggestive of hemorrhoids, tumor, or inflammation.

DIAGNOSTIC TESTS

An important laboratory test in patients with constipation is serum calcium, since hypercalcemia is an easily reversible cause of constipation. Serum potassium level can also be helpful since hypokalemia can cause constipation. Thyroid hormone studies to rule out hypothyroidism can be helpful in patients with other signs and symptoms of this disorder.

A plain abdominal radiograph can be extremely useful in the assessment of constipation. Diagnosis of constipation by history and physical examination alone has been shown to be unreliable, inaccurate, and often omitted by healthcare professionals.[11**] The diagnosis can be greatly improved by obtaining an abdominal radiograph, a non-invasive and inexpensive test that is more appropriate to the palliative care population than other more sophisticated tests, such as defecography and colonic transit time studies. The abdominal radiograph can provide an objective assessment of fecal load by obtaining a constipation score. A constipation scoring system has been proposed based on the amount of stool in each quadrant (ascending, transverse, descending colon, and rectum). Each quadrant is assigned a score from 0 to 3 where:

- 0 = no stool
- 1 = stool occupies less than 50 percent
- 2 = stool occupies >50 percent but <100 percent
- 3 = stool occupies 100 percent of the lumen.

A score greater than or equal to 7/12 is considered to reflect severe constipation.[15**]

Etiology

In the palliative care population the causes of constipation can be related to the primary illness or secondary associated factors (Fig. 60.2). Chronic illnesses often lead to physical and mental impairments that can produce or exaggerate constipation. This condition may be further exacerbated by inactivity or physical immobility, which can lead to fecal retention. A bedridden patient may be unable to respond to defecatory signals because of inadequate toileting arrangements; as a result, fecal retention may lead to
Figure 60.2 *Common causes of constipation in palliative care patients.*

megarectum, diminished rectal sensation, and fecal impaction. Other factors that may contribute to constipation in the bedridden patient include underlying illness, medications such as opioids, low fluid intake, low-fiber diet, sedation, and depression.[2,16] A survey conducted by Twycross suggested the importance of these factors: in a hospice population, 50 percent of the patients not receiving opioids required regular laxatives.[28]

Diseases associated with constipation include structural disorders that lead to mechanical obstruction (intra- or extraluminal), metabolic and endocrine disorders, and those neurogenic disorders that affect the gastrointestinal tract. Structural disorders include both intracolonic and extracolonic mass lesions, either primary or metastatic, radiation fibrosis and other anorectal pathology including painful anal fissures, hemorrhoids, or perianal abscess. Metabolic disorders that predispose to constipation include dehydration (due to poor oral intake, vomiting, fever, polyuria or diuretics), hypercalcemia, hypokalemia, and uremia.[16] Other systemic endocrine disorders that can cause constipation may also coexist in these patients such as diabetes and hypothyroidism.[17,18] Because colonic and anorectal motor functions are coordinated by both the enteric nerves and the extrinsic innervation of the sympathetic and parasympathetic nerves, diseases of the central and peripheral nervous systems are often associated with constipation.[19] Constipation can be caused by epidural metastasis leading to compression of the spinal cord, conus medullaris or cauda equina. Other neurological disorders that can cause constipation include peripheral neuropathy and local sacral plexus disease. In addition patient with advance cancer frequently develop autonomic failure that leads to abnormal gastrointestinal motility and symptoms such as chronic nausea, anorexia, and constipation. This abnormality is more frequent in patients with the anorexia/cachexia syndrome.

Several medications induce constipation (see Box 60.3). Opioid analgesics are the most common offending agents. In a large retrospective study, Skyes showed that opioids accounted for about a quarter of constipation found in terminally ill cancer patients in a hospice.[20*] Opioids affect the intestine by one of three mechanisms: reduction in motility (propulsive peristalsis), reduction in secretions (pancreatic, biliary, fluid, and electrolyte abnormalities), and increase in

intestinal absorption and blood flow.[21,22] Opioids also increase transit time in the colon and ileum. Morphine can lead to constipation partly by local accumulation in the intestinal tissue.[23] Opioid receptors are present on the gut smooth level and at all levels of the nervous input to the intestine. Tolerance to the constipation effect of opioids develops slowly and many patients require laxatives as long as they take the medication. The effect on the bowel varies between the different opioids and there is also wide interindividual variability. Research suggests that methadone and transdermal fentanyl cause less constipation than other opioids.[24*,25**] In a report of four cases, Daeninck and Bruera found reduction of laxative requirements after opioid rotation to methadone.[24*] Other medications that are commonly used in palliative care patients have prominent constipating effect, including those with anticholinergic action (antispasmodics, antidepressants, phenothiazines, antacids, and haloperidol), some anticonvulsants or anti-hypertensive drugs, antiemetics (ondansetron), and diuretics.[2] Chemotherapeutic agents that can cause peripheral neuropathy such as vinca alkaloids can also lead to constipation.

Complications

Chronic constipation may lead to pudendal nerve damage and fecal incontinence in middle-aged and older women.[10] In more advanced cases, rectal prolapse may result. Stercorous ulcers with bleeding or perforation constitute a hazard in patients with fecal impaction. Constipation has also been determined to be a risk factor for patients receiving corticosteroids for intracranial lesions.[1,2]

Management

Management of constipation can be divided into preventive measures and therapeutic measures. Preventive measures include prophylaxis with laxatives when initiating opioids.[26] Nonpharmacological interventions are appropriate in some patients, such as increase in dietary fiber and fluid intake. It is important to ensure adequate fluid intake when increasing dietary fiber, since fiber can be problematic in some patients and can lead to paradoxical worsening of constipation. Patients with partial obstruction should not be given fiber because of the risk of increased obstructive symptoms.[2] Anorectic patients should be given fiber cautiously since the satiety produced by a high-fiber diet worsens malnutrition. Patients should be encouraged to increase physical activity to avoid decrease in colonic motility caused by inactivity.[27] It is also important to educate the patient, family and healthcare providers about the myth of the relation between regularity of bowel movement and food intake. Palliative care professionals should emphasize the fact that stool content is comprised mostly of sloughed intestinal endothelial cells and microorganisms rather than digested food.

Table 60.1 *Classification, dosages, and pharmacological properties of laxatives*

Laxative	Onset of action (h)	Mechanism	Usual adult dose	Comments
Bulk forming agents	12–24	Hold water in stool and cause distension		Patients should be able to increase fluid intake, otherwise fluid impaction might occur
Natural (psyllium)			7 g/day	
Synthetic (methylcellulose)			4–6 g/day	
Saline laxatives	0.5–3	Draw fluid into the intestine		Avoid in patients with renal or heart failure
Magnesium hydroxide			30 mL	
Magnesium citrate			200 mL	
Hyperosmolar agents	Variable, generally 24–48	Increase stool osmolarity leading to accumulation of fluid in the colon		Might cause flatulence and distension
Polyethylene glycol			8–25 g/day	
Lactulose			15–30 mL	
Sorbitol			15–30 mL	
Contact cathartics	6–10	Stimulate peristalsis by direct action on the myenteric plexus Reduce net absorption of water and electrolytes		Additive risk of hepatotoxicity when docusate is used in combination with other contact cathartics
Anthraquinones			Variable	
Diphenylmethane			65–130 mg	
Castor oil	2–6		15–60 mL	
Docusate	24–72		100–800 mg	
Emollient laxatives	6–8	Lubricant and stool softener	15–45 mL/day	Might lead to serious lipoid pneumonia if aspiration occurs
Mineral oil				
Prokinetic agents	Variable	Decrease transit time through intestine		For refractory constipation. Might be useful in colonic inertia secondary to spinal cord injury
Metoclopramide			40–120 mg/day	
Domperidone			30–80 mg/day	

Therapeutic modalities to treat existing constipation can be divided into general interventions and pharmacological treatment. The nonpharmacological measures used in prevention can also be incorporated in treatment of constipation. Other measures include treatment of underlying medical factors that can lead to constipation (discontinuation of offending drugs, treatment of electrolyte and metabolic abnormalities) and the availability of comfort, privacy, and convenience during defecation. Therapeutic interventions for the routine management of constipation could be administered orally or rectally.[1,2,9,16] For most patients, the use of enemas and rectal suppositories is limited for the acute short-term management of more severe episodes.[1] Surveys of hospice populations suggest that more than 40 percent of

these patients use rectally administered laxative therapy on a regular basis.[28] Oral laxatives include bulk forming agents, osmotic (saline) agents, hyperosmolar agents, contact cathartics, agents for colonic lavage, lubricants, prokinetic drugs, and opioid antagonists (Table 60.1).[1]

Bulk-forming laxatives comprise natural (psyllium) or synthetic polysaccharides or cellulose derivatives that act in a manner similar to fiber that is naturally contained in the diet. Because fluid intake should be increased with these preparations,[29**] they should be used cautiously in patients who are unable to maintain good oral intake, otherwise a viscous mass may form and aggravate a partial bowel obstruction. These products are typically effective after 2–4 days of regular use and they are generally unsuitable

for palliative care patients and/or for relief of severe constipation.

Saline laxatives including magnesium salts (magnesium hydroxide and magnesium citrate) and sodium salts (sodium phosphate) contain relatively nonabsorbable cations and anions that exert an osmotic effect to increase intraluminal water content. Magnesium increases intestinal motor activity; because an appreciable amount of magnesium may be absorbed, these agents should be avoided in patients with renal insufficiency because of the danger of magnesium toxicity. Saline laxatives can also be administered by enemas or suppositories.

Hyperosmolar agents include polyethylene glycol and nonabsorbable sugars such as lactulose and sorbitol. Sorbitol and lactulose are degraded by colonic bacteria to low-molecular-weight acids that increase stool acidity and osmolarity and lead to accumulation of fluid in the colon. The use of these substances may cause flatulence in about 20 percent of patients and their sweet taste is sickly to some. Doses should be adjusted to reduce abdominal bloating and flatulence and to modulate defecation.

Contact cathartics are the most commonly prescribed agents for opioid-induced constipation.[1] This group comprises the anthraquinones (cascara sagrada, senna, casanthranol, and danthron), diphenylmethanes (phenolphthalein and bisacodyl, and oxyphenisatin), the docusates, and castor oil. Although there is some difference in action in different classes, all of these drugs stimulate peristalsis by direct stimulation of the myenteric plexus and reducing net absorption of water and electrolytes from the intraluminal content.[30*,31,32] Anthraquinone derivatives increase fluid and electrolyte accumulation in the distal ileum and colon through incompletely understood actions. They act primarily on the colon, and colonic electromyography following administration of senna in humans shows an increase in myoelectrical activity of the type seen in diarrhea. Pathological changes in the colon produced by long-term anthraquinone use include melanosis coli, a benign and reversible condition. Although smooth muscle atrophy and damage to the myenteric plexus were suggested in earlier studies, there is no evidence that anthraquinones given in clinically relevant doses cause enteric damage in experimental animals or humans.[33**] These laxatives are generally effective within 12–24 hours. The diphenylmethane derivatives (phenolphthalein and bisacodyl, and oxyphenisatin) also act primarily on the colon and produce effects similar to those of anthraquinone derivatives. Allergy to these substances has been reported. In 1997, the phenolphthaleins were voluntarily withdrawn from the market after the US Food and Drug Administration (FDA) reclassified the drugs as 'not generally recognized as safe and effective' after a study in rodents found an increased incidence of nongastrointestinal neoplasms. This has not been proved to be the case in humans.[34*,35*,36*] Bisacodyl is structurally similar to phenolphthalein and exhibits similar actions on small intestine fluid accumulation and colonic motor activity.[37] Because the drug is a gastric irritant, tablets

are enteric coated and should not be broken or chewed. Docusate salts are anionic surfactants that lower the surface tension of stool to allow mixing of aqueous and fatty substances. This action softens stool to permit easier defecation. These agents also stimulate intestinal fluid and electrolyte secretion by increasing mucosal cyclic adenosine monophosphate.[38] Although not absorbed, they alter intestinal mucosal permeability and increase the absorption of other laxatives, such as mineral oil, phenolphthalein, and danthron. Docusate salts are often added to other laxatives as a stool softener. This is reasonable although there are no controlled studies establishing the efficacy of such a combination. There is an additive risk of hepatotoxicity when used in combination with other contact cathartics, and liver function should be evaluated periodically.[39*] Castor oil is hydrolyzed by gut microflora to ricinoleic acid, which acts on small intestine producing abundant mucosal secretions. Castor oil may have a rapid onset of action and can cause considerable cramping. With chronic use, malabsorption of nutrients may occur. This drug should be reserved only for the management of acute constipation.

Agents for colonic lavage such as polyethylene glycol electrolyte solutions are most often given for bowel cleansing before colonoscopy or before institution of bowel programs. Consumption of small quantities (25–500 mL) can be used to reverse chronic constipation in patients who are refractory to other laxatives.[2,40**] Lubricant laxatives (mineral oil) lubricate the stool surface and soften the stool, allowing easier elimination. These substances are generally recommended for the management of acute transient constipation and are not suitable for chronic laxative use. Long-term use is limited by perianal irritation, malabsorption of fat-soluble vitamins and the serious potential for lipoid pneumonia should aspiration occur. Mineral oil should not be used in obtunded or demented patients.[1,2]

Prokinetic agents (bethanechol, metoclopramide, or domperidone) are drugs that stimulate gastrointestinal motor activity to enhance transit of intraluminal contents. These drugs enhance intestinal motility by one of two mechanisms; they mediate the effect of a local transmitter that enhances motility such as acetylcholine or by antagonizing the effect of an inhibitory transmitter such as dopamine.[41,42] These agents could be considered for the treatment of constipation that does not respond to conventional measures. Cholinergic agents such as bethanechol have been used with little success and exhibit moderate side effects, including abdominal cramps, diarrhea, salivation, flushing, bradycardia, and blurred vision. Cisapride appeared to enhance transit through the proximal colon and has been shown to stimulate colonic motility and improve rectal sensation in chronically constipated patients. Although some studies suggest that clinical improvement occurs with the drug,[43**] others report highly variable and often disappointing results in patients with severe idiopathic constipation. Cisapride had been withdrawn by the FDA because of the risk of cardiac toxicity. Metoclopramide enhances gastrointestinal motility through three distinct mechanisms: central antidopamine effect,

peripheral antidopamine effect, and both direct and indirect stimulation of cholinergic receptors.[44] Basic studies have shown the effect of metoclopramide on colonic activity,[45,46] but clinical studies have failed to demonstrate effectiveness in treatment of constipated patients.[47] Domperidone is a benzimidazole derivative that acts as a specific antagonist to the inhibitory effects of dopamine on the upper intestinal tract and causes dose-dependent antroduodenal coordination.[48,49] It has no cholinergic activity and diffuses poorly into the central nervous system causing less extrapyramidal side effects than metoclopramide.

It has been shown that the opioid receptor antagonist naloxone can reverse certain cases of constipation. Scintigraphic techniques have shown that naloxone accelerates transit in various parts of the colon in normal volunteers.[50] Presumably this is because opioid receptors are involved in normal control of gut motility. Preliminary studies suggest that oral naloxone, compared with placebo, may increase stool volumes in elderly constipated persons.[51**] Such agents have been used successfully to treat constipation associated with long-term use of narcotic agents.[52] In a study by Skyes, the daily oral administration of naloxone at 20 percent or more of the prevailing 24-hour morphine dose was capable of providing a clinical effect without antagonizing the analgesic effect of opioid.[53**] However, opioid withdrawal was observed and it is suggested that initial naloxone administration dose should not exceed 5 mg. Methylnaltrexone is a quaternary ammonium opioid receptor antagonist, which does not cross the blood–brain barrier in humans. Intravenous or oral methylnaltrexone has been shown to reverse chronic opioid-induced constipation in patients in methadone maintenance programs without causing adverse effects such as withdrawal or abdominal cramps.[54,55] The dose of methylnaltrexone ranged from 0.3 mg/kg to 3 mg/kg with an effect that was significantly dose dependent.

The use of rectally administered agents including enemas and rectal suppositories should generally be limited to the acute short-term management of severe and intractable constipation. The occasional patient who cannot tolerate oral laxatives may be able to use long-term rectal laxatives or enemas effectively. These are usually administered two to three times per week. Surveys of hospice population suggest that more than 40 percent of this population uses rectally administered laxative therapy on a regular basis.[28] These agents are contraindicated in patients with thrombocytopenia. Rectal suppositories may be inert or active. Inert suppositories are usually fashioned from glycerin alone. They draw fluid into the rectum and act as a stimulus to defecation. Active suppositories contain a cathartic agent. Enemas are used to treat constipation unrelieved by suppositories. Enema may consist of small volume (microenemas) or large volume. Various commercially prepared formulations are available, based on a variety of laxative substances. Sodium phosphate enemas may cause fluid and electrolyte imbalance particularly in dehydrated patients. Large volume enemas can use tap water, soap suds, or saline. These can lead to mucosal irritation and can potentially cause fluid overload if a significant amount of water is absorbed.[1,2]

Future trends

There has been intense interest in the pharmacological actions of serotonin (5-HT) agonists on gastrointestinal motility; 5-HT$_4$ agonists stimulate intestinal motility, in part by facilitating enteric cholinergic transmission.[56,57] Clinical trials indicate that several 5-HT$_4$ receptor agonists accelerate colonic transit time and improve symptoms in patients with constipation. Tegaserod, a partial 5-HT$_4$ receptor agonist, reduces symptoms in patients with constipation-predominant irritable bowel syndrome. Tegaserod has also been shown to accelerate gastric emptying and small bowel transit. It is being evaluated for gastroparesis.[58]

The preliminary study on donepezil found that this drug could help constipation. Bruera *et al.* found that bowel movement per week (bm/week) did not increase among nonconstipated patients, but did increase from 2.9 to 5.5 bm/week in the eight constipated patients after 1 week of donepezil 5 mg/day. This centrally acting cholinergic drug has diarrhea as its main side effect and therefore it would be appropriate to consider clinical trials of its potential usefulness in constipation in patients requiring it for sedation or fatigue.[59]

DIARRHEA

Definition

Diarrhea is loosely defined as passage of abnormally liquid or unformed stools at an increased frequency. For adults on a typical Western diet, stool weight >200 g/day can generally be considered diarrheal. Because of the fundamental importance of duration to diagnostic considerations, diarrhea may be further defined as acute if <2 weeks, persistent if 2–4 weeks, and chronic if >4 weeks in duration.[13] Pseudodiarrhea and fecal incontinence are caused by anorectal problems or neuromuscular problems, respectively. These disorders are associated with passage of less than 200 g of stool and must be distinguished from diarrhea.[60–62] Diarrhea can also be an atypical presentation of constipation. Stool consistency probably best defines diarrhea, but it cannot be easily measured. Consistency is best defined as the ratio of fecal water to the water-holding capacity of insoluble solids.[63] Infectious agents cause more than 90 percent of cases of acute diarrhea; these cases are often accompanied by vomiting, fever, and abdominal pain. The remaining 10 percent or so are caused by medications, toxic ingestions, ischemia, and other conditions. Infectious diarrhea is one of the most frequent categories of nosocomial infections in many hospitals and long-term
Figure 60.3 *Common causes of diarrhea in palliative care patients.*

care facilities; the causes include a variety of microorganisms but most commonly *Clostridium difficile* (Fig. 60.3). Special categories of diarrhea including graft-versus-host disease (GVHD) and diarrhea in HIV patients will be discussed separately.

Pathophysiology

Most of the diarrheal conditions that have been studied have shown alterations of both intestinal fluid and electrolyte transport and the induction of propagative forms of intestinal motility. Diarrhée motrice is diarrhea caused by autonomic dysfunction in patients with hexosaminidase B deficiency (Sandhoff disease). It is thought to be caused specifically and only by abnormal motility. Deranged motility may reduce the contact time between the intestinal epithelium and luminal content. This commonly occurs in patient with postsurgical disorders (such as post-gastrectomy dumping syndrome, post-vagotomy, iliocecal valve resection) or neoplastic and chronic disease (such as malignant carcinoid syndrome, medullary carcinoma of the thyroid, and diabetes). Diarrhea in diabetic patients is a complication of diabetic neuropathy leading to sympathetic denervation of the bowel with prevalence of unopposed cholinergic innervation.

During each 24 hours, about 8–10 L of fluid enters the duodenum. This fluid contains 800 mmol sodium (Na^+), 700 mmol chloride (Cl^-), and 100 mmol potassium (K^+). Two liters of this duodenal load is derived from the diet; the remainder comes from secretions of the salivary glands, stomach, liver, pancreas, and the duodenum itself. Generally 1.5 L is absorbed in the small intestine and the remainder is presented to the colon. The absorptive capacity of the small intestine is undefined, but the capacity of the normal adult human colon is 4–5 L/24 h.[64]

Theoretically, diarrhea can result from decreased absorption by either the small intestine or the colon. If either deranged epithelial transport mechanisms or the presence of nonabsorbable solutes in the intestinal lumen reduce the absorptive capacity of the small intestine by 50 percent, the daily volume of fluid then presented to the normal colon (approximately 5 L) would exceed its absorptive capacity.

In recent decades it has been shown that intestinal secretions contribute greatly to the development of diarrhea. It was initially thought that bacterial enterotoxins cause secretion only by a direct effect on enterocyte receptors, but it has now been shown that 50 percent or more of the intestinal secretion initiated by bacterial enterotoxins *in vivo* comes about from stimulation of receptors on enterochromaffin cells that release hormones that activate the enteric nervous system, secondarily stimulating the enterocyte.[65,66] Inflammatory mediators also play a role. Phagocytes such as eosinophils, macrophages, and neutrophils and mesenchymal cells (myofibroblasts, endothelium, and smooth muscle) in the lamina propria and submucosa are also capable of initiating intestinal secretion. These mediators may directly stimulate the enterocyte and may also activate the enteric nervous system.

Chronic diarrhea is divided into three general categories: malabsorption (osmotic diarrheas), secretory diarrheas, and inflammatory diarrheas.

OSMOTIC DIARRHEA

This is caused by the ingestion of poorly absorbable solutes such polyethylene glycol and lactulose. The proximal small bowel is highly permeable to water and sodium, and water influx across the duodenum rapidly adjusts the osmolarity of the luminal content toward that of plasma. The mucosa of the ileum and colon is not readily permeable to sodium and solutes. However, there is an efficient active ion transport mechanism that allows the reabsorption of electrolytes and water even against electrochemical gradients.[67] Colonic bacteria play a major protective role by fermenting dietary proteins and carbohydrates into short chain fatty acids and gas. Anaerobic colonic flora is necessary for the fermentation of fiber into short chain fatty acids and constitutes the bulk of the fecal mass. Lactulose, an unabsorbable sugar in the small intestine, when ingested in large amount, leads to loss of this protective mechanism of colonic flora and diarrhea will occur. Osmotic diarrhea due to carbohydrate malabsorption is characterized by low pH due to short chain fatty acids, a high carbohydrate content, high stool osmolality, and flatulence. In osmotic diarrhea caused by poorly absorbable salts such as magnesium and sulfate, the pH is normal. Osmotic diarrhea commonly subsides by fasting or discontinuation of the poorly absorbable solute laxatives. With ingestion of either unabsorbable solute (i.e. Mg^{2+} or polyethyleneglycol) or unabsorbed carbohydrate (i.e. lactulose[68] or, in some persons, lactose),[69] a considerable amount of the osmolality of stool results from the nonabsorbed solute, so there is a significant difference, or gap, between stool osmolality and the sum of the electrolytes in the stool.[70]

Secretory diarrhea is rarely present as a sole mechanism and is often associated with other mechanisms. An abnormal ion transport in the intestinal epithelial cells, with a reduction in absorptive function or increase in increase in the secretion of the epithelial cells, is observed in secretory

diarrhea. In contrast to osmotic diarrhea, the anionic gap is usually small and the diarrhea does resolve by fasting. As is the case with osmotic causes of diarrhea, the stimuli causing secretory diarrhea may be of exogenous origin or they may be endogenous. The detergent stool softener dioctyl sodium sulfosuccinate and the cathartic ricinoleic acid (castor oil)[71] are examples of exogenous long-chain fatty acids that stimulate colonic secretion.

INFLAMMATORY DIARRHEA

Inflammatory diarrhea is characterized by enterocyte damage and death, villus atrophy, and crypt hyperplasia. In cases of severe inflammation, immune-mediated vascular damage or ulceration allows protein to exudate from capillaries and lymphatics and contribute to the diarrhea. Activation of lymphocytes, phagocytes, and fibroblasts releases various inflammatory mediators that induce intestinal chloride secretion.[72] Release of mediators such as prostaglandins, leukotrienes, platelet-activating factor, and hydrogen peroxide from phagocytes induces intestinal secretion by acting on the enterocyte and also by activating enteric nerves.[65,66,73] There are four general categories of inflammatory diarrhea: infection, hypersensitivity, cytostatic (anticancer) agents, and idiopathic (possibly autoimmune) diseases.

ACUTE DIARRHEA

Acute diarrhea is defined as diarrhea of less than 2–3 weeks' duration and, at most, 6–8 weeks' duration. The most common causes are infectious, medications, and chemicals. Acute infectious diarrhea is a major cause of death in developing countries. Death rates from diarrhea in the USA are probably underestimated, but they may be as high as 5000/year from food-borne infections alone.[74] Preliminary data from the US Centers for Disease Control and Prevention (CDC) indicate that the rates of *Salmonella*, *Shigella*, *Listeria*, *Escherichia coli*, and *Yersinia* (but not *Vibrio*) infections have declined by 20–30 percent, most likely as the result of increased attention to food safety.

Assessment

Experienced clinicians[75,76] suggest that 75–80 percent of chronic diarrheas can be diagnosed by an expert history and physical examination, coupled with certain screening and focused laboratory examinations.

HISTORY

Frequency, amount, and consistency of the stool should be carefully obtained. Stools that are large in volume, light in color, watery or greasy, and contain undigested food particles are associated with small bowel and proximal colon etiology. Stools that are small in volume, dark, often contain mucus or blood, and are frequent are associated with left colonic or rectal etiologies. Diarrhea associated with flatus and

mushy stool is associated with carbohydrate malabsorption. Intermittent diarrhea and constipation is frequent in diabetic neuropathy. Fecal impaction can cause apparent diarrhea because only liquids pass through a partial obstruction. The association of heat intolerance, palpitations and weight loss suggest hyperthyroidism. Dietary habits, alcohol consumption, or food intolerances should be investigated. Medications should be reviewed including prescription medications and antibiotic use in the preceding few months. Impact of diarrhea on quality of life should also be elucidated from history.

PHYSICAL EXAMINATION

A complete physical examination may reveal important clues to the etiology of diarrhea, including abdominal mass, abdominal tenderness or distension, ascites, fever, lymphadenopathy, and postural hypotension. Rectal examination should be performed to rule out fecal impaction or rectal mass, perianal fistula or abscess, loss of anal sphincter tone and to exclude intestinal obstruction. Rectal involvement is suggested by presence of little or no stool with a sense of rectal urgency, commonly named tenesmus.

INVESTIGATIONS

The diagnostic evaluation must be rationally directed by a careful history and physical examination, and simple triage tests are often warranted before complex investigations are launched. If feasible, collected stool should be sent for chemical and microbiological analysis. Peripheral blood counts may reveal leukocytosis that suggests inflammation; anemia that reflects blood loss or nutritional deficiencies; or eosinophilia that may occur with parasitoses, neoplasia, collagen-vascular disease, allergy, or eosinophilic gastroenteritis. Blood chemistries may demonstrate electrolyte, hepatic, or other metabolic disturbances. Quantitative stool collection and analyses can yield important objective data that may establish a diagnosis or characterize the type of diarrhea as a triage for focused additional studies. If stool weight is >20 g/day, additional stool analyses should be performed that might include electrolyte concentration, pH, occult blood testing, leukocyte inspection (or leukocyte protein assay), fat quantitation, and laxative screens.[77] Microbiological studies should be done including fecal bacterial cultures (including media for *Aeromonas* and *Plesiomonas*), inspection for ova and parasites, and *Giardia* antigen assay (the most sensitive test for giardiasis). This should be guided by suggestive history and physical examination. Gram stain of the stool can reveal the presence of *Staphylococcus*, *Campylobacter*, or *Candida* infection. The presence of microorganisms in the stool is diagnostic. Fecal occult blood testing should also be performed. Positive fecal occult blood or stool leukocyte test would suggest an exudative mechanism, such as radiation colitis, colonic neoplasm, or infectious diarrhea. Fecal leukocyte tests have poor sensitivity for ruling out inflammatory diarrheas.[78–80]

Stool analysis for *C. difficile* toxins A and B is an essential element of work-up of nosocomial diarrhea.

Abdominal radiography may reveal the presence of fecal impaction, intestinal obstruction or mass. Routine contrast radiographs of the gastrointestinal tract are not usually helpful in the diagnosis of watery diarrheas, unless they show a previous vagotomy, extensive small bowel resection or cholecystectomy, the presence of a tumor (carcinoid or villous adenoma), or a bowel filled with fluid (endocrine tumor). Contrast radiography may show diagnostic evidence of inflammatory bowel disease or changes suggestive of eosinophilic gastroenteritis or radiation enterocolitis.[81] Endoscopy and other invasive tests are rarely needed to establish the diagnosis of diarrhea.

Management

Treatment of chronic diarrhea depends on the specific etiology and may be curative, suppressive, or empirical. If the cause can be eradicated, treatment is curative as with resection of a colorectal cancer, antibiotic administration for Whipple disease, or discontinuation of an offending drug. For many chronic conditions, diarrhea can be controlled by suppression of the underlying mechanism.

In the majority of cases oral dietary therapy may provide effective symptom management. A gluten-free diet can reduce abdominal cramping and bowel movement frequency in the presence of intestinal fermentation with bowel distension, Binders of osmotically active substances (kaolin-pectin) give a thicker consistency to the stool, but their antidiarrheal effectiveness is unclear. Oral hydration solutions are rich in glucose and electrolytes, which takes advantage of the presence of the intestinal glucose–sodium cotransporter to promote increased sodium and water absorption. Dietary sugar beet fiber may ameliorate the diarrhea caused by abdominal irradiation.[82]

Because death in acute diarrhea is caused by dehydration, an important principle is to assess the degree of dehydration and replace fluid and electrolyte deficits. Severely dehydrated individuals should be rehydrated with intravenous Ringer lactate or saline solutions to which additional K^+ and $NaHCO_3^-$ may be added as necessary. Alert patients should be given oral rehydration solutions. Intravenous hydration is also indicated in presence of clinical signs of dehydration in patients with nausea and vomiting, in whom oral therapy is ineffective.

Antidiarrheal agents are of two types: agents useful for mild-to-moderate diarrheas and agents helpful in secretory and other severe diarrheas. The bulk-forming agents (kaolin-pectin, psyllium, and methylcellulose) increase the consistency of stool and have no antisecretory activity. Pectin has been shown to have proabsorptive activity. Other antidiarrheal agents have only mild proabsorptive or antisecretory action, and most have antidiarrheal activity by altering the intestinal motility. Bismuth salicylates, opioids, loperamide, clonidine, phenothiazine,

and somatostatin have mild antisecretory activity but also cause dilation of the small intestine and colon and decrease peristalsis.

Opioids increase anal sphincter tone leading to fluid entrapment within the intestine and put it in contact with the mucosa for a greater period of time, allowing more complete absorption. Opioids may be symptomatically useful in mild diarrheas. Opioid receptors are present at different sites, including smooth muscle, the myenteric plexus, the spinal cord, and the brain. Paregorics, deodorized tincture of opium, codeine, and diphenoxylate with atropine largely have been supplanted by loperamide. Loperamide does not pass the blood–brain barrier and has a high first-pass metabolism in the liver; it has a high therapeutic-to-toxic ratio and is essentially devoid of addiction potential. It is safe in adults, even in total doses of 24 mg/day. The usual dose is 2–4 mg two to four times daily. The dosage should be titrated against the effect, and higher doses, 2 mg every 2 hours, have been recommended in conjunction with chemotherapeutic agents associated with high incidence of diarrhea.[83] When giving opioids, stool output is not a reliable gauge for replacing fluid losses because the antimotility effects of opioids cause fluid to sequester in the bowel lumen (third space).

Sucralfate has been shown to mitigate diarrhea after pelvic radiation therapy. However, recent controlled studies were not able to demonstrate significant benefit.[84] Cholestyramine has been favorably used in radiation-induced diarrhea. In the same way aspirin has been reported effective in post radiotherapy diarrhea. It reduced prostaglandin synthesis, thereby increasing water and electrolyte secretion, which has a role in many types of diarrhea due to an inflammatory process.[85] Corticosteroids may exert a positive effect in treatment of radiation-induced diarrhea. Steroids can also decrease intestinal tract edema in cases of pseudoobstruction and exert a proabsorptive effect on the intestine that is demonstrable by 5 hours after administration. Budesonide, a topical active steroid is effective in treatment of diarrhea induced by 5-fluorouracil and irinotecan-induced diarrhea after failure of loperamide treatment.[86] Bismuth subsalicylate (Pepto-Bismol) is safe and efficacious in bacterial infectious diarrheas. Because of the possibility of worsening the colonization or invasion of infectious organisms by paralyzing intestinal motility, and because of evidence that the use of motility-altering drugs may prolong microorganism excretion time, neither opioids nor anticholinergic drugs are recommended for infectious diarrheas. Racecadotril, an intestinal enkephalinase inhibitor that is antisecretory but does not paralyze intestinal motility, is effective in the treatment of acute diarrhea in children and adults.[87]

Certain infectious diarrheas should be treated with antibiotics: shigellosis, cholera, traveler's diarrhea, pseudomembranous enterocolitis, parasitic infestations, and sexually transmitted diseases. Antibiotics are not usually indicated in viral diarrhea and cryptosporidiosis because they are not effective. Treatment of *E. coli* serotype O157:H7 infection is not recommended at present because current antibiotics do not seem to be helpful, and the incidence of complications

(hemolytic uremic syndrome) may be greater after antibiotic therapy. Regardless of the cause of infectious diarrhea, patients should be treated if they are immunosuppressed; have valvular, vascular, or orthopedic prostheses; have congenital hemolytic anemias or if they are elderly.

Refractory diarrhea that does not respond to specific therapy may present a challenging and serious clinical problem. Octreotide, a somatostatin analog with a more favorable pharmacokinetic profile, exerts a wide range of physiological effects on the gastrointestinal tract.[88] Several clinical trials suggest that this antisecretory agent may be useful in the symptomatic management of refractory diarrhea. The mechanisms by which octreotide produces these effects are probably multifactorial. It suppresses the secretion on many of the gut peptides implicated in the control of secretory and motor activity. Furthermore, it reduces splanchnic blood flow, inhibits exocrine secretion from the stomach, pancreas and small intestine, thus impairing gastrointestinal motility and facilitating absorption of water and electrolytes.[89,90] Octreotide may not be helpful in the diarrhea of medullary carcinoma of the thyroid, and it is of only limited usefulness in short bowel syndrome, and the refractory diarrhea of AIDS. Octreotide has been found to be effective in the management of chemotherapy-induced diarrhea[91] and diarrhea induced by celiac-plexus block, as well as diabetic diarrhea.[92,93] The newer long-acting preparations, Sandostatin-LAR (Novartis) and Lanreotide-PR (Ipsen-Biotech), for monthly subcutaneous administration have made therapy with this drug more convenient for the patient.

Agents such as phenothiazine, calcium-channel blockers, or clonidine can have serious side effects but may be tried if octreotide fails. Clonidine can be useful in the diarrhea of opioid withdrawal and occasionally in patients with diabetic diarrhea. Indometacin, a cyclooxygenase blocker that inhibits prostaglandin production, occasionally may be useful in neuroendocrine tumors, irritable bowel syndrome, and food allergy and is most useful in patients with diarrhea caused by acute radiation, AIDS, and villous adenomas of the rectum or colon. Cyclooxygenase blockers may be harmful in inflammatory bowel disease.

Diarrhea associated with special situations

NOSOCOMIAL DIARRHEA

Diarrhea is either the first or the second most common nosocomial illness among hospitalized patients and residents in long-term care facilities. Fecal impaction, medication and infections (*E. coli* and *C. difficile*) are common causes. Often this is a hidden problem, known only to the nurse's aide who changes the bed sheets. In the intensive care setting, it occurs in 30–50 percent of patients. Fecal impaction is thought to be one of the most common causes of diarrhea in hospitalized or institutionalized patients. Such paradoxical diarrhea and incontinence appear to be most common in patients with dementia or psychosis.[61] Any of a patient's medications may

initiate diarrhea. However, certain medications are more apt to cause diarrhea than others[62] (Box 60.4). Antibiotic-associated diarrhea is certainly the most common manifestation of drug-related diarrhea. Liquid formulations of any medication may cause diarrhea (elixir diarrhea) because of the high content of sorbitol used to sweeten the elixir. Patients prescribed liquid medications through feeding tubes may receive more than 20 g of sorbitol daily. An important but poorly understood cause of diarrhea is enteral (tube) feeding, particularly in critically ill patients, who often develop diarrhea. Dysmotility, increased intestinal permeability, and low sodium content in enteral formulas may be contributing factors. The incidence of acute, mild diarrhea with cancer chemotherapy or radiation therapy is high, approaching 100 percent with some agents, such as amsacrine, azacitidine, cytarabine, dactinomycin, daunorubicin, doxorubicin, floxuridine, 5-fluorouracil, 6-mercaptopurine, methotrexate, plicamycin, and irinotecan (CPT-11). Interleukin-2 therapy and the combination of 5-fluorouracil plus leucovorin are frequent causes of severe watery diarrhea.

Box 60.4 Drugs commonly associated with diarrhea in palliative care patients

Osmotic diarrhea
- Laxatives
- Antacid (containing magnesium)
- Olestra, orlistat (lipase inhibitor)
- Colchicine
- Cholestyramine
- Neomycin
- Methyldopa
- Paraaminosalicylic acid
- Biguanides

Secretory diarrhea
- Laxatives
- Diuretics (furosemide, thiazides)
- Theophylline
- Thyroxine
- Metformin
- Cholinergic drugs (glaucoma eye drops)
- Cholinesterase inhibitors
- Quinidine and quinine
- Metoclopramide
- Chemotherapy
- Misoprostol
- Gold
- Nonsteroidal anti-inflammatory drugs (NSAIDs)

DIARRHEA ASSOCIATED WITH GRAFT–VERSUS–HOST DISEASE

Graft-versus-host disease (GVHD) occurs when genetically disparate lymphocytes are transferred into an immunologically compromised recipient incapable of rejecting the donor graft. Acute GVHD involves primarily three organ systems: the skin, the gastrointestinal tract, and the liver. Risk factors for the development of acute GVHD include the degree of the human leukocyte antigen (HLA) match, a sex mismatch with the donor, a prior history of donor parity, an increased dose of total body irradiation (TBI), and the type of acute GVHD prophylaxis used.[94,95] The CD34-positive cell dose is an independent risk factor for acute GVHD after peripheral blood stem cell transplantation.[96] The severity of the intestinal condition generally parallels that of the skin and liver involvement, although profound gastrointestinal symptoms can occur without any gross skin or liver changes. Gastrointestinal GVHD involves the small and large intestines, which may result in diarrhea, nausea or vomiting, crampy abdominal pain, intestinal bleeding, and ileus. The onset or continuance of profuse, watery diarrhea 3 weeks following bone marrow transplantation is indicative of intestinal acute GVHD.

The clinical picture, when severe, includes anorexia, vomiting, buccal mucositis, abdominal pain, intestinal bleeding, protein loss, and secondary infection. High-volume diarrhea may occur, and the amount of fluid generated is an index of the extent and severity of disease activity. Extensive disease may be associated with up to 10 L of diarrheal fluid loss per day. The large stool volume may lead to distension and pain. Distension of the bowel may be exacerbated by opioid analgesics, which should be used with caution. Features that distinguish acute GVHD from the enteritis associated with the induction protocol and opportunistic intestinal infection include an erythematous, maculopapular skin rash over the palms, soles, and trunk, as well as liver test abnormalities, including hyperbilirubinemia. The patient who presents with gastrointestinal symptoms but without jaundice or skin rash represents a much more difficult diagnostic challenge.

Stool analysis and barium radiography might help the diagnosis. The stool usually contains large amounts of cellular debris and red and white blood cells. Protein loss in the stool may be sufficiently severe to lead to profound hypoalbuminemia. The absence of pathogens in the stool is important but does not necessarily rule out an infection of the gastrointestinal tract. Barium roentgenography may be helpful in the differential diagnosis and in establishing extent of disease. Widespread changes may occur, including mucosal and submucosal edema, pneumatosis cystoides intestinalis, and mucosal ulcerations.

Management of intestinal acute GVHD consists of nutritional support, maintenance of fluid and electrolyte balance, steroid and immunosuppressive treatment, and vigilance for secondary infectious complications. Common opportunistic pathogens include astrovirus, *C. difficile*, and adenovirus.[97] For patients with severe high-volume diarrhea, subcutaneous administration of octreotide may provide relief.[98] To improve long-term survival, doses ranging up to 2 mg/kg of prednisone, for up to 1–2 weeks, may be used. Ciclosporin may be used in combination with specific anti-T-cell monoclonal antibodies and inhibition of tumor necrosis factor α (TNF-α) is promising.[99,100]

AIDS–ASSOCIATED DIARRHEA

Acute or chronic diarrhea is a frequent complication of AIDS and may be caused by medications, opportunistic infections, or common causes occurring in the general population such as viral gastroenteritis or irritable bowel syndrome. The antiretroviral agents that most commonly cause diarrhea are lopinavir, nelfinavir, didanosine, and saquinavir. Treatment with bacterial agents may be complicated by *C. difficile*-associated diarrhea or colitis, but the frequency and severity do not appear to be increased by immunosuppression. Infections of the small and large intestine leading to diarrhea, abdominal pain, and occasionally fever are among the most significant gastrointestinal problems in HIV-infected patients. They include infections with bacteria, protozoa, and viruses. Among the bacteria may be those responsible for secondary infections of the gastrointestinal tract. Infections with enteric pathogens such as *Salmonella*, *Shigella*, and *Campylobacter* are more common in homosexual men and are often more severe and more apt to relapse in patients with HIV infection. Patients with untreated HIV have approximately a 20-fold increased risk of infection with *S. typhimurium*. With CD4 counts less than 200/mm^3 especially if less than 50/mm^3, acute diarrhea may represent the early stages of enteric infection caused by pathogens more commonly associated with chronic diarrhea. Common opportunistic pathogens that cause chronic diarrhea with CD4 counts less than 200/mm^3 are typically referred to as the 'big four', which are *Cryptosporidium parvum*, microsporidia (*Enterocytozoon bieneusi* and *Encephalitozoon intestinalis*), *M. avium*, and cytomegalovirus (CMV); less common is *Isospora belli*. Fungal infections may also be a cause of diarrhea in patients with HIV infection. Histoplasmosis, coccidioidomycosis, and penicilliosis have all been identified as a cause of fever and diarrhea in patients with HIV infection. Peritonitis has been seen with *C. immitis*.

In addition to disease caused by specific secondary infections, patients with HIV infection may also experience a chronic diarrheal syndrome for which no etiological agent other than HIV can be identified. This entity is referred to as AIDS enteropathy or HIV enteropathy. It is most likely a direct result of HIV infection in the gastrointestinal tract. The diagnostic evaluation is dictated by the symptoms and CD4 count. Standard screening tests for HIV-infected patients who have diarrhea that is severe, chronic, and not medication-associated includes a stool culture for enteric pathogens, ova and parasite exam times two with acid-fast stain (to detect cryptosporidia, isospora, and cyclospora),

stool stain, and microscopy for microsporidia (×1000 magnification with trichrome stain), *C. difficile* toxin assay (especially with recent antibiotic use), and stool analysis for fecal leukocytes and red blood cells. Approximately 50 percent of the time this work-up will demonstrate infection with pathogenic bacteria, mycobacteria, or protozoa. Endoscopy is usually reserved for patients with severe or persistent symptoms and a negative evaluation using noninvasive studies. Endoscopy is often necessary to establish the diagnosis of CMV colitis or enteritis.

Treatment of chronic infectious diarrhea in the HIV-infected patient is determined by the severity of symptoms and pathogen. With chronic cryptosporidiosis and most cases of CMV colitis and microsporidiosis, the only intervention that is likely to be effective is immune reconstitution with antiretroviral agents. Nonspecific interventions that are commonly used and are effective include antiperistaltic agents such as loperamide and diet modification including small, frequent, bland feedings without caffeine, fat, milk, or milk products. Octreotide is often used in symptomatic treatment of diarrhea associated with HIV, however clinical evidence of its efficacy in controlling diarrhea is not conclusive.[101,102] Antimicrobial agents are used to treat specific pathogens. Cryptosporidiosis is commonly treated with paromomycin, but evidence of benefit by this or other antimicrobials is sparse. *E. intestinalis* responds to albendazole, but *E. bieneusi* causes 80 percent of microsporidia cases and cannot be treated with antimicrobials. Cytomegalovirus is usually treated with intravenous ganciclovir or oral valganciclovir, but response is modest and recurrence rates are high. *M. avium* usually responds to standard treatment, but therapy must be lifelong unless there is immune reconstitution.

MUCOSITIS–ASSOCIATED DIARRHEA

Mucositis pertains to pharyngeal-esophago-gastrointestinal inflammation that manifests as red, burnlike sores or ulcerations throughout the mouth. Stomatitis is an inflammation of the oral tissues, which can present with or without sores, and is made worse by poor dental hygiene. Gastrointestinal mucositis increases mortality and morbidity and contributes to rising healthcare costs. Mucositis is common among oncology patients. Early estimates proposed that mucositis occurred in over 40 percent of patients who receive cancer chemotherapy or irradiation. Other recent data indicate that oral and gastrointestinal mucositis can affect up to 100 percent of patients undergoing high-dose chemotherapy and hematopoietic stem cell transplantation, 80 percent of patients with malignancies of the head and neck receiving radiotherapy, and over 50 percent of patients receiving chemotherapy.[103] The pathophysiology of mucositis in the alimentary tract beyond the oral cavity is a collective consequence of a number of concurrent and sequential biological processes. After radiotherapy or chemotherapy, mucositis is heralded by an initiation phase that is characterized by injury to tissues of the submucosa.

After the upregulation of a series of early-response genes, changes are observed in the endothelium, connective tissue, and extracellular matrix that are mediated by reactive oxygen species (ROS), the ceramide pathway, and a number of transcription factors, including nuclear factor kappa B (NF-κB). Diarrhea is frequently associated with gastrointestinal mucositis secondary to chemotherapy, hematopoietic stem cell transplant (HSCT), radiation therapy and GVHD. Chemotherapy-induced mucositis and diarrhea is a common clinical problem associated with certain drugs used to treat colon cancer and other solid tumors (5-fluorouracil, irinotecan) and with high-dose chemotherapy coupled with HSCT. Irinotecan-induced diarrhea occurs in two phases: an acute syndrome (within the first 24 hours), which is mediated by acetylcholine and blocked by atropine, followed by a delayed phase, which is inflammatory.

Prevention of radiation and chemotherapy-induced mucositis and diarrhea was outlined in the clinical practice guidelines for the prevention and treatment of cancer therapy-induced oral and gastrointestinal mucositis.[104] The panel suggests the use of 500 mg of sulfasalazine orally twice daily to help reduce the incidence and severity of radiation-induced enteropathy in patients receiving external-beam radiotherapy to the pelvis. Radiation-induced enteropathy with abdominal pain and diarrhea occurs in 75–90 percent of patients receiving external-beam radiotherapy for such common pelvic malignancies as prostate, rectal, or cervical cancer and typically begins in the second or third week of treatment.[105] Oral sucralfate does not prevent acute diarrhea in patients with pelvic malignancies who are undergoing external-beam radiotherapy. Compared with placebo, sucralfate was found to be associated with increased gastrointestinal side effects, including rectal bleeding.[84,106] 5-Aminosalycilic acid (ASA) and the related compounds mesalazine and olsalazine are not generally recommended for the prevention of gastrointestinal mucositis. In randomized clinical studies it has been found that 5-ASA, mesalazine, and olsalazine were of no benefit or caused more diarrhea than placebo in patients receiving pelvic radiotherapy.[107–109]

Loperamide can be used to treat mucositis associated-diarrhea. When loperamide fails to control diarrhea induced by standard-dose or high-dose chemotherapy associated with HSCT recipients, the panel recommends octreotide at a dose of at least 100 μg administered subcutaneously twice daily. Octreotide administration during radiation and for 2 weeks after radiation was complete was associated with a reduction in both acute and subsequent chronic intestinal toxicity.[110,111]

SUMMARY

Constipation is a multidimensional clinical syndrome that requires thorough assessment and high degree of clinical suspicion. The etiology of constipation is multifactorial and involves derangement in neurological as well as endocrine

factors that ultimately affect the bowel motility and function. Assessment of the patient who presents with constipation requires thorough history, including medications, associated symptoms and underlying comorbid conditions. The management of constipation involves eradicating any precipitation factors and treatment of reversible causes. Several medication classes can be used to treat constipation in the palliative care patient, and clinical judgment should be used in individualizing the appropriate treatment algorithm. Novel agents include opioid antagonists such as methylnaltrexone, the 5-HT$_4$ receptor agonist tegaserod, and donepezil.

Diarrhea is also a multidimensional and common clinical syndrome in the palliative care population. Diarrhea is generally divided into acute or chronic, secretory or osmotic diarrhea. Common causes of diarrhea include medications, infections, mucositis, GVHD and AIDS. Assessment of diarrhea requires a thorough history and physical examination as well as targeted laboratory test and radiological investigations. Treatment of diarrhea should focus initially on rehydration and correction of electrolyte abnormalities. Further management should be individualized to treat the underlying etiology of diarrhea as well as general measures such as antidiarrheal agents. Octreotide might be helpful in treatment of refractory diarrhea associated with mucositis, GVHD, and AIDS.

Key learning points

Constipation

- Common and multidimensional problem.

- Can present as atypical symptoms and frequently coexists with diarrhea.

- Requires high degree of clinical suspicion, especially in the delirious patient.

- Needs thorough assessment to determine the underlying cause.

- Multiple laxatives forms and preparations are available.

- Rectally administered medications should be preserved for short-term use only.

Diarrhea

- Common and distressing symptom.

- Diarrhea is a multifactorial and multidimensional syndrome.

- Careful history and examination along with targeted investigations are needed.

- Treatment is divided into general measures such as hydration and antidiarrheal agents and specific treatment for the underlying cause.

Malignant ascites

JEREMY KEEN

INTRODUCTION

A survey of Canadian physicians and their management of malignant ascites produced comments such as 'generally impossible to manage', 'it is a frustrating clinical situation', and 'a practical and effective solution is needed'.[1]

This chapter will aim to review briefly the pathophysiology of ascites formation in malignant disease and then to examine the prevalence, associated symptoms and, in more detail, the reported methods of clinical management. The main frustrations in the management of ascites relate to questions such as the role of diuretic therapy, imaging and the method of paracentesis, each of which remain poorly tested in formal trials. However, new work in the pathophysiology of ascites formation may lead to more individualized and novel methods of management.

INCIDENCE/PREVALENCE

Problems related to the presence of malignant ascites are present in 3.6–6 percent of patients admitted to palliative care units.[2,3] Malignant ascites is most frequently associated with a primary diagnosis of ovarian carcinoma and less frequently with endometrial, breast, colonic, gastric, pancreatic, or unknown primary carcinoma.[4–6] The presence of ascites is usually an indicator of advanced disease and, unfortunately, is detectable at the time of initial diagnosis in over half of the patients in whom it develops.[7] Patients with ovarian cancer, however, do have a longer mean survival from the time of development of ascites compared with those with other malignancies.[6] This may relate to ascites being a complication of relatively early stage ovarian cancer

and its relative sensitivity to cytotoxic chemotherapy. However, in one study of patients with stage III and IV disease receiving chemotherapy, the presence of ascites at the start of treatment reduced 5-year survival from 46 percent to 5 percent.[8] In another study of debulking surgery for patients with stage IV disease the presence of ascites was the only independent predictive factor for early tumor progression.[9] Control of ascites often requires repeated inpatient episodes that, in one recent series of patients with ovarian cancer, showed a rapid increase in frequency over the last year of life to a median of seven admissions in the last 3 months.[10]

SYMPTOMS

Symptoms requiring palliation relate to increased intra-abdominal pressure; discomfort of the abdominal wall, dyspnea, anorexia, early satiety, nausea and vomiting, esophageal reflux, poor mobility, insomnia related to general discomfort, pain in the groins and subcostal regions, and lower limb edema (Table 61.1). Abdominal compartment syndrome with resultant multisystem failure has also been recently

Table 61.1 *Malignant ascites in 1000 consecutive admissions to St Columba's Hospice (January 1, 1997 to October 16, 1999)*

No of admissions with ascites	36 (3.6% of all admissions)
With visceral pain	15 (42% of those with ascites)
With nausea	13 (36%)
With dyspnea	9 (25%)
With pain, nausea, and dyspnea	3 (8%)

reported.[11] Easily overlooked can be the significant negative effect of abdominal distension on body image.

PATHOPHYSIOLOGY

The accumulation of ascites is a result of an imbalance in the normal state of influx and efflux of fluid from the peritoneal cavity. The absorption of radiolabeled serum albumin after intraperitoneal injection has been measured in humans to be 4–5 mL/h.[12] Drainage of peritoneal fluid occurs via the lymphatic system with the open-ended diaphragmatic lymphatics probably providing the major pathway.

A decreased rate of fluid efflux may occur as a result of blockage of the lymphatic system by tumor and this has been shown histologically in association with malignant ascites in animal models.[13] In human subjects, one study demonstrated that 32 of 38 patients with malignant ascites showed no lymphatic absorption of radiolabeled sulfur colloid that had been injected into the peritoneum.[14] Conversely 13 of 14 control subjects with either no ascites or nonmalignant ascites did demonstrate lymphatic uptake of the colloid. It is unlikely that a reduced rate of fluid efflux alone is sufficient to cause the accumulation of massive amounts of ascitic fluid. Indeed, the rate of efflux has been shown to increase as ascites accumulates and intra abdominal pressure increases, possibly up to rates approaching 80 mL/h.[15]

The rate of fluid influx into the peritoneal space may be increased in malignancy as a result of two distinct mechanisms. Each mechanism will result in ascitic fluid of different biochemical properties and may respond to different modes of treatment.

1 Increased hepatic venous pressure, as an anatomical consequence of multiple hepatic metastases, or single large (sometimes benign) tumors causing a Budd–Chiari syndrome.[16] An increase in venous pressure results in both fluid leakage into the peritoneum from the sinusoids and, via an increase in plasma renin concentration, to the retention of salt and water by the kidneys. The ascitic fluid resulting from this mechanism is similar to that seen as a result of cirrhosis and has the properties of a transudate.

2 An exudate of relatively high protein concentration may be produced as a result of increased vascular permeability. Tumor neovasculature is thought to be intrinsically leaky, allowing extravasation of fluid, and from peritoneal tumor deposits would contribute to ascites formation. However it has long been recognized that ascitic fluid also arises from areas of peritoneum unaffected by tumor.[15] Beecham and colleagues observed marked neovascularization of the parietal peritoneum in patients with malignant ascites and ovarian carcinoma.[17]

In rats there appears to be an increase in permeability of peritoneal capillaries after cell-free malignant ascitic fluid is infused intraperitoneally.[7] The permeability of normal microvessels, such as those which line the peritoneal cavity,

can be increased by a variety of cytokines including transforming growth factors α and β, epidermal growth factor and vascular endothelial growth factor (VEGF).[18] Cytokines may be secreted by tumor cells and/or inflammatory monocytes and macrophages.

VEGF is expressed by the normal ovary during phases of follicular development and corpora lutea formation[19] and, in one series, the degree of tumor expression was related to patient survival.[20] VEGF not only increases capillary permeability but also stimulates angiogenesis, facilitating tumor growth and also, potentially, the observed neovascularization of normal peritoneum. Animal experiments have demonstrated a significant relation between the degree of tumor cell expression of VEGF and observed levels of angiogenesis and ascites production.[21,22] VEGF has been detected in high concentrations in malignant as opposed to nonmalignant ascites and associated with metastases from a variety of primary sites.[23–25] The exception has been the observation of high levels of VEGF in ovarian hyperstimulation syndrome, also associated with ascites formation.[26] The potential for therapeutic interventions that target the production or actions of VEGF will be discussed below.

In an individual patient, the relative contribution of these two principal mechanisms of ascitic fluid production can be estimated from the calculation of the serum–ascites albumin gradient. The serum–ascites gradient is calculated by subtracting the albumin concentration of the ascitic fluid from that within a serum specimen obtained on the same day. The gradient correlates with the portal venous pressure and a value of ≥11 g/L is indicative of a transudate and the presence of portal hypertension.[27] This may be of importance in assessing the likelihood of response to diuretic therapy with an aldosterone antagonist.

The formation of chylous ascites is a complication of retroperitoneal tumor spread or its treatment and arises either from damage to lymphatic vessels or through obstruction of lymphatic flow through lymph nodes or the pancreas.

DIAGNOSIS

The diagnosis of the presence of ascites in an individual is usually straightforward, relying on relevant clinical history and examination.[28] Where there is doubt, usually with typical symptoms present in a patient with an obese abdomen or with potential bowel obstruction, ultrasound examination can detect as little as 100 mL of free fluid in the peritoneum.[29] Computed tomography is equally as accurate but not always as easily available as ultrasound. Plain abdominal X-rays may be helpful not only in excluding signs suggestive of bowel obstruction but also positive signs of ascites such as a 'ground glass' appearance, loss of psoas shadows and organ definition, and increased spacing of intestinal loops. Clearly the presence of ascites in a patient with known malignancy cannot always be assumed to be secondary to the presence of intraabdominal tumor, and other causes, such as cirrhosis, congestive heart failure, nephrotic syndrome, tuberculosis,

and pancreatitis which necessitate specific modalities of treatment, must be excluded.

Several tests have been proposed to differentiate malignant from other forms of ascites such as fluid levels of sialic acid,[30] telomerase,[31] β-human chorionic gonadotrophin (β-hCG),[32] fibronectin[33] or, in one study, a combination of total protein, lactate dehydrogenase, tumor necrosis factor α (TNFα), C4, and haptoglobin.[34] Such diagnostic tests may, of course, be helpful in terms of prognosis and possibly decisions regarding antitumor therapy but not as an aid to decisions about other forms of palliative treatment.

MANAGEMENT

The palliation of all symptoms related to malignant disease follows the same broad principles of totally individualized care based on the best evidence available from larger populations. Guidelines and treatment algorithms for management of problems such as ascites have been developed and are helpful[18,35,36] but the temptation is to manipulate every patient into particular protocols or guidelines and lose sight of the individual risk-benefit analyses for certain management plans.

Antitumor therapy

For the relief of symptoms resulting from complications, such as ascites, which reflect tumor activity, specific antitumor therapy should always be considered particularly for patients with ovarian or breast carcinoma. The development of ascites often complicates ovarian carcinoma relatively early in the course of the disease and is, in fact, a presenting feature in a third of all cases.[37] Malik et al.[38*] demonstrated complete clearance or significant reduction of ascites in 46 percent of patients with ovarian cancer treated with systemic cytotoxic chemotherapy. Significant response in ovarian cancer can be observed with second- and even third-line chemotherapy, so should always be considered.

Cytotoxic agents have been given intraperitoneally from as early as the 1950s.[39] There has been a resurgence of interest with the development of a hyperthermic intraperitoneal technique that appears to allow greater tissue penetration and lowers levels of drug resistance.[40] This technique has been particularly used in combination with aggressive cytoreductive surgery.[41*,42*] Chylous ascites, when associated with retroperitoneal lymphoma and a consequent disruption of normal lymphatic drainage pathways, may be expected to show some response to chemotherapy if it be first- or second-line treatment. Radiotherapy may also have a role in the relief of symptoms of lymphoma.

The success of the intracavitary instillation of a variety of agents in the control of malignant pleural effusions has encouraged a similar approach to the treatment of malignant ascites. There have been numerous small trials and case series reporting the use of radioisotopes, cytotoxics,

and more recently, biological agents and response modifiers to reduce ascitic fluid formation (Box 61.1). A recently reported phase II study found that intraperitoneal instillation of the corticosteroid triamcinolone hexacetonide resulted in a significant slowing of ascites accumulation.[43*] The effect was noted particularly in patients with an albumin serum–ascites gradient of <11 g/L. The authors postulated the effect to have been mediated through a steroid-induced reduction of the secretion of VEGF.

Other approaches

Initial preclinical trials with anti-VEGF antibodies, anti-VEGF receptor antibodies, and an inhibitor of VEGF receptor tyrosine kinase activity[44] have been reported to show a reduction in ascites formation in animal models. Transfection of a mutated gene controlling production of VEGF has decreased ascites production in mice.[45] Tumor

necrosis factor has been found to block reaccumulation of ascites in an animal model by inhibiting the expression of VEGF mRNA[46] and an early clinical study suggested benefit from the administration of recombinant TNFα.[47*] Interestingly, a recent report of the use of the anti-TNF agent infliximab showed a reduction in levels of VEGF and angiogenesis in the synovia of patients with psoriatic arthritis.[48*] VEGF expression and associated angiogenesis has also been shown to be reduced by ketoprofen,[49] green tea,[50] and angiotensin-converting enzyme inhibitors.[51]

Matrix metalloproteinases are a group of enzymes that, after loss of normal inhibitory control during tumor development, potentiate tumor invasion and metastases. Early clinical trials of metalloproteinase inhibitors have been reported to have benefit.[52*] Octreotide, the somatostatin analog, has been suggested to have therapeutic potential for a myriad of different disorders and indeed, there has been a small case series demonstrating a reduction in malignant ascites in two of three patients treated.[53*] The physiological mechanism remains unclear although one other report does suggest a benefit to patients with hepatic cirrhosis and ascites.[54]

DIURETIC THERAPY

Diuretic therapy remains the mainstay of the treatment of patients with ascites of nonmalignant origin but the role of diuretics in the management of malignant ascites remains controversial. A recent Canadian survey of the management of malignant ascites reported that whereas 98 percent of physicians used paracentesis, only 61 percent prescribed diuretics and of these a quarter felt them to be ineffective.[1] The rates of response to diuretics in reported studies range from 38 percent[55*] to 86 percent.[56*] Theoretically, it would be expected that those patients who demonstrate raised plasma renin activity and hence increased sodium and water retention would have a greater likelihood of response to diuretics. These patients are those who tend to demonstrate a serum–ascites albumin gradient of ⩾11 g/L where ascites is formed exclusively or principally as a result of intrahepatic metastases. A small study of the use of diuretics in patients with ascites and either massive hepatic metastases, 'peritoneal carcinomatosis' or chylous ascites only demonstrated a reduction in estimated ascitic volume in the group with hepatic metastases.[57] Each of the three patients in the group with hepatic metastases had raised plasma renin levels, a high serum–ascites albumin gradient and responded to the aldosterone antagonist spironolactone. In another small series 13 of 15 patients with malignant ascites responded to spironolactone therapy.[56*] Plasma renin levels were measured in only five patients but were raised in each case. There is a significant body of evidence relating to the optimum use of diuretics in ascites secondary to cirrhosis where 90 percent of patients would be expected to respond to treatment.[27] The majority of trials report the use of spironolactone, but given the long half-life of the parent drug and its

active metabolites there is often a delay of up to 2 weeks before the onset of a significant diuresis. The alternative potassium-sparing diuretic amiloride has a much faster onset of action. Although amiloride is not a classical mineralocorticoid receptor antagonist it appears to interfere with aldosterone effects in model systems.[58] Interestingly, both amiloride and spironolactone interfere with the effect of aldosterone on endothelial cells. Amiloride with a faster onset of action may be a more appropriate choice for patients with relatively short prognoses or in whom early prevention of reaccumulation of ascites after paracentesis is desired. The use of a loading dose of spironolactone has not been reported and the usual regimen comprises a starting dose of 100 mg as a single daily dose increasing at 2- to 3-day intervals to 400 mg if needed and tolerated. Regular girth measurement may be a more appropriate method of monitoring response to treatment than daily weights and accurate fluid balance recordings. The response to diuretics is thought to occur, in part, as a result of a redistribution of fluid within body compartments rather than being wholly dependent on a diuresis.[59] The addition of a loop diuretic may improve the speed of response, with one study reporting a rapid initial response to the use of an intravenous infusion of furosemide during the accumulation period of spironolactone therapy.[60]

The initiation of spironolactone therapy is not infrequently associated with nausea unrelated to electrolyte imbalance. The most debilitating side effects however relate to intravascular volume depletion and include postural hypotension, uremia and, in some cases, renal failure. A proportion of patients will have a concurrent paraneoplastic autonomic neuropathy and resultant postural hypotension[61] that will be augmented by aggressive diuretic therapy. Hepatic encephalopathy is an additional potential complication of aggressive diuresis in patients with limited residual hepatic function. It is important to monitor the response to diuretics and titrate the dose to a maintenance level to lessen the chance of side effects.

PARACENTESIS

Abdominal paracentesis remains the most commonly employed modality of treatment for malignant ascites.[1] It affords quick symptomatic relief in a population that often has a relatively short prognosis and for whom diuretic therapy, if effective, may include a significant lag period and be associated with postural hypotension. The reported techniques and equipment used for the procedure are numerous and particularly amongst palliative care physicians appear to allow full expression of their creativity. The most significant differences in approach relate to the cannula or catheter used for puncturing the peritoneum, the rate of ascitic fluid drainage and the necessity or not of maintenance of intravascular volume with albumin, colloid, or crystalloid infusions.

The large experience of the potential problems associated with paracentesis in patients with hepatic cirrhosis, particularly hypotension and renal impairment, has colored

the approach of many to the procedure in malignant ascites. It is likely that, in the absence of a serum–ascites gradient of ⩾11 g/L, these complications of paracentesis are rare in patients with malignant ascites and fluid may be drained off relatively rapidly with no need to routinely administer intravenous colloid or albumin.[36] Indeed, the use of vacuum bottles allowing several liters to be removed in a matter of minutes, with apparently few complications, has been reported to be particularly useful in the outpatient clinic or even the patient's home.[62]

A study of 35 patients with ascites and ovarian cancer demonstrated a direct correlation between the measured value of intraperitoneal pressure and the severity of symptoms reported.[63*] Another recent study helps to confirm that raised intraabdominal pressure and related symptoms can be significantly relieved after drainage of just a 'few liters' over 2 hours.[64*] The group of patients reported had a mean of 5.3 L drained over 24 hours but no significant improvement in symptom relief (of those assessed) after 24 hours than that noted after only 2 hours of drainage. Indeed only dyspnea (and not discomfort, nausea, or vomiting) was improved significantly more at 72 hours than at 2 hours of ascitic drainage. It would be of interest if perception of body image had been factored into these studies.

Since symptoms can often be relieved by the removal of relatively small volumes of ascites over a short time period this is to be recommended particularly in the very frail with a limited prognosis. One to two liters of fluid can be removed simply over 30 minutes via a plastic intravenous cannula. The insertion of the cannula is simple and, if used in conjunction with local infiltration of local anesthetic, is a relatively comfortable procedure. The removal of such a modest volume is unlikely to cause symptomatic hypovolemia and the use of a small cannula for a short time is highly unlikely to cause local complications.

Clearly, however, ascites is likely to reaccumulate and should a prognosis be more than a few days then frequent recurrent small volume paracenteses will be required. Two case series and two case reports suggest that this can be achieved by a permanent indwelling catheter that allows frequent small volume drainage without the risks of large volume fluid shifts and repeated peritoneal puncture.[65–68] However, most clinicians in this situation would give consideration to the less frequent drainage of larger volumes of ascites through some form of temporary catheter. Peritoneal dialysis, suprapubic urinary bladder and self-retaining nephrostomy catheters have all been described as useful drainage devices.

Stephenson and Gilbert reported the successful introduction of guidelines for paracentesis into an oncology unit that resulted in reductions in the use of ultrasound to mark sites for drainage, the mean duration of drainage and length of inpatient stay.[36] Catheters were left in for no more than 6 hours with up to 5 L being drained and intravenous fluids only considered if patients were hypotensive, dehydrated, or known to have severe renal impairment. Patients without

peripheral edema may be particularly prone to hypovolemia. It is prudent to monitor blood pressure during the procedure with intravascular volume replenished by intravenous infusion of either colloid or plasma protein solution should hypotension develop. A low threshold for the administration of intravenous fluid should be present for patients with high serum–ascitic albumin gradient who do not respond to diuretics and are treated by paracentesis.

After withdrawal of the drain there is a tendency for a continued leakage of fluid from the drain site. This can be lessened by the use of a 'Z-technique' when introducing the catheter through the skin and then the peritoneal wall. Some operators tie a purse-string suture around the site, others place a stoma bag over the site until leakage stops, and one group has suggested the application of enbucrilate adhesive to seal the skin.[69]

Complications of paracentesis relate mainly to the potential for a relatively rapid shift of fluid between body compartments. One study reported two deaths from hypotension in a series of 109 consecutive paracenteses performed on 43 patients.[70] More likely in malignant ascites are procedural complications including bowel perforation, peritonitis, and localized cellulitis surrounding the drain site. One study reported two deaths from peritonitis in a series of 127 paracenteses in 100 patients.[12] Infection was a particular problem in a reported case series of patients with permanent implanted drains.[66] A recent series of 10 patients treated with tunneled Pleurx catheters recorded no catheter-related infections with a mean catheter survival of 70 days.[71] In this series serial serum albumin measurements demonstrated a progressive decline. However, one case report of the use of an implanted peritoneal dialysis catheter reported only one superficial infection in 17 months during which time the patient drained 1000–1500 mL of ascites twice a week.[67] Interestingly, this same patient maintained serum albumin levels despite such prolonged and frequent drainage. However, anecdotal experience would suggest that many patients feel extremely tired for several days following paracentesis and both hyponatremia and a progressive fall in plasma albumin concentration with repeated paracenteses has been recorded in some series. Patients with severely compromised hepatic function are at particular risk of hepatic failure and encephalopathy over the first 24 hours after ascitic drainage.

PERITONEOVENOUS SHUNTING

Potential problems of repeated paracentesis such as intravascular hypovolemia, hypoalbuminemia, infection, and visceral damage, and the expense, discomfort, and inconvenience of repeated hospital admissions have prompted the development of alternative drainage procedures. Peritoneovenous shunting was established in the mid-1970s[72] and remains the most common procedure performed. Shunting of ascitic fluid into the stomach[73] and urinary bladder[74] have also been reported but have presented too many

technical difficulties to be useful at present. There have, however, been no randomized controlled trials to date comparing peritoneovenous shunting with repeated abdominal paracentesis.

Two forms of shunt are commonly used, the original Le Veen and the Denver shunt. Both are designed to allow drainage of ascites into the central venous system, usually via the internal jugular or femoral veins. They may be placed surgically, laparoscopically, or percutaneously with a recent study reporting no difference in performance or complication rate on direct comparison of these methods.[75*] The most common reason for shunt failure is lumen occlusion, which appears to occur more frequently during drainage of malignant ascites than cirrhotic ascites (for the control of which these shunts were first described). The Denver shunt has the theoretical advantage of a manual pumping mechanism to facilitate ascitic flow and clearance of debris. However, no statistical difference in the performance of the two shunts could be found in one comparative study.[76*]

Successful resolution of ascites and symptom relief with the use of peritoneovenous shunts has been reported in between 62 and 87 percent of patients.[55,77–80] One non-controlled study showed, in addition, a maintenance of serum albumin levels in comparison to a progressive decrease in patients treated with repeated paracentesis.[55*] This same study measured 'quality of life' by a single question and visual analog scale and found a nonsignificant trend to an improvement with either paracenteses or shunts and no difference between the two methods of drainage. In the previously quoted survey of physicians' practice only 12 of 44 respondents had used peritoneovenous shunts and seven found them to be useful.[1] The apparent reluctance to use this method is probably a result of the significant complication rate of both the operative procedure and the ongoing operation of the shunt. There is a significant operative mortality in patients with malignant ascites quoted as 13 percent in one of the larger studies,[77] although this is less than that associated with the procedure for ascites associated with cirrhosis. Whereas this high mortality rate is in part to be expected in a frail population undergoing a general anesthetic or even local anesthetic and sedation, specific procedure-related mortality is more commonly a result of pulmonary edema. This complication of a sudden increase in fluid volume within the central venous system can be avoided, in part, by removing a proportion of the ascites (50–70 percent quoted in one study[81]) at operation to reduce pressure and hence flow through the shunt. Many centers would still advocate 'intensive' monitoring with central venous pressure lines for the first 24 hours after surgery.

Overall, complication rates of peritoneovenous shunts of between 25 percent and 50 percent are reported.[55,77,78] The most common complication is shunt occlusion, either, more commonly, from thrombosis of the venous terminal or alternatively from debris in the peritoneal end. Two studies reported alterations in laboratory measurements of coagulation parameters (increased concentration of fibrinogen degradation products) consistent with subclinical

disseminated intervascular coagulation (DIC) in all patients with patent shunts.[82*,76*] Indeed, while such findings may be used as surrogate evidence of shunt patency, frank DIC remains a rare complication. The incidence of DIC is greater in patients with shunts and cirrhotic ascites possibly as a result of a higher concentration of plasminogen-activator-inhibitor in malignant ascites with consequently less potential for fibrinolytic activity.[83] The incidence of postoperative DIC can be reduced by removal of a significant proportion of the ascitic volume intraoperatively.[82] Other complications include thromboembolism, vena caval thrombosis, hepatic encephalopathy, peritonitis, and tumor seeding to the subcutaneous tissues of the anterior abdominal wall.

The potential effects of the introduction of tumor cells from the peritoneal cavity into the circulation via the shunt has been examined in a small series of postmortem examinations.[84] The study reported a variety of observations but concluded that metastases, although occurring in some patients as a direct result of shunt placement, are not clinically significant and do not alter prognosis. This is likely to be related to the short prognosis of the majority of patients who develop malignant ascites. Peritoneovenous shunts are clearly unsuitable for patients with loculated ascites and are not advised if the ascites is hemorrhagic or chylous or the patient has poor cardiac or renal function or a tendency to hepatic encephalopathy. Patients with elevated bilirubin levels have an increased risk of intravascular coagulation with shunting.[85*] Portal hypertension, massive pleural effusion, and coagulation disorders are relative contraindications.[86,87] The presence of malignant cells in ascitic fluid, if no antitumor treatment is to be given, correlates with a poor prognosis (median survival of 26 days compared with 140 days if cytology is negative) and is thus also a relative contraindication.[88] A recently reported series of patients with ascites and nongynecological primary tumors showed the best outcomes of peritoneovenous shunts to occur in patients with normal renal function and tumors of non-gastrointestinal primary origin.[89] The relatively long survival of patients with ascites and gynecological malignancies and the potential savings in terms of repeated hospitalizations for paracentesis makes peritoneovenous shunting an option to be considered in all cases.

SUMMARY

The burden of ascites as a complication of malignancy remains highly significant, particularly for the individual patient but also in terms of the healthcare resources consumed in clinical management. Despite numerous small studies of the intraperitoneal administration of various cytotoxic agents, radioisotopes, and immune/biological response modifiers, management continues to rely upon the use of diuretics, abdominal paracentesis, and peritoneovenous shunts.

There has been recent interest in hyperthermic intra-peritoneal chemotherapy. However, it is from recent studies into the pathophysiology of ascites production in intra-abdominal malignancy that new and specific ways to slow or halt ascitic fluid production are likely to emerge. In particular, the present interest in the role of VEGF in tumor angiogenesis along with the realization of the role of peritoneal neovascularization in ascites production has highlighted a possible new, specific, target for therapy. One would hope, given the high frequency of occurrence of this complication of malignancy, that there would be good levels of recruitment to large, multicenter, trials. However, surprisingly, such trials have not been a feature of research into ascites management to date.

Key learning points

Diuretics

- Most effective if serum–ascites albumin gradient is ≥11 g/L.

- Spironolactone requires high doses and does have a significant lag-time. Amiloride, a faster acting diuretic that interferes with the effects of aldosterone, is potentially useful but has not been assessed in formal trials.

Paracentesis

- Most widely used method of managing malignant ascites.

- Symptomatic relief is often afforded with the removal of a relatively small volume of ascites. For patients with a prognosis measured in days consider using an intravenous cannula to drain ascitic fluid for minimal discomfort.

- For patients with a longer prognosis, larger volumes of ascites may be drained relatively quickly without the necessity of intravenous fluid replacement in all individuals.

- Consider the use of implanted/tunneled catheters with regular drainage performed by the patient at home.

Peritoneovenous shunts

- Associated with significant morbidity but potentially useful if ascites is rapidly recurrent after paracentesis and is diuretic-resistant.

- Most useful for patients with gynecological (principally ovarian) and nongastrointestinal primary tumors and normal renal function.

- Complications can be significantly reduced if the majority of the ascitic volume is removed at the time of shunt insertion.

Jaundice

NATHAN I CHERNY

INTRODUCTION

In the West, jaundice in patients with terminal illness is most commonly encountered in advanced malignancy. In this setting it is generally caused by obstruction of biliary drainage, extensive hepatocellular failure due to liver infiltration by metastases, or a combination of both. Indeed, cancer-related jaundice is one of the most common causes of severe jaundice. In a recent series from Sweden it accounted for 58 of 173 sequential cases.[1] Uncommonly it may be due to comorbid conditions such as infectious or drug-induced hepatitis.

GENERALIZED HEPATIC DYSFUNCTION

Jaundice is a common feature of generalized hepatic dysfunction. Intrahepatic cholestasis involves either diffuse injury to small bile ducts or metabolic derangements in the bile secretory apparatus at the level of the hepatocyte and canaliculus. Intrahepatic cholestasis is typically not associated with ductal dilatation and is not amenable to mechanical interventions.

Cancer

Jaundice caused by primary liver cancer or intrahepatic metastases is a sign of extensive dysfunction and it is usually accompanied by other features of liver failure. Patients commonly display signs of incipient encephalopathy, ascites and have evidence of hypoalbuminemia, and laboratory findings of coagulopathy. Ultrasonic or computed tomography (CT) of the liver usually demonstrates extensive involvement of the liver by metastases. Gastrointestinal malignancies are especially prone to spread to the liver because of its portal venous drainage. Extraabdominal tumors such as bronchogenic carcinoma, breast cancer, and malignant melanoma often spread hematogenously to the liver. Irrespective of the site of origin of the tumor, jaundice associated with extensive tumor infiltration of the liver is a sign of far advanced disease and is an adverse prognostic factor associated with a relatively short anticipated survival.[2–7] The role of antitumor therapies in this setting depends on the likelihood of anticipated response, the performance status of the patient and the goals of care. Among patients with tumors that are sensitive to systemic therapies (chemotherapy, hormonal therapy, tyrosine kinase inhibitors, or immunotherapy) occasionally patients will achieve a remission with adequate restoration of liver function to facilitate resolution of jaundice. In patients with unresponsive disease, liver failure ensues with progression until death.

AIDS cholangiopathy

Acquired immune deficiency syndrome (AIDS) may be associated with a number of biliary tract abnormalities.[8] Patients with advanced immunodeficiency may develop acalculous cholecystitis, focal distal biliary stenosis at the ampulla of Vater, or multifocal stenoses of the biliary tree which resembles primary biliary cirrhosis. AIDS cholangiopathy is strongly associated with colonization of bile with cryptosporidia or microsporidia. Patients typically describe right upper quadrant abdominal pain and often have abnormal liver test results, particularly that of alkaline phosphatase. The diagnosis may be warranted when an ultrasound examination of the gallbladder reveals edema of the wall;

endoscopic retrograde cholangiopancreatography (ERCP) demonstrates strictures and delayed emptying and may permit direct sampling of bile for pathogens. These syndromes are late complications of AIDS which, although rarely fatal of itself, indicate a poor prognosis.

Chronic graft–versus–host disease

After bone marrow transplantation chronic graft-versus-host disease may be associated with an intrahepatic cholestasis syndrome.[9] Liver involvement is characterized by mononuclear infiltration of portal tracts with obliteration of small bile ductules, similar to that seen in primary biliary cirrhosis. Intensive immunosuppression may control the graft-versus-host reaction, and if this fails, ursodeoxycholic acid may improve cholestasis; however, the cholestasis often progresses to biliary cirrhosis.

BILIARY OBSTRUCTION

Tumors may obstruct biliary flow within the liver parenchyma, at the porta hepatis or at any point along the common bile duct until the ampulla of Vater. High obstruction at the ductal confluence may be caused by cholangiocarcinoma, gallbladder carcinoma, intrabiliary metastases or adenopathy in the porta hepatis secondary to a variety of metastases.[10,11] Rarely sarcoid reaction in hilar lymph nodes has been associated with obstructive jaundice in cases of cholangiocarcinoma.[12]

Obstruction of the common bile duct is most commonly caused by cancer of the head of pancreas, ampullary carcinoma, or less commonly cholangiocarcinoma or gallbladder carcinoma.[13–15] Among patients with hepatocellular carcinoma, bile duct thrombosis is one of the main causes for obstructive jaundice, and the reported incidence is 1.2–9 percent.[16] Thrombi can be benign (clots, pus, or sludge), malignant, or a combination of both. Rarely, rupture of hepatocellular carcinoma into the common bile duct may cause a fluctuating obstruction by floating tumor debris.[17] Extensive tumor metastases within the liver may produce intrahepatic cholestasis by obstructing smaller intrahepatic ducts. Diffuse infiltration of malignant cells along hepatic sinusoids with consequent cholestasis also may occur, especially in small cell carcinoma of the lung and in lymphoma.

CLINICAL PRESENTATION

Patients with advanced cholestatic jaundice experience generalized malaise, weakness, easy fatigability, nausea, anorexia, and pruritus. Introduction of bacteria into bile above an obstructing lesion can cause ascending cholangitis; purulent infection of the biliary tree and liver. Contributing factors include high biliary pressure and stasis. In the absence of infection, however, cholestasis may be well tolerated for long periods of time. Chronic biliary obstruction, regardless of cause, eventually leads to cirrhosis with all its complications. The mechanism by which increased bile secretory pressure leads to cirrhosis has not as yet been established, but it can occur with either extrahepatic or intrahepatic obstruction.

INVESTIGATION

Clinical evaluation often yields substantial information in the assessment of the cancer patient who presents with jaundice. It is important to ascertain the tumor type and history to date, if known. The presence of pale stools is strongly suggestive of cholestasis. The abdomen is examined for evidence of hepatomegaly, ascites, and features of portal hypertension. Patients should undergo a brief mental status examination and neurological examination for evidence of asterixis.

Diagnostic evaluation

BLOOD TESTS

The diagnosis of jaundice is confirmed by the finding of hyperbilirubinemia. Serum bilirubin concentration in normal adults is less than 1–1.5 mg/dL and varies directly with bilirubin production and inversely with hepatic bilirubin clearance. A serum bilirubin value of 3 mg/dL is usually required for jaundice or scleral icterus to be clinically evident.

Other initial studies should include a complete blood cell count as well as liver function tests including activities of alkaline phosphatase and alanine and aspartate aminotransferases, albumin and prothrombin time. Both γ-glutamyl transpeptidase and alkaline phosphatase are typically elevated in patients with cholestasis; the combination of an elevated alkaline phosphatase and normal γ-glutamyl transpeptidase suggests that the alkaline phosphatase is from bone. Conversely, an isolated elevation of γ-glutamyl transpeptidase may result from certain drugs (e.g. phenytoin) or alcohol even in the absence of liver disease.

IMAGING STUDIES

Imaging studies help identify the presence or absence of intrahepatic metastases, the presence of intrahepatic or extrahepatic cholestasis and the site of obstruction if present.

Ultrasound

External ultrasound is a noninvasive test that can identify the presence or absence of metastases and determine whether the intrahepatic and/or extrahepatic biliary system is dilated. The sensitivity of abdominal ultrasonography for the detection of biliary obstruction in jaundiced patients ranges

from 55 percent to 91 percent, and the specificity ranges from 82 percent to 95 percent.

Computed tomography

Computed tomography (CT) may be preferred when precise definition of anatomical structure and information about the level of obstruction are desired. Both CT and ultrasound may occasionally fail to identify dilated ducts in obstructed patients with cirrhosis and poorly compliant hepatic parenchyma or in patients with primary sclerosing cholangitis. Conversely, the presence of dilated ducts in a patient who has previously undergone cholecystectomy does not necessarily signify obstruction. To maximize lesion detection CT images should be routinely evaluated by two different window levels. A soft-tissue window (width of 300–500 Hounsfield Units [HU]) is used for the initial examination of the liver; this allows for evaluation of adjacent abdominal architecture. A second setting with a narrow window and a lower width (100–150 HU) is then used to evaluate the liver, since this setting increases contrast differences between the normal liver parenchyma and abnormalities.

Endoscopic retrograde cholangiopancreatography

Endoscopic retrograde cholangiopancreatography (ERCP) is highly accurate in the diagnosis of biliary obstruction, with a sensitivity of 89 percent to 98 percent and specificity of 89 percent to 100 percent. If dilated ducts are identified, it is generally appropriate to visualize the biliary tree directly by ERCP. The procedure involves passing an endoscope into the duodenum, introducing a catheter into the ampulla of Vater, and injecting contrast medium into the distal common bile duct and/or pancreatic duct. Choledochoscopy and bile duct brushing cytology are potentially useful techniques in the differentiating obstructions due to intraluminal mass, infiltrating ductal lesions or extrinsic mass compression applicable before and after duct exploration. Furthermore, if a focal cause for biliary obstruction is identified (e.g. choledocholithiasis, biliary stricture), therapeutic maneuvers to relieve obstruction (e.g. sphincterotomy, stone extraction, dilation, stent placement) can be performed during the procedure. It is not a benign procedure and significant adverse events occur in 0.5–2 percent of patients. Risks include respiratory depression, aspiration, bleeding, perforation, cholangitis, and pancreatitis.

Percutaneous transhepatic cholangiography

Percutaneous transhepatic cholangiography (PTC) involves percutaneous passage of a needle through the hepatic parenchyma and injection of contrast medium into the proximal biliary tree through a peripheral bile duct. It is often preferred when the level of biliary obstruction is proximal to the common hepatic duct or when altered anatomy precludes ERCP. When, however, bile ducts are not dilated, this approach may be technically difficult and it may be unsuccessful in up to 25 percent of attempts. As with ERCP, interventional procedures, such as balloon dilation and stent placement can be performed at the time of PTC.

Magnetic resonance cholangiopancreatography

Magnetic resonance cholangiopancreatography (MRCP) is a technical refinement of standard magnetic resonance imaging that permits rapid clear-cut delineation of the biliary tree without the requirement of intravenous contrast agents. This approach is superior to ERCP in interpreting the cause and depicting the anatomical extent of the perihilar obstructive jaundice, and is particularly distinctive in cases associated with tight biliary stenosis and along segmental biliary stricture.[18,19] Its greatest usefulness may be in circumstances in which the patient is thought to be at high risk for complications from ERCP or PTC. In patients with hilar tumor MRCP can be used to determine the dominant ductal drainage for the liver segments for subsequent stent placement.[20]

Endoscopic ultrasonography

Endoscopic ultrasound is a valuable imaging test for diagnosing and staging pancreatic cancer. In skilled hands it is more accurate than spiral CT scanning[21,22] or MRCP.[23] This approach is particularly useful when no visible mass is observed on routine imaging studies. In this setting it has both a high positive and negative predictive value.[21] It is also particularly useful in the diagnosis of cancer of papilla of Vater.[22]

MANAGEMENT OF BILIARY OBSTRUCTION

Symptomatic management

Biliary obstruction that is asymptomatic in a patient who has a short life expectancy does not require intervention. In many cases, however, jaundice is associated with symptoms of itch, anorexia, and fatigue. Indeed studies that have evaluated the quality of life of patients before and after relief of biliary obstruction highlight improvements in itch, anorexia, fatigue, and global wellbeing.[24]

Surgical management

Historically, the approach to obstructive jaundice has been biliary bypass surgery. In an extensive review of the literature from 1965 to 1980, Sarr and Cameron explored the role of surgical palliation for patients with unresectable pancreas cancer.[25*] In this collected series of over 8000 patients, in comparison with those who underwent abdominal exploration alone, patients who underwent biliary bypass had a lower operative mortality (19 percent vs. 26 percent) and longer survival (5.4 months vs. 3.5 months). Whether these results reflect therapeutic benefit or simply selection of better-risk patients for the bigger operation remains speculative. Nonetheless, in this review, 56–85 percent of patients who underwent biliary bypass surgery had some degree of clinical benefit; most notably relief of pruritus, improvement

in hepatic function, and return of appetite. In modern studies, the mortality associated with bypass surgery is approximately 1–3 percent.[26–30]

The preferred surgical bypass procedure remains a matter of debate. Bypass procedures include cholecystojejunostomy, choledochoduodenostomy, and a choledocho/hepaticoduodenostomy with jejunal Roux-en-Y reconstruction. Some surgeons have advocated cholecystoenterostomy because it can be performed quickly, however, recurrent jaundice is more common due to obstruction at the cystic duct. A major retrospective cohort study of 1919 patients confirmed that patients who initially had a gallbladder bypass were more likely to require further surgery and that this approach was associated with a shorter median survival was longer following bile duct bypass.[31**]

Whereas surgery of this sort had previously required extensive laparotomy, in some centers bypass surgery can be achieved with minimally invasive laparoscopic techniques.[30,32]

PERCUTANEOUS DRAINAGE

Percutaneous drainage can be achieved with an internal–external catheter that can drain either externally or internally.[33–35] These transhepatic catheters are designed with side-holes both above and below the level of obstruction in the biliary tree; the tip of the catheter resides within the bowel, so that bile drains through the catheter across the obstruction and out of the side-holes into the duodenum. Even when biliary obstruction is complete, in many instances an interventional radiologist can negotiate through a stricture with a combination of guidewires and catheters under fluoroscopic guidance. With placement of an internally draining catheter, nutrition is improved, and metabolic imbalance no longer becomes an issue. Transhepatic catheters are associated with complications of obstruction, leakage, and infection.[36] Usually transhepatic biliary catheters are routinely changed every 2 months to avoid any chance of obstruction.

Recently, some authors have suggested that there may be benefit in bile replacement following external drainage. They hypothesize that impaired intestinal barrier function does not recover by external drainage without bile replacement. In a pilot experience with 25 patients bile replacement through a nasoduodenal tube was able to restore the intestinal barrier and that this was primarily due to repair of physical damage to the intestinal mucosa.[37]

PERCUTANEOUS BILIARY STENT

The percutaneous approach to biliary cannulation can be used to inset expandable metallic stents. A comparison of direct stent insertion with an approach of delayed stenting after initial drainage and dilatation demonstrated substantially less morbidity with the more direct approach.[38] In a recent series of 224 patients, there were no procedure-related deaths and the clinical success rate within the first 30 days was 88 percent.[39]

ENDOSCOPIC BILIARY STENT

Endoscopic placement of biliary endoprostheses overcomes the stigma and care requirement of an external drain. A 1990 review of the extensive literature describing the results of this technique found that stent placement was successful in 91 percent of attempts.[40] Procedure-related mortality was 1.3 percent, and the overall incidence of cholangitis, fever, or hemorrhage was 20 percent. Median time before occlusion was 4.6 months. Median survival of patients with stents was 4.9 months. Percutaneous insertion can be employed successfully in the majority of the 10–15 percent of patients who fail attempts at endoscopic stenting.

There are data to suggest that this is a safer approach than the percutaneous route. In a small, randomized trial which included patients with distal as well as proximal malignant biliary obstruction, endoscopic stent insertion was associated with a lower frequency of complications than percutaneous insertion.[41] Although both techniques resulted in cholangitis in approximately 20 percent of patients, the percutaneous technique was associated with a higher 30-day mortality, attributed to complications resulting from hemorrhage or leakage of bile into peritoneal cavity or pleural space. In addition, the percutaneous technique resulted in discomfort at the insertion site, not experienced by the patients who had endoscopic insertion. In a study comparing the course, costs and outcome of surgical bypass and metallic stents in patients with unresectable pancreatic cancer, both procedures had high rates of procedural success and there was no difference in survival.[42***] Biliary bypass without gastric bypass was sometimes complicated by delayed duodenal obstruction. Metallic stent insertion was associated with shorter hospitalization and lower cost, but a higher prevalence of late complications. In particular, stent occlusion tended to occur in patients with uncovered metallic stents. This study concluded that insertion of covered metallic stents is preferable to surgical bypass, but, in patients with a relatively long expected prognosis, or in those with existing duodenal obstruction, biliary bypass with gastrojejunostomy may provide an advantage.[42]

Combined percutaneous-endoscopic procedures have been described for patients in whom endoscopic insertion is unsuccessful.[43–45] In this approach, a guidewire and fine-bore catheter is introduced percutaneously, and the biliary tree is decompressed. The guidewire is advanced through the obstruction, and into the duodenum. An endoscopist then introduces a stent over the guidewire. Once adequate internal drainage has been achieved, the percutaneously placed guidewire and catheter may be withdrawn.

Multiple prospective controlled trials have compared endoscopic polyethylene or Teflon stent placement with surgical bypass in patients with malignant extrahepatic biliary obstruction.[46***] The overwhelming majority of patients in

the three trials had pancreas cancer, although some included patients with bile duct cancer as well. The results of all three studies are quite consistent. The two methods were equally successful in alleviating jaundice, and there was no difference in overall survival. Patients who underwent endoscopic stent placement had a shorter initial hospital stay, but a greater frequency of late complications. Occlusion of plastic endoprostheses generally is managed with repeat endoscopy and stent replacement. Exchange of endoprostheses may be done as long as duodenal intubation with an adequate endoscope remains possible, but does require a second endoscopy. Early prophylactic stent exchange at 3–6 months has been advocated, but an optimal time has not been defined. In patients whose stents have occluded but who are not candidates for endoscopic replacement, percutaneous stenting may be palliative.

Stent blockage is a major problem with Teflon catheters. Obstruction has been attributed to adherence of bacteria to the wall of the stent, resulting in the production of a biofilm that traps debris and ultimately occludes the lumen.[47] Self-expanding metal prostheses were introduced to overcome the problem of occlusion. The most commonly used device, the Wallstent®, consists of a stainless steel mesh that is mounted on a 9 Fr delivery catheter. These metal stents have a larger diameter (8–10 mm) and are not removable. They are introduced into the bile duct enclosed in a sheath which is then retracted, enabling the stent to expand against the wall of the bile duct. However, metal stents also are permanent, and much more expensive than plastic.

There have been four prospective trials in which patients with biliary obstruction were randomized to stenting with either polyethylene or metal stents[47–49,50***] and one trial in which patients were randomized to percutaneous transhepatic stenting with either plastic or metal stents.[51***] The results are quite consistent. Successful stent placement is seen in at least 95 percent of patients, and is independent of stent material. There is no impact of type of stent on survival, but the duration of patency is greater for metal stents, resulting in fewer episodes of cholangitis, and fewer total days in the hospital. In contrast to plastic stents, when metal stents become occluded, the occlusion is usually the result of tumor growth invading into the lumen around the wire that makes up the wall of the stent. These occlusions are best managed by insertion of a plastic stent through the occluded metal stent.[52]

Special case: obstruction at the bifurcation of the hepatic ducts

Patients with biliary obstruction at the bifurcation of the hepatic ducts present a difficult challenge and there is much controversy as to the importance of establishing drainage of both liver lobes in malignant hilar obstruction. Data from a retrospective review of 141 patients indicated that the longest survival was achieved with bilateral drainage, and the worst survival in those with obstruction of both lobes but drainage of only one.[53*]

Recently one group has described an approach using MRCP to determine the dominant ductal drainage for the liver segments, thus directing stent placement. In a series of 35 patients who underwent MRCP with subsequent unilateral stent deployment at ERCP jaundice resolved in 86 percent.[20]

SYMPTOMATIC MANAGEMENT OF CHOLESTATIC PRURITUS

Pruritus is the major symptom of obstructive jaundice.[54,55] It may occur with any type of liver disease but is primarily associated with acute or chronic cholestasis. It has been estimated to occur in 20–50 percent of jaundiced patients. The intensity of the pruritus varies from mild to severe. It can be persistent or intermittent and it may be generalized or localized to specific parts of the body: commonly the soles of the feet and palms of the hands.

The pathogenesis of cholestatic jaundice is complex and multifactorial.[56] Indirect evidence suggests that it may be caused, at least in part by dermal itch receptor stimulation by a bile acid, a bile acid derivative, or some other substance that undergoes enterohepatic circulation. A central mechanism, associated with altered neurotransmission in the brain has also been imputed based on observations that opioid and serotonin antagonists reduce scratching activity in cholestatic patients.

The management of pruritus in this setting is often difficult and it should involve specific antipruritic therapies along with general supportive measures.

Anion exchange resins

Anion exchange resins, which are given by mouth, bind bile acids and other anionic compounds in the intestine, resulting in increased fecal excretion of bound substances. Thus they decrease the enterohepatic circulation of bile acids. The most widely administered treatment for the pruritus of cholestasis has been the basic anion exchange resin cholestyramine but other resins, colestipol and colesevelam, are also available.[56*] The maximum recommended dose of cholestyramine is 16 g/24 h. The resins should be taken at least 2 hours apart from other medications to ensure adequate absorption of the latter. Cholestyramine is not very palatable. The most common side effects of resin treatment are bloating and constipation. It is prudent to monitor the prothrombin time during prolonged administration of these agents, because treatment may result in malabsorption of fat-soluble vitamins.

Antihistamines

Despite common application in this setting, antihistamines are rarely effective in this setting.[56]

Phenobarbital

Phenobarbital may relieve pruritus in individual patients, but its utility has not been supported in controlled trials.[57] It has sedative effects as well as effects on the liver. This drug nonspecifically increases the activity of the hepatic microsomal enzyme system by enzyme induction and it is hypothesized that it may act by enhancing the excretion of pruritogens.

Rifampicin

Rifampicin is another microsomal enzyme inducer. There are conflicting data regarding the efficacy of rifampicin. When effective, the onset of effect is relatively rapid. The usual dose is 300–600 mg/day in divided oral doses.[58–60] In a double blind, crossover, randomized short-term study that included nine patients with primary biliary cirrhosis, rifampicin therapy at doses of 150 mg orally twice a day or 150 mg three times a day in patients with serum bilirubin less than or higher than 3 mg/dL, respectively, was reported to be associated with amelioration of the pruritus of cholestasis as assessed by a visual analog scale of the perception of pruritus.[61***] The long-term administration of rifampicin for refractory pruritus is associated with occasional hepatotoxicity.[60]

Opioid antagonists

The observation that intravenous naloxone can reduce cholestatic pruritus[62,63] prompted trials of therapy with orally administered antagonists nalmefene and naltrexone. In an open label study of nalmefene 2 mg orally twice was associated with a significant subjective amelioration of pruritus, as measured by a visual analog scale of pruritus, and a significant decrease in scratching activity.[64***] Naltrexone at doses of 50 mg per day has been studied in a placebo controlled study of patients with the pruritus of cholestasis without apparent toxicity and with subjective relief of their pruritus as assessed subjectively.[65***] In a small study, some patients achieved relief with buprenorphine.[66]

5–Hydroxytryptamine 3 antagonists

Very limited data from two small placebo-controlled studies support a trial of the 5-HT$_3$ antagonist ondansetron in the management of cholestatic pruritis.[67,68]

Propofol

Propofol, at subhypnotic doses of 15 mg, was reported to ameliorate the cholestatic pruritus in a small placebo-controlled trial.[69,70]

Other measures

In addition to these specific therapies, simple measures have been recommended. Such measures include the use of emollients and mild fragrance-free soaps (e.g. fragrance-free Dove, Basis, Aveeno), less frequent bathing, wearing light clothing, and frequent cutting of fingernails.

Key learning points

- Jaundice in patients with terminal illness is most commonly encountered in the setting of advanced malignancy.

- Jaundice caused by primary liver cancer or intrahepatic metastases is a sign of extensive dysfunction and it is usually accompanied by other features of liver failure.

- Imaging studies help identify the presence or absence of intrahepatic metastases, the presence of intrahepatic or extrahepatic cholestasis and the site of obstruction if present.

- Management of biliary obstruction may be symptomatic or surgical.

- Several treatment options exist for the symptomatic management of cholestatic juandice.

Bowel obstruction

CARLA RIPAMONTI

FREQUENCY AND PATHOPHYSIOLOGY OF BOWEL OBSTRUCTION

Bowel obstruction is defined as any process preventing the movement of bowel contents. Bowel obstruction may be a mode of presentation of intraabdominal and pelvic malignancy or a feature of recurrent disease following anticancer therapy. Malignant bowel obstruction (MBO) is well recognized in gynecological patients with advanced cancer. Retrospective and autopsy studies found the frequency of MBO to be approximately 5–51 percent of patients with gynecological malignancy.[1–5,6***] It is particularly frequent in patients with ovarian cancer where it is the most frequent cause of death.[3,4,6***] Patients with stage III and IV ovarian cancer and those with high-grade lesions are at higher risk for MBO as compared with patients with lower stage or low-grade tumors.[7,8] The reported frequency of bowel obstruction ranges from 4 percent to 24 percent in colorectal cancer.

Bowel obstruction can be partial or complete, single or multiple. Benign causes are reported in nearly half the patients with colorectal cancer and in approximately 6 percent of patients with gynecological cancer. The small bowel is more commonly involved than the large bowel (61 percent vs. 33 percent, respectively) and both are involved in over 20 percent of the patients.[1–5]

Several pathophysiological mechanisms may be involved in the onset of bowel obstruction and there is variability in both presentation and etiology (Box 63.1). Any mechanism limiting or preventing the propulsion of the intestinal content from passing distally induces a cascade of events producing definitive bowel obstruction (Fig. 63.1).

Box 63.1 Pathophysiological mechanisms of MBO

Mechanical obstruction is caused by:

- extrinsic occlusion of the lumen due to an enlargement of the primary tumor or recurrence, mesenteric and omental masses, abdominal or pelvic adhesions (caused either by the tumor or secondary to surgery), postirradiation fibrosis

- intraluminal occlusion of the lumen due to neoplastic mass or annular tumoral dissemination

- intramural occlusion of the lumen due to intestinal linitis plastica

Functional obstruction (or adynamic ileus) is caused by intestinal motility disorders consequent to:

- tumor infiltration of the mesentery or bowel muscle and nerves (carcinomatosis), malignant involvement of the coeliac plexus

- paraneoplastic neuropathy in patients with lung cancer

- chronic intestinal pseudoobstruction (CIP) mainly due to diabetes mellitus, previous gastric surgery and other neurological disorders. These factors may affect extrinsic neural control to viscera. Vagal dysfunction is confirmed in a majority of patients with CIP associated with diabetes or neurological disorders

- paraneoplastic pseudoobstruction

Other causes such as inflammatory edema, fecal impaction, constipating drugs (such as opioids, anticholinergics, etc.), and dehydration, are likely to contribute to the development of bowel obstruction or to worsen the clinical picture.

At least three factors occur in bowel obstruction

1 Accumulation of gastric, pancreatic, and biliary secretions that are a potent stimulus for further intestinal secretions
2 Decreased absorption of water and sodium from the intestinal lumen.
3 Increased secretion of water and sodium into the lumen as distension increases[9] (see Fig. 63.1).

As a result of the breakdown of the sequence and reabsorption in the gastrointestinal tract, there is a loss of fluids and electrolytes. The pancreatic, biliary, and gastrointestinal secretions accumulate in the bowel above the obstruction,

and the volume of secretions tends to increase following intestinal distension and the consequent increase in the surface area, thus producing a vicious circle of secretion-distension-secretion.[9] Depletion of water and salt in the lumen is considered the most important 'toxic factor' in bowel obstruction.

SIGNS AND SYMPTOMS: ASSESSMENT AND DIFFERENTIAL DIAGNOSIS

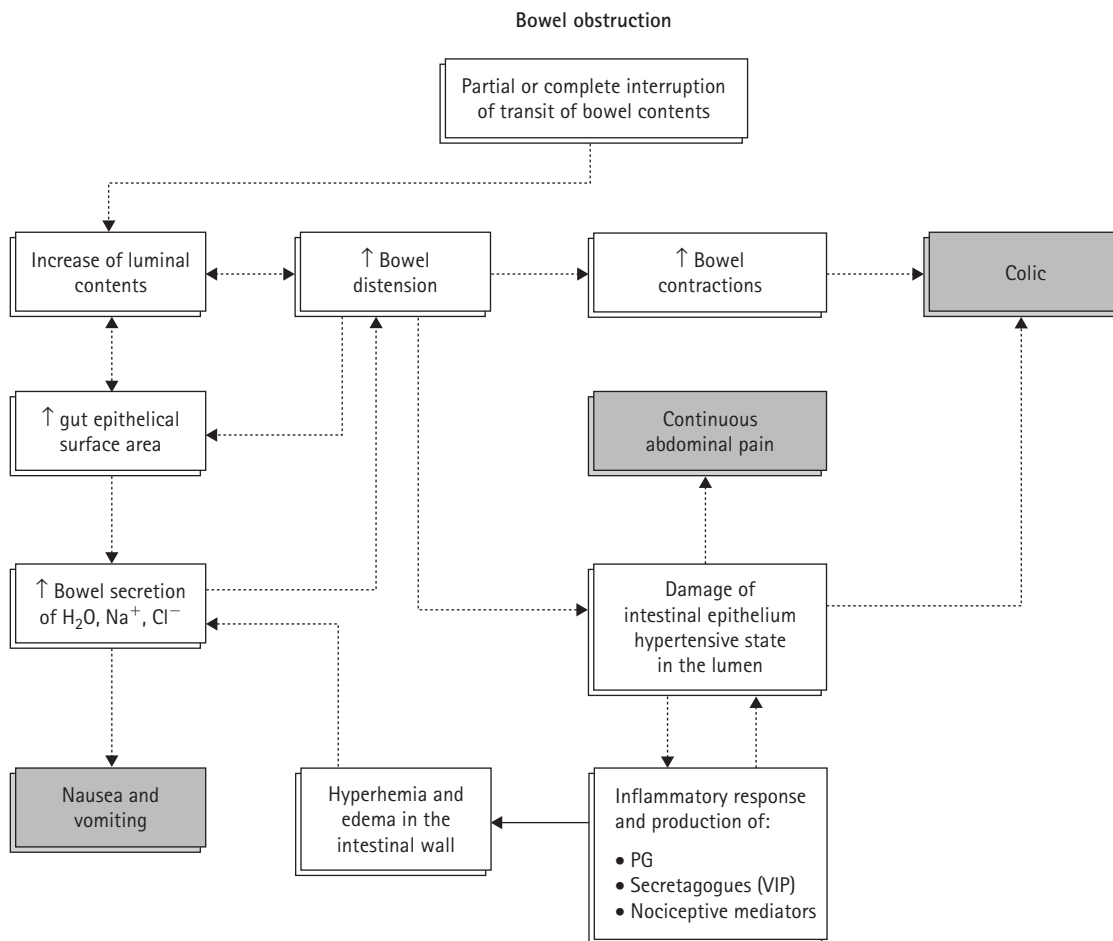
In patients with cancer, compression of the bowel lumen develops slowly and often remains partial. The initial symptoms are frequently abdominal cramps, nausea, vomiting, and abdominal distension, which usually present periodically and resolve spontaneously. These episodes are frequently followed by passage of gas or loose stools. Gastrointestinal symptoms caused by the sequence of distension-secretion-motor activity of the obstructed bowel (Fig. 63.1) occur in different combinations and intensity depending on the site


Figure 63.1 *Bowel obstruction. Distension-secretion-motor activity causing gastrointestinal symptoms. PG, prostaglandins; VIP, vasoactive intestinal polypeptide.*

Table 63.1 *Common symptoms in cancer patients with malignant bowel obstruction*

Vomiting	Intermittent or continuous	Develops early and in large amounts in gastric, duodenum and small bowel obstruction and develops later in large bowel obstruction	Biliary vomiting is almost odorless and indicates an obstruction in the upper part of the abdomen. The presence of bad smelling and fecaloid vomiting can be the first sign of an ileal or colic obstruction
Nausea	Intermittent or continuous		
Colicky pain	Variable intensity and localization due to distension proximal to the obstruction; secondary to gas and fluid accumulation, most of which are produced by the gut	If it is intense, periumbilical and occurring at brief intervals, may be an indication of an obstruction at the jejunum-ileal level. In large bowel obstruction the pain is less intense, deeper, occurring at longer intervals and spreads toward the colon wall	An overall acute pain which begins intensely and becomes stronger, or a pain which is specifically localized, may be a symptom of a perforation or an ileal or colic strangulation. A pain which increases with palpation may be due to peritoneal irritation or the beginning of a perforation
Continuous pain	Variable intensity and localization	It is due to abdominal distension, tumor mass, tumor mass growth compressing the intestine, intestinal distension and/or hepatomegaly	
Dry mouth		It is due to severe dehydration, metabolic alterations but above all it is due to the use of drugs with anticholinergic properties	
Constipation	Intermittent or complete	In case of complete obstruction there is no evacuation of feces and no flatus	In case of partial obstruction the symptom is intermittent
Overflow (paradoxical) diarrhea		It is the result of bacterial liquefaction of the fecal material blocked in the sigma or rectum	

Table 63.2 *Radiologic investigations*

Plain radiography	Abdominal radiography taken in supine and standing position to document the dilated loops of bowel, air–fluid interfaces or both
Contrast radiography	Helps to evaluate dysmotility, partial obstruction and to define the site and extent of obstruction Barium can interfere with subsequent endoscopic studies or cause severe impaction or aspiration pneumonia Gastrografin (diatrizoate meglumine) is useful in such cases; moreover, it often provides excellent visualization of proximal obstructions and can reduce luminal edema and help resolve partial obstructions. Contrast studies of the stomach, gastric outlet and small bowel can distinguish obstructions from metastases, radiation injury or adhesions The diagnosis of a motility disorder is revealed by the slow passage of barium through undilated bowel with no demonstrable point of obstruction Retrograde, transrectal contrast studies (barium or water-soluble medium enema) can rule out and diagnose isolated or concomitant obstruction of the large bowel
Computed tomography	Abdominal CT is useful to evaluate the global extent of disease, to perform staging and to assist in the choice of surgical, endoscopic or simple pharmacological palliative intervention for the management of the obstruction
Endoscopy	Once a site of obstruction is identified in either the gastric outlet or colon, endoscopic studies may be helpful to evaluate the exact cause of the obstruction. This is particularly important when endoscopic treatment approaches, such as stent placement, are considered

of obstruction and tend to worsen (Table 63.1). Vomiting can be assessed in terms of numbers, volume, and overall duration. Other symptoms such as nausea, pain (both colicky and/or continuous), xerostomia, somnolence, dyspnea, even sensation of hunger can be present and can be evaluated with visual analog, numerical, or verbal scales. The assessment of patients with suspected MBO should consider:

- Other causes of nausea, vomiting and constipation
- Metabolic abnormalities
- Type and dosages of drugs
- Nutritional and hydration status
- Bowel movements and the presence of overflow diarrhea
- Presence of abdominal fecal masses, distension to all the abdomen or above the obstacle, ascites as well as painful sites
- Presence of feces in the rectal ampulla (rectal exploration)

From the metabolic point of view, dehydration, electrolyte losses and disorders of acid–base balance are frequently associated with bowel obstruction. The hypovolemic state may induce a functional renal failure due to a decrease of the renal flow and, as a consequence, of the glomerular filtration. Different respiratory patterns may be observed, depending on the level of obstruction. Whereas the level is high, metabolic alkalosis, hypochloremia and hypokalemia, due to a prevalent loss of gastric secretions, determine hypoventilation. If the level of obstruction is distal, the secondary deficit is global including chlorum, sodium, potassium, bicarbonates owning to intestinal stasis of biliary, pancreatic, intestinal as well as gastric secretions. The dehydration reflects the accumulation of fluids and electrolytes in the third space. With a low level of obstruction, including ileum or colon, acidosis prevails due to ischemic lesions or septic complications.

The diagnosis of intestinal obstruction is established or suspected on clinical grounds and usually confirmed with abdominal radiographs demonstrating air–fluid levels. Table 63.2 shows the possible radiological investigations that might be performed in patients with symptoms and signs of bowel obstruction. However, there is no point in proceeding with any of these if the patient is too ill or has declined surgery.

MANAGEMENT OF BOWEL OBSTRUCTION: THERAPEUTIC APPROACHES

The management of patients with malignant bowel obstruction is one of the greatest challenges for physicians who care for patients with cancer. This management has to be highly individualized according to the stage of the illness, the prognosis, the possibility of further antineoplastic therapies, and the general status and choices of the patients.

In the face of a clearly incurable situation, significant patient discomfort and suffering must be balanced with the need to simplify the care of those patients with a short time to live. A multidisciplinary working group of the European Association for Palliative Care reviewed issues regarding bowel obstruction, and published clinical practice recommendations for the management of MBO in patients with end-stage cancer.[5]

Surgery

Surgery remains the primary treatment in these patients. Palliative surgery is usually considered when relief from symptoms due to bowel obstruction is not obtained within 48–72 hours after decompression with a nasogastric tube has been implemented.[4] In advanced cancer patients, however, guidelines for conservative vs. surgical treatment are still unresolved. Published data show that, in advanced cancer, the operative mortality is 30–40 percent and complication rates vary from 27 percent to 90 percent. The type of obstruction (partial vs. complete) and the method of surgical treatment (bypass vs. resection and reanastomosis) has no significant effect on the outcome. As recently published results are no better than those published in the past, improvements in surgical techniques and perioperative care appear not to influence the outcome. Not all patients are fit for surgery. According to different authors, the rate of inoperable patients ranges from 6.2 percent to 50 percent.[1–5]

Several authors have emphasized that prognostic criteria are needed to help doctors select patients who are likely to benefit from surgical intervention. The available data suggesting the poor prognostic factors are shown in Box 63.2.[1–5] Surgical palliation in advanced cancer patients is a complex issue, and the decision to proceed with surgery must be carefully evaluated for each individual patient.

Box 63.2 Prognostic indicators of low likelihood of clinical benefit from surgery of MBO

- Obstruction secondary to cancer

- Intestinal motility problems due to diffuse intraperitoneal carcinomatosis*

- Widespread tumor†

- Patients over 63 years in association with cachexia†

- Ascites requiring frequent paracentesis*

- Low serum albumin level and low serum prealbumin level

- Previous radiotherapy of the abdomen or pelvis†

- Poor nutritional status†

- Diffuse palpable intraabdominal masses*

- Liver metastases, distant metastases, pleural effusion or pulmonary metastases producing dyspnea†

- Multiple partial bowel obstruction with prolonged passage time on radiograph examination*

- Elevated blood urea nitrogen levels, elevated alkaline phosphatase levels, advanced tumor stage, short diagnosis to obstruction interval†

- Poor performance status†

- A recent laparotomy which demonstrated that further corrective surgery was not possible*

- Previous abdominal surgery which showed diffuse metastatic cancer*

- Involvement of proximal stomach*

- Extraabdominal metastases producing symptoms difficult to control (e.g. dyspnea)†

Data from retrospective studies. * Absolute and † relative contraindications to surgery

Modified from Ripamonti *et al.* Clinical-practice recommendations for the management of bowel obstruction in patients with end-stage cancer. *Support Care Cancer* 2001; **19**: 23–34.[5]

Venting procedures

In inoperable patients, the usual treatment consists of drainage using a **nasogastric suction associated with parenteral hydration**. This treatment decompresses the stomach and/or intestine, and corrects fluid and electrolyte imbalance before surgery, or while a decision is being made. The tube often becomes occluded and requires flushing and/or replacement. During long-term drainage, a nasogastric tube can interfere with coughing for clearing pulmonary secretions and may be associated with nasal cartilage erosion, otitis media, aspiration pneumonia, esophagitis, and bleeding. This treatment can also create discomfort in patients who are already distressed by previous anticancer and surgical therapies. Long-term use of nasogastric tube should only be considered when pharmacological therapy for symptom control is ineffective or when gastrostomy cannot be carried out.[1–3]

The **percutaneous endoscopically placed gastrostomy (PEG) tube**, initially developed for enteral feeding, has been recently used effectively for intractable vomiting due to obstruction of the upper gastrointestinal tract.[10,11] In PEG, a tube is inserted at the stomach, through the abdominal wall, under endoscopic, ultrasonographic, or fluoroscopic guidance.[11,12] This procedure can easily conducted under mild sedation and local anesthetics. Gastrostomy drainage allows for nausea and vomiting control in 83–93 percent of patients.[13–16] It is a much more acceptable method for longer term decompression of an obstructed gastrointestinal tract than a nasogastric tube. Intermittent decompression allows patients to continue to eat and drink small quantities and to maintain an active lifestyle without the physical and psychological distress associated with the

presence of the nasogastric tube. A decompressive gastrostomy must be avoided in patients with portal hypertension, large volume of ascites, and those at risk for systemic bleeding. Relative contraindications include previous multiple abdominal surgeries, carcinomatosis, adhesions, colostomies, and abdominal ulcers that are open and infected. Occasionally a decompressive gastrostomy can end up being useful for feeding if the patient is able to resume intestinal transit.[17] Decompressive tube esophagostomy is an under-utilized, minimally invasive alternative in patients with complete, irreversible upper gastrointestinal tract obstruction.[18]

Self-expanding metallic stents

In recent years there has been a growing experience in the use of expandable metallic stents in the management of bowel obstructions in the gastric outlet, proximal small bowel and colon. The goal is to convert an emergent procedure to a safer, elective operation and one that can be curative.[19]

These stents may be useful in the management of patients with advanced metastatic disease, who are at poor surgical risk or in those presenting with large bowel obstruction in which decompression by a stent allows treatment of coexisting medical complications to enable surgery to be carried out at a later date, after staging of the disease and optimal colonic preparation.[20] This technique can be palliative or can serve as an adjunct to curative resection.

Malignant duodenal obstruction is most commonly secondary to neoplastic invasion but more frequently due to extrinsic compression from carcinoma of the head of the pancreas or from compression by lymphadenopathy. In patients unfit for general anesthesia and/or surgery or in patients unfit for laparoscopic drainage procedure such as gastroenterostomy because of ascites and/or peritoneal metastases, internal stenting of the lesion may be indicated. Flexible, self-expanding metallic stents may be inserted using radiological or endoscopic techniques. The major limiting factor using the endoscopic technique is the inability to pass the endoscope through the stricture. Several authors report relief of malignant gastric and/or duodenal obstruction in the majority of patients treated by peroral[21–23] or percutaneous insertion of a metal stent.[24–26] Most patients had an immediate benefit and were able to eat small amounts of food without vomiting. No recurrence of gastric outlet obstruction was noted in the follow-up period of 1–5 months.[23–25]

As with any procedure, complications are possible. The major complications reported were gastric ulceration, bowel perforation after balloon dilatation of the stent and stent migration. Contraindications for the position of self-expanding stent are the presence of multiple stenoses, peritoneal carcinomatosis located distally in the small bowel that may be undiagnosed at the preprocedural opacification because of the severity of the duodenal stenosis. Failure to relieve the obstruction may be secondary to an inability to cross the stricture, incomplete opening of the stent or stent malposition that fails to traverse the entire stricture. In this case it is necessary to apply additional stents across the remaining obstruction.

Seventy percent of colon and rectal cancers are left sided and are considered accessible to stent placement.[19] Positive results have been reported by various authors after insertion of colonic stents in colorectal obstruction.[19,20,27–29] Complications, which potentially include perforation, bleeding and stent migration, have been reported in less than 3 percent of cases[19, 27–29] and only in few patients treated with self-expanding mesh stents was there a recurrent obstruction due to tumor ingrowth.[30] Temporary incontinence may be observed.[30]

Normal bowel contractions could cause stent migration especially if the stent diameter is too small, if the stent length is too short, or if the stent is placed too distal in the lesion. The migration into the rectal ampulla can result in obstruction and in painful spasm. Canon et al.[31] stated that before a patient is selected as a candidate for having an expandable metal stent placed in the colon, three factors were determined:

- location of the lesion within the colon
- length of the tumor
- presence or absence of a synchronous carcinoma.

Thus, meticulous evaluation of the digestive tract downstream is mandatory to avoid pointless stent placement. The usefulness of metallic stents in patients with end-stage cancer has not yet been formally evaluated. Further studies are necessary to identify those patients with advanced and terminal cancer and MBO who may have some benefit in terms of symptom control and quality of life after these procedures.

Pharmacological management

The pharmacological management of bowel obstruction due to advanced cancer focuses on the treatment of nausea, vomiting, pain and other symptoms without the use of a nasogastric tube. If a central venous catheter has been previously inserted, this can be used to administer drugs for symptom control. Continuous subcutaneous infusion of drugs using a portable syringe driver allows the parenteral administration of different drug combinations, produces minimal discomfort for the patient, and is easy to use in a home setting.

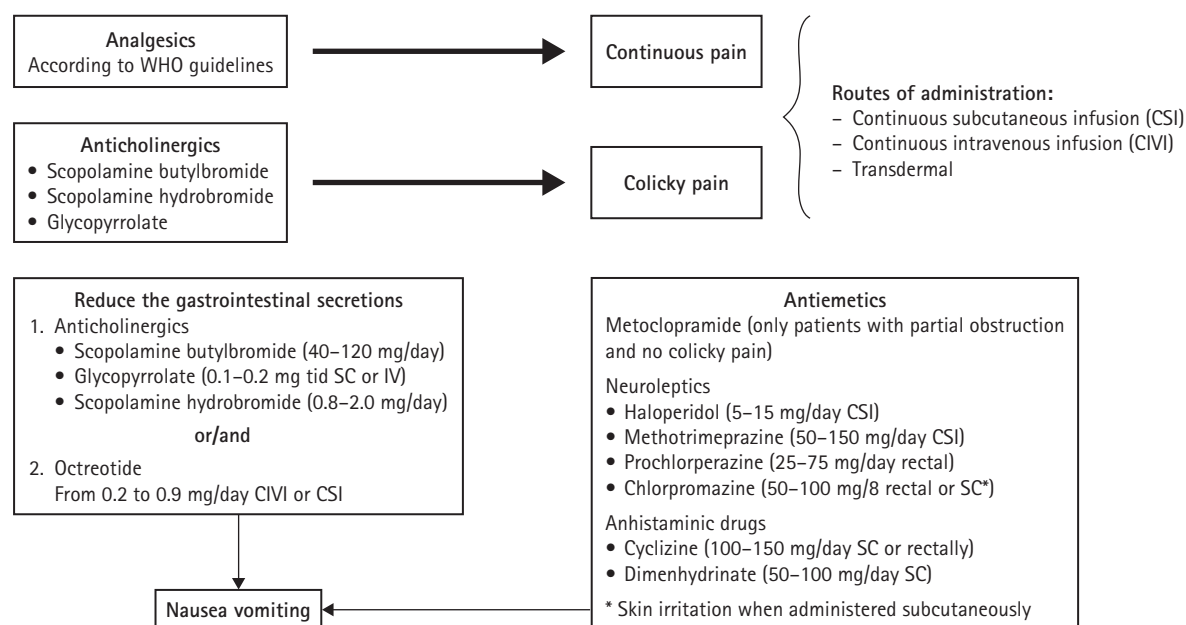
Drug therapy comprising analgesics, antisecretory drugs, and antiemetics, without using a nasogastric tube, was first described by Baines et al.[32] Several authors have confirmed the efficacy of this approach.[1–5] Medications should be tailored to each patient regarding both the drugs to be administered, the dosages, the drug associations and the route of their administration (Fig. 63.2).[5] In most patients with bowel obstruction, oral administration is not suitable and


Figure 63.2 *Symptomatic pharmacological approach. CIVI, continuous intravenous infusion; CSI, continuous subcutaneous infusion; SC, subcutaneous; tid, three times daily; IV, intravenous.*

alternatives routes have to be considered. Most of the recommended drugs can be administered in association via parenteral continuous infusion.

To relieve continuous abdominal pain, opioid analgesics via continuous subcutaneous or intravenous infusion are necessary in most of the patients. The dosage has to be titrated for each patient until pain relief is achieved. Anticholinergics may be administered in association with opioids to control colicky pain[5] (Fig. 63.2).

Vomiting can be managed using two different pharmacological approaches and reduced to an acceptable level for the patient (e.g. one to two times per day):

1 Drugs such as anticholinergics (scopolamine butylbromide, glycopyrrolate) or/and octreotide, which reduce gastrointestinal secretions.
2 Antiemetics acting on the central nervous system, alone or in association with drugs to reduce gastrointestinal secretions (Fig. 63.2).

Several authors recommend the use of corticosteroids for the symptoms due to bowel obstruction because it can reduce peritumoral inflammatory edema, thus improving intestinal motility. No controlled clinical trials have been carried out and administration routes and dosing of these drugs have not been standardized as yet. The role of corticosteroids in treating bowel obstruction is still controversial.[33***]

SCOPOLAMINE BUTYLBROMIDE

Scopolamine butylbromide is a frequently used drug for both vomiting and colicky pain by some palliative care

centers.[32,34–36] This drug differs from both atropine and scopolamine hydrobromide in having a low lipid solubility. It does not penetrate the blood–brain barrier as well as these other drugs and, consequently, may produce fewer side effects, such as somnolence and hallucinations, when administered in combination with opioids. The anticholinergic activity of scopolamine butylbromide decreases the tonus and peristalsis in smooth muscle and decreases the secretions in the gastrointestinal tract. The antiemetic, antisecretory as well as the analgesic role of scopolamine butylbromide administered subcutaneously by a syringe driver has been well documented by different authors. Dry mouth is reported to be the most significant side effect, but patients tolerated it by sucking ice cubes and drinking small sips of water. Also anticholinergic agents such as scopolamine hydrobromide or butylbromide and glycopyrrolate, reduce colicky pain and the volume of intestinal secretions. Glycopyrrolate, which is used as an antisecretory drug in the USA, is more potent than scopolamine hydrobromide and may be effective in some patients who fail to respond to scopolamine.[37] It has little central nervous system penetration and is unlikely to cause the delirium that has been associated with tertiary amine anticholinergics.

OCTREOTIDE

This is a synthetic analog of somatostatin that has a more potent biological activity and a longer half-life has also been used to manage the symptoms of bowel obstruction. Somatostatin and its analogs have been shown to inhibit the release and activity of gastrointestinal hormones,

modulate gastrointestinal function by reducing gastric acid secretion, slow intestinal motility, decrease bile flow, increase mucus production, and reduce splanchnic blood flow. It reduces gastrointestinal contents and increases absorption of water and electrolytes at intracellular level, via cAMP and calcium regulation. Submucosal somatostatin-containing neurons, activated by octreotide, inhibit excitatory nerves, mainly by an inhibition of acetylcholine output. As a result muscle relaxation can occur, ameliorating the spastic activity responsible for colicky pain. These effects may be due to vasoactive intestinal polypeptide (VIP) inhibition, which is increased in experimental bowel obstruction and is known to have adverse effects on intestinal secretions, splanchnic flow and peristalsis.[38]

The inhibitory effect of octreotide on both peristalsis and gastrointestinal secretions reduces bowel distension and the secretion of water and sodium by the intestinal epithelium, thereby reducing vomiting and pain. The drug may therefore break the vicious circle represented by secretion, distension, and contractile hyperactivity. Octreotide has been shown to have a potent anti-VIP effect resulting in the inhibition of intestinal secretions.[39,40] Also in the *in vitro* experiments on rabbit ileum, somatostatin was able to stimulate water and sodium chloride absorption and inhibit bicarbonate secretion and to inhibit water secretion in the jejunum.[9,41]

Experimental studies suggest that the principal mechanism of fluid secretion in bowel obstruction depends on VIP-induced inflammatory events.[38,42] Another inhibitory mechanism of hormonal release occurs through the activation of a G-protein which, on stimulating the potassium channels, determines the hyperpolarization of the cell, with the consequent blockage of the flux of calcium to the cell.[43] Octreotide may be administered by subcutaneous bolus or continuous subcutaneous or intravenous infusion. Its half-life is about 1.5 hours after intravenous or subcutaneous administration, and its kinetics are linear. The recommended starting dose is 0.3 mg/day subcutaneously. The dose can be titrated upward until symptom control is achieved, in general 0.6–0.9 mg/day. Octreotide is an expensive drug and its cost–benefit ratio should be carefully considered, especially for prolonged treatment. However, the cost of the drug should be interpreted in the widest possible sense, that is if the use of a drug results in a more rapid improvement of gastrointestinal symptoms which potentially limits the bed stay or the admission to an inpatient unit in addition to a better quality of life of the patient.[9,44]

Many experimental studies have evaluated the efficacy of somatostatin and octreotide in respect to placebo on intestinal distension, electrolyte losses, and ischemia.[9]

Efficacy of octreotide before surgery for bowel obstruction

Surgical gastrointestinal complications are common and postoperative outcome is poor in patients with advanced cancer. As luminal contents accumulate proximal to the obstruction, the bowel becomes distended and the increase in intraluminal pressure stimulates intestinal fluid secretion, which further stretches the bowel wall. The consequent pathological findings are accumulation of fluids and gases above the obstruction with altered motility producing distension, wall edema, vessel congestion, necrosis and perforation of the bowel above the obstruction and the presence of peritoneal fluids. Patients with obstruction are hypovolemic, tachycardiac, and frequently hypotensive as a result of fluids and electrolytes sequestered in the gut wall and in its lumen. Successful surgery may be compromised by these alterations and higher morbidity and mortality are expected.[45]

Octreotide at a daily dose of 0.3 μg has been preoperatively administered in patients undergoing surgery for bowel obstruction due to cancer. The patients were managed by an intravenous replacement of fluids and electrolytes, nasogastric tube and antibiotics. Diameter of the bowel above the obstruction was normal and no local gross pathological findings due to the accumulation of fluids in the lumen, such as edema, vessel congestion, or necrosis of the bowel above the obstruction, commonly observed in this situation, were observed. Samples of intestine above and below the obstruction revealed a normal anatomical and biochemical pattern. Intestinal anastomosis after resection was successful.[46] These preliminary results were confirmed in a randomized, double blind clinical trial carried out on 54 consecutive patients with mechanical bowel obstruction. Patients who received octreotide preoperatively required surgery less often than patients who did not receive the drug. Moreover, severe dilatation and necrosis of the bowel proximal to the area of obstruction was significantly less frequent as compared with those patients who did not receive the drug preoperatively.[47]

EFFICACY OF OCTREOTIDE IN PATIENTS WITH GASTROINTESTINAL SYMPTOMS DUE TO INOPERABLE MALIGNANT BOWEL OBSTRUCTION

Table 63.3 shows the efficacy of octreotide administration in the control of gastrointestinal symptoms due to bowel obstruction.[48–53] All the authors were able to show the efficacy on emesis in cancer patients with intractable continual vomiting due to small/large bowel obstruction that was unresponsive to conventional therapy (prochlorperazine, metoclopramide, cyclizine and dexamethasone). Octreotide was administered subcutaneously in association or not with opioid analgesics and with antiemetics.

Symptom control was maintained until death. No adverse effects were attributable to the drugs. The nasogastric tube was removed in most patients. In the presence of marked and diffuse bowel distension the administration of octreotide may reduce gastrointestinal secretions and thus allow an appropriate site for PEG placement to be obtained.[54]

Table 63.3 *Role of octreotide (OCT) in malignant bowel obstruction*

Author(s)	No. of patients	Site of cancer(s) Site of obstruction	Symptom(s)	OCT dose/route other drugs	Results
Khoo et al.[48a]	5	Various intraabdominal Small bowel	Intractable vomiting unresponsive to conventional therapy	0.1–0.5 mg/day SCb at start then CSI	Vomiting stopped within 1 hour of start of treatment The only patient with a NGT presented a reduction in aspirate from 2000 mL/day to under 300 mL/day No important toxicity was reported
Mercadante et al.[49a]	2	Intraabdominal Small and/or large bowel carcinomatosis	Abdominal pain and vomiting (1°) Colic pain and vomiting despite the use of NGT and haloperidol (2°)	0.3–0.2 mg/day Buprenorphine CSI 0.9 mg/day + 3 mg haloperidol	Pain and vomiting disappeared within 24 hours NGT was removed. No adverse effects were reported Within 24 hours NGT secretions decreased from 2600 mL/day to 350 mL/day and vomiting disappeared NGT was removed. No further need for analgesics or IV fluids. No adverse effects were reported
Mercadante et al.[50]	14	Various intraabdominal Small and/or large bowel	Nausea, vomiting unresponsive to haloperidol or chlorpromazine	0.3–0.6 mg/day SCb or CSI +haloperidol +analgesics	Vomiting was controlled in 12 patients and reduced in 2 In 2 out of 3 patients NGT was removed and the symptoms controlled No important toxicity was reported
Riley et al.[51]	24	Various intraabdominal Small and/or large bowel	Intractable vomiting not responsive to a combination of antiemetics, steroids and/or NGT drainage for 24 hours	0.1–1.2 mg/day SCb or CSI	14 patients had no further vomiting and 4 patients showed some improvements with a dose 0.1–0.6 mg/day There was a reduction of aspirate in all 5 patients with NGT 6 patients did not respond despite dosages of 0.6–1.2 mg/day no adverse effects were reported also at higher dosages
Mangili et al.[52]	13	Ovary Small and/or large bowel	Vomiting not responsive to metoclopramide and haloperidol	0.3–0.6 mg/day SCb or CSI ± analgesics	Vomiting was controlled in all cases within 3 days (range 1–6). In 8 patients with a NGT there was a reduction of secretions and NGT was removed No adverse effects were reported
Steadman et al.[53a]	1	Pancreas Small bowel	Vomiting and drowsiness with diamorphine, cyclizine, hyoscine	0.2 mg/day + diamorphine	Good symptom relief without causing unwanted uncomfortable drowsiness

[a] Case reports.

SCb, subcutaneous bolus; CSI, continuous subcutaneous infusion; IV, intravenous; NGT, naso-gastric tube.

These studies, although uncontrolled, support the use of octreotide in the management of gastrointestinal symptoms due to inoperable MBO. Reported effective doses range from 0.1 mg/day to 0.6 mg/day either as a continuous parenteral infusion or as intermittent subcutaneous or intravenous boluses. Octreotide, administered in association respectively with morphine or hyoscine butylbromide or haloperidol (0.5–1.2 mg/mL) does not show visual precipitation when mixed in the syringe.[5]

COMPARATIVE STUDIES BETWEEN OCTREOTIDE AND SCOPOLAMINE BUTYLBROMIDE

Two randomized prospective studies were carried out to compare the antisecretory effects of octreotide (0.3 mg/day) and scopolamine butylbromide (SB) (60 mg/day) administered by continuous subcutaneous infusion for 3 days in 17 patients with inoperable bowel obstruction having a nasogastric tube[55**] and in 15 patients without a nasogastric tube.[56**] In both studies 50 percent of the patients were cared for at home and the rest were hospitalized in surgical wards. In both studies the hospitalized patients received significantly more parenteral hydration (2000 mL vs. 500 mL daily) compared with the patients cared for at home.

Ripamonti et al.[55] showed that octreotide significantly reduced the amount of gastrointestinal secretions already 2 days after baseline ($P = 0.016$) and 3 days after baseline ($P = 0.020$). The nasogastric tube could be removed in all 10 homecare patients and in 3 hospitalized patients without changing the dosage of the drug. In three patients, it was possible to remove the nasogastric tube when the octreotide was added to SB (1 patient) or when the SB dose was doubled and parenteral hydration was reduced (1 patient). Also in these patients, octreotide showed a trend toward better efficacy than SB. It can be hypothesized that in the hospitalized patients the major difficulty in removing the nasogastric tube was associated with the higher amount of parenteral hydration.

In the second study[56**] octreotide treatment induced a significantly rapid reduction in the number of daily episodes of vomiting and intensity of nausea when compared to SB-treated patients, examined at the different time intervals. The association of the two drugs (octreotide and SB) may reduce gastrointestinal secretions and vomiting whenever one drug alone is ineffective.[55**,57]

In a recent study of 68 terminally ill cancer patients randomly receiving continuous subcutaneous administration of chlorpromazine 15–25 mg/day, combined with hyoscine butylbromide 60–80 mg/day or octreotide 600–800 μg/day, significant favorable differences in vomiting and nausea, fatigue and anorexia were reported in patients receiving octreotide.[58**]

PARTIAL OR REVERSIBLE BOWEL OBSTRUCTION

Other than reducing the gastrointestinal symptoms in definitive bowel obstruction, octreotide may be useful in reversing clinical conditions of subobstruction, as it can reduce the hypertensive state in the lumen, producing the sequence distension-secretion, which proceeds to definitive obstruction if not treated.[46,59] The most important mechanism in these circumstances is functional and can be reversible, if an aggressive treatment is initiated early before fecal impaction and edema render MBO irreversible. An early and intensive pharmacological treatment may not only reduce gastrointestinal symptoms but also reverse malignant bowel obstruction, in clinical conditions commonly considered definitive.[59] Octreotide, combined with metoclopramide, dexamethasone and an initial bolus of amidotrizoate, allowed the recovery of intestinal transit within 1–5 days in most advanced cancer patients, who continued this treatment without presenting symptoms of bowel obstruction until death.[60]

HYDRATION AND TOTAL PARENTERAL NUTRITION

In patients with inoperable bowel obstruction the amount of fluid administered should be assessed carefully. High levels of intravenous fluids may result in more bowel secretions, thus it is necessary to keep a balance between the efficacy of the treatment and the side effects such as increased vomiting, abdominal distension, and pain. The intensity of dry mouth and thirst are independent of the quantity of both intravenous or oral hydration.[55,56] However the intensity of nausea is significantly lower in patients treated with more than 1 L/day of parenteral fluids. Intravenous hydration can be difficult and uncomfortable for patients with end-stage cancer, so it should be reserved for patients who have a central venous catheter. Hypodermoclysis is a simple technique for rehydration that offers many advantages over the intravenous route.[61] The role of total parenteral nutrition (TPN) in the management of patients with inoperable bowel obstruction is controversial. No data are available on the survival rates or quality of life in advanced cancer patients treated with this modality. Depending on the context a patient provides, TPN may be considered a futile treatment or an acceptable means of maintaining patient autonomy.[5,62,63]

CONCLUSIONS

The optimal treatment of bowel obstruction in patients with advanced cancer is still an open and widely debated issue. Patient are usually considered suitable candidates for surgery when survival is expected to be more than 2 months. Studies of prognostic indicators of survival in advanced cancer patients are necessary to assist doctors in making appropriate therapeutic decisions, together with the patient and family members. Medical treatment by continuous

subcutaneous or intravenous administration of opioids, corticosteroids, anticholinergic drugs, octreotide, and antiemetic drugs can be an effective approach for controlling pain, nausea and vomiting in patients with inoperable gastrointestinal obstruction. Nasogastric suction or percutaneous gastrostomy may be considered for patients with refractory symptoms and/or upper bowel obstruction who do not respond satisfactorily to pharmacological measures alone. The efforts of the doctor/nurse team must be aimed at both symptom control and other aspects of the patient's suffering, including psychological distress and spiritual concerns.

Key learning points

- Bowel obstruction is a distressing outcome above all in patients with abdominal and pelvic cancer in the advanced and terminal stage of disease.

- Surgery should not routinely be undertaken in patients with poor prognostic criteria such as intraabdominal carcinomatosis, poor performance status and massive ascites.

- Medical measures such as analgesics, antisecretory drugs and antiemetics administered alone or in combination should be used to relieve symptoms.

- A nasogastric tube should be used only as a temporary measure and a venting gastrostomy should be considered if drugs fail in reducing vomiting to an acceptable level.

- TPN should be considered only for patients who may die for starvation rather than from tumor spread.

- Parenteral hydration is sometimes indicated to correct nausea and regular mouth care is the treatment of choice for dry mouth.

- A collaborative approach by surgeons and physicians can offer patients an individualized and appropriate symptom management plan.

Endoscopic treatment of gastrointestinal symptoms

PASQUALE SPINELLI

INTRODUCTION

Most tumors, and 99 percent of the digestive ones, are *endo*-*cavitary* and thus *endo*scopy is the most suitable approach for them, for diagnostic as well as for therapeutic purposes. Endocavitary treatment of cancer may lead to the cure of superficial, locally extending, nonmetastatic lesions or palliation of noncurable tumors. Digestive cancers form about 20 percent of all diagnosed cancers; when these are advanced, most of them are poorly responsive to curative treatments; consequently, patients not responding to curative treatment will need symptomatic, palliative treatment.

Palliative care has appropriately been receiving increased attention in recent years. Palliation, by itself, can be defined as the treatment of the symptoms of a disease. Palliative treatment is planned when it is impossible to treat a disease for cure. Palliation would be better defined by dividing it into:

- Palliative care – which includes the treatments required during the course of patients with advanced tumors from a stage of specific disease status to the stage of terminal events.
- Control of symptoms – which concerns an earlier stage in the natural history of the disease, when there is an acceptable disease-related quality of life.[1]

In view of these distinctions, palliative treatments to control symptoms should start as soon as the disease is classified as being incurable.[2] It could happen at the time of the diagnosis if conditions preventing curative treatments already exist. Palliation must be undertaken if anticancer treatments are not considered advisable because of general or local reasons, such as in cases where anticancer treatments would waste the time and resources that could be used for a more tolerable and profitable symptomatic approach.

Diagnosis of a solid cancer must be followed by the staging, as therapeutic options and prognosis are strictly related to the stage. Staging procedures are based on sophisticated and precise diagnostic tools, so that the oncologist should be able to separate localized from diffused and curable from noncurable diseases in the majority of cases. In fact, all suitable diagnostic possibilities must be considered to identify patients with noncurable disease as early as possible, and thus avoid giving them inefficacious, sometime toxic and always costly anticancer treatments, instead managing their symptoms appropriately.[3] Before deciding on palliative care to treat only the symptoms and waiving the possibility of directly treating the disease, the following points should be considered:

- the different curative potentials of surgery, radiotherapy, chemotherapy, immunotherapy, and any other kind of certified treatments
- risk factors in a particular patient
- side effects of a treatment
- quality of the remaining life of the patient
- weighing up the real impact of the therapeutic procedures with regard to the expected benefits.[4*]

With the availability of a variety of new prognostic indicators in the form of molecular, clinical, and pathological testing, the possibility that they could be used also for selecting potentially curable from noncurable patients has emerged. Analysis of gene expression patterns may be useful in the future for predicting the response to an anticancer treatment.[4,5*]

PALLIATIVE TREATMENTS: GENERAL CONCEPTS

Surgery

Surgery can be indicated in various contexts and is generally the first option to be considered.[6**] From the surgeon's standpoint, therapy is considered palliative when resection of all known tumor sites is no longer possible or advisable. Since a cure, as it is commonly defined, is not possible, the success of the therapy is determined by the alleviation of the suffering. A part of the gastrointestinal tract may be resected in presence of painful obstructive symptoms with the aim of relieving pain, restoring the lumen and reducing bleeding by removing a tumor. Bypass operations, indicated in cases of nonresectable tumor masses, may be performed through traditional laparotomy and also through laparoscopic access, achieving the double goal of minimum trauma and quick recovery. The appropriate use of surgery in these settings can improve the quality of life of patients with cancer.

Radiotherapy

In presence of unresectable tumors, radiotherapy reduces the tumor volume. It does seem to be of benefit in selected cases with large cancers because it may reduce the mass and make it resectable. Under specific circumstances, it can be given together with endoscopic treatments, thus combining endoluminal with the extraluminal benefits of mass reduction. In some cancers causing local symptoms, reduction of the size of the tumor and of the extravisceral extension of the tumor with radiation therapy results in partial control of pain. This treatment can be used alone or in combination with other anticancer treatments.[7] Among the different radiotherapeutic options, brachytherapy can better localize radiation dose with limited side effects; this is important when treating previously irradiated areas.[8]

Chemotherapy

Chemotherapy using multiagent regimens has an advantage for palliation of unresectable or metastatic cancer in cases of medium survival, but there is no confirmed advantage in cases of long-term survival. Chemotherapy is used to reduce the size of masses and to alleviate symptoms. Furthermore, in patients who have locally advanced, unresectable disease and in patients in whom tumors are resected with positive margins the duration of survival can be increased with palliative chemotherapy and irradiation.[9] Along with chemotherapy, endoscopic treatments aimed at immediately relieving obstruction of an occluded cavity may be strongly advisable in selected cases, allowing for functional recovery.[10]

PALLIATIVE CARE FOR GASTROINTESTINAL SYMPTOMS

From the endoscopic point of view, both primary digestive cancers as well as their metastases can compromise esophageal, tracheobronchial, biliary, and urinary functions, depending on their location. In consideration of these concepts, palliative care should not be limited to the patients with preterminal disease, but greatly expanded, starting with the control of symptoms as soon as the disease is classified as incurable and avoiding unnecessary anticancer treatments. As stated earlier in this chapter, when a solid cancer is diagnosed, the disease must be staged, as therapeutic options and prognosis are related to the stage. Since the disease is staged through precise diagnostic procedures, one should be able to separate localized from diffused and curable from noncurable cancers in most cases.

The continuing increase of the lifespan that has happened in recent years entails a constant increase in the incidence of age-related malignant neoplasms; advanced age, together with related risk factors, reduces the possibility of performing radical treatments and opens the doors to palliative treatments. In current clinical practice, however, most patients are treated with curative intent, even when palliation of symptoms would have been the right choice. Furthermore, the majority of clinical trials currently in progress are evaluating the response to treatments in terms of decrease in the volume of the tumor mass and global survival, but neglecting the evaluation of the impact of the treatment toxicity, of the general side effects on the quality of life and on the relationships of the patients with the people around them.

Although the primary purpose of a palliative procedure is not to increase survival, the treatment of severe symptoms (nutritional, respiratory, or metabolic) as in tumors resulting in stenosis of the esophagus, trachea, or intestinal, biliary, or urinary tracts, very often results in an effective extension of the survival time. Consequently, palliation becomes, in many cases, not just the simple treatment of symptoms, but it offers to the patient a wide range of therapeutic opportunities during the entire course of the disease.

Endoscopic palliative treatments aim to obtain the best possible quality of life with immediate and durable benefits with negligible trauma, side effects and incidence of complications related to the proposed advantages. Although these objectives seem to be obvious, it often happens that these simple principles – essential to the correct approach to the oncological patient – are not adopted and patients are submitted to treatments that are not suited to their requirements and their health status. In everyday practice it frequently happens that patients who only need control of symptoms related to the size and site of the tumor masses and to their relations with the surrounding anatomical structures, are over treated.

Palliative treatment of an oncological patient under these conditions must be tailored so that the quality of life

offered by the treatment is more consistent with their lifestyle and, when possible, it should be planned in agreement with the patient. This is because there are different ways to achieve relief from one symptom. The physician must be able to inform the patient about the different methods available so that they can choose the one that fits better with their preferred lifestyle. For example, esophageal stenosis can be relieved by a nasogastric tube, by a laser treatment, by a gastrostomy, or by a palliative radiochemotherapy: patients must be informed about these options so that they can decide which one is the most suitable for their way of life.

In the field of clinical research, human resources are insufficient and dedicated researchers are spread out among numerous – and partly curative – projects and not focused on specific palliation research. This is of concern also to endoscopic palliative treatments, as these are less widely known and used than they should be, considering the palliative opportunities they offer to oncological patients. Methodologically appropriate research is needed to bring into focus the indications of these methods and disseminate awareness about them.

Gastrointestinal symptoms may be produced by digestive or extradigestive tumors. Most of these tumors affect the digestive cavities and grow into them, occupying the spaces required for the digestive functions. The gastrointestinal tract has cavities that function as 'containers' or as 'canals' (stomach, esophagus, intestine, biliary, and pancreatic tract). Tumors reduce the space available and impair the functions of containing and flowing; moreover, tumors that infiltrate and ulcerate the walls of these cavities generate symptoms, in particular, they cause hemorrhage, obstruction, perforation and fistula formation. The most important symptoms of digestive tumors are: dysphagia, salivation, vomiting, jaundice, pain, and hemorrhage. All these symptoms can be treated by endoscopic modalities.

Dysphagia

Dysphagia is the most severe symptom of pharyngo-esophageal tumors. Malignant dysphagia can be in relation to the presence of a primary or secondary esophageal tumor or it can be consequent to a surgical treatment or to a radiotherapy or chemotherapy. Dysphagia can be defined as an abnormal swallowing, characterized by difficulty in transferring solid or liquid food from the mouth to the stomach; it is the initial symptom of an esophageal cancer in 90 percent of cases, but it also may be caused by compression or infiltration by thyroid or lung tumors, mediastinal lymphomas or by metastatic involvement of the mediastinum, mainly by breast cancer. Dysphagia can be associated with pain (odynophagia) and aspiration of food and saliva into the trachea and bronchi and with chronic cough, asthma, laryngitis, and, eventually, pneumonia.

Beyond the most common causes, in oncological patients dysphagia may be due to:

- neurological reasons, e.g. cricopharyngeal dysphagia because of recurrent nerve palsy due to perineural and neural infiltration by tumor tissue; neurological dysphagia may be also due to vagal or sympathetic tumoral infiltration, with involvement of the skull base or due to brain metastases.
- mucositis related to candidosis, bacterial infection, herpes, radiotherapy, chemotherapy.
- asthenia/cachexia.

From the mechanical viewpoint, a patient becomes dysphagic when the diameter of the esophageal lumen is less than 14 mm, but an uncertain feeling of trouble in swallowing is generally complained of some weeks or months before the diagnosis of esophageal cancer.

Esophagoscopy is indicated when a patient complains of dysphagia; its performance can be indicated in the various phases of diagnosis, staging and treatment. It allows the surgeon to characterize and exactly locate a tumor, to measure its length and appreciate the circular extent and the size of the residual esophageal lumen, and to obtain histological confirmation of the clinical diagnosis. Echoendoscopy is extremely useful for determining the level of infiltration of the lesion across the esophageal wall, the involvement of neighboring anatomical structures and the eventual presence of metastatic lymph nodes. Infiltration of the wall interrupts the progression of peristaltic contraction and stops, temporarily or definitively, the progression of food; this interruption is related to the extent of the obstruction and it causes a variety of symptoms, depending on whether it is partial or total. Partial obstruction can stop solid food, but allows passage of liquids; total obstruction, which stops the flow of liquids too, causes liquids to collect above the site of the obstruction, between the obstruction and the upper esophageal sphincter.

Regurgitation, salivation, odynophagia

Longstanding stenoses can cause incompetence – permanent or episodic – of the upper esophageal sphincter and the regurgitation of undigested material together with the possibility of inhalation; the amount of this collection is related to the level of the obstruction, being much larger when the lesion is close to the cardia; moreover, total obstruction stops the passage of saliva and causes the onset of another invalidating symptom, that is, salivation.

The patient complaining of salivation is obliged to spit or dribble continuously and walks around with a bag full of handkerchiefs – deprived of a social life. Dysphagia can be associated with odynophagia, generally caused by inflammation of the esophageal wall or by candidiasis or herpesvirus; odynophagia too may cause salivation. Salivation and

regurgitation often cause coughing as patients attempt to swallow and may simulate an esophagorespiratory fistula. This false diagnosis can be confirmed by a bronchogram due to the regurgitation of contrast medium when performing an esophagogram; it may be further confirmed by the fact that, after insertion of a stent into a stenotic esophagus, cough on swallowing disappears not because the inexistent fistula has been closed, but because, after opening of the esophageal transit, there is no more esophagorespiratory regurgitation. Consequently, the diagnosis of esophagorespiratory fistula must be confirmed by a tracheobronchoscopy, although nasal regurgitation is suggestive of the presence of a tracheoesophageal or bronchoesophageal fistula. When dealing with an oncological patient for palliative purposes, one should learn to give the patient the opportunity to fully explain the symptoms of the disease. A combination of an accurate clinical history and the results of the investigations often allows planning of treatment with a reduced number and frequency of traumatic and time-consuming examinations in these patients with a limited survival time.

Palliative endoscopic options for dysphagia

NASOGASTRIC TUBE

The objective of esophagoscopic treatment of dysphagia and its sequelae is based on crossing the obstacle that prevents the passage of food: this can be achieved by a nasogastric tube, by restoring the esophageal lumen by dilation, laser treatment, photodynamic treatment, or prostheses insertion, or performing a gastrostomy. These different options have specific indications.[10] The purpose of inserting a nasogastric tube is feeding liquid food, and it is an alternative to a gastrostomy. The indication is restricted to cases in which the stenotic obstacle cannot be dilated more than 4–5 mm; this mainly happens when there is postoperative or post-radiotherapy fibrotic stenosis that makes forced dilation dangerous as there is a possibility of perforation.

There are several different disadvantages of the nasogastric tube:

- esthetic – the patient is obliged to live with the tube coming out of his or her nose
- functional – the external surface of the tube adheres strictly to the inner surface of the stenotic tract and this prevents saliva being swallowed leading to salivation
- sensuous – with food introduced through the tube, the patient is unable to enjoy its taste, one of the few pleasant sensations remaining at this stage of the life.

These disadvantages have to be considered also when planning to perform a gastrostomy, because, except for the presence of the nasal tube, patients complain of these symptoms after the creation of a gastrostomy.

DILATION

Dilation can be performed by pneumatic balloon dilators or by plastic bougies: both can slide along a guidewire and enlarge the esophageal lumen up to 20 mm. There are also balloons that can be introduced through the operative channel of the endoscope and guided into the stenotic tract under direct vision; the drawback of the dilation is that the stenosis will recur in 1–3 weeks and dilations must be frequently repeated.

LASER TREATMENT

This aims to reopen the esophageal lumen through the thermal coagulation-destruction of the cancer tissue: power laser radiation increases the local temperature of the irradiated tissues and causes the tissue water to evaporate. The neodymium:yttrium aluminum garnet (Nd:YAG) laser is the most frequently used due to the depth of penetration of its radiation into the cancer tissue. The treatment is precise and safe in appropriate hands and the esophageal lumen can be fully restored so as to obtain a satisfactory eating function; the mean duration of the patency of the lumen is estimated to be 4–8 weeks.[11]

PHOTODYNAMIC THERAPY

Photodynamic therapy (PDT) uses photosensitizing drugs from the group of porphyrins that are selectively fixed by the tumor. The photosensitizer, activated by light, produces singlet oxygen that is toxic for biological tissues and causes a necrotic effect; unlike the procedures discussed above which are performed to allow the passage of food, the necrotic effect of PDT needs 4–8 days to become apparent and the relief from obstruction lasts for 5–10 weeks.[12] However, patients submitted to PDT have to avoid direct sunlight for 4–6 weeks because of the skin photosensitization.[13]

PROSTHESES

The fate of all these procedures is the recurrence of the obstruction due to the regrowth of the tumor, unless a prosthesis is inserted after dilation of the stenotic tract.[14] Both disposal plastic as well as metallic prostheses are available. The plastic ones require full dilation of the lumen (17 mm to insert a 15 mm prosthesis), unlike the metallic ones, that, being expandable, can be introduced through a narrow (7–9 mm) passage, to reach, at the end of the expansion, an internal diameter of 20–22 mm, allowing an optimal and immediate transit for any kind of food.[15] The insertion of an expandable prosthesis is no more traumatic than a flexible esophagoscopy.

The differences between plastic and expandable prostheses are: the plastic ones have a narrower lumen and give rise to a larger number of complications (migration, perforation, obstruction by solid food) whereas the expandable ones are much more expensive, cannot be removed and, being

woven as meshes, cannot be used to close fistulas. Recently, covered stents to be used in cases with fistulas have been manufactured, but the possibility of migration is higher than with noncovered stents, particularly when inserted through the cardia. Prostheses can be obstructed by large morsels or by regrowth of the tumor. The best results are obtained when the prosthesis does not interfere with the mechanism of a sphincter (the pharyngo-esophageal or the cardiac sphincter).[16] When the cardiac sphincter is infiltrated by the tumor, and the prosthesis keeps it open, the valvular antireflux mechanism is impaired and the gastric content flows back into the esophagus. The acid gastric secretion can be responsible for supra-prosthetic esophagitis and this condition causes dysphagia even though the esophagus is patent. However, in patients submitted to gastrectomy or operated on with techniques including vagotomy, in which the gastric environment is alkaline, the reflux through the prosthesis may give rise to an alkaline esophagitis. While in the first group of patients drugs that increase the pH, such as proton pump inhibitors, are indicated, in the second group, with alkaline esophagitis, these drugs worsen the dysphagic symptoms. Therefore special attention must be paid to the medical treatment of patients with patent prosthesis complaining of resistant dysphagia. Special prostheses with antireflux mechanisms have been recently manufactured, but definite results of their use are not yet available.[17,18] When the pharyngo-esophageal sphincter is involved and the insertion of the prosthesis keeps it open, the patient must adapt the swallowing mechanism to this new condition and that may need some days or weeks to be perfected.

In patients predicted to have a long survival, the evolution of the cancer through the esophageal wall can be in the form of the development of a fistula, connecting the esophageal lumen with the skin of the neck, the trachea, a bronchus, the mediastinum or the pleural space. Prostheses are equally used in these patients to bypass the fistula, allowing immediate passage of the oral intake. Fistulas can be consequent to tumor infiltration or previous surgery or radiotherapy. Insertion of a prosthesis to bypass a fistula allows immediate restoration of oral feeding and curing of concomitant dermatitis (in cervical fistulas), bronchopneumonia (in tracheo- and broncho-esophageal fistulas), mediastinitis (in mediastinal fistulas) and pleural effusions (in esophago-pleural fistulas). Obviously, only plastic stents or covered mesh stents can be used in the indication of closing a fistulous passage, because a simple mesh stent would allow the filtration of liquids through the mesh.[19] Covered stents have a tendency to migrate and their application must be carefully evaluated, because an eventual removal may be extremely difficult. The new self-expanding plastic stents have been used in the treatment of thoracic leaks after esophagectomy for cancer; these stents can be easily removed after the fistula repair and their application reduces leak-related morbidity and mortality and can be considered as a cost-effective alternative to surgery and to the other endoscopic treatments.[20]

If an esophago-tracheal or an esophago-bronchial fistula cannot be treated by inserting a stent into the esophagus (no concomitant stenosis to avoid migration of the stent), the prosthesis can be inserted into the respiratory tract to close the tracheal or the bronchial opening to avoid aspiration pneumonia, a frequent cause of death in these patients. Generally, plastic stents are used. The most widely marketed are the Dumon stents, introduced with a rigid tracheobronchoscope under general anesthesia. These stents have the advantage that they can be easily repositioned in case of migration or removed if the fistula closes, as it can happen in postsurgical cases.

PERCUTANEOUS GASTROSTOMY

Percutaneous gastrostomy is considered only when there is no possibility to carry out one of the previously described procedures. Percutaneous endoscopic gastrostomy (PEG) consists of the insertion of a feeding/venting tube into the stomach, through the abdominal wall under direct endoscopic control, to choose the best position to access the gastric cavity. Such a tube can be advanced to reach the jejunum, thus becoming a jejunostomy and it can be used also for decompressing an obstructed intestine.

Bleeding and vomiting

Endoscopic treatment can be beneficial for bleeding and vomiting, when these symptoms result mainly from intragastric or pancreatic tumors infiltrating the gastric wall. Polypoid or ulcerated, they may be endoscopically treated because they produce symptoms linked to the bleeding or to the food progression. This second group of symptoms is generally linked to the compression of the gastric antrum. Malignant ulcerations bleed and produce anemic conditions speeding up the progression toward cachexia. Decisions concerning the management of a bleeding gastrointestinal cancer need to consider the general clinical condition of the patient and the burden and the extent of the disease.

PALLIATIVE ENDOSCOPIC OPTIONS FOR BLEEDING AND VOMITING

To stop bleeding, endoscopic laser photocoagulation, unipolar or multipolar electrocoagulation, cryotherapy, injection of sclerosing drugs can be used for cytoreductive as well as for hemostatic purposes. These treatments are effective, but the duration of the effect is limited and the recurrence of the bleeding is a rule. The progression of the infiltration of the gastric wall and the presence of polypoid intragastric masses, mainly in the antrum, obstructs the gastric passage and causes gastric distension, nausea and, finally, vomiting. Because all these symptoms are produced by gastric obstruction, they disappear when the obstruction is relieved after an endoscopic treatment performed through administration of thermal energy (electrocoagulation, laser [argon

beam] coagulation) or positioning a stent. Duodenal obstructions, as well as the gastric ones, can also be treated by performing a translaparoscopic bypass between the gastric body and the first jejunal loop, although expandable prostheses are also used to bypass duodenal and gastric compressive and stenosing lesions. Duodenum and gastric antrum can be obstructed by primary or metastatic tumors. Malignant lymph nodes, pancreatic and ampullary cancers are the most frequent causes of duodenal obstruction. Together with biliary tumors, these conditions are responsible for biliary obstruction and cause malignant jaundice.

Malignant jaundice

After the first cannulation of the papilla of Vater performed by Classen and Demling in 1972[21] and the consequent operative procedures, jaundice became one of the most important fields of application of the endoscopic techniques.

Biliary obstruction causes malignant jaundice. The obstruction can be caused by biliary, pancreatic, or metastatic cancer or by lymphomas, obstructing the common bile duct or the hepatic ducts. It is generally concomitant with whitish stools, brown urine and diffuse itching. Pancreatic cancer is the most common cause of malignant biliary obstruction, followed by cholangiocarcinoma, carcinoma of the papilla of Vater, and metastatic tumors. When biliary obstruction and the consequent jaundice occurs, the patient has advanced stage disease and palliation of the jaundice is the real purpose of the treatment.

PALLIATIVE ENDOSCOPIC OPTIONS FOR MALIGNANT JAUNDICE

An endoscopic approach[22] by inserting biliary endoprostheses through the transpapillary route has become the palliative treatment of choice, particularly for distal stenoses located at the choledochal level. When the obstruction is located into the hepatic hilum, the endoscopic approach is more difficult. However, palliative treatments that are alternatives to the endoscopic ones (surgical and percutaneous) have higher costs and complications and a lower success rate. They are indicated in case of failure of the endoscopic procedure.[23] Moreover the endoscopic approach allows a careful inspection of the alimentary tract and particularly of the antro-pyloric and duodenal area: this inspection is useful because of the frequent association of biliary and duodenal obstruction.

Insertion of gastroduodenal prostheses can relieve a concomitant obstruction of the gastric outlet and of the gastroduodenal passage. To obtain endoscopic biliary drainage, the obstructed biliary tract must be crossed with a guidewire introduced through the papilla under endoscopic guidance; a guide catheter is then passed over it and, lastly, a plastic prosthesis is pushed through the stenotic tract and allows bile to flow. These plastic stents present a main late complication consisting of the occlusion with biliary sludge; in this case they must be removed and replaced with new ones, it generally happens within 6 months after the stent is introduced. Metallic expandable prostheses, similar to those used in the coronary vessels, in the urethra and in the tracheobronchial tree, have been proposed for the biliary tract. They have a low occlusion and complication rate, are easy to place and can be considered as a permanent procedure in the malignant jaundice.

The main advantages of the endoscopic approach are the low rate of trauma and the immediate effect. In fact, whitish stools become well-stained in the 24–48 hours after the procedure, the urine loses progressively its intensive brown color and itchiness disappears. When endoscopic drainage is impossible, percutaneous, video-laparoscopic or open surgical routes can be used: the first one allows the insertion of a transhepatic tube, whereas the second and third allow wide exploration of the peritoneal cavity and the performance of a bilio-digestive bypass.[22]

Constipation

Constipation is a very frequent symptom; more than 50 percent of advanced cancer patients need to be treated for the infrequent passage of hard stool. The cause should be clarified. When caused by anticancer chemotherapeutic drugs (mainly vincristine), opioids, metabolic problems like hypokalemia or global electrolyte imbalances, it is mostly of the type of adynamic ileus and is frequently accompanied by generalized abdominal pain. Intestinal obstruction by endoluminal masses or by extraintestinal compressions is more frequently accompanied by colicky pain.

PALLIATIVE ENDOSCOPIC OPTIONS FOR CONSTIPATION

Longstanding constipation resistant to common treatments must be managed in an effective way, but the safety of the treatment is compulsory. Endoscopy can help in the purpose of perfecting the diagnosis as well as in treating the distension. These patients are generally submitted to nasogastric intubation or other venting procedures for gastroduodenal decompression. A transanal approach can be necessary, so that, after cleaning enemas have been performed at low pressure, colonoscopy with large channel endoscopes allows gas and liquid aspiration and distension of the bowel wall. It must be performed carefully, injecting small quantities of warm water to clean the lumen, considering that the bowel wall is often very fragile because of concomitant ischemic lesions.

PALLIATIVE OPTIONS FOR OBSTRUCTION

A cancer growing into the intestinal lumen will obstruct the progression of intestinal content. Obstruction can also occur due to metastatic involvement of the mesenteric

lymph nodes or diffuse peritoneal nodular metastases, e.g. in papillary carcinomas, mainly, ovarian and pancreatic. About 10 percent of intestinal obstructions are caused by malignancies; up to 30 percent of obstructions result in resolution. More than 60 percent of malignant obstructions are caused by recurrent cancers.

The plan of investigations and the treatment in each case is tailored to the individual patient. If a patient, already treated for an intestinal tumor, presents with abdominal distension, vomiting, constipation and crampy pain, and plain X-ray of the abdomen shows air–fluid levels and bowel distension, the first choice is endoscopy. This is to locate precisely the cause of the obstruction and to perform, when possible, the first palliative treatment by dilation, laser, or stenting.

Surgery

Surgery is indicated consequent to endoscopic examination and to re-staging examinations. Surgical procedures can be classified as bowel resections, preparing ostomy or bypass operations; the kind of procedure is related to the position of the stenosing lesion and to the type of previous surgery. Providing optimal palliative care for the patient with advanced colorectal cancer is a complex and challenging process and may be a departure from the traditional surgical satisfaction derived from the complete excision of a malignancy. However, surgeons aspiring excellence in palliative care will likely find this a rewarding endeavor.[23]

Considering the pros and the cons of the different surgical procedures, on the one hand bypass operations and diverting stomas do not remove the tumor and consequently do not interfere with symptoms related to its presence, such as bleeding and pain due to infiltration of anatomical structures (peritoneum in intraabdominal cancers or periosteum in the pelvic localizations) although they alleviate symptoms due to obstruction. On the other hand surgical removal, when possible, alleviates all the tumor-related symptoms, but morbidity and mortality rates are higher in patients who undergo palliative versus curative surgery.

When only palliation of symptoms is possible, the purpose of surgery is to bypass the stenotic tract, removing the malignancy. Before surgery, some points must be noted, such as the location of the lesion, whether it is single or multiple, the degree of the stenosis, the viability of the bowel wall, the real and ultimate cause of symptoms (malignancy, adherences, bands), and the likelihood of spontaneous resolution. Persistence of bowel obstruction has a strong influence on prognostic outcome and in a multivariate analysis it was the only symptom that had an independent effect. Consequently, it must be managed, and possibly interrupted as soon as possible. Conventional medical treatment has to be established with nasogastric or nasojejunal intubation, and supply of intravenous fluids and electrolytes. The patient must be monitored with serial physical examinations

performed by the same physician, enemas should be performed to clean the colon and a colonoscopy should be done with the purpose of localizing and possibly treating the obstructing lesion. This type of examination must be performed carefully by an experienced endoscopist because of the fragility of the patient and of the intestinal wall, of the hypersensitivity to pain, and the risk of perforation.

Endoscopic options

Endoscopic procedures to be considered in case of obstruction are dilation, electrocoagulation, laser coagulation, cryotherapy and, lastly, endoprostheses, all of them with low mortality and morbidity.[24] Any treatment has to be performed only in patients presenting symptoms (obstruction, pain, bleeding) clearly attributable to the tumor and must be directed to bypass the symptom. In asymptomatic patients any palliative treatment must be deferred. Patients to be submitted to palliation are those with very advanced and non-removable cancers. They generally present with cachexia and weight loss and surgical operations carry a high mortality, about 10 percent, and a survival rate of around 5 percent at 5 years.

There are different endoscopic possibilities of treatment, related to the kind of the obstructing lesion and in particular to its shape and to the tumor bulk, growing into the lumen or infiltrating the bowel wall. In the first case – the presence of an obstructing mass – the mass has to be removed to reopen the intestinal lumen; this can be done through an endoscopic laser treatment. In the second case – lesion infiltrating the bowel wall – introduce under endoscopic visual guidance a trans-stenotic guidewire and slide a dilator on it; once dilation has been achieved, the fecal transit can been reestablished and the emergency problem overcome and the bowel cleaned. If the tumor is operable, the lesion can be resected or a bypass operation performed through a surgical laparotomy or a laparoscopic procedure which is planned for the following days; if the patient is inoperable because of high risk conditions or because the lesion is not removable, the endoscopic alternative is the only feasible option. To keep open the intestinal lumen and maintain the bowel functions, an expandable prosthesis must be inserted in these cases to obtain a durable effect.[25] The results of the endoscopic treatments can be summarized as follows:

- Dilation with inflatable balloons has a high rate of success (~90 percent), but stenosis recurs in 1–2 weeks
- Similar rate of success is obtained with Nd:YAG laser but the duration of the dilation is longer
- Insertion of a prosthesis with a correct technique and indication allows the patency of the large bowel to be maintained in more than 80 percent of treated patients. We started to insert stents in primary rectal tumors and in recurrences in rectal anastomoses with a success rate of more than 90 percent. In most of our cases patency of the stent lasts until death.[26]

CONCLUSION

The features of endoscopic palliation are: (i) achievement of an immediate result in the control of symptoms and in the restoration of a normal function, whereas other options of palliation, like radiotherapy and chemotherapy and surgery are generally more risky, and need incomparably longer times to become effective; (ii) absence of contraindications and side effects; and (iii) the possible combination of endoscopic treatments with any other form of treatment.

Palliative treatments, in each case, should be tailored to the individual patient, and some clinical benefit, subject to the patient's capacity to undergo the treatments, consisting of a decrease or disappearance of symptoms and of improvement of performance status, should be the primary endpoint.

Key learning points

- Palliative treatments should start to control the symptoms as soon as the disease is classified as incurable.

- Digestive cancers form about 20 percent of all diagnosed cancers and most of them, when advanced, are poorly responsive to curative treatments; consequently, patients not responding to curative treatment will need symptomatic, palliative treatments.

- Before deciding to treat only symptoms, we should consider the different curative options offered by surgery, radiotherapy, chemotherapy, immunotherapy, through a multidisciplinary approach.

- Gastrointestinal symptoms may be produced by digestive or extradigestive tumors. Most of them affect the digestive cavities and grow into them, occupying spaces required for digestive functions.

- Tumors reduce the spaces and impair the functions of containing and flowing, and they infiltrate and lead to ulceration the walls of these cavities thus producing symptoms; in particular, they cause hemorrhages, obstructions, perforations and fistulas.

- More than 95 percent of the digestive tumors are *endo*cavitary and *endo*scopy is the most suitable approach for precise and selective treatment.

Fatigue

This page intentionally left blank

Pathophysiology of fatigue

CLAUDIA GAMONDI, HANS NEUENSCHWANDER

INTRODUCTION

Fatigue is the most frequent symptom in patients with advanced cancer.[1] It is reported as a symptom that heavily interferes with daily life. The prevalence is estimated, depending on the studies, to be between 60 percent and 90 percent among advanced cancer patients.[2–6**] In many malignant and nonmalignant diseases, fatigue becomes a leading, nonspecific symptom that accompanies patients from diagnosis to death. Fatigue can be one of the symptoms that leads to diagnosis; it may first occur during chemotherapy and radiotherapy and may remain one of the major complaints of the patient during the recovery after treatment.

Fatigue commonly has a major impact on function. Descriptive studies show an inverse relation between fatigue and various indicators of quality of life.[7–13*] Some studies have explored the gender difference in fatigue: data suggest that there is no gender difference, even if there are some indications that women generally report higher rates of symptoms than men.[14–19] Fatigue may easily interfere with social and physical activities, may influence the patient's decision making and may lead a patient to refuse a potentially curative treatment. For all these reasons, during the past few years, there has been an increasing awareness of the importance of this symptom in palliative care and oncology.

The basic mechanisms by which fatigue is caused are not well understood. Occasionally one predominant abnormality is present and appears to be the main contributor to the symptom, but in most cases several abnormalities and many symptoms coexist and may contribute to the genesis of fatigue. There are, however, three main types of mechanism causing asthenia: direct tumor effects, tumor-induced products, and tumor-accompanying factors.

DIRECT TUMOR EFFECTS AND TUMOR-INDUCED PRODUCTS

On the one hand, cancer by itself is able to release a number of substances, termed 'asthenine', able to interfere with host metabolism. On the other hand cancer can induce host macrophages and lymphocytes to produce a number of inflammatory cytokines such as tumor necrosis factor α (TNFα), interleukin (IL)-1, IL-6, and IL-2, which are active in the muscle tissue and in the central nervous system (Fig. 65.1).

Muscle is a main target tissue of cancer fatigue: histologically, there is an atrophy of type II muscle fibres, which are responsible for anaerobic performance.[1] Muscles of cancer-bearing animals show alterations in the activity of various enzymes, distribution of isoenzymes and synthesis and breakdown of myofibrillar and sarcoplastic proteins.[20,21] In humans there is an evidence of excessive lactate production in tumor-free muscle tissue: this represents an expression of both weakness and pathophysiological mechanism.[22,23]

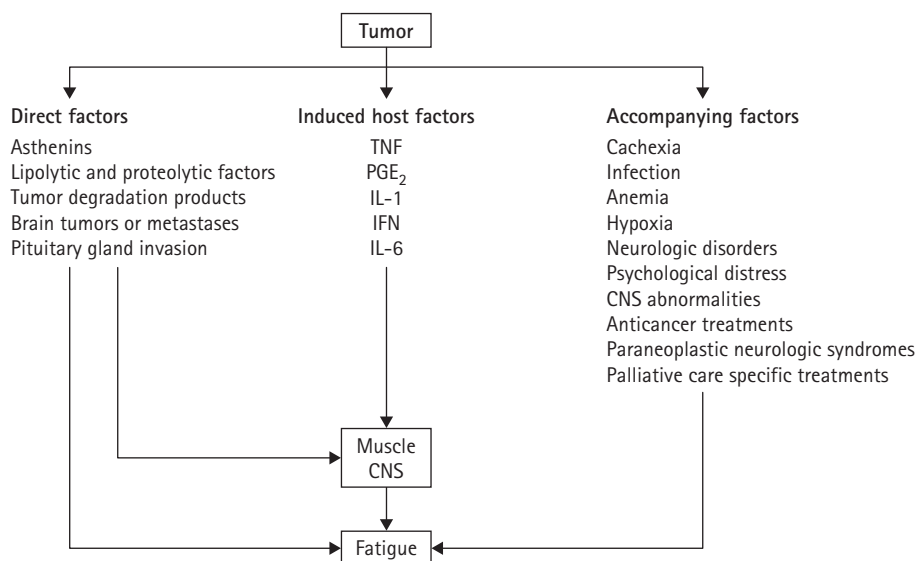
Patients with chronic heart failure may show profound metabolic abnormalities leading to a catabolic state with progressive loss of muscle bulk: indeed a significant correlation between muscular fatigability and reduced electromyographic activity was found in patients with chronic heart failure.[24] A reduction in skeletal muscle protein stores may result from endogenous TNF or from TNF administered as antineoplastic therapy.[25] Thorud *et al.*, in a study conducted on rats with congestive heart failure, observed that elevated circulatory concentrations of TNFα and monocyte chemoattractant protein-1 is a frequent finding. These molecules are supposed to stimulate matrix metalloproteinase activity and thereby contribute to distort the normal contractile muscle function, increasing skeletal muscle fatigue.[26] Prolonged bed rest and immobility leads to loss


Figure 65.1 *Fatigue generating mechanisms. TNF, tumor necrosis factor; IFN, interferon; IL, interleukin; PGE, prostaglandine E; CNS, central nervous system.*

of muscle mass and reduced cardiac output. This deconditioning results in reduced endurance for exercise and activities of daily living and may be compounded by other muscle abnormalities in patients with cancer.[27,28]

Franssen *et al.* pointed out the contribution of starvation, deconditioning, and aging to alterations of peripheral skeletal muscle in chronic organ diseases, such as chronic obstructive pulmonary disease, chronic heart, and renal failure.[29] Studies have demonstrated that endurance training can reduce fatigue and improve physical performance in cancer patients while they are receiving chemotherapy and bone marrow or autologous stem cell transplantation.[30–35]

Aerobic training and combination of exercise modalities in patients with heart failure are shown to be effective in decreasing global rating of symptoms, including fatigue.[36]

TUMOR–ACCOMPANYING FACTORS

Fatigue and cachexia

The relationship between fatigue and cachexia is complex. In the main, there is agreement that these two conditions are strongly associated or at least coexist.[1] Malnutrition, muscle mass loss, and progressive cachexia are valid reasons for fatigue and they are strongly related one to the other. Cancer patients present a catabolic metabolism: they show increased rate of metabolism and energy expenditure compared with control groups with similar weight loss; in addition they show an increased need for amino acids, which leads to protein breakdown.[37–39]

Cachexia in cancer is characterized by severe muscle wasting: reactive oxygen and nitrogen species have been proposed as underlying mechanisms. The inefficiency of the antioxidant enzymes may be responsible for the development
Figure 65.2 *Possible relation between cachexia and fatigue.*

of both oxidative and nitrosative stress in cancer-induced cachexia.[40] These muscle abnormalities, such as reduced skeletal muscle and impaired skeletal muscle quality, are common in a variety of chronic conditions. In patients with chronic heart failure, cardiac cachexia is common: some authors observed raised plasma levels of norepinephrine, epinephrine, and cortisol, with high plasma renin activity and increased plasma aldosterone levels. There is increasing evidence that neurohormonal and immune abnormalities may play a crucial role.[41] However, in a number of conditions this relationship is not as close as expected: patients with breast cancer or lymphomas might complain of profound fatigue, but they have low incidence of cachexia.[42] Furthermore, patients with chronic fatigue syndrome or major depression show no malnutrition but high incidence of fatigue. On the other hand, in diseases such as anorexia nervosa there is severe malnutrition without fatigue.[1]

In conclusion, cachexia and fatigue may be part of an expression of major metabolic abnormalities, rather than simply expression of malnutrition *per se* (Fig. 65.2).[1]

Anemia

Anemia is a common finding in patients with malignant disease. It can be caused by the cancer itself or it can be cancer-induced or due to correlated factors such as bleeding, hemolysis, nutritional deficiencies, iron deficiency, antineoplastic treatment such as chemotherapy or radiotherapy, or by cancer independent factors. Hemoglobin levels below 8 g/dL are associated with profound fatigue.[1]

In some circumstances anemia may be a major factor in cancer-related fatigue and impairment of quality of life in cancer patients.[5,43,44] For individual patients, it is difficult to discern the real impact of anemia from that of other competing contributing factors to fatigue. The impact of anemia varies depending on factors such as the rapidity of onset, patient's age, plasma volume status, and the number and severity of co-morbidities.[45]

In patients with mean levels of hemoglobin between 9 g/dL and 11 g/dL receiving chemotherapy, the correction of anemia is shown to be effective in ameliorating quality of life, activity levels, and energy levels.[43] In our experience, even though anemia is a major contributor to asthenia, the correction of anemia is not always followed by an improvement in fatigue. The difficulty is correlating hemoglobin levels with degree of fatigue and its potential alterability.

In a study conducted among women undergoing pelvic radiotherapy for uterine cancer, Ahlberg *et al.* observed an increase in fatigue during treatment and no significant correlation between general fatigue and hemoglobin levels after 3 weeks of therapy.[46] Combined data from three randomized, placebo controlled trials on epoetin alfa, the recombinant form of human erythropoietin, revealed an association between increased hematocrit and an improvement in overall quality of life.[47] Patients with an increase in hematocrit of >6 percent had significant improvement in energy level and daily activities. Three large, prospective, nonrandomized, multicenter, community trials similarly observed that epoetin alfa-treated patients who experienced a rise in hemoglobin reported significant improvements in energy level, activity level, functional status, and overall quality of life.[43,44,48,49]

Since none of these studies had fatigue as a primary endpoint caution in interpreting these findings remains mandatory. All the studies refer to fatigue and chemotherapy; no controlled trials have been published so far on the correlation between fatigue and anemia in a palliative care population.

Infection

Correlation between fatigue and infection is well documented. Fatigue can be a prodromal symptom and it can outlast the infection for weeks and months.[50,51] In cancer patients, because of the immunodepression, acute and chronic infections are very common, and one of the underlying mechanisms of pathophysiology is the production of some mediators of inflammatory response, such as TNFα.[52] The production of some cytokines (TNFα, IL-1, IL-2, IL-6, interferon [IFN]) and the consequent activation of the inflammatory reaction can, in some cases, be considered the main mechanism leading to the cachexia-anorexia syndrome.[20,53,54] It can be assumed that there is a similar underlying mechanism in the genesis of infection-induced fatigue.

Metabolic and endocrine disorders

In many abnormalities of the metabolism and the endocrine system, e.g. diabetes mellitus, Addison disease, or electrolytic disorders, fatigue is a leading symptom. Dysfunction of the hypothalamic–pituitary–adrenal (HPA) axis is a field of research. Abnormalities of the HPA axis have been postulated as possible additional factors in the chronic fatigue syndrome.[1]

There is also evidence suggesting that IFNα initiates a cytokine cascade that affects the HPA and hypothalamic–pituitary–gonadal axis, thus affecting regulation of glucocorticoid and sex steroid hormone secretion. However the clinical significance of these observations has not yet been established.[55] There is clear evidence that hormonal deficiency syndromes, such as hypothyroidism, occur in a relatively large portion of patients receiving systemic IFNα therapy.

Some authors, after acknowledging the limitations of current clinical data, have concluded that adrenal and gonadal axis dysfunction also must be considered in patients with IFNα-induced fatigue.[56] The possibility of hypothyroidism must be considered. However, diagnosis of hypothyroidism in cancer patients might be complicated by the occurrence of the 'sick euthyroid syndrome' (ESS). This syndrome is defined as the decrease of serum free triiodothyronine with normal free L-thyroxin and thyrotropin.[57] Recent reports have shown that IL-6 plays a key role in the pathogenesis of ESS: some authors have demonstrated that IL-6 can suppress the thyroid function.[58–60]

Kumar *et al.* conducted a prospective observational study on 198 consecutive breast cancer patients receiving adjuvant chemotherapy.[61] Changes in anthropometric data, fatigue, nutritional intake, physical activity, thyroid and steroid hormones were monitored from start to end of the chemotherapy and 6 months after therapy. They concluded that cytotoxic agents may influence thyroid function in this population, contributing to and progressively worsening symptoms such as weight gain, amenorrhea, fatigue and lowered physical activity. They suggested to screen breast cancer patients for thyroid function at diagnosis or at the beginning of the adjuvant treatment.[61]

The role of testosterone has also been studied: age-associated hypogonadism occurs in 30 percent of men after the age of 55. It is associated with decreased muscle mass, bone mineral density, and libido, hemoglobin levels and

with anorexia, fatigue, and irritability.[62] Even if some of these symptoms overlap with those of depression, the association between the two disorders is unclear. There is some evidence that there is an increased incidence of depressive illness and a shorter time to diagnosis of depression in hypogonadal men.[63] In male patients with cancer, hypogonadism is correlated with fatigue, and androgen insufficiency can be caused by anorexia-cachexia syndrome.

Profound hypogonadism with low levels of serum testosterone or estrogen coupled with low levels of pituitary gonadotropins has been noted in male and female patients receiving intrathecal opioids.[64,65] Hormone levels are related to the opioid consumed, dosage and dosage form, nonopioid medication use, and several personal characteristics.[66] A recent study demonstrated that cancer survivors who were chronic opioids consumers experienced symptomatic hypogonadism with significantly higher levels of depression, fatigue, and sexual dysfunction.[67] The reduction in opioid consumption can dramatically increase libido and sexual function with a possible mechanism involving opioid-related effects on the HPA axis.[68*]

The determination of testosterone in men under opioid treatment who are experiencing fatigue might therefore be worthwhile, since there might be some therapeutic consequences. Hormonal ablative therapy in prostate cancer patients can double the incidence of fatigue and the replacement therapy in hypogonadic and testosterone depleted HIV patients results in an improvement of energy, libido and hemoglobin levels.[1]

Psychological distress

The prevalence of depression in cancer patients varies: major depression has a prevalence of 0–38 percent, depression spectrum syndromes from 0 percent to 58 percent. In palliative care, the reported prevalence of depression varies from 17 percent to 42 percent.[69] In psychiatric patients, fatigue is a common somatic symptom of clinical depression and it is included in the diagnostic criteria for major depressive disorders, bipolar disorders, and dysthymic disorders. Anderson *et al.* conclude that patients with cancer report significantly more severe fatigue and fatigue-related interference in their daily life activities than the community-dwelling subjects. Furthermore, patients with depressive disorders reported more severe fatigue and more interference with their daily lives due to fatigue than either cancer or community individuals.[70]

Several investigators have suggested that depression and fatigue may have overlapping but not equivalent physiopathological mechanisms: this could explain why patients with clinical depression who respond to antidepressant medication may continue to experience residual fatigue.[71] In a large representative sample of cancer patients where the most frequently reported problem was fatigue, 37.8 percent met criteria for general distress in the clinical range.[72] This

finding supports the view of the chronic stress condition mentioned above. In addition a recent study supports the evidence that in treating depression with sustained released (SR) bupropion there can be a reduction of the symptom fatigue experienced by cancer patients.[73]

Central nervous system abnormalities

The relation between central nervous system (CNS) and fatigue is poorly studied. Abnormalities of the CNS can themselves be a cause of fatigue, and, at the same time, the brain is also the area where fatigue is perceived.[1] Primary or secondary CNS tumors may cause endocrine abnormalities and, as a consequence, fatigue. Patients with acute lymphoblastic leukemia receiving cranial radiotherapy experience fatigue, depression and sleepiness.[74] Chronic pain stimulates the reticular activating system, which seems to be responsible for the experience of fatigue. All these findings should stimulate research in this field.

Anticancer treatments

Anticancer treatments have a high impact on energy levels: most of the patients complain of fatigue while receiving chemotherapeutic agents.[75–78] Several studies have shown a correlation between fatigue and different types of oncological treatment: it has been observed that 65–100 percent of patients undergoing radiotherapy and up to 82–96 percent of those receiving chemotherapy suffer from fatigue during treatment.[79] In supportive care, drugs used to control nausea and vomiting are themselves contributors to fatigue. However, it may be difficult, in the individual patient, to demonstrate if fatigue is more related to treatment or to the underlying disease.

In a multivariate analysis, 43 percent of the variance in fatigue was ascribed to disease-related symptoms and 35 percent to toxicity of treatment.[79] Radiotherapy and chemotherapy can result in anemia, diarrhea, anorexia and weight loss, all contributors to fatigue. For example, treatment with dexamethasone may be beneficial to reduce postchemotherapy symptoms induced by irinotecan, specifically anorexia and fatigue.[80**] In patients treated with biological response modifiers such as IFNα, fatigue is an important dose-limiting side effect.

Autoimmune thyroid disease, another contributor to fatigue, is a well-recognized consequence of IFNα therapy and may be mediated by the induction of IFNγ production by lymphocytes.[56] Recent data suggest that IFNα depression may be composed of two overlapping syndromes: a depression-specific syndrome characterized by mood, anxiety, and cognitive complaints, and a neurovegetative syndrome characterized by fatigue, anorexia, and psychomotor slowing.[81]

Fann *et al.* in a study conducted on delirium episodes in patients undergoing hematopoietic stem cell transplantation

observed that affective distress and fatigue were common and appeared to be associated most with psychosis-behavioral delirium symptoms.[82] The new emerging feature called 'chemobrain' should stimulate further research in the possible relation between delirium and fatigue.[83]

Paraneoplastic neurological syndromes

Even though quite rare, these neurological complications of cancer are probably underestimated. Sometimes these symptoms can precede the outbreak of the malignant disease by months or even more, or may lead to the diagnosis of cancer. Box 65.1 shows some of the syndromes associated with fatigue. Lung cancer has the highest incidence of paraneoplastic syndrome.[84]

Box 65.1 Paraneoplastic neurological syndromes associated with fatigue

- Progressive multifocal leukoencephalopathy

- Peripheral paraneoplastic neurological syndrome

- Paraneoplastic encephalomyelitis

- Ascending acute polyneuropathy

- Amyotrophic lateral sclerosis

- Neuromuscular paraneoplastic syndromes: dermatomyositis; polymyositis; Eaton–Lambert syndrome; myasthenia gravis

- Subacute motor neuropathy

- Subacute necrotic myelopathy

Symptom control oriented treatments

OPIOIDS

Nearly 90 percent of patients with advanced cancer receive opioids;[1] these drugs are known to act on the reticular system and cause sedation and drowsiness, which can be perceived by patients as a dimension of fatigue. Opioids may interfere with concentration and can contribute to mental fatigue. On the other hand, their effect in relieving pain may contribute to a less sleep deprivation and possibly to less fatigue.

ANTIDEPRESSANTS

Common side effects of antidepressants are weight gain, sexual dysfunction, sleep disturbances, fatigue, apathy, and cognitive impairment. Selective serotonin reuptake inhibitors and atypical antidepressants (e.g. venlafaxine, bupropion, and nefazodone) show relatively favorable short-term as well as long-term tolerability compared with older drugs (e.g. tricyclics and monoamine oxidase inhibitors).[85]

ANXIOLYTICS

All central actions of the benzodiazepines are based on a common molecular mechanism. Reactions that are CNS depressant, such as sedation, fatigue, ataxia, impairment of motor coordination, and intellectual functions including memory are most frequent, especially in the elderly.[86]

ANTIEMETICS

There is clear evidence that almost all antiemetics might cause fatigue. In an anecdotal report, however, five female patients with chronic fatigue syndrome were eligible to receive oral granisetron for one month: the treatment with granisetron resulted in significant improvement in fatigue and functional impairment. Activity level showed no significant increase.[87] The significance of this finding has still to be assessed.

STEROIDS

On the one hand steroids can be a cause of fatigue by inducing myopathy, and on the other hand they can be part of the treatment of asthenia and their withdrawal can contribute to a worsening of the symptom.

Other symptoms as contributors to fatigue

Uncontrolled pain or dyspnea exacerbate fatigue. Poorly controlled symptoms may lead to insomnia, depression and anxiety, all contributors to fatigue.[1] Autonomic dysfunction, a common finding in patients with advanced cancer, characterized in others by postural hypotension, fixed heart rate, gastroparesis, is in many cases an important contributor to fatigue.

Sleep disturbance, defined as insomnia or hypersomnia occurring nearly every day, may appear as a self-standing symptom or as an epiphenomenon of depression. Among cancer patients it has received limited attention in clinical studies: it is estimated to range from 23 percent to over 50 percent.[70] There is a correlation between sleep patterns and fatigue: most patients with chronic fatigue syndrome complain of unrefreshing sleep. It can be supposed that the perceived sleep quality is of greater importance than the sleep characteristics. There is some evidence that sleep disturbance is associated with patient's fatigue level: a recent study, conducted in patients undergoing radiotherapy, found a correlation between improvement in sleep patterns and decrease in fatigue.[88] The relation between sleep disturbance and fatigue in cancer patients may be related to disease and treatment-induced abnormalities in cytokine levels. Many cytokines involved in cancer and cancer treatments have been associated with fatigue and sleep disorders. For example, injection of TNFα or IL-1 induces non-REM sleep and IFNα reduces the amount of both

slow-wave and REM sleep.[89] Anderson *et al.* indicate that symptoms of sleep disturbance are highly prevalent among cancer patients and that sleep disturbance is a significant predictor of severe fatigue in these patients.[70]

Key learning points

- Fatigue is the most prevalent finding in patients with malignant disease. In the mean time it is the most underestimated condition that impairs function and quality of life. It has unfortunately still to be considered a mostly silent symptom, because it is not reported by the patient, not perceived and therefore not investigated by the physician.

- Even though quite often fatigue, or at least a part of it, might be attributed to other findings (symptoms, therapy side effects) therefore considered as an epiphenomenon, there is now enough evidence that fatigue is a self-standing symptom complex. In this sense, it deserves to be considered as a syndrome.

- Fatigue is almost always a multifactorial symptom. However in several cases one of the contributing factors may be apparently predominant. For this reason it is worth investigating the different possible causes, with respect to important therapeutic consequences.

- A lot of research in the field of fatigue is needed. In the past few years some contributing factors, such as cachexia and anemia have been investigated much more than others. Unfortunately the choice of research fields is sometimes also influenced by the pharmaceutical companies, which identify a potentially huge market for their products. There are two sides to the coin: on the one hand this helps to recognize fatigue as a major problem with major impact on quality of life and stimulates research. On the other hand fields of research that might also be important are overlooked. We feel that beside clinical interest and research on anemia and cachexia, clinical researchers should also have an interest in the study of sleep disturbances, endocrinological dysfunction, psychiatric conditions and the therapeutic balance between utility and futility of physical training and rest.

Assessment of fatigue in palliative care

JON H LOGE

WHAT IS FATIGUE?

Fatigue is an ambiguous phenomenon commonly described by patients as a sensation of tiredness, lack of energy, or exhaustion. In accordance with this, fatigue is often defined as a nonspecific and subjective feeling of tiredness, physically and/or mentally. However, no common agreed upon definition exists.[1,2] Fatigue may therefore represent different phenomena.

First, fatigue may be a physical symptom commonly defined as a perception, feeling or belief about the state of the body.[3] Physical symptoms are most commonly associated with pathological processes. Still, there is not a direct association between the pathological processes and the accompanying physical symptoms. Physical symptoms are influenced by the individual's perceptions, such as stated in the current definition of pain.[4] Second, fatigue may be a psychophysical symptom. These symptoms are commonly associated with mental health such as in the chronic fatigue syndrome (CFS) and in other psychosomatic conditions dominated by medically unexplained symptoms.[3] Psychophysical symptoms are not clearly physical or psychological in origin. Third, fatigue may be an emotional symptom. Fatigue is commonly observed in depressive conditions, and it is included as a depressive symptom in the current diagnostic criteria for depression.[3,5] However, it has been suggested that fatigue should be excluded as a depressive symptom in somatically ill patients due to the similarities between fatigue and the expressions of the disease processes (i.e. fatigue is a physical symptom).[3,5]

Thus there are different types of fatigue, but at present we are not able to clearly distinguish between them.[6] Fatigue is often categorized in various dimensions, but experts do not agree into which dimensions it should be categorized.[2,7] The multidimensionality of fatigue is grounded on theory and empirical data from different populations including cancer patients,[8–10] patients with nonmalignant diseases,[11,12] and disease-free cancer survivors.[13–15] Qualitative studies have suggested that cancer-related fatigue implies at least three distinct dimensions: a physical sensation (decreased capacity for physical work), affective sensations (reduced energy level, low mood), and cognitive sensations (lack of concentration, impaired memory).[8] However, it is unresolved whether these dimensions are stable and reproduced in more general settings.

FATIGUE IS A FINAL COMMON ENDPOINT

Several factors may cause fatigue, but specific biological mechanisms are at present relatively poorly understood.[7,16] The majority of the studies on fatigue have been cross-sectional which limits the possibility to explore causality. Although several proposed mechanisms are theoretically sound, a simple mechanistic approach (one cause – one symptom) is too simplistic in most clinical and scientific settings. The latter view is supported by the fact that most physical diseases are accompanied by fatigue.[7] Further, in cancer and palliative patients, many common symptoms such as pain, dyspnea, cachexia, and sleep disturbances correlate significantly with fatigue.[17–19] Additionally, correlates of fatigue also differ between populations. Stone et al. demonstrated that among palliative care inpatients, fatigue severity was significantly associated with pain and dyspnea scores. In healthy controls fatigue severity was significantly

associated with anxiety and depression.[20] Finally, fatigue characteristics do not differentiate between fatigue of physical or mental origin.[21] The predictive value of fatigue as a symptom is consequently low, and fatigue is probably best seen as a final common pathway to which many factors contribute.[22] The pathways may differ between populations. In palliative patients, fatigue is strongly related to physical aspects of the disease as opposed to healthy persons. In the latter, fatigue is most strongly related to psychological distress.[20]

FATIGUE: A SIMPLE SYMPTOM OR PART OF ILLNESS BEHAVIOR?

The individual patient will probably experience fatigue as a symptom comparable to other subjective symptoms such as nausea, pain or dyspnea. As stated, there is never a direct relationship between a pathological process and a symptom, and this is important to be aware of in assessments of fatigue.[23] Symptoms are more or less influenced by psychological and social factors.[24] The distinction between the pathological process (the disease) and the subjective experience of disease (the illness) is therefore of special relevance in relation to fatigue.[23] For some symptoms such as nausea and pain there are specific neuronal pathways, which convey the message from the affected part of the body to the brain where the information is processed and eventually expressed. In clinical settings we can therefore assume that a subjective sensation of pain reflects an underlying pathological process (for example skeletal metastases) that has activated the neuronal pathway. No specific neuronal pathway has been demonstrated for fatigue, and the specificity of fatigue as a symptom is low, i.e. most known diseases and many different pathological processes are accompanied by fatigue. Fatigue is therefore a common part of being ill.

Fatigue in patients with cancer correlates with increased symptom distress, decreased quality of life and even shortened survival.[25] Approaching fatigue as a 'simple' symptom that can be alleviated through one single intervention is therefore an oversimplification. Fatigue must be assessed and understood as part of the illness experience in most situations. Thus, patients with terminal cancer and other severe diseases probably have to experience fatigue at some level. Fatiguelike behavior can also be observed in other mammals, and from an evolutionary viewpoint one may argue that the 'fatiguelike' behavior must have been selected for some reason, for example improved protection from predators.

These points illustrate the complexity of the fatigue phenomenon in research and in practice. Instead of asking if a patient experiences fatigue, one should ask how much fatigue she or he experiences. Ideally one should anchor the level of fatigue to other criteria such as an expected level or a relevant comparison group. Comparison groups must be adjusted or matched for age and gender since these variables have an effect upon fatigue.[26]

HOW PREVALENT IS FATIGUE?

Fatigue is reported to be prevalent in most studied populations including patients with cancer and palliative care patients.[7,9] Prevalence estimates above 75 percent among cancer patients are commonly cited.[9,16,22,27,28] All palliative care patients will experience fatigue during their disease trajectory.[20,29]

Still, the prevalence of fatigue is strongly related to how fatigue is measured. The prevalence of 'severe' fatigue (defined as fatigue above a certain cut-point originally defined in the validation study of the Fatigue Questionnaire [the FQ][30]) in the general Norwegian population was 22 percent.[26] When a time-criterion was included (6 months or longer duration), the prevalence dropped to 11 percent.[26] This also illustrates the importance of the distinction between acute and chronic fatigue (usually defined by duration $\geqslant$6 months[31]).

Figure 66.1 illustrates the distribution of fatigue scores measured by the FQ in the general Norwegian population. Fatigue is close to normally distributed, and this has consequences for measurement and their interpretation.[19] Based upon such a distribution researchers on the CFS have proposed that severe fatigue as seen in CFS is the extreme part of a normally distributed phenomenon.[7] Another way of interpreting the distribution is to apply an analogy with blood pressure. Blood pressure is normally distributed, and a high level is defined by the consequences such as renal failure or cardiovascular diseases. An elevated level of blood pressure is defined on the basis of empirical data on acute and late morbidity (cardiovascular disease or renal failure). Further, an elevated blood pressure does not indicate anything about the possible underlying mechanisms (i.e. renal, endocrinologic, essential, etc.). Consequently, assessments of fatigue without referring to clinical consequences,
Figure 66.1 *Distribution of fatigue-scores on the Fatigue Questionnaire in the Norwegian general population (possible range: 0–33). Mis., missing data; TF, total fatigue.*

comparison groups or other external criteria are often of limited value.

MEASUREMENT OF FATIGUE: SOME GENERAL ASPECTS

A prerequisite for including fatigue as a study endpoint are valid and reliable measurement techniques. Several different measurement techniques have been used. These include observation, self-rating scales and objective tests.[7,27,28,32,33] There is a lack of consensus on how to define fatigue, but there is agreement on the subjective nature of the phenomenon.[34] Consequently, measurement by self-report is the preferred method.[2] Most of the early studies on fatigue used single-item self-rating measures. The validity of such measures is questionable because the wording so strongly influences the answers. For example, 'feeling tired' is reported 10 times more often than 'feeling weak'.[7] Studies in the general populations report prevalences of fatigue in the range of 11–50 percent.[7,26] This large difference is most probably explained by the use of different questions/questionnaires.

Efforts have been made to measure fatigue objectively by for example counting movements by an electronic device and using the number of movements as an expression for fatigue.[33] This is simple from a technical point of view, but the number of movements (i.e. the validity) corresponds poorly with the subjective experience of fatigue.[33]

An expert panel recently pointed to the need for systematic assessment of subjective symptoms including fatigue in cancer care.[35] In spite of the challenges related to definitions, operationalizations, and measurement of fatigue, a nihilistic approach which has been common among physicians partly related to these challenges[1] is not in line with the burden fatigue represents for the patients. In practical clinical work the choice of a measure will often be a compromise between optimal psychometric properties, brevity, simplicity, and the purpose of the assessment. It is better to measure fatigue by a single item with a verbal/numerical rating scale as

response alternatives than not measuring it at all. Still, the single items have limited reliability which restricts their use in studies. A simple question combined with a numerical rating scale such as in the Edmonton Symptom Assessment Scale is found to be a useful clinical tool.[36]

FATIGUE INSTRUMENTS

At present, measurement by self-rating multi-item instruments is the preferred method for studies of fatigue. Several self-rating fatigue instruments are available and relatively recent publications present data on the instruments' content and psychometric properties.[2,37] The instruments can be grouped within the terminology of health-related quality-of-life (HRQOL) instruments. These are commonly divided into generic (i.e. not specific to any population or disease such as the Medical Outcome Survey Short Form 36 (SF-36)[38]), disease-specific (such as EORTC QLQ-C30[39] for use in cancer patients) and domain-specific instruments, which generally include measures for psychological distress, pain, fatigue or other symptoms. Most recent generic and disease-specific HRQOL instruments include fatigue and measure fatigue in one dimension.[40] By inspection, the items on fatigue within these instruments measure physical fatigue. The psychometric properties of these instruments are generally the best documented.

Domain-specific fatigue instruments have become relatively numerous during the last 10 years, and some of the most commonly used instruments are presented in Table 66.1. Some instruments measure fatigue as a one-dimensional phenomenon, others measure it as a multidimensional phenomenon. This reflects the lack of consensus on definition and measurement of fatigue.[2] Most of the publications on the instruments are from patients with cancer in general, and the optimal instrument for palliative care is at present not agreed-upon. Still, there are some points that relate specifically to palliative patients. First, the length of the instrument is of special concern in palliative care.

Table 66.1   *Some fatigue-specific instruments applied in cancer patients*

Instruments	Characteristics	Reference
Unidimensional instruments		
Rhoten Fatigue Scale	Single item + visual analog scale	41
Visual Analog Fatigue Scale	Single item + visual analog scale	42
Brief Fatigue Inventory	9 items on numerical rating scales	43
FACIT-F	13 items, 5 response categories	44
Multidimensional instruments		
Fatigue Symptom Inventory	14 items, 4 subscales	45
Revised Piper Fatigue Scale	22 items, 4 subscales	46
Fatigue Questionnaire	11 items, 2 subscales	30
Multidimensional Fatigue Inventory	20 items, 5 subscales	10

Table 66.2   *The Fatigue Questionnaire (FQ)[30] versus the Multidimensional Fatigue Inventory (MFI-20)[10]*

	FQ	MFI–20
Number of items	11	20
Number of subscales	2	5
Number of response categories	4	5
Caseness-score	Yes	No
Intercorrelations[a]	0.55	0.30–0.86
Reliability[b]	0.79 and 0.89	0.79–0.93
Correlations with HADS-depression[c]	0.39 and 0.46	0.61–0.77
Percentage of max/min scores	0/0	3.7–15.7/9.2–33.6
Percentage of complete questionnaires	87	89

[a] Correlations between subscales.
[b] Assessed by Cronbach α.
[c] Correlation with the depression subscale of the Hospital Anxiety and Depression Scale (HADS).[51]

This was found to be of special relevance to the measurement of pain, and is probably as relevant in relation to measurement of fatigue.[47] Long instruments are too demanding to fill in, resulting in missing forms and increasing the possibility for introducing a selection bias. Second, physical fatigue, which is the feeling of being exhausted physically, is probably the most relevant type of fatigue in palliative care as opposed to, for example, mental fatigue or affective fatigue.[48] Third, including functional limitations due to fatigue (interference) is disputable since the majority of palliative patients experience several symptoms at the same time, and most of them have functional consequences. It is questionable whether it is possible to differentiate between, for example, functional limitations due to fatigue, dyspnea, nausea, or pain. Fourth, some measures presuppose fatigue, and these are inappropriate to use in individuals not experiencing fatigue. Fifth, the time frame covered by the instrument should be considered as this may vary significantly. If the purpose is to assess the level of fatigue before and after an intervention a shorter time frame is preferable. On the other hand if the purpose is to assess fatigue in cancer survivors, minor fluctuations are of lesser relevance and a longer time frame is preferable.

Generally, recent instruments have acceptable internal consistency (Cronbach $\alpha > 0.70$).[2,32] Few measures have been tested for their responsiveness to change, and the instruments' capacity to detect changes during interventions is consequently uncertain. The content of each instrument should be carefully evaluated to see if it is appropriate. This might be a challenge, and a similar challenge has been reported in relation to measurement of pain.[49] Furthermore, few instruments have been validated in palliative patients. One study compared a fatigue-specific instrument to a cancer-specific HRQOL instrument.[48] Thus, the documentation on the strengths of the instruments' validity and reliability should always be considered carefully.

The possibility to perform external validation of fatigue instruments is restricted because of the lack of a 'gold standard', and validation must consequently be indirect. However, the construct validity of fatigue-specific instruments is generally not very well documented. It is therefore not known to what degree the instruments measure the same or different phenomena. The convergent validity, which means the degree to which instruments supposed to measure the same phenomenon actually do so, has not been documented for most of the instruments. The divergent validity, which means the degree to which a measure assesses a phenomenon as distinct from similar but different phenomena, has to our knowledge not been addressed for the majority of the instruments.

Some data from the validation studies of the Multidimensional Fatigue Inventory (MFI-20)[2] and data on the FQ[30] from studies of Hodgkin disease survivors[15,50] illustrate these points and are presented in Table 66.2. The table demonstrates that the FQ and the MFI-20 differ substantially in their psychometric properties. However, the examples are from different samples and therefore definite conclusions cannot be drawn. In the study of Smets *et al.* the correlations between physical and mental fatigue and HADS depression were 0.67 and 0.61, respectively.[52] The same dimensions of the FQ correlated 0.46 and 0.39 with Hospital Anxiety Depression Scale – depression.[50] The correlation between the two dimensions (mental and physical fatigue) in the FQ was 0.55.[50] Except for low to moderate correlations between the Mental Fatigue subscale and the other subscales, all the other subscales in the MFI-20 correlated in the range of 0.66–0.86.[52] These correlations indicate that the postulated dimensions of the MFI-20 are questionable, and that the MFI-20 measures depression to a higher degree than the FQ. Studies comparing different fatigue instruments are therefore needed. A recent study which compared three fatigue instruments concluded that single questions about lack of energy or fatigue severity may provide a simple and acceptable way to assess fatigue.[53]

INTERPRETING MEASUREMENTS OF FATIGUE

Most studies of fatigue in patients with cancer have been performed in convenience samples by cross-sectional designs and without use of comparison groups.[19,28] Our present knowledge of fatigue in cancer patients may therefore consist of arbitrary snapshots of a phenomenon that fluctuates over time. The cross-sectional studies of fatigue in convenience samples can generate hypotheses, but do not give opportunities for generalizations. Further, without knowing the natural course, it is also difficult to assess the need for interventions. For example, fatigue may be a self-limiting process as demonstrated by Greenberg et al., who measured fatigue during radiotherapy after lumpectomy in women with breast cancer (stages I and II).[54] The level of fatigue increased during the first part of the radiotherapy, then reached a plateau and dropped to the pretreatment level after termination of the radiotherapy.[54]

The choice of comparison groups in studies of fatigue may strongly affect the results and thereby the interpretation of the findings. This is illustrated by an example from a survey on fatigue in a representative sample of the Norwegian general population.[26] The respondents were asked if they had any of five different target diseases or nine different current health problems as used in the International Quality of Life Assessment project.[55] Based upon the answers, the sample was divided into four groups (no disease or current health problem, past or current disease only, current health problem only, both past or current disease and current health problem).[26] Fatigue is reported as cases (i.e. fatigue of a substantial level for 6 months or longer).[56] As presented in Figure 66.2, there were few patients with fatigue in the group not reporting diseases or health problems. The percentage of patients was fairly equally distributed in the groups only reporting diseases or current health problems. The highest proportion of cases was found in the group reporting both health problems and past or current diseases. Due to the normal distribution of fatigue in the general population, comparing cancer patients with subjects without health problems will boost up the differences. Such differences might be of lesser clinical significance. In the worst case, such comparisons may result in type I errors.

In general, several possibilities for interpretation of fatigue measurements exist.[57] The use of general population norms (norm-based comparisons) has some advantages and is of special relevance in cross-sectional studies. One advantage is that the level in the patient group is anchored to the population as a whole. The clinical significance of the findings may therefore be addressed without the tautological deduction from statistical significance to clinical significance. The norms are the best estimate for an expected value in the general population. Other comparison groups might be more or less representative, and it is generally a challenge to decide the representativity of a comparison group. The selection of an appropriate control
Figure 66.2 *Fatigue cases in the Norwegian general population grouped by health condition. NDCHP, no disease or current health problem; PCD, past or current disease only; CHP, current health problem only; DCHP, both past or current disease and current health problem.*

group is the main difficulty with the case–control study.[58] Population norms might be used several times, and subgroups of the norms can be matched with the patient group on age, gender, and other variables known to impact upon fatigue or these variables can be controlled for.[26] Further, the norms may be used for estimation of effect sizes by calculating standardized deviations from the norms (subtracting the norm mean score from the patients' mean score and dividing by the standard deviation of the norm).[57] Effect sizes calculated in this way compare well with evidence-based effect sizes.[59] Effect sizes can be used to interpret both cross-sectional and longitudinal group-based differences.[60] Additionally, clinical meaningful effect sizes are also necessary for performing power calculations in the planning phase of a study.

ASSESSMENT OF FATIGUE IN CLINICAL PRACTICE

Assessment of fatigue in palliative practice might be a challenge, and fatigue is probably often neglected or overlooked.[61] Physicians' neglect of fatigue might have historical reasons,[1] but it is also probably related to the nonspecificity of fatigue as a symptom. By asking, the physician might fear ending up in a long consultation, taking several tests, not finding any treatment options and ending up with presenting general advice. For these reasons, physicians probably omit to address fatigue, and the lack of documentation on treatment alternatives might further support such a nihilistic or avoidant approach. The physicians' beliefs about fatigue are therefore of relevance.[62]

However, the prevalence of fatigue, the overall aim of palliative care to prioritize the patients' quality of life and the burden fatigue imposes on the patients and their families both psychologically and functionally do not support an avoidant approach. In fact, many patients are relieved just by being asked, they feel assured by adequate information tailored to their level of knowledge, and many are well aware of the limited possibilities for documented treatment alternatives. The aims for assessment of a patient with a possible CFS can be modified for use in palliative care:[62]

- to establish a working relationship with the patient
- to elaborate on the symptom with a biopsychosocial assessment
- to address possible medical explanations
- to consider possible psychiatric explanations
- create an initial management plan.

The clinical assessment of fatigue as a symptom should follow general guidelines for symptom assessment in palliative care.[63] The assessment should include characterizing the severity, temporal features (onset, duration, course and daily pattern), exacerbating and relieving factors, associated distress and if possible impact on daily life.[22,61] To measure fatigue severity, a simple verbal rating scale or a numerical rating scale such as the item on fatigue in the Edmonton Symptom Assessment Scale might be useful both for the physician and the patient.[22,36] It is not documented that multi-item instruments have advantages compared to single-item measures in individual assessments of fatigue in palliative care. This is because the multi-item measures are designed for group assessments. However, one should be aware of the effect of the wordings in the single-item measures.

Illness beliefs are found to be of particular relevance in assessment of chronic fatigue in settings other than palliative care,[62] but might be relevant in palliative care as well. In general, addressing illness beliefs open-mindedly and in respect of the patient's beliefs strengthens the physician–patient relationship.[62] Assessment of illness beliefs is also of practical use because it might help to clear up misconceptions and also indicate possibilities for successful treatment. For example, a patient with a strong belief of fatigue being a direct consequence of a specific physiological disturbance might need more information and prompting to start physical training than a patient who believes fatigue to be the consequence of all the stressors affecting her or him. Further, assessment of previous experiences with health personnel in relation to fatigue is often productive. Many fatigued patients report that previous complaints about fatigue have not been taken seriously, and this might have been experienced as a rejection. Such 'illness disconfirmation' from health personnel might negatively affect the working alliance with the patient, and airing previous negative experiences might be a good starting point for a constructive therapeutic alliance.[62] Fatigue is for most patients a personnel experience and often accompanied by feelings of personnel insufficiency.[34] For example, lack of energy might limit the possibility to take part in the family's life, and lowered self-efficacy and self-esteem and in the worst case feelings of guilt and personal failure might be the result. An inability to participate in ordinary life due to fatigue can be experienced as a serious loss and might further add to the stress of having a life-threatening disease.[34] The patient's way of coping with their fatigue might therefore be as relevant to assess as the functional consequences *per se.*

Finally, specific factors potentially contributing to fatigue should be assessed. These should include pain, mood, sleep disturbances, immobility and lack of exercise, medications and comorbid conditions.[61] This part of the assessment should focus on possible correctable causes. The list of possible 'causes' is long and includes direct effects of the underlying disease, effects of treatments, intercurrent systemic disorders such as anemia or infections, medications such as opioids, and psychiatric conditions such as depression.[22,61] In practical clinical work the distinction towards depression is best assessed by asking about mood. The simple question 'Are you depressed?' is a good screening tool for depression in palliative patients.[64] The question might easily be supplemented with questions about mood during the day, about what brings pleasure and about loss of interest in things or persons that usually bring pleasure. If a patient does not feel depressed, experiences normal mood during the day and experiences pleasure as expected, a depression is not the likely cause for the fatigue. It is also noteworthy that the standard criteria for depression are not fully valid in somatically ill people, and the correlation between fatigue and depression is probably much weaker in palliative care patients than in other cancer patients.[20,65]

An ordinary physical examination should always be done. Signs of infection, anemia, weight loss, and respiratory distress should be looked for. Since fatigue has so many possible etiologies, a number of laboratory tests can be relevant. Such tests should be guided by the clinical picture. A management algorithm for cancer-related fatigue has been suggested, but its usefulness in clinical practice in general and in palliative clinical practice in particular has not been documented.[22]

Diagnostically the proposed criteria for cancer-related fatigue might be of some use although they have not yet become 'official' and are not fully validated.[66] An interview guide to facilitate and standardize the diagnostic process has also been tested out.[67] The diagnostic criteria have been tested out in a mixed population of cancer survivors.[68] At the moment it is uncertain whether there is any gain in using them in clinical settings. However, the criteria might be of greater value in relation to research, similar to the criteria for CFS which were developed for use in research.[31]

CONCLUDING REMARKS

Fatigue is fascinating, complex and hard to explore. In the beginning of the last century, it was proposed to ban the

identical phenomenon, asthenia, from science.[69] Our present technology makes research on fatigue possible, but the complexity of the phenomenon should be reflected in the research questions, study designs, measurements, and interpretation of results. Clinical experience tells us that fatigue is of great concern for palliative patients. Therefore the lack of knowledge on specific mechanisms and effective treatment options should not keep us from addressing the issue in clinical settings.

Key learning points

- Fatigue is a subjective phenomenon with multi-causal etiology.

- Fatigue is assessed by reports from the patients (i.e. by questionnaires).

- Many questionnaires are available, but few have been compared.

- The dimensionality of fatigue is unresolved but physical fatigue is most relevant in palliative care.

- A comparison group is warranted in most assessments and population norms have some major advantages.

- In clinical settings the most important assessment is to ask the patients about their fatigue, how it affects them and how they handle it.

- Assessment of possible underlying mechanisms in clinical settings should be guided by the possibility to base treatment decisions on the findings.

Exercise, physical function, and fatigue in palliative care

KERRY S COURNEYA, JEFFREY K H VALLANCE, MARGARET L McNEELY, CAROLYN J PEDDLE

INTRODUCTION

Cancer-related fatigue (CRF) is defined as a common, persistent, and subjective sense of tiredness related to cancer and/or its treatments that interferes with usual functioning.[1***] This is distinguishable from normal fatigue in that CRF symptoms are severe, distressing, and persist regardless of adequate amounts of sleep and rest.[2] Whereas approximately 20–30 percent of the general population report frequent tiredness,[3] between 60 percent and 90 percent of cancer survivors report CRF.[2] The etiology of CRF is unclear but multiple factors are likely involved. It may be caused by tumor-related and/or treatment-related factors such as decreases in the availability of metabolic substrates, hormonal changes, increase in proinflammatory cytokines, cachexia, neurophysiological changes in skeletal muscle, muscle wasting, decreased ventilatory ability, anemia, and altered sleep patterns.[4–7]

Cancer-related fatigue has proved to be a difficult symptom to manage.[2] One pharmacological intervention that has been found to be effective is correction of anemia by erythropoietin.[8***] Most nonpharmacological interventions can be categorized as energy conserving (i.e. a passive response to the fatigue). These interventions include rest, sleep, pacing oneself, relaxation training, and group psychotherapy. Interestingly, these approaches to managing fatigue have had limited success.[8***] For example, a meta-analysis of 15 randomized controlled trials found that relaxation training in cancer survivors showed significant

improvements in blood pressure, pulse rate, nausea, pain, depression, tension, anxiety, mood, and hostility, but not fatigue.[9***] Similarly, a randomized controlled trial of group psychotherapy in 235 women with metastatic breast cancer showed improvements in depression, anxiety, anger, and confusion but not fatigue or vigor.[10**] Despite these data, however, energy conserving strategies are still commonly recommended to cancer survivors with CRF. For example, one survey reported that when cancer survivors asked their physicians what they recommended to reduce fatigue, 40 percent said nothing, 37 percent said rest or relaxation, and only 5 percent said exercise.[11] In the present chapter, we review the growing literature examining exercise as a therapy for managing CRF.

POSSIBLE MECHANISMS FOR HOW EXERCISE MIGHT REDUCE CANCER–RELATED FATIGUE

Exercise may reduce fatigue in cancer survivors by alterations in physical functioning, behavioral functioning, psychological functioning, and/or social functioning (Fig. 67.1). In the present chapter, we focus on the physical functioning category. Exercise training has the potential to attenuate fatigue by means of optimizing physical efficiency and performance.[12] The ability to resist physical fatigue is determined, in part, by both muscular and cardiopulmonary fitness.[13] With repeated bouts of appropriately prescribed exercise the various body systems undergo a progressive

adaptation to the imposed stress. These adaptations result in improved physical functioning[14] and an enhancement of energy capacity.[15]

Muscular fatigue may be defined as a reversible decrease in contractile strength that occurs after repeated muscle activity.[16] Local muscle fatigue may occur due to disturbances in the contractile mechanism of the muscle itself because of a decrease in energy stores, insufficient oxygen, and/or a build-up of lactic acid.[16] Endurance muscle fibers, or oxidative muscle fibers, are used in everyday activity both at work and in the home. These slow-twitch muscle fibers do not produce much force but are highly aerobic and therefore can sustain low levels of work for long periods of time. Disuse or deconditioning due to a period of significantly reduced activity or bed rest results in muscle atrophy and a decrease in the population of efficient, oxidative muscle fibers.[17***] Functional limitations from impaired muscular endurance can lead to significant fatigue when simply performing instrumental activities of daily living (e.g. housework or yard work).

Muscular endurance is improved by performing repeated contractions against a mild resistance.[16,18] Endurance training results in cells with increased mitochondrial size, number, and enzymatic activity.[15,16] Increased enzymatic activity in the cells allows the muscle to better use the oxygen delivered. Muscles trained for endurance also exhibit increased local glycogen fuel storage.[15,16] In addition to improving fuel stores, the endurance-trained muscle also increases fatty acid use and decreases the use of glycogen as a fuel.[15,16] Furthermore, endurance muscle training enhances the oxygen delivery system by increasing the local capillary network, producing more capillaries per muscle fiber.[16] These changes improve efficiency of the muscular system and thus allow more exercise to be performed before muscular fatigue occurs.

Cardiopulmonary endurance is determined by the ability of the cardiopulmonary system to consume, extract, deliver, and use oxygen, and to remove waste products from the body tissues. Cardiopulmonary endurance is necessary to be able to perform activities for extended periods of time without becoming short of breath.[16] Although cardiopulmonary endurance also requires muscular endurance, activities requiring muscular endurance do not always require high levels of cardiopulmonary endurance.

Cardiopulmonary endurance is improved by activities such as walking, swimming and cycling. These activities use large muscle groups, are maintained for a prolonged period of time, and are rhythmic and aerobic in nature. Cardiopulmonary endurance training produces significant changes in both cardiovascular and pulmonary systems.[15] These changes include increases in stroke volume and cardiac output and an increase in the weight and volume of the heart.[16] Blood volume is expanded along with increases in plasma volume, total hemoglobin concentration, and peripheral capillary formation. Increased breathing volumes accompany improvements in fitness and exercise training results in a significant increase in the quantity of oxygen extracted from the circulating blood.[15] Oxygen use is improved with increases in aerobic enzyme and muscle myoglobin levels, while substrate use is enhanced with increases in fat-mobilizing enzymes and free fatty acid delivery to muscle. Regular exercise also reduces resting and submaximal heart rate, systolic and diastolic blood pressure, and can alter body composition by decreasing body fat.[16] As a result, a prescribed submaximal activity can be carried out more readily and with less subjective perception of effort.[16] Furthermore, a higher peak rate of working becomes possible, and the rate of recovery of physiological variables after physical activity is enhanced.[14]

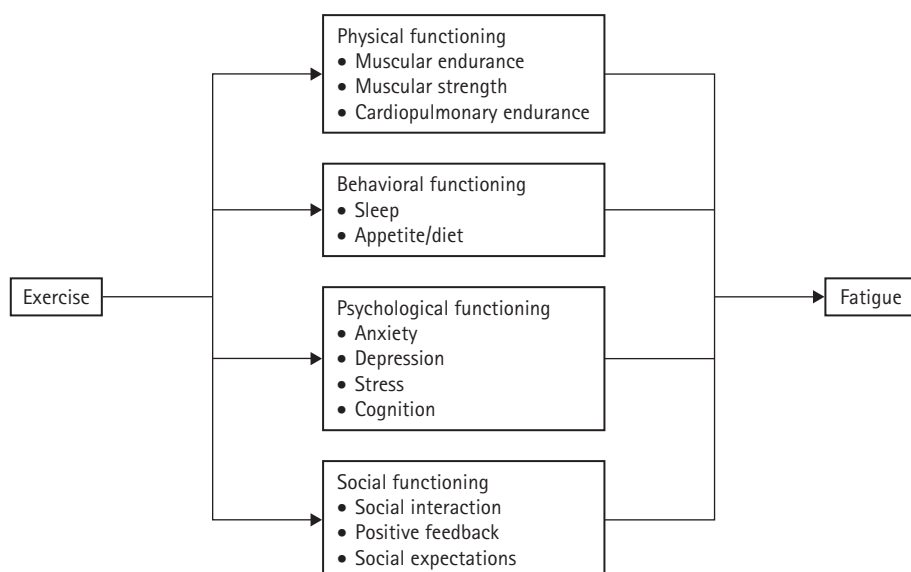
While typical day-to-day activities primarily require adequate muscular and cardiopulmonary endurance, many work and recreational activities require muscular strength and power. As the force requirement for work increases,


Figure 67.1 *Model of exercise and fatigue in cancer survivors.*

intermediate (oxidative-glycolytic) and fast-twitch (glycolytic) muscle fibers are recruited by the central nervous system.[18] Fast twitch muscle fibers are able to generate energy rapidly for quick forceful contractions; however, they do so with greater reliance on anaerobic pathways, resulting in earlier fatigue.[18]

Muscular strength is best enhanced by progressive resistance exercise training performed with high intensity (resistance) but fewer repetitions.[16] As the strength of a muscle increases, the cardiovascular response of the muscle improves so that muscular endurance and power also increase.[19] Increase in muscle cross-sectional area, as well as energy sources (creatine phosphate, ATP, myokinase, and phosphofructokinase) result from appropriately prescribed progressive resistance exercise training.[16] Neural adaptations to exercise include increases in neural activation and in the muscle's ability to produce torque.[16] Progressive resistance exercise training can also increase the maximum tensile strength of connective tissues such as tendon and ligaments, and can maintain or improve bone density.[16] Long-term performance of resistance training also benefits the cardiovascular system as evidenced by a decrease in heart rate and improvements in blood pressure and maximum oxygen consumption.[16] Muscular strength training is particularly important to attenuate both sarcopenia and disease-related declines in muscle mass.[17***]

EXERCISE AND FATIGUE IN CANCER SURVIVORS

A literature review of all studies examining exercise and fatigue in cancer survivors was conducted in July 2004 using the CD-ROM databases CancerLit, CINAHL, HERACLES, MEDLINE, PsycINFO, and SPORT Discus. Key words that related to cancer (i.e. cancer, oncology, tumor, neoplasm, carcinoma), the postdiagnosis time period (i.e. rehabilitation, therapy, adjuvant therapy, treatment, intervention, palliation), and exercise (i.e. exercise, physical activity, physical therapy, sport, weight training) were combined and searched. Relevant articles were then hand searched for further pertinent references. To be included in the review, a study had to be published in a peer-reviewed journal and examine aerobic or resistance exercise. Studies also had to include fatigue as an endpoint. We found 28 studies that examined exercise and fatigue in cancer survivors. Details of the studies are reported in Tables 67.1 (observational studies) and 67.2 (intervention studies) and we briefly summarize them here.

Table 67.1   *Summary of observational studies examining the association between exercise and fatigue in cancer survivors*

Author(s)	Sample	Design	Exercise measurement	Fatigue measure(s)	Fatigue results
Dimeo *et al.*, 1997[27*]	78 cancer survivors (34 breast, 21 non-Hodgkin lymphoma, 11 testicular, 12 other) admitted for chemotherapy and bone marrow transplantation	Cross-sectional	Maximal performance assessed by treadmill test	POMS	Higher maximal exercise significantly associated with lower fatigue
Berger, 1998[21*]	72 breast cancer survivors	Prospective	Wrist actigraphs to quantify participants movement	Piper Fatigue Scale	Higher activity levels during treatment associated with lower fatigue
Courneya *et al.*, 2000[26*]	25 cancer survivors (8 breast, 7 multiple myeloma, 7 non-Hodgkin lymphoma, 3 other) who had just completed chemotherapy and bone marrow transplantation	Prospective	Self-reported stationary cycling during hospital stay	FACT-F	Higher cycling duration per day associated with lower fatigue at discharge
Pinto and Trunzo, 2004[22*]	119 breast cancer survivors	Prospective	Self-reported exercise (7-day recall), Rockport 1-Mile Walk Test	POMS	Exercisers reported less fatigue than non exercisers

(Continued)

Table 67.1   (*Continued*)

Author(s)	Sample	Design	Exercise measurement	Fatigue measure(s)	Fatigue results
Jones *et al.*, 2004[23*]	88 multiple myeloma survivors	Retrospective	Self-reported exercise during treatment and off-treatment	FACT-F	Higher strenuous and total exercise associated with lower fatigue both during and off treatment
Vallance *et al.*, 2005[24*]	438 non-Hodgkin lymphoma survivors	Retrospective	Self-reported exercise during treatment and off-treatment	FACT-F	Survivors meeting public health exercise guidelines reported less fatigue than survivors not meeting guidelines both during and off treatment
Courneya *et al.*, 2005[25*]	386 endometrial cancer survivors	Retrospective	Self-reported exercise during the past month	FACT-F	Survivors meeting public health exercise guidelines reported less fatigue than survivors not meeting guidelines

FACT-F, Functional Assessment of Cancer Therapy – Fatigue; POMS, Profile of Mood States.

Table 67.2   *Summary of intervention studies examining the effects of exercise on fatigue in cancer survivors*

Author(s)	Sample	Design	Exercise intervention	Fatigue measure(s)	Fatigue results
MacVicar and Winningham, 1986[28*]	10 breast cancer survivors receiving treatment, 6 healthy controls	Nonrandomized controlled trial	Laboratory-based cycle ergometer, 3/week at 60–80% HR max. for 10 weeks	POMS	Exercise group and control group both decreased in fatigue
Mock *et al.*, 1994[29**]	14 breast cancer survivor receiving treatment	Randomized controlled trial	Home-based walking, 4–5/week for 30 minutes + social support group for 6 weeks	Visual analog scale	Exercise group reported less fatigue than control 1 month post chemotherapy
Dimeo *et al.*, 1997[20*]	32 cancer survivors (17 breast, 12 non-Hodgkin lymphoma, 3 other) who underwent high-dose chemotherapy and autologous peripheral blood stem cell transplantation	Nonrandomized controlled trial	Supervised treadmill walking 5/week, 15–30 minutes at 80% HR max. using interval training for 6 weeks	Not specified	0% of exercise group and 25% of controls reported fatigue with usual daily activities
Mock *et al.*, 1997[30**]	46 breast cancer survivors receiving treatment	Randomized controlled trial	Home-based, self-paced walking, 4–5/week for 20–30 minutes at 'brisk' intensity for duration of radiation therapy for 6 weeks	Visual analog scale, Piper Fatigue Scale	Exercise group reported less fatigue at posttest compared to controls
Dimeo *et al.*, 1998[31*]	5 cancer survivors who reported fatigue	Uncontrolled trial	Daily supervised treadmill walking, 15–30 minutes at 80% HR max. for 6 weeks	Clinical observation of fatigue	Clear decrease in fatigue

Table 67.2   (*Continued*)

Author(s)	Sample	Design	Exercise intervention	Fatigue measure(s)	Fatigue results
Dimeo *et al.,* 1999[32*]	59 cancer survivors (31 breast, 28 other) who had just completed high-dose chemotherapy and bone marrow transplantation	Nonrandomized controlled trial	Daily supervised bed ergometer biking during hospitalization (about 2 weeks) for 30 minutes at 50% HR reserve.	POMS	Exercise group reported no change in fatigue. Control group reported increased fatigue
Schwartz, 1999[33*]	27 breast cancer survivors starting chemotherapy	Uncontrolled trial	Home-based aerobic exercise, 3–4 times/week, 15–30/minutes, at low-to-moderate intensity for 8 weeks	POMS, Schwartz Cancer Fatigue Scale	Exercise adherers reported lower fatigue than nonadherers
Porock *et al.,* 2000[34*]	9 advanced cancer patients (4 bowel, 2 pancreas, 1 breast, 1 oral, 1 melanoma)	Uncontrolled trial	Home-based individualized program (walking and stretching) of daily activity for 28 days	Multidimensional Fatigue inventory	No change in fatigue
Schwartz, 2000[35*]	27 breast cancer survivors receiving treatment	Uncontrolled Trial	Home-based walking or patient choice, 3–4 times/week for 30 minutes for 8 weeks	Visual analog scale	Exercise reduced the levels of average and worst fatigue. Exercise adherers reported fewer days of high fatigue levels and more days of low fatigue levels
Mock *et al.,* 2001[36**]	50 breast cancer survivors receiving treatment	Randomized controlled trial ('as treated' analysis performed)	Home-based walking, 4–5/week for 30 minutes for the duration of chemotherapy (approximately 4–6 months)	Piper Fatigue Scale	Survivors who exercised at least 90 minutes per week on 3 or more days reported significantly less fatigue than survivors who were less active during treatment
Schwartz *et al.,* 2001[37*]	61 breast cancer survivors receiving treatment	Uncontrolled Trial	Home-based walking or patient choice, 3–4 times/week for 30 minutes for 8 weeks	Visual analog scale	Exercise significantly reduced fatigue
Burnham and Wilcox, 2002[38**]	18 cancer survivors (15 breast, 3 colon) posttreatment	Randomized controlled trial	Supervised low intensity (25–35% HR reserve) or moderate intensity (40–50% HR reserve) aerobic exercise program, 3 times/week for 10 weeks	Visual analog scale	Exercise group reported significantly lower fatigue compared with controls
Schwartz *et al.,* 2002[39*]	12 melanoma patients prescribed methylphenidate and 6 usual care historical controls with melanoma	Nonrandomized controlled trial	Aerobic exercise 15–30 minutes, 4/week for 4 months	Schwartz Cancer Fatigue Scale	Exercise + methylphenidate group reported reduced fatigue compared with historical controls who only took methylphenidate

Table 67.2   (*Continued*)

Author(s)	Sample	Design	Exercise intervention	Fatigue measure(s)	Fatigue results
Coleman *et al.*, 2003[47**]	16 multiple myeloma cancer survivors receiving high-dose chemotherapy and bone marrow transplant	Randomized controlled trial	Home-based combined aerobic and upper and lower strength training program, 3/week for 30–60 minutes, walking or preferred exercise for 6 months	POMS	Exercise group reported less fatigue than control group
Courneya *et al.*, 2003[40**]	108 cancer survivors (44 breast, 10 colon, 54 other)	Randomized controlled trial	Home-based, moderate-intensity walking program for 20–30 minutes, 3–5/week at 65–75% estimated HR max. for approximately 10 weeks	FACT-F	Exercise + group psychotherapy reported less fatigue than group psychotherapy alone
Courneya *et al.*, 2003[41**]	93 postsurgical colorectal cancer survivors, 66% were receiving adjuvant therapy	Randomized controlled trial	Home-based exercise program, 3–5/week, moderate intensity for 20–30 minutes for 16 weeks	FACT-F	Intention-to-treat analysis revealed no significant differences. 'As treated' analysis revealed that survivors who had ↑ fitness reported less fatigue that survivors who had ↓ finess levels
Courneya *et al.*, 2003[42**]	52 breast cancer survivors	Randomized controlled trial	Supervised cycle ergometer, 3 times/week for 15–35 minutes for 15 weeks	FACT-F	Exercise group reported less fatigue than the control group
Galantino *et al.*, 2003[43**]	11 breast cancer survivors reporting CRF	Randomized controlled trial	3 × 60 minute sessions of tai chi vs. home walking program 3/week minimum for 6 weeks	Brief Fatigue Inventory	Both the walking and tai chi groups reported a trend toward lower fatigue
Oldervoll *et al.*, 2003[44*]	9 posttreatment Hodgkin cancer survivors reporting fatigue	Uncontrolled trial	Home-based aerobic exercise training program 3/week, 40–60 minutes at 65–80% intensity for 20 weeks	Fatigue Questionnaire	Exercise reduced fatigue
Segal *et al.*, 2003[45**]	155 men with prostate cancer receiving androgen deprivation	Randomized controlled trial	Supervised resistance exercise, 2 sets of 8–12 reps at 60–70% 1 RM, 3/week for 12 weeks	FACT-F	Exercise group reported lower fatigue compared with controls
Windsor et al., 2004[46**]	66 men with localized prostate carcinoma receiving radiation	Randomized controlled trial	Home-based, moderate intensity, continuous walking for 30 minutes, 3/week at 60–70% of HR max. for the duration of their radiation treatments	Brief Fatigue Inventory	Exercise group reported no significant increase in fatigue. Control group reported significant increase in fatigue

SUMMARY OF STUDIES EXAMINING EXERCISE AND FATIGUE IN CANCER SURVIVORS

Seven observational studies have examined the association between exercise and fatigue in cancer survivors.[21*,22*,23*,24*,25*,26*,27*] Overall, the results showed that all seven observational studies reported a significant negative association between exercise/fitness and fatigue. That is, higher levels of exercise/fitness were associated with lower levels of fatigue. The primary limitation of these studies, of course, is that the causal association between exercise and fatigue cannot be established. It is certainly possible that fatigue causes reductions in exercise activity or that some third variable (e.g. depression) causes both higher levels of fatigue and lower levels of exercise.

A total of 21 intervention studies have examined the effects of exercise on fatigue in cancer survivors.[20*,28*,29**,30**,31*,32*,33*,34*,35*,36**,37*,38**,39*,40**,41**,42**,43**,44*,45**,46**,47**] With the exception of one study,[34*] all of the intervention studies showed positive effects of exercise on fatigue. Generally speaking, the intervention studies examining exercise and fatigue in cancer survivors were of good quality, consisting of randomized controlled trial designs, supervised exercise sessions, an appropriate exercise stimulus, objective fitness indicators, and validated fatigue scales. The primary methodological limitations of these studies include :

- failure to describe the methodology in sufficient detail (e.g. enrolment, randomization, blinding, loss to follow-up, and analytical plan)
- recruitment of small convenience samples
- relatively short exercise interventions
- limited follow-up
- unidimensional measures of fatigue.

Moreover, it is important to note that few studies:

- explicitly focused on cancer survivors with CRF
- included cancer survivors with metastatic or advanced disease
- attempted to identify the mechanisms for the exercise effect.
Figure 67.2 *Mediation of fatigue by peak power output. Data from Courneya* et al.[40]

Although the focus of this chapter is on cancer, the supportive role of exercise in other chronic and progressive populations has also been documented. In particular, exercise is an important component of symptomatic and supportive treatment(s) for patients with multiple sclerosis,[48***] chronic heart failure,[49***] chronic obstructive pulmonary disease,[50***] and human immunodeficiency virus (HIV)/acquired immune deficiency syndrome (AIDS).[51***]

STUDIES OF MECHANISMS OF REDUCED FATIGUE FROM EXERCISE IN CANCER SURVIVORS

Only one study has examined the potential mechanisms for the effects of exercise on fatigue in cancer survivors. Courneya *et al.*[40**] conducted a randomized controlled trial to determine the effects of a 15-week exercise training program in 52 postmenopausal breast cancer survivors who had completed adjuvant therapy with or without current hormone therapy use. The authors reported significant effects of the intervention on various fitness indices including peak oxygen consumption and peak power output, and various psychosocial measures including fatigue. Multiple regression analyses were used to provide a statistical test of the possible mediating role of physical fitness. The researchers found evidence that the reduction in fatigue that occurred with the exercise intervention was largely mediated by a change in peak power output (Fig. 67.2). These data suggest that fitness changes may mediate the effects of exercise on fatigue in cancer survivors.

FUTURE RESEARCH DIRECTIONS

Although there are almost 30 studies that have examined exercise and fatigue in cancer survivors a significant amount of research remains to be done. The primary limitation of our current knowledge is that few studies have focused on fatigue as the primary endpoint in cancer survivors with CRF. Consequently, there is good evidence that exercise reduces fatigue in the general population of cancer survivors but limited evidence that exercise can reduce fatigue in cancer survivors with CRF, especially severe CRF. It is not at all obvious that exercise will prove therapeutic for cancer survivors with severe CRF, therefore, randomized controlled trials of exercise interventions that explicitly target cancer survivors with various levels of CRF are needed.

Studies focusing on cancer survivors with metastatic or advanced disease are also needed. Most of what is known about exercise and fatigue in cancer survivors is based on studies of early-stage breast cancer survivors. Research should also examine all dimensions of CRF including physical, emotional, and cognitive to determine if exercise will be

particularly effective for one dimension of fatigue (e.g. physical) or will be equally effective for all dimensions of fatigue. It will also be important to elucidate the mechanisms by which exercise may reduce fatigue. For example, is it really necessary to improve physical fitness in order to reduce CRF? Finally, it will be important to determine the optimal type (e.g. aerobic versus resistance training), volume (i.e. frequency, intensity, and duration), progression, and context (e.g. center-based versus home-based, individual versus group format) of exercise for fatigued cancer survivors. Moreover, this research will need to overcome the methodological limitations of previous research including the use of rigorous randomized controlled trials, randomly selected samples, and longer interventions with longer follow-up.

CLINICAL IMPLICATIONS

Convincing evidence suggests that exercise reduces fatigue in cancer survivors although few studies have focused on cancer survivors with CRF. Nevertheless, exercise is now recommended as a therapy for cancer survivors with CRF.[36***,52***] For example in the USA, the National Comprehensive Cancer Network (NCCN) recommends that clinicians encourage cancer survivors with CRF to at least maintain current levels of physical activity. Furthermore, the NCCN suggests that most cancer survivors could experience benefits from a moderate exercise program implemented throughout the duration of their treatment regimen.[36***,52***] In all patients a thorough screening for comorbidities is required. Such screening should identify contraindications to exercise or a need for a referral of specialized services such as physiotherapy or rehabilitation services. Cancer survivors suffering from high levels of fatigue should be prescribed exercise on an individual basis[52***] including information from functional tests.

Tests of functional capacity are used extensively in research and clinical settings to evaluate patients suffering from heart and lung diseases (i.e. chronic obstructive pulmonary disease, heart failure, peripheral arterial disease, surgical candidates, pediatric cystic fibrosis).[53***] The tests used most often are the 6-minute walk test (6MWT), 2-minute walk test (2MWT), 12-minute walk test (12MWT), self-paced walk test (SPWT), and the shuttle walk test (SWT).[53***] The most widely researched of these is the 6MWT, which is considered easy to administer and is generally well tolerated. This test also tends to be most reflective of activities of daily living and is often used to assess response to medical interventions in patients with mild, moderate, or severe heart and lung disease.[53] The 6MWT has been indicated for use as a tool in evaluating functional status, as well as for the prediction of morbidity and mortality.[54] The 2MWT has also been proposed for populations who are not able to ambulate for 6 minutes.[55] This test has been shown to be sensitive to change following surgery, but

has not been extensively validated.[55] The shuttle walk test has also been proposed for use in patients with a wide range of disease and functional status. The SWT has preliminary evidence of sensitivity to change following a rehabilitation intervention, but has not been extensively tested. Overall, the 6MWT is the most widely researched and established functional walk test used in clinical and research settings.[53***]

Programming must make considerations for various factors such as age, current level of physical activity, type of cancer, stage of cancer, as well as the type of cancer treatment.[52***] These factors will impact the type, frequency, intensity, and duration of the exercise prescribed. Exercise should begin at low levels of intensity and duration. Modification and gradual increase of exercise is dependent upon individual ability and tolerance.[52***] Survivors with metastasis to bone, immunosuppression, anemia, neutropenia, thrombocytopenia, or fever require special attention in prescription and delivery of exercise programs.[52***] Moreover, the NCCN notes that survivors suffering from immunosuppression or neutropenia should exercise only in environments where risk of infection is a minimized (i.e. swimming pools are contraindicated by the NCCN).[36***,52***] It may be that exercise will be most appropriate for cancer survivors with chronic mild-to-moderate CRF or in the prevention of CRF. Pharmacological and energy conserving strategies may be more appropriate for cancer survivors with acute and/or severe CRF.

Exercise may also be beneficial to manage symptoms and optimize quality of life in patients with advanced stages of illness. An exercise regimen can be developed to help maintain and/or attenuate declines in physical functioning, within the context of the patient's health status, level of function and personal goals. Determining the optimal regimen may be best accomplished by an interdisciplinary team that includes physician, nurse, physical and occupational therapists, dietician, respiratory therapist, and the exercise specialist.

Cardiorespiratory exercise may be performed by 'biking' with a bed ergometer.[20*] Arm ergometry is an alternative option for those who are able to sit but unable to use their lower extremities. The primary focus of resistance exercise for the bedridden patient should be on strengthening of the extensor muscle groups (e.g. quadriceps, triceps) which are most affected by bed rest. Resistance exercise may be performed using resistance exercise bands/tubing, free weights and/or devices such as the horizontal leg press training device.[56*] Stretching and range of motion exercises may also be prescribed to maintain range of motion of a joint, improve muscle capability for circulation and oxygen exchange, provide a stimulus for bone and joint tissue integrity and reduce muscle tension (promote relaxation).[16,19] Active range of motion exercise is used when there is no contraindication to active movement and no inflammation. Active-assisted and passive range of motion exercises are beneficial when support of the body segment

allows for movement without pain or when a patient is unable to actively move a segment.[19]

Exercise regimens, in general, will need to be performed at a lower intensity, shorter duration, and with longer rest periods. Therefore, exercise sessions may need to occur more frequently during the day (two to five sessions per day) to obtain benefit and yet avoid exacerbating fatigue.[16] Furthermore, to enhance a sense of well-being, exercise may be incorporated into self-care and/or functional activities that are in line with the patient's goals.

SUMMARY AND CONCLUSIONS

Compelling evidence suggests that exercise may play an important role in reducing fatigue in cancer survivors although few studies have focused explicitly on cancer survivors with CRF. Nevertheless, there are plausible physiological mechanisms by which exercise may reduce CRF. Future research is needed, however, to delineate the role of exercise in the management of CRF. Until then, exercise may be recommended for CRF on an individual basis. It may be that exercise will be an effective therapy for the prevention and management of chronic mild-to-moderate CRF but that pharmacological and energy-conserving strategies are indicated in cases of acute and/or severe CRF.

Key learning points

- Cancer-related fatigue (CRF) has proved to be a difficult symptom to manage.

- Energy conserving interventions (e.g. rest, sleep, relaxation training) have had modest success.

- The ability to resist physical fatigue is partly determined by muscular and cardiopulmonary fitness.

- Exercise may reduce fatigue in cancer survivors by alterations in physical functioning.

- Seven observational studies and 21 intervention studies have demonstrated that exercise training can reduce fatigue in various cancer survivor populations including during and after adjuvant therapies.

- Future exercise trials should explicitly target cancer survivors with high levels of CRF.

- The NCCN encourages cancer survivors with CRF to maintain current levels of physical activity and to adopt a moderate intensity exercise program if feasible.

- Exercise may be most appropriate for cancer survivors with mild-to-moderate CRF or in the prevention of CRF.

Treatment of fatigue in palliative care

JEANETTE A BOOHENE, EDUARDO BRUERA

INTRODUCTION

Fatigue has been defined as tiring easily with decreased capacity to maintain adequate performance.[1–3] It is one of the most common symptoms in palliative care. This is because most patients seen in palliative care have advanced disease, such as acquired immune deficiency syndrome (AIDS), end-stage congestive heart failure, and most common of all, cancer. All of these diseases in their advanced stage have a high degree of fatigue, for instance fatigue is present in 60–90 percent of all patients with advanced cancer.[4–6,7*,8*,9**] Assessment and treatment of this common symptom however, is difficult as it is subjective and often underreported.

The pathophysiology and assessment of fatigue has already been discussed in the previous chapters and it is clear that fatigue is usually multifactorial. To this end, when considering how to treat fatigue, a multidimensional approach is the best. It is important to determine whether the etiology is reversible and treating these reversible causes as best as possible. However, despite treating reversible causes fatigue often persists in this patient population and treatment then needs to be symptomatic, based on the presumed mechanism.

In this chapter, we will discuss the treatment of reversible and irreversible causes of fatigue using both pharmacological and nonpharmacological modalities. To be able to manage fatigue adequately, the contributing factors, often multiple, need to be determined (Fig. 68.1), some of which may be irreversible. Detailed assessment is required to be able to target therapy and this has been discussed elsewhere in this book. Once appropriate assessment is completed, the therapeutic approach to fatigue can be divided into treating underlying causes and symptomatic treatment (Fig. 68.2).

TREATING THE UNDERLYING CAUSES OF FATIGUE

Cancer treatment

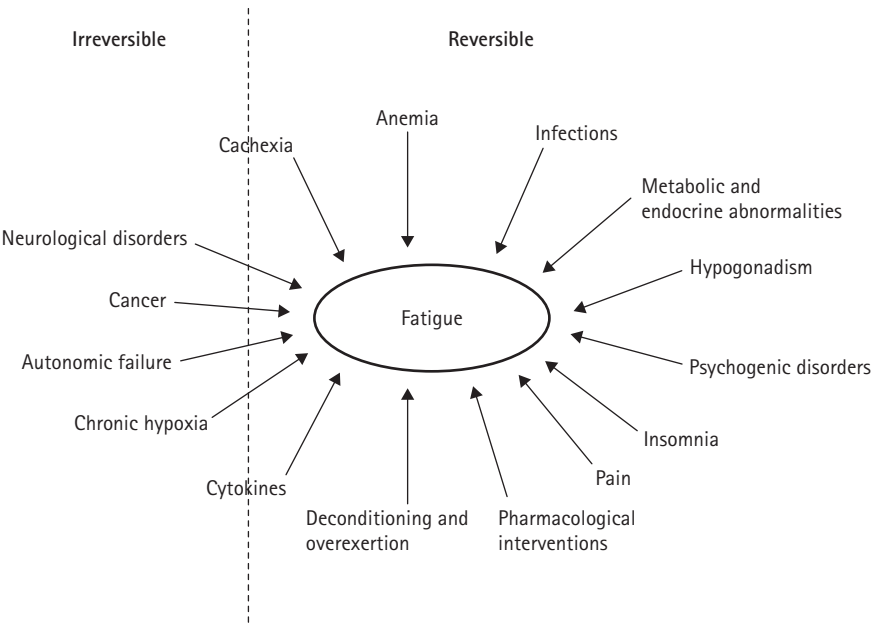
The complex association between cancer and fatigue has not been completely defined. There is little doubt however, that most patients with cancer at some time in their illness develop fatigue, and especially in the terminal phase this is thought to be as a direct result of the cancer.[6,10*,11] In a cross-sectional follow-up study of 459 Hodgkin disease patients, fatigue was significantly higher than in controls from the general population. Follow-up was by mail, and a fatigue questionnaire measuring physical and mental fatigue as well as total fatigue score was used.[12*] In patients with cancer, there is a complex interaction occurring between tumor and host, which is not well understood but is thought to result in fatigue in several ways. Tumors produce proteolytic and lipolytic factors which can interfere with host metabolism. These factors are thought to play a role in the development of cancer cachexia with which there is complex overlap and interplay with fatigue[13] as discussed in other chapters in this book and also below. Moreover, there may be other substances induced or released directly by the tumor which can also lead to fatigue.[14,15] Tumors can also act by direct invasion of brain tissue, particularly the pituitary gland, and cause fatigue by both direct (disturbance in cognition) or indirect (endocrine disturbances via the pituitary axis) mechanisms.[2,16] Management in this case is essentially treating the cancer. The successful treatment of the malignancy can result in significant and sustained improvement in fatigue.[17***] The patient and caregivers must be educated about how common fatigue is as a complication of cancer and its treatment.


Figure 68.1   *Contributors to fatigue.*
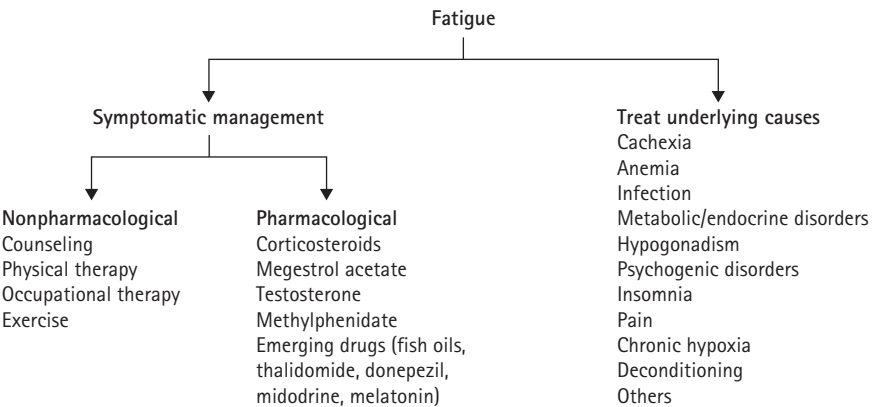

Figure 68.2   *Therapeutic approaches to the management of fatigue.*

They must also be counseled and educated about what to anticipate during and after therapy is completed with regards fatigue and mechanisms by which this common symptom can be managed such as vigilance with structured exercise and energy conservation.

Many of the cancer therapies and symptomatic treatment of other effects of the cancer such as pain, can themselves result in transient and/or prolonged fatigue and management of this is discussed below.

Therapies and medications

CHEMOTHERAPY AND RADIOTHERAPY

These treatment modalities in patients with cancer cause a specific fatigue syndrome. In isolation they both can cause

fatigue but this is augmented further when both modalities are given concurrently. Fatigue associated with chemotherapy tends to have a cyclical pattern. It occurs within the first few days of starting therapy, gets to a peak at about the time the white blood cell count is at its lowest level then improves in the week or so thereafter. The cycle is repeated with each cycle of chemotherapy and worsens with subsequent cycles, suggestive of a cumulative dose-related toxic effect.[3] Multiple chemotherapeutic agents have been studied in fatigue either in isolation or in combination with most generating some degree of fatigue. Different types of cancer have also been studied with specific chemotherapeutic regimens with varying degrees of fatigue noted depending on the cancer and the regimen.[18,19*,20**,21*,22*,23*,24*,25*,27*] A longitudinal prospective controlled study assessed 104 women with breast cancer receiving adjuvant chemotherapy

and 102 controls. Tools used included the Functional Assessment of Cancer Treatment-General Quality of Life questionnaire, with subscales for fatigue and endocrine symptoms and the High Sensitivity Cognitive Screen. Ninety-one and 83 patients, and 81 controls were assessable at the end of 1 and 2 years, respectively. Differences between patients and controls were significant for both scales. It showed that fatigue, menopausal symptoms and cognitive dysfunction were important adverse effects of chemotherapy that improved in most patients with time.[28*]

Radiotherapy causes a different pattern of fatigue when given alone. It tends to start more abruptly soon after treatment and diminishes soon thereafter but may get progressively worse as therapy continues. A prospective study of 15 women with stage I or II breast cancer having radiation treatment revealed fatigue that did not increase linearly with cumulative radiation dose over time. There was a decrease in fatigue from the first to second week then increase in the third week. Cumulative effects reached a plateau in the fourth week then were maintained for the remaining treatment course. Fatigue diminished within 3 weeks after treatment.[29*] Fatigue has been noted to diminish but not completely resolve when short breaks in therapy occur, for example at weekends.[30]

BIOLOGICAL THERAPY

Biological response modifying agents such as interferon-α cause fatigue in 70 percent of patients who receive this therapy.[31] Fatigue is one of the most important dose limiting side effects of this type of therapy. The mechanism here is unknown though some investigators have postulated diffuse encephalopathy may occur.[32*,33*]

Management of fatigue in these situations is essentially symptomatic and nonpharmacological. Patients and their caregivers need to be counseled and educated prior to commencing therapy about the anticipated fatigue associated with the different treatment modalities. Exercise, without overexertion as well as physical and occupational therapy during treatment can help minimize the sometimes overwhelming fatigue and prevent deconditioning. One common side effect of chemotherapy which may impact fatigue and has been associated with symptom improvement if treated early is anemia. This will be discussed later in this chapter.

OPIOIDS

A large proportion of cancer patients experiencing pain are on opioids. This group of medications has significant effects on the reticular system and can cause sedation, cognitive changes, and fatigue in some but not all patients. The central acting effects would explain the mental fatigue but it is more likely that the drowsiness or somnolence is what is perceived as fatigue by some patients. Most patients develop tolerance over time to the drowsiness and may as such perceive improvement in fatigue.[1,2] A trial of dose reduction if pain is well controlled and fatigue is becoming the predominant symptom can be effective. Psychostimulants such as methylphenidate and donepezil have been used to improve opioid-induced fatigue.[34**,35*,36*]

Cytokine modulation

Circulating cytokines and inflammatory proteins are thought to be associated with many of the symptoms exhibited in patients with advanced cancer such as fatigue, pain, depression, cachexia, and sleep disorders.[37,38*,39*] These products have also been associated with infections, the effects of cancer treatments including chemotherapy and radiation therapy, and with the presence of the cancer itself. One of the mechanisms shown in laboratory studies by which cytokines mediate symptoms is via a number of signals through the hypothalamic–pituitary–adrenal axis.[40*] Since fatigue is one of the most common symptoms in advanced cancer, researchers have proposed that one possible explanation for fatigue in this patient population is the increased secretion of proinflammatory cytokines, such as interleukin (IL)-2, IL-6, interferon α (INFα) and tumor necrosis factor α (TNFα), in response to both the disease and its treatment.[41,42*] Several lines of evidence support cytokines in the pathophysiology of fatigue. These include:

- The occurrence of fatigue as a major side effect of cytokines used in the treatment of cancer patients.[2,43*,44*]
- The increased levels of cytokines in nononcological conditions characterized by fatigue, such as chronic fatigue syndrome.[3,45*,46*]
- The elevation of cytokine levels seen in chemotherapy treatments for cancer.[4,47*]
- The upregulation of proinflammatory cytokines seen in several malignancies and their correlation with fatigue.[42,48,49*]

Treatment in this case can be challenging and depends to some extent on the mechanism. Evidence to date strongly supports a role for cytokine modulation with agents such as corticosteroids, cyclooxygenase (COX) 1 and 2 inhibitors (nonsteroidal anti-inflammatory drugs, nabumetone) thalidomide, monoclonal antibodies (anti-TNF, infliximab), and specific soluble receptor antagonists, some of which are currently being studied to modulate the effects of cytokines on the brain and other sites.[50,51***]

Treatment of cachexia

Cachexia has been covered in detail elsewhere in this book but there are a number of important points to note with cachexia in association with fatigue.[2] There is a complex overlap between cachexia and fatigue especially in advanced cancer. Cachexia can be reversible when due to malnutrition or starvation or in catabolic states such as acute or chronic infections. However, when due to underlying illness usually in the terminal phase such as cancer, AIDS, end-stage cardiac

disease, or chronic obstructive airways disease, it is often more difficult to reverse.[52] The significant loss of muscle mass in cachexia could explain the profound weakness and fatigue with which it is associated. Of note though is that fatigue can be present in the absence of significant weight loss and vice versa where profound cachexia and malnutrition may exist without fatigue.[2]

Treatment for cachexia secondary to malnutrition or starvation involves nutritional support. Though there is no evidence that aggressive nutritional therapy improves the quality of life in advanced cancer patients or that parenteral feeding has much impact on fatigue,[53,54] in patients where cachexia is deemed to be secondary to malnutrition these are exactly the measures that should be employed. In such patients aggressive nutritional support can result in reversing the cachexia and associated fatigue.[55*] The majority of cachexia in palliative care patients is unfortunately irreversible and treatment is often symptomatic. In addition to established agents in use including progestins (megestrol acetate), corticosteroids, and prokinetics (metoclopramide), many newer agents are being studied such as thalidomide, cannabinoids and omega 3 fatty acids found in fish oils.[56***]

Management of autonomic failure

Autonomic failure is a common outcome of advanced cancer,[57*] but can also occur in other noncancer diseases encountered in palliative care such as Parkinson disease. Symptoms associated with autonomic failure include postural hypotension with or without intermittent episodes of syncope, gastrointestinal symptoms such as nausea, vomiting, diarrhea or constipation, and anorexia.[57,58] Some of these symptoms may contribute directly or indirectly to fatigue such as postural hypotension, anorexia, and persistent diarrhea. A subset of chronic fatigue syndrome has been associated with autonomic dysfunction,[59] but this association has not been studied much in advanced diseases encountered in palliative care.

Autonomic failure is usually irreversible and can be difficult to treat in the setting of fatigue. Midodrine, a specific α_1 sympathomimetic agent, has been used to manage autonomic failure in other conditions such as diabetes and might have a therapeutic role in autonomic failure in the palliative care population. In a double-blind randomized crossover study with midodrine and ephedrine, eight patients with refractory orthostatic hypotension secondary to autonomic failure were assessed. Midodrine produced a significant increase in both systolic and diastolic blood pressure with associated improved ability to stand as compared with ephedrine and placebo.[60**] Another double-blind, placebo controlled, four way crossover trial looked at 25 patients with neurogenic orthostatic hypotension. Patients were randomized to receive either placebo or three different doses of midodrine (2.5, 10, or 20 mg) on successive days. Supine and standing blood pressures were measured sequentially and

midodrine was shown to significantly increase standing systolic blood pressure (peaking at 1 hour after dosing) with mean score of global improvement of symptoms being significantly higher for midodrine at doses of 10 mg and 20 mg compared with placebo.[61**] Other measures, including discontinuing all possible contributing medications, plasma volume expansion with increased salt intake and use of fludrocortisone, wearing pressure stockings and rising up in stages and slowly for patients with postural hypotension used in other causes of autonomic failure might also be applicable in this patient population.[62***]

Neurological disorders

A number of neurological disorders are associated with fatigue, some of which may be the primary disease such as amyotrophic lateral sclerosis, myasthenia gravis, Parkinson disease, multiple sclerosis, and other demyelinating diseases.[2] On the other hand, some neurological disorders occur as a result of the terminal disease and may sometimes precede the disease by quite a long time, such as the paraneoplastic syndromes including Eaton–Lambert syndrome and dermatomyositis/polymyositis (Table 68.1).[63] Treatment here is disease specific though most of these diseases are progressive despite treatment and both the disease and associated fatigue become irreversible, at which point symptomatic therapies both pharmacological and nonpharmacological are introduced (see Fig. 68.1).

Treating anemia

The patient group in which mild to moderate levels of anemia may exacerbate fatigue for which there is evidence that treating less severe anemia improves energy levels and quality of life includes those receiving chemotherapy. In an open label study 2342 patients from community-based hospitals, with malignancies undergoing chemotherapy, were treated with epoetin alfa. A total of 1047 patients completed the full 4 months of epoetin therapy and showed significant increase in mean self-rated scores of energy level, activity level, and overall quality of life. These improvements correlated with the magnitude of the hemoglobin increase.[64*] Another prospective community-based study with 2289 patients with nonmyeloid malignancies receiving chemotherapy received epoetin for 16 weeks. Patients reported improvement in quality of life parameters which correlated with significant increases in hemoglobin levels independent of tumor response.[65*] Some authors, however, believe that the improvement noted in treating this level of anemia may be secondary to improvement in exertional dyspnea rather than fatigue *per se*. In a retrospective cohort study of 355 patients receiving chemotherapy, both palliative and potential curative, 19 percent received blood transfusion (18 percent for anemia, 1 percent for bleeding). The chemotherapy caused reduced hemoglobin in all groups of

Table 68.1 *Paraneoplastic neurological syndromes associated with fatigue*

Syndrome	Association
Progressive multifocal leukoencephalopathy	Lymphoma, leukemia
Paraneoplastic encephalomyelitis	70% lung, 30% other malignancies,
Subacute motor neuropathy	e.g. after irradiation in lymphoma
Subacute necrotic myelopathy	Lung cancer
Peripheral paraneoplastic neuropathy	Often precedes the primary
Ascending acute polyneuropathy (GBS)	Lymphoma
Dermatomyositis/polymyositis	Associated with malignancy in 50%
Eaton–Lambert syndrome	Small cell lung cancer
Myasthenia gravis	Lymphoma, thymoma (30%)
Amyotrophic lateral sclerosis	Primary disorder with fatigue

GBS, Guillain–Barré syndrome.

cancer studied but of note was that lung cancer patients required transfusion at much higher hemoglobin levels. This was thought to be due to underlying lung disease causing more symptoms associated with anemia particularly dysnea. Factors significantly associated with transfusion were lung cancer, leukemia, and low baseline hemoglobin (<8 g/dL).[66*]

In patients with advanced disease and in the palliative care patient population, anemia is probably overdiagnosed as a cause for fatigue. Fatigue measured on a scale of 0–10 in a retrospective study of 147 patients seen in palliative care consultation with a median hemoglobin level of 11.6 g/dL did not show significant correlation between fatigue and hemoglobin level though there was a trend ($P = 0.09$).[67*] There is little doubt that anemia is prevalent in such disease states, especially advanced cancer, but it is unclear at what hemoglobin level the treatment of anemia either with blood transfusions or epoetin impacts fatigue. A retrospective cohort study on 31 patients who received transfusions of packed red blood cells in a palliative care unit in the presence of a low hemoglobin (≤8 g/dL) with or without severe fatigue or dyspnea showed some subjective improvement in wellbeing which was not related to the severity of dyspnea or fatigue. Pretransfusion hemoglobin level did not differ significantly in patients who benefited and did not benefit from transfusion.[68*] This lack of significant benefit from transfusion alone for severe anemia in this patient population further confirms the multifactorial etiology of fatigue where other more overwhelming factors such as cachexia, depression, pain, and overall debilitation may become more predominant in the terminal phase of disease.

In managing fatigue thought to be associated with anemia, assessment of the underlying cause as well as the acuity of anemia becomes important as this may influence the choice of treatment. The two mainstays of treatment here are blood transfusions, often indicated in severe anemia (hemoglobin < 8 g/dL) or synthetic erythropoietin. The goals of care need to be determined on an individual basis as well as overall prognosis since transfusions would give almost immediate results and erythropoietin could take up to 4 weeks to show response. Moreover, erythropoietin is administered by subcutaneous injection either weekly or in the case of darbepoetin sometimes less often (every 2 weeks).[64,65,69*,70***] Iron deficiency can also be fairly easily corrected with iron supplements but again this takes weeks to produce significant effect and may not be practical in palliative care patients with short life expectancies.[71**]

Infection

Patients with advanced cancer and other advanced disease states seen in palliative care are at increased risk of infection due to relative and sometimes profound immunosuppression. Fatigue is often associated with infections, especially when the course is protracted or when infections are recurrent. Prolonged viral infections are especially notorious for producing longlasting episodes of fatigue.[72*,73*,74] Fatigue may occur as a prodromal symptom and persist sometimes long after the infection has resolved. Chronic infection and cancer induce the same cytokine mediators for cachexia such as TNFα,[15] so it is possible that they share similar mediators for fatigue as well due to the overlap between cachexia and fatigue described earlier. Vigilance in avoiding recurrent infections is important here and having a low threshold for using appropriate antimicrobial therapy can minimize some of these infections.

Treating psychogenic disorders

Depression and anxiety are discussed in more detail elsewhere in this book but a few key points are worth mentioning here due to the strong correlation between these disorders and fatigue. The diagnosis of psychological distress makes up approximately 75 percent of patients without cancer presenting with fatigue.[3,75] Symptoms of psychological distress and adjustment disorders with depressive or anxious moods are much more common in this patient population than major psychiatric disorders. The incidence of depression in this group tends to be overestimated.

Self-reported scales suggest a prevalence as high as 25 percent, but in fact only 6 percent of cancer patients are estimated to have major depression and 2 percent have anxiety disorders.[76,77*] Fatigue can be the prevalent symptom in any of these disorders. It is sometimes difficult to tease out cause and effect as depression for instance may be the cause of or occur as a result of fatigue. Some groups have found significant association between fatigue and psychological distress but again this is by no means the only variable causing fatigue, reiterating the multifactorial contributors to fatigue.[78*]

Treatment here is by and large symptomatic with good expressive supportive counseling though antidepressants may sometimes be indicated especially when depressive mood makes up a large component of the adjustment disorder. Mirtazapine, an antidepressant which enhances norepinephrine and serotonin release and inhibits 5-hydroxytryptamine $(5-HT)_2$ and $5-HT_3$ receptors, has been shown in pilot studies with fibromyalgia syndrome to improve multiple symptoms including depression, fatigue, pain and sleep disturbance.[79] It will be interesting to see if this can be confirmed with double-blind, placebo controlled studies and also shown to be effective in the palliative care patient population.

Insomnia

Lack of sleep occurs for multiple reasons which themselves may be indirectly causing fatigue. Sleep may be disturbed because of uncontrolled symptoms such as pain, depression or anxiety, mild delirium with sleep cycle inversion, drugs and suboptimal conditions causing poor sleep hygiene. Insomnia is less likely therefore to be an independent variable in the etiology of fatigue and though it can cause fatigue does not cause physical weakness.[4,80*]

Appropriately assessing the patient and treating the underlying contributing factors such as pain and psychogenic disorders, as well as teaching good sleep hygiene, can improve the insomnia and may sometimes be more effective in the long run than using hypnotics and sedatives which sometimes may be indicated for short-term use.[81,82]

Metabolic and endocrine abnormalities

These are often very reversible causes of fatigue, which can be easy to treat. It is therefore important when a patient presents with fatigue to run a simple chemistry panel as part of the work-up. Abnormalities such as hyponatremia, hypokalemia, hypomagnesemia, hypercalcemia, and hyper or hypoglycemia can be readily diagnosed and corrected with simple measures such as hydration and replacement therapy. A lot of these electrolyte disturbances cause physical/muscle weakness, which can cause significant fatigue. Endocrine disorders are easily missed but can also often be readily reversible or treatable causes of fatigue. Addison disease for instance causes significant fatigue and although this is now uncommon in

Western society, hypoadrenalism *per se* is still fairly common. Many drugs can cause secondary hypoadrenalism, which has identical symptoms to the primary disorder, e.g. steroids (when discontinued abruptly). Other common endocrine disorders such as diabetes and hypothyroidism should also be excluded and if diagnosed treated promptly with appropriate replacement therapies.[1,2]

Hypogonadism

This condition deserves a separate mention from the other endocrine disorders due to recent research interest in this as a cause of fatigue with associated loss of muscle mass. Low testosterone results in loss of muscle mass, fatigue, reduced libido, and reduced hemoglobin.[83] Two large patient groups encountered in palliative care, namely cancer patients and patients with AIDS, have been found to have testosterone deficiency which in males can often be easily reversible by replacement therapy with testosterone. Some antineoplastic therapies as well as both systemic and intrathecal opioids have been shown to cause hypogonadotropic hypogonadism[84*,85*,86*,87*] and a low threshold for measuring testosterone levels and offering replacement therapy is key in managing fatigue in this patient population. Hormonal ablative therapy has been shown to double the incidence of fatigue in men with prostate cancer[88*] but of note is that this is one patient population in which testosterone replacement therapy is contraindicated.[89***]

Chronic hypoxia

The association here with fatigue is probably best studied in chronic airways disease where oxygen therapy has been shown to improve quality of life in patients with fatigue as one of the symptoms. In a prospective longitudinal study of 43 consecutive chronic obstructive pulmonary disease (COPD) patients fulfilling criteria for long-term oxygen therapy and 25 patients not fulfilling criteria, there was significant improvement noted in health-related quality of life in patients on long-term oxygen therapy. This improvement in symptoms included fatigue, emotional, and mental function and was sustained over a 6-month period.[90*]

The use of supplemental oxygen in decreasing dyspnea and fatigue or improving exercise tolerance has not been shown to be beneficial in cancer patients with mild hypoxemia. A double-blind, randomized controlled crossover trial with 31 lung cancer patients without severe hypoxemia (O_2 saturation level $\geq$ 90 percent) assessed whether or not oxygen is more effective than air in decreasing dyspnea and fatigue and increasing physical performance. There was no significant difference observed between treatment and control groups in dyspnea, fatigue, or physical performance.[91**] Earlier studies showed that patients with cancer who had hypoxemia and dyspnea at rest benefit from oxygen therapy, but further studies are required to determine whether oxygen

therapy could improve fatigue or exercise tolerance in hypoxia patients with advanced disease.[92**,93**]

Pain

Some authors have found a strong correlation between pain intensity/severity and fatigue in patients with cancer.[94***,95*] Others however, found no association between the two symptoms.[78] It is more likely that there is an indirect correlation with chronic uncontrolled pain causing psychological distress, insomnia, etc. thus impacting fatigue. Moreover, as mentioned above, some of the treatment modalities of pain can cause fatigue, for example opioids. As such, detailed assessment and targeting treatment toward the associated factors and symptoms, as well as achieving good pain control, would be the most appropriate management here.

SYMPTOMATIC MANAGEMENT OF FATIGUE

This can be divided into pharmacological and nonpharmacological management.

Pharmacological management

Pharmacological management can be further divided into established and emerging agents (Box 68.1).

Box 68.1 Pharmacological agents for fatigue

Established agents

- Corticosteroids
- Megestrol acetate
- Psychostimulants, e.g. methylphenidate, modafinil, dextroamphetamine
- Testosterone

Emerging agents

- Agents that inhibit cytokine action, e.g. thalidomide, COX-1 and COX-2 inhibitors (NSAIDs), selective COX-2 inhibitors, omega 3 fatty acids, α-melanocyte stimulating hormone
- Agents that block cytokine release, e.g. pentoxifylline, bradykinin antagonists
- Donepezil
- Monoclonal antibodies, e.g. infliximab, soluble receptor antagonists
- L-Carnitine

ESTABLISHED AGENTS

Unfortunately there is no single agent that can be used to treat fatigue in advanced diseases effectively. This is probably because of the multifactorial etiologies contributing to fatigue. However, a number of agents have been studied and shown to be effective in treating fatigue, often in combination with other modalities including nonpharmacological ones.

Corticosteroids

Studies have been done on steroids, dexamethasone, and methylprednisone and have shown improvement in fatigue. One group showed a significant improvement in appetite and strength following 2 weeks of dexamethasone. In a double-blind controlled study with 116 patients with advanced gastrointestinal cancer, dexamethasone given at a dose of 0.75 mg and 1.5 mg four times daily showed improvement in appetite and sense of wellbeing. There was however, no associated weight gain or improvement in performance status. There was also initial symptomatic improvement in the placebo group but after 4 weeks this disappeared and at this point, dexamethasone showed a statistically significant advantage over placebo.[96**] Other groups found methylprednisolone caused improvement in activity level quite rapidly but this was not sustained over a 3-week period. Forty terminally ill cancer patients were studied in a 14-day randomized double-blind, crossover trial comparing methylprednisolone with placebo. The daily dose was 32 mg and endpoints studied were pain, appetite, nutritional status, psychiatric status, daily activity, and performance. Appetite and daily activity increased in 77 percent and 21 percent of patients, respectively, with 71 percent and 57 percent reduction in depression and analgesic use, respectively.[97**] Corticosteroids to treat fatigue are probably best used on a short-term basis, as long-term use can cause myopathy and other side effects which could make fatigue worse. Moreover, studies have shown that the beneficial effects generally last between 2 and 4 weeks. Recommended doses based on studies are a dose equivalent of prednisone 40 mg daily.[2] Other beneficial effects of steroids that may impact fatigue include the effect on nausea, appetite, and pain. The mechanism of action of corticosteroids on fatigue is not known though there is evidence that they inhibit cytokines and may also have inhibitory effects directly on tumor.[98**,99*,100] The central euphoric effects of steroids are also another potential mechanism.[97]

Megestrol acetate

A number of studies in terminally ill patients given megestrol acetate have shown a rapid improvement within 1 week to 10 days, in a number of symptoms including fatigue, appetite, calorie intake, and nutritional status. Doses used range from 160 to 480 mg per day. In a randomized, double-blind crossover study with 53 evaluable patients with

advanced solid tumors not responsive to hormone therapy, megestrol acetate given at a dose of 160 mg three times daily for 10 days reported a significant improvement in appetite, activity, and wellbeing. There was also significant improvement in overall fatigue score. There was no significant change in nausea, nutrition, or energy intake.[101**] Another double-blind crossover trial to assess effects of megestrol acetate on cancer-induced cachexia looked at 40 consecutive malnourished patients with advanced non-hormone responsive tumors receiving no antineoplastic treatment. The dose used here was 480 mg daily for 7 days with crossover on days 8–15. Pain, nausea, depression, appetite, energy level, and wellbeing were assessed on a visual analog scale. Among the 31 evaluable patients, there was significant improvement in appetite, energy, and wellbeing. Caloric intake was also increased.[102**] The mechanism of action of megestrol acetate is unclear and may be due to the glucocorticoid or anabolic activity or due to effects on cytokine release or a combination.

Psychostimulants

Methylphenidate at doses of 5–10 mg in the morning and 5 mg at noon has been shown in pilot studies to be useful in treating patients with advanced cancer. In a prospective open study with 31 patients with advanced cancer and fatigue, methylphenidate at a dose of 5 mg every 2 hours as needed was given for a total of 7 days. The daily maximum dose was 20 mg. The primary endpoint was fatigue (though multiple other symptoms were also assessed daily) measured on a 0–10 scale and Functional Assessment for Chronic Illness Therapy – Fatigue (FACIT-F) was performed at baseline, and days 7 and 28. Thirty patients were evaluable and showed significantly improved fatigue between baseline and day 7. Anxiety, pain, appetite, nausea, depression, and drowsiness also improved significantly.[103*] A phase II study enrolled 37 patients with a history of breast cancer and absence of disease for >6 months but <5 years, hemoglobin level >12 g/dL, less than moderate depression and a score of ≥4 on the Brief Fatigue Inventory (BFI) scale. Patients received methylphenidate 5 mg orally twice daily for 6 weeks. Response was defined as a decrease in BFI score of at least 2 points. On weeks 4 and 6, 54 percent had a response though 19 percent withdrew due to adverse events.[104*] There is also evidence that methylphenidate results in significant improvement in activity level in patients on large doses of opioids. In a randomized double-blind crossover study, 28 patients with chronic pain due to advanced cancer (on opioids) were treated with methylphenidate (10 mg with breakfast and 5 mg with lunch) for 3 days. Activity improved and drowsiness decreased on methylphenidate. The intensity of pain and number of extra doses of analgesics also decreased.[34**] The effect of methylphenidate in this patient population may therefore be an indirect effect by improving opioid-induced sedation as well as improving pain. Also of

note are the rapid onset antidepressant effects of psychostimulants such as methylphenidate, which may indirectly impact fatigue.

Subsequent studies have not shown methylphenidate to be any more effective than placebo in the management of fatigue. Larger studies are currently under way to clarify the role of methylphenidate in fatigue. A double-blind, randomized controlled study as a follow-up to a preliminary pilot study, which showed methylphenidate to be effective for treatment of cancer-related fatigue, revealed that patient-controlled methylphenidate was not significantly superior to placebo after 1 week. This study looked at 105 evaluable patients (52 patients and 53 patients in placebo arm) randomized to patient-controlled methylphenidate taking 5 mg of methylphenidate every 2 hours as needed by mouth (maximum daily dose 20 mg) for 7 days.[105**] Currently there is insufficient evidence to use psychostimulants for the management of fatigue in cancer patients without opioid-related sedation.

Other psychostimulants studied in noncancer palliative groups include modafinil and amantadine in multiple sclerosis,[106,107] and modafinil in human immunodeficiency virus (HIV) and amyotrophic lateral sclerosis (ALS). A pilot study and a 4-week open-label trial was conducted on 30 HIV-positive patients with clinically significant fatigue on antiretroviral medications without any treatable medical conditions known to cause fatigue. After 4 weeks on modafinil, the 24 responders showed statistically significant improvement on all measures of fatigue, depressive symptoms, and executive function. The most common side effects included headache, irritability and feeling hyperactive.[108*] In an open-label trial of modafinil looking at effect on fatigue in ALS, 15 patients with ALS were treated with 200 mg or 400 mg of modafinil. After treatment for 2 weeks, fatigue and drowsiness were assessed on the Fatigue Severity Scale (FSS) and Epsworth Sleepiness Scale (ESS). There was significant reduction in scores on both scales after modafinil use.[109*] The use of modafinil in the cancer population is currently being studied.[110] Dextroamphetamine has also been studied in HIV patients with some improvement in fatigue. Wagner and Rabkin[111] have shown initially in an open-label pilot study, and later in a small double-blind, placebo controlled trial, that dextroamphetamine in this patient population is a potentially effective antidepressant treatment for both depression and debilitating fatigue. The pilot study looked at 19 men with DSM-III-R criteria for a depressive disorder with debilitating low energy, CD4 count of <200 cells/mm^3 and no history of drug dependence. There was a treatment period of 6 weeks with indefinite follow-up. Ninety-five percent of the patients reported substantial improvement in mood and energy level at a median dosage of 10 mg/day of dextroamphetamine.[111*] In the placebo-controlled trial, the inclusion criteria were essentially the same with a 2-week randomized placebo controlled trial period and blinding maintained until week 8 for responders followed by open treatment to completion of 6 months. Seventy-three percent

of patients randomly assigned to dextroamphetamine reported significant improvement in mood and energy compared with 25 percent of the placebo patients. There was no evidence of development of tolerance, abuse, or dependence on taking dextroamphetamine for the trial duration.[112**]

Testosterone

This has been discussed earlier with the treatment of hypogonadism as a cause of fatigue. The use of testosterone and its derivatives and other androgenic anabolic steroids have been shown, predominantly in patients with hypogonadism due to HIV disease, to increase muscle mass, improve energy and libido and increase hemoglobin levels. In a prospective longitudinal study over a 3-year period, 18 hypogonadal men who had never been treated were given transdermal testosterone. The mean testosterone level reached the normal range by 3 months of treatment and remained normal for the duration of treatment. Outcomes measured were bone mineral density, fat free mass, prostate volume, erythropoiesis, energy, and sexual function. The full effect on bone mineral density took 24 months but the full effects on the other tissues and energy levels took 3–6 months.[113*] A randomized, double-blind, placebo controlled study in a group of hypogonadal men with AIDS wasting looked at the effect of testosterone administration on the depression score. Fifty-two hypogonadal males with AIDS demonstrated significantly higher scores on the BDI than matched eugonadal men also with AIDS. The hypogonadal men were then treated with testosterone and there was a significant decrease noted in the BDI score for the 39 patients who completed the study.[114**] The correlation between depression and fatigue has been made earlier and hence by improving depression in this way, fatigue could potentially improve. Testosterone deficiency has also been shown to occur as a result of cancer therapy including radiation and chemotherapy as well as in the hormonal treatment of certain cancers such as prostate cancer (where testosterone replacement is not possible). The use of testosterone replacement therapy either transdermally or parenterally in patients who are hypogonadic is now on the increase.

EMERGING PHARMACOLOGICAL AGENTS

Fatigue, as stated earlier in this chapter, is the most common symptom in palliative patients and yet is probably one of the most difficult symptoms to treat. Multiple agents have been studied and found not to be effective in the treatment of fatigue, such as mazindol.[115**] With regards the established agents, results are often short term or they are associated with unacceptable side effects, e.g. corticosteroids with myopathy in long-term use or megestrol acetate with associated thrombotic risk. This often makes them unsuitable for many in this patient population. Moreover because of the multifactorial complex etiology of fatigue, it has been challenging to find a single effective pharmacological

agent to treat fatigue. Currently a number of agents are under investigation for the treatment of fatigue (see Box 68.1), some of which are discussed below.

Thalidomide

Thalidomide has been shown to be of potential benefit in the management of cachexia and may have some beneficial effect on fatigue due to the complex overlap between these two symptoms as mentioned earlier. Cytokines are thought to play a key role in this complex interaction and thalidomide is thought to act by inhibiting TNFα and modulating interleukins. It has been shown to improve the overall sensation of wellbeing in patients with cancer cachexia.[38*] A randomized controlled trial with patients with advanced pancreatic cancer and cachexia showed a statistically significant improvement in physical function associated with weight gain. Fifty patients with advanced pancreatic cancer and at least 10 percent of body weight loss were randomized to receive either 200 mg of thalidomide daily or placebo for a total of 24 weeks in a single center, double-blind, randomized controlled trial. The primary outcome was nutritional status and change in weight and there was a positive correlation between weight gain and improvement in physical function.[116**] Thalidomide was found to preserve performance status in a randomized placebo-controlled study in patients with advanced HIV disease and cachexia. Twenty-eight adult patients with advanced HIV disease on antiretroviral therapy for at least 6 months without any active opportunistic infection and who had 10 percent weight loss in the previous 6 months were randomized to receive 100 mg of thalidomide four times daily or placebo for 12 weeks. The primary outcomes measured were weight gain or no progression of wasting and secondary outcomes were Karnofsky performance status, HIV viral burden and CD4 cell count. The Karnofsky index was significantly higher in the thalidomide group by the end of the study period.[117**]

Omega 3 fatty acids

Omega 3 fatty acids (fish oil) has been shown to improve performance status in pancreatic cancer patients with cachexia after 3 weeks of treatment. Twenty patients with unresectable pancreatic adenocarcinoma consumed two cans of a fish oil-enriched nutritional supplement per day in addition to their usual dietary daily intake. At the end of 3 weeks and again at 7 weeks, patients showed a significant weight gain with improvement in performance status and appetite.[118*] The mechanism here is thought to be similar to thalidomide acting on cytokines and studies have mainly been in cachexia.[119***] Other studies however, have not found any significant difference between fish oil and placebo in influencing fatigue, nutritional status, or function in patients with advanced cancer. In a randomized double-blind, placebo-controlled study of 60 patients with advanced cancer randomly assigned to

take fish oil capsules or placebo, there was no significant improvement in appetite, fatigue, nutritional status, caloric intake, wellbeing, or functional status after 2 weeks.[120**]

Donepezil

Medications which enhance intracerebral cholinergic activity may offer an alternative approach to psychostimulants such as methylphenidate for treating opioid-induced sedation and fatigue with less side effects. Pilot studies have shown donepezil, a centrally acting acetylcholine esterase inhibitor, to be effective in the treatment of opioid-induced sedation and related symptoms (fatigue, anxiety, depression, anorexia, insomnia and wellbeing) in patients with cancer pain. In a retrospective study in which 40 patients (37 of whom had cancer) receiving long-term opioid therapy (on a stable dose for at least 2 weeks) were also taking donepezil at a dose of on average 9 mg/day for an average of 21 days, 73 percent of the evaluable 19 patients experienced improvement on the Epworth Sleepiness Scale and Clinical Global Improvement Scale. The morphine equivalent daily dose in these patients was on average 844 mg.[35*] A pilot study assessed 27 patients receiving strong opioids for pain related to cancer and reporting sedation. They were given 5 mg donepezil every morning for 7 days and symptoms including pain, sedation, and fatigue were assessed using the Edmonton Symptom Assessment Scale. Fatigue was also measured with the FACIT-F scale. Twenty evaluable patients reported significant improvement in multiple symptoms including fatigue and sedation.[36*] Randomized controlled trials are currently under way to study this effect further.

L–Carnitine

Nutritional deficiencies are among the postulated causes of fatigue in cancer patients. Deficiency in the micronutrient carnitine has been postulated to play a role here by reducing energy production through fatty acid oxidation. Some early studies have found that a number of cancer patients are deficient in carnitine and have shown some improvement in fatigue scores after supplementation with L-carnitine. An open-label dose-finding study assessed 18 cancer patients for carnitine deficiency and found 83 percent to be deficient. Preliminary data analysis of 13 patients revealed an increase in carnitine levels following supplementation with L-carnitine for 1 week. Outcome measures included fatigue, depression, sleep disruption, and performance status. With the exception of performance status, there was improvement in all the other symptoms.[121*] More well-conducted (randomized, double-blind, placebo-controlled) studies are needed to further clarify the role of L-carnitine in fatigue.

Other emerging and proposed agents for targeting the treatment of fatigue in palliative care include α-melanocyte-stimulating hormone, monoclonal antibodies against TNFα

such as infliximab, COX-1 and COX-2 inhibitors, to name a few. Herbal remedies are often used by patients with cancer-related fatigue. Ginkgo biloba for example has some activity against TNF and the potential benefits of natural products in fatigue should also be explored with good clinical studies.[51***]

Nonpharmacological management

EDUCATION

Educating the patient and caregivers about the possible causes of fatigue and informing them of how frequent a symptom it is at this stage in their disease may help them have more realistic expectations. Also providing them with information about the different modalities of treatment, some of which can be self-implemented, such as education about sleep hygiene and progressive limitation in physical activity can help empower the patient.

COUNSELING

There is some overlap here with education. Counseling a patient about what symptoms to expect, including fatigue, with disease progression or with cancer treatment helps to better prepare them for the symptom when it occurs. Studies have shown that only a small percentage of patients expect fatigue from their therapy whereas up to 89 percent of them experience it.[122*] Counseling for coping with other symptoms, such as adjustment disorder with depressed mood and anxiety, which may impact fatigue could also help with improving fatigue.

EXERCISE (OVEREXERTION/DECONDITIONING)

This has been discussed in detail in other chapters of this book. It is important however, to mention this again briefly here as it does impact the management of fatigue. Impaired muscle function may be one of the underlying mechanisms in fatigue (at least the physical component to fatigue). There are a number of studies showing muscle alterations in cancer patients and the association between reduced muscle mass in cachexia and fatigue.[123*] Prolonged bed rest or immobility has been shown to cause deconditioning with associated loss of muscle mass and decreased cardiac output. This state results in reduced endurance both for normal activities of daily living and exercise. Normal exercise has been shown to have a beneficial effect on muscle and cardiovascular fitness, however, overexertion is a frequent cause of fatigue in noncancer patients. This is an important problem to recognize in younger cancer patients who are trying to maintain their social and professional lives while receiving aggressive antineoplastic therapies such as chemotherapy and radiotherapy.[3]

Exercise is recommended as part of the therapy for fatigue in cancer patients,[124*,125] and physiotherapists and occupational therapists can suggest suitable exercises and

help achieve increased activity. The precaution here however, is that the level of exercise is appropriate for the patient and does not result in overexertion and subsequent worsening of the fatigue.[126]**

CONCLUSION

Fatigue is a multifactorial symptom which is extremely common in advanced cancer and other advanced disease states. Approach to the management of this complex symptom must therefore be multidimensional to be effective. Detailed assessment is key to appropriate management and as noted here there is still a lot of research to be done to offer adequate therapy to this patient population for such a common symptom.

Key learning points

- Fatigue is a common yet complex multifactorial symptom in palliative care.

- To offer appropriate treatment a detailed assessment is important.

- Treat reversible causes then add in symptomatic treatment if indicated – pharmacological as well as nonpharmacological.

- Multiple agents are emerging with constant research, but it will be difficult to find a single agent to manage this complex symptom.

Dyspnea

JAY R THOMAS, CHARLES F VON GUNTEN

DEFINITION/SCOPE

Dyspnea is a highly prevalent source of suffering for palliative care patients. Many patients, caregivers, and practitioners use the synonymous term breathlessness to refer to dyspnea. It is most simply defined as an uncomfortable sensation or awareness of breathing. This definition highlights the subjective nature of dyspnea. Furthermore, it supports the concept that psychological, social, and spiritual/existential issues can amplify the suffering a person experiences with dyspnea. This concept is similar to the concept of total pain or total suffering.

Dyspnea in palliative medicine must be approached within the context of a patient's goals of care. Dependent on these goals, investigations to identify and interventions to reverse sources of dyspnea may be warranted. While waiting for underlying etiologies to be reversed, palliation of dyspnea should still be pursued. Sometimes sources of dyspnea are irreversible or their reversal is incapable of restoring a patient to a subjectively defined state of quality of life. In these cases symptomatic relief of dyspnea may be the goal.

We will first present the epidemiology and what is known about the pathophysiology of dyspnea. Then we will briefly discuss the identification and treatment of the reversible causes of dyspnea. Other sources for more indepth coverage of treatment for specific causes will be indicated. The management of congestive heart failure (CHF) and chronic obstructive pulmonary disease (COPD) are presented in Chapters 97 (page 918) and 99 (page 935) , respectively. The primary focus of this chapter will be to present the evidence base for the symptomatic relief of dyspnea.

EPIDEMIOLOGY

Dyspnea is a common complaint in both cancer and noncancer diagnoses. In a representative population sample of 988 Americans living at home identified by their physicians as being terminally ill with a prognosis of less than 6 months, 71 percent had shortness of breath.[1] Depending on the stage of cancer, the prevalence of dyspnea ranges from 21 percent to 90 percent.[2–4] When there is primary or metastatic involvement of the lung, dyspnea is understandable; however, it is also a common complaint of patients with no direct lung involvement. In one study, 24 percent of cancer patients had dyspnea but no known cardiopulmonary pathology.[4] Moreover, cancer is often diagnosed in patients who have significant underlying cardiopulmonary problems, such as COPD and CHF, the two most common noncancer causes of chronic progressive dyspnea.

Worldwide, there are no good estimates of the incidence and prevalence of noncancer conditions that cause dyspnea. In 2002, the prevalence of COPD and CHF in the USA was estimated at 11.2 million and 5 million, respectively. The World Health Organization (WHO) estimates deaths in 2002 from noncancer conditions that are likely to be associated with dyspnea as follows: cardiovascular disease ~8 million, lower respiratory infections ~3.9 million, COPD ~2.7 million, asthma ~0.24 million, and iron deficiency anemia ~0.14 million.[5]

PATHOPHYSIOLOGY OF DYSPNEA

With the advent of functional brain imaging using positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), researchers may be identifying cortical areas involved in the perception of dyspnea.[6–11] One area implicated in all studies to date is the anterior insula, a part of the limbic system. Animal studies have identified neural connections between the medullary respiratory center and the cortex, including the anterior insula.[12] These connections support the hypothesis that the respiratory center may send signals concomitantly to activate respiratory muscles as well as to the cortex leading to conscious perceptions of breathing. Interestingly, the anterior insula has also been implicated in the perception of pain, hunger, and thirst.[13–19] Thus, it is intriguing to speculate that there may be some commonality to the perception of unpleasant sensations or suffering.

What signals are transmitted to the brain that trigger dyspnea? Although incompletely understood, most studies indicate three types of signal:[20,21]

- the work of breathing
- chemoreception of oxygen and carbon dioxide levels
- neuromechanical dissociation.

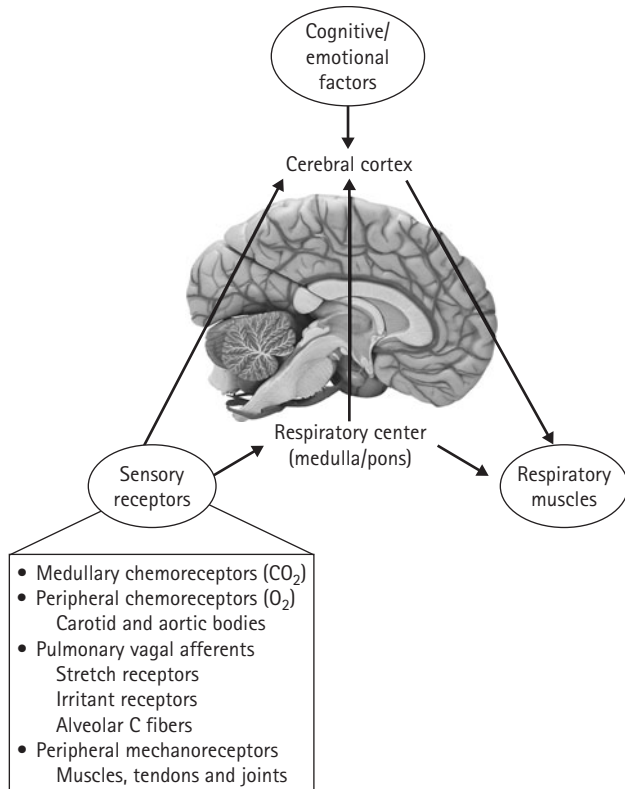
The respiratory center in the medulla and pons coordinates the activity of the diaphragm, the intercostal muscles, and the accessory muscles of respiration (Fig. 69.1). It


Figure 69.1 *Scheme of the flow of information between the peripheral and central components involved in the perception of breathing and breathlessness.*

receives sensory information from multiple sources. Peripheral mechanoreceptors in muscles, tendons, and joints send information regarding lung expansion and contractile force. The increased effort required for breathing against increased resistance (e.g. COPD) or breathing with weakened muscles (e.g. neuromuscular disease or cachexia) is sensed as dyspnea. This sense of effort probably comes not only from the increased work of ventilation relayed by mechanoreceptors but also from the increased strength of central nervous system efferent signals required to activate the muscles of breathing. As mentioned previously, these efferent signals appear to be sent concomitantly to the cortex where they presumably trigger dyspnea.

There are also pulmonary vagal afferents. These include:

- pulmonary stretch receptors, which are activated by lung inflation
- pulmonary irritant receptors triggered by certain chemicals, airflow, and smooth muscle tone
- alveolar C fibers that respond to pulmonary interstitial and capillary pressure.

These afferents may also send information directly to the cerebral cortex. An example of the role vagal afferents may play was elucidated by an experiment comparing dyspnea induced by bronchoconstriction to that induced by an external increase in breathing load.[22] The work of breathing was similar in both cases, but bronchoconstriction induced more dyspnea. Moreover, inhaled lidocaine blocked dyspnea from bronchoconstriction whereas dyspnea from external resistance was unchanged. This result implies pulmonary afferents are involved in some causes of dyspnea.

There are central and peripheral chemoreceptors sensitive to oxygen and carbon dioxide levels. Medullary chemoreceptors predominantly sense hypercapnia. Carotid and aortic body chemoreceptors predominantly sense hypoxemia. These sensations can lead to dyspnea in a way that is independent of increased respiratory effort.[23,24] Despite common belief, hypoxemia appears to play a less significant role in dyspnea. First, it takes moderately severe levels of hypoxemia to trigger the peripheral chemoreceptors.[25] Second, the compensatory increase in ventilation triggered by hypoxemia drives down the carbon dioxide level, which then partially negates the effect of the hypoxemia.

Finally, the concept of neuromechanical dissociation proposes that when there is a mismatch between what the brain desires for respiration and the sensory feedback it receives, dyspnea is enhanced.[26] For example, when researchers limit the inspiratory flow rate at which a subject is allowed to breathe, dyspnea results despite there being no change in respiratory work or chemical status.[27] Therefore, there are multiple independent and potentially synergistic mechanisms that can trigger dyspnea. Although these mechanisms all lead to dyspnea, individual mechanisms may trigger different perceptions in the type of dyspnea. Questionnaires have identified different words used by patients to describe dyspnea that may have mechanistic

implications. For example, the bronchospasm of asthma is often characterized as 'tightness'; whereas hypercapnia is often described as 'air hunger'.[23,28,29] Further study is needed to determine if treatment can reliably be based on this 'language of dyspnea'.

ASSESSMENT AND IDENTIFICATION OF CAUSES OF DYSPNEA

Box 69.1 lists the important elements of a thorough assessment. The degree of assessment is determined by the burdens

---

Box 69.1 Assessment of dyspnea

History

- Characterization of dyspnea (onset, description, quantification, associated symptoms, exacerbators and relievers)
- Past medical history (including smoking history, occupational history, prior radiation or chemotherapy)
- Psychosocial/spiritual history

Physical

- Observation (cachexia, cyanosis, clubbing, breathing pattern)
- Vital signs
- Cardiac examination (rhythm, adventitious sounds, murmurs, jugular venous distention, paradoxical pulse)
- Pulmonary examination (hyperinflation, stridor, adventitious sounds)
- Ascites
- Peripheral edema

Additional studies

- Laboratory studies (complete blood count, arterial blood gas, B-type natriuretic peptide)
- Pulse oximetry
- Pulmonary function tests
- Electrocardiogram
- Echocardiogram
- Angiography
- Imaging studies (chest X-ray, computed tomography, MRI, PET, ventilation–perfusion scan)

---

and benefits of interventions in the context of a patient's goals of care.

Patient self-report is the only accurate measure of dyspnea. Although objective measures such as respiratory rate or arterial blood gas determinations may imply dyspnea and possibly help identify the causes, they do not directly measure dyspnea. For example, patients may be hypoxic, tachypneic, and 'look dyspneic', but when they are well palliated they report no sense of dyspnea. Validated scales such as a visual analog scale[30] or the Borg scale[31] are clinically useful to quantify dyspnea.

After thorough assessment, it may be possible to identify and treat underlying causes of dyspnea. Box 69.2 lists common causes for dyspnea associated with malignant and nonmalignant processes.

Box 69.2 Causes of dyspnea

- Infection
- Anemia
- Deconditioning
- Hypoxia
- Hypercapnia
- Metabolic acidosis
- Bronchospasm
- Pulmonary edema
- Pleural effusion
- Restrictive processes (chest wall restriction, decreased lung compliance)
- Pneumothorax
- Pulmonary embolus
- Muscle weakness (neuromuscular diseases, cachexia, steroid myopathy, phrenic nerve paralysis)
- Airway mechanical obstruction
- Lymphangitic carcinomatosis
- Pulmonary hypertension
- Pericardial effusion
- Ascites
- Psychosocial/spiritual issues

SYMPTOMATIC MANAGEMENT OF DYSPNEA

Opioids

Opioids are the first-line therapy for the symptomatic relief of dyspnea. Unfortunately, the mechanism is not well understood. Endogenous opioids have been implicated in the control of dyspnea by the following experiment:[32] opioid-naïve normal volunteers were exercised to the point of dyspnea. When given intravenous naloxone, a systemically acting opioid antagonist, dyspnea was enhanced. This finding implies antagonism of endogenous opioids which were working to dampen dyspnea.

Opioid receptors are located throughout the peripheral and central nervous systems. They are also located throughout the lung with the highest concentration in the alveoli.[33] As previously noted, fMRI has identified loci in the brain believed to be involved in the perception of dyspnea, such as the anterior insula, that also seems to be involved in perceiving other types of suffering, such as pain. Thus, it is possible that opioids alter the perception of dyspnea in a manner similar to that of pain.

There is evidence that opioids can be safe and effective in controlling dyspnea in several clinical populations. In a placebo-controlled crossover study in cancer patients, Bruera et al. demonstrated that opioids relieved dyspnea without a decrease in respiratory rate or oxygen saturation.[34**] In this study at baseline, patients were dyspneic at rest despite opioids being used for pain with tolerable pain control. Thus additional opioids were effective for dyspnea even on this background of opioid use for pain. In opioid-naïve patients, as little as 5 mg of subcutaneous morphine sulfate was shown to be effective in controlling dyspnea.[35**] The effect lasted for 4 hours, which is consistent with morphine's known half-life and its effects for pain relief. Allard et al. showed that a 25 percent increase in the baseline opioid dose for cancer pain provided relief of dyspnea for up to 4 hours.[36*] Extrapolating from these results and by analogy with the treatment of pain, a reasonable regimen to control chronic dyspnea would include both a sustained-release opioid for baseline control and an immediate-release opioid for breakthrough dyspnea (Box 69.3).

Box 69.3 Opioid dosing recommendations for opioid–naïve patients

1   Start with oral morphine or equivalent 2.5–5 mg

2   Based on response at the time of maximum serum concentration (~1 hour per oral, ~30 minutes for subcutaneus/intramuscular, ~6 minutes for intravenous), the dose may be repeated or titrated up (for continued mild to moderate dyspnea, the dose can be titrated up 25–50 percent; for moderate to severe dyspnea, the dose can be titrated up 50–100 percent)

3   Calculate 24-hour opioid requirements and provide equivalent as long-acting opioid

4   Allow 5–15 percent of the 24-hour opioid dose for breakthrough dyspnea every hour orally as needed

---

Three small randomized, double-blind, placebo-controlled studies have investigated the effect of opioids in relief of dyspnea in opioid-naïve CHF patients. Chua et al. studied patients with an average ejection fraction of 21.3 percent who were New York Heart Association (NYHA) class II or III despite a good medical regimen.[37**] Compared with placebo, patients who received a single oral dose of dihydrocodeine (1 mg/kg) had better exercise tolerance with less dyspnea 1 hour after dosing. Williams et al. also studied bolus dosing just before exercise using intravenous diamorphine (1 or 2 mg) versus placebo.[38**] In these CHF patients with an average ejection fraction of 35.5 percent, diamorphine yielded a significant improvement in aerobic exercise capacity without suppressing respirations. Using a crossover design, Johnson et al. treated stable NYHA class III or IV patients on a good medical regimen with either placebo or morphine 5 mg orally four times a day over 4 days.[39**] At steady state, morphine led to a significant reduction in breathlessness on a visual analog scale without evidence of respiratory depression. Several patients were noted to remain on opioids long term with good effects.

The effects of opioids on patients with COPD have also been examined. In one single-dose study, opioid-naïve COPD patients with an average FEV_1 (forced expiratory volume in 1 second) of 0.99 L, $PaCO_2 < 46$ mmHg, and $PaO_2 > 55$ mmHg were given an oral morphine dose of 0.8 mg/kg prior to exercise.[40*] At this dosing, a patient weighing 70 kg would have received 56 mg of oral morphine, which is many times greater than a typically effective starting dose of 2.5–5 mg for an opioid-naïve COPD patient. Although there was an increase in $PaCO_2$ and decrease in PaO_2, respirations were not suppressed in a life-threatening way. In fact, dyspnea and exercise tolerance improved. Abernethy et al. performed a randomized, double-blind, placebo-controlled crossover trial of oral morphine in a group of patients who were dyspneic at rest despite maximal medical therapy.[41**] The majority of the patients (88 percent) had COPD. These opioid-naïve patients received either 20 mg of sustained-release morphine per day or placebo over 4 days. At steady state, morphine significantly decreased visual analog scores of dyspnea, again without suppressing respirations.

Unfortunately, most studies have included small numbers of patients. To overcome this problem, one systematic meta-analysis was performed.[42***] The authors identified double-blind, randomized, placebo-controlled studies that

had assessed the efficacy of opioids in the treatment of dyspnea from any cause at the time of analysis: nine studies using oral or parenteral opioids (n = 7 for COPD, n = 1 for cancer, and n = 1 for CHF) and nine studies using nebulized opioids (n = 7 for COPD, n = 1 for cancer, and n = 1 for interstitial lung disease). The meta-analysis demonstrated a statistically significant overall subjective improvement in dyspnea. A subgroup analysis of the COPD studies also demonstrated benefits of the opioids. Importantly, no deaths were attributed to the opioids. Patients did experience opioid side effects such as nausea, lethargy, and constipation. Typically, tolerance develops to these effects with the exception of constipation, but their presence highlights the need to treat these predictable side effects proactively when chronic opioids are prescribed. Despite known opioid receptors in lung and anecdotal reports that nebulized opioids improve dyspnea, a subgroup analysis failed to show any benefit from nebulized opioids. Opioid antagonists that are only peripherally acting may help further define the role of opioid receptors outside the central nervous system (CNS), such as those present in lung. Because such agents will not cross the blood–brain barrier, it should be possible to block lung opioid receptors without affecting those in the CNS. Thus, the potential contribution of lung opioid receptors in the control of dyspnea could be assessed. Methylnaltrexone is one such agent currently undergoing clinical trials for opioid-induced constipation.

Further research is needed to define the benefits and burdens of opioids in specific diseases and individuals. However, given what is currently known, a trial of a low-dose opioid such as 2.5–5 mg of oral morphine or equivalent for an opioid-naïve patient is warranted. Oral opioid peak serum levels are reached in about 1 hour. If patients remain symptomatic, an appropriate dose of opioid can be safely given again. Patients can be monitored for any adverse event. The half-life of short-acting opioids ensures that any adverse event is equally short lived. In the rare event of a severe opioid adverse event, specific antagonists exist that are highly effective.

Anxiolytics

Benzodiazepines are frequently prescribed for anxiety that often coexists with dyspnea. Overall, however, the data indicate benzodiazepines alone should not be first line therapy for dyspnea. One placebo-controlled, single-blind study of four patients with COPD demonstrated that moderate doses of diazepam improved dyspnea.[43] However, subsequent double-blind studies on healthy subjects or COPD patients with diazepam or alprazolam failed to show any benefit over placebo.[44**,45**,46**] Dudgeon and Lertzman[47] found anxiety to be correlated with dyspnea; but in their multivariate model, it was sufficient to explain only 10 percent of the variance of dyspnea. Opioids, by removing the perception of dyspnea, may be sufficient to relieve anxiety in many cases. Nevertheless, some patients may continue to have anxiety despite appropriate opioid dosing or may have an underlying anxiety disorder. In these patients, it is rational and safe to prescribe benzodiazepines in conjunction with opioids. As long as dosing guidelines are followed, there is no fear of respiratory depression.

Other psychoactive agents have also been studied. Buspirone, a nonbenzodiazepine anxiolytic, has yielded conflicting results in two studies.[48,49] The major tranquilizer chlorpromazine was tested in a small randomized, double-blind trial in healthy volunteers.[50**] Chlorpromazine 25 mg orally was able to significantly reduce dyspnea compared with placebo without increasing sedation. Larger studies will be needed to clarify its role in the symptomatic treatment of dyspnea. However, in dyspneic patients with a component of delirium/psychosis, it may be a reasonable choice.

Oxygen

Many clinicians use oxygen for dyspnea independent of etiology, whether or not hypoxemia is present. Often, patients report improved dyspnea with oxygen when they are not hypoxemic or when they remain hypoxemic despite oxygen. A partial explanation for this observation may be that oxygen has a placebo effect, potentially due to the medical symbolism inherent in its use. However, another explanation comes from studies that have demonstrated that stimulation of the trigeminal nerve (V2 branch) dampens dyspnea.[51**,52**,53**] Subjects who are made experimentally dyspneic report less dyspnea or have a decreased ventilatory response to provocation when cool, moving air is directed at the cheek or nasal mucosa. This result is consistent with the observed improvement in dyspnea seen simply by having a fan blow air across a patient's face.

Thus, if patients are hypoxemic and symptomatic, it is rational to attempt to reverse the hypoxemia and dyspnea with oxygen. If palliation of dyspnea is unsuccessful, oxygen does not need to be continued simply because of the hypoxemia. The use of oxygen must be individualized. In COPD patients with hypoxemia, oxygen may decrease mortality without significantly affecting quality of life. However, oxygen also has burdens that must be included in the decision about its use. Oxygen is costly, explosive, restricts mobility, affects self-image, and may cause CO_2 retention in some patients. If these burdens outweigh its benefits, it should not be used. However, independent of dyspnea etiology, one can consider a fan that provides cool, moving air across the trigeminal nerve distribution.

Lidocaine

As previously cited, inhaled lidocaine decreased dyspnea experimentally induced by bronchoconstriction.[22] However, small studies of patients with interstitial lung disease[54] and cancer[55] failed to show lidocaine to be better than saline. Larger studies need to be conducted to determine what, if any, subset of dyspnea is responsive to inhaled lidocaine.

NONPHARMACOLOGICAL THERAPIES

Cognitive/behavioral interventions

Dyspnea occurs in a whole person. In palliative care, there is a firm belief that to treat dyspnea and other symptoms optimally, psychological, social, and spiritual/existential issues must also be addressed. This includes assisting patients and families with education, practical care issues, interpersonal relationships, coping with fears, redefining meaning and hope, and attaining a self-defined sense of peace despite an illness. This task is best accomplished with an interdisciplinary team. This concept is beginning to gain support from clinical studies.

Bredin *et al.* conducted a multicenter, randomized controlled study that evaluated the effect of a nurse-run dyspnea clinic for patients with lung cancer.[56**] This approach is similar to pulmonary rehabilitation clinics for COPD, which have also been shown to improve quality of life and function.[57] The intervention consisted of teaching breathing control, activity pacing, relaxation techniques, and psychosocial support. Relative to controls, the patients who underwent the intervention showed improvement in dyspnea scores, performance status, and emotional states. Such nonpharmacological approaches include:

- A healthcare provider employing a calm demeanor to deescalate the anxiety a patient may be feeling.
- Educating patients and their caregivers about the underlying causes of dyspnea and proactive techniques to treat dyspnea in order to reestablish some sense of control of their lives.
- Simple repositioning to improve ventilation and perfusion matching when a disease process affects the lungs asymmetrically.
- Leaning forward while sitting or standing and supporting the thorax by bracing the arms against a chair or a patient's knees has been shown to increase ventilatory capacity.
- Use of devices such as a wheelchair to reduce metabolic demands.
- Education on the optimal preemptive use of medications such as opioids or bronchodilators before known exertional triggers to improve exercise tolerance.
- Pursed lip breathing to increase end-expiratory pressure, which in turn prevents alveolar collapse and thus improves oxygenation.
- Keeping a room well ventilated, with a fan gently blowing cool air across a patient's face (trigeminal nerve stimulation as discussed previously), while maintaining a line of sight to the outside.

Integrative therapies

Pan *et al.* performed a systematic review of integrative therapies (formerly known as complementary and alternative medicine) for several symptoms including dyspnea.[58] In single-blind, randomized controlled trials of COPD patients, acupuncture[59] and acupressure[60] significantly relieved dyspnea compared with sham interventions. The role acupuncture and other integrative therapies will play in the control of dyspnea awaits more study.

NONINVASIVE POSITIVE PRESSURE VENTILATION

Noninvasive positive pressure ventilation (NIPPV) employing facemasks, nasal masks, or helmets has been used in several scenarios of respiratory failure, including neuromuscular disease,[61–63] COPD,[64] and cancer.[65] Both lung failure (primarily hypoxia) and respiratory pump failure (primarily hypercapnia) have been treated using NIPPV. Gas under pressure inflates the lungs, and exhalation occurs by passive recoil of the respiratory system. Often, pressure support ventilation is used together with continuous positive airway pressure (CPAP). A patient triggers an inspiration and the ventilator assists the breath with a preset pressure. When flow rate decreases to a certain point, the ventilator cycles down, and expiration is allowed to occur.

When CPAP is used, end-expiratory alveolar collapse is reduced enhancing oxygenation and reducing right-to-left shunting. In certain stages of a chronic condition such as amyotrophic lateral sclerosis and in some acute, reversible clinical situations such as a COPD exacerbation or pneumonia in a patients with cancer, there may be some utility to the use of NIPPV. Patients may be restored to some level of quality of life or enabled to achieve some short-term goal. This benefit must be carefully weighed against the burdens of the intervention for each individual. The role NIPPV will play in palliative care remains to be elucidated.

REFRACTORY DYSPNEA

Rarely, some patients may have dyspnea that is refractory to interventions. In these cases, palliative sedation is an ethical and legal option with patient or surrogate informed consent. The reader is referred to Chapter 103 (page 976) for further details of palliative sedation.

Key learning points

- The physiological basis of dyspnea is still being elucidated but is likely related to chemical signals (O_2, CO_2), the work of breathing, and/or neuromechanical dissociation.

- Dyspnea is a subjective phenomenon that can only be quantified by asking a patient.

- When consistent with a patient's goals of care, an attempt to identify and reverse the underlying causes of dyspnea is reasonable. While waiting for an etiology to be reversed, effective palliation is still indicated.

- When interventions to reverse the causes of dyspnea are not possible or when these interventions are not consistent with a patient's goals of care, opioids are the best therapy for the symptomatic relief of dyspnea.

- Benzodiazepines are not a first-line therapy for dyspnea but can be safely used as an adjunct to opioid therapy.

- For symptomatic relief, oxygen can be rationally tried if hypoxia is present but does not need to be continued if symptoms remain unabated. Stimulation of the trigeminal nerve distribution with cool, moving air is reasonable for symptomatic relief of dyspnea independent of cause.

- Dyspnea must also be understood in the context of a whole person, and all sources of suffering must be addressed for optimal symptom control.

Other respiratory symptoms (cough, hiccup, and secretions)

TABITHA THOMAS, ROSEMARY WADE, SARA BOOTH

INTRODUCTION

The aim of this chapter is to outline the management of cough, hiccup, and excessive respiratory secretions in the palliative care setting. The majority of research into chronic cough and hiccup has been carried out in patients with non-malignant disease, and this provides the bulk of evidence for their management in palliative care. Evidence for the management of excessive bronchial secretions and death rattle is lacking because of the difficulties in undertaking research in these areas. For this reason, some therapies are included in this chapter based on general consensus within the specialty, despite there being very little evidence for their efficacy.

COUGH

Cough is common in the general population and is generally self-limiting or can be managed by treating the precipitating cause.[1] Where this cannot be achieved, however, cough can become a persistent and distressing symptom. Approximately 65 percent of patients with lung cancer complain of cough at presentation, and its incidence and severity remain the same throughout the disease course, indicating that it is generally not well palliated.[2] Cough is also a common symptom in patients with any type of advanced cancer. In one survey, 37 percent of patients with advanced cancer complained of cough, and of these, 38 percent of these rated it as moderate or severe.[3,4]

Relentless coughing can have a profound impact on quality of life. It leads to exhaustion, breathlessness, musculoskeletal pain, vomiting, and incontinence. Disturbed sleep affects both patients and partners with consequent strain on family and social relationships.

Physiology

Cough serves as a reflex defense mechanism to remove either inhaled foreign material, or excess endogenous inflammatory products. The reflex begins with either mechanical or chemical stimulation of irritant receptors in the epithelium of the respiratory tract. Impulses are then transmitted via vagal afferents to the medulla oblongata where a cough response is coordinated. The efferent pathways are anatomically distinct from those involved in spontaneous respiration and travel via the phrenic and spinal motor nerves to the respiratory musculature, and via the recurrent laryngeal nerve to the larynx. Bronchial smooth muscle constriction is also necessary for cough production and is under vagal control.

Cough involves the initial inspiration of air followed by glottis closure and the development of high intrapleural pressure. The greater the volume of inspired air, the better the length tension ratio of the expiratory muscles, and the greater the intrathoracic pressure. When the glottis opens, a biphasic turbulent blast of air is produced as a result of the high pressure and the dynamic compression of the central airways. At high airflow velocities, the surface of the mucus is sheared off and droplets are propelled into the airway lumen.[5]

Pathogenesis

An effective cough, resulting in mucus displacement, depends upon:

- the velocity of the airstream

- the tenacity of the mucus
- a functioning mucociliary transport system.

Thus weak respiratory and abdominal muscles, for example in paraplegic patients, reduce the ability to produce a high expiratory pressure and therefore reduce the velocity of airflow and produce an ineffective cough. Mucus tenacity increases when the water content of mucus decreases, which leads to ineffective clearance. Finally, a functioning mucociliary apparatus is required to move mucus from the periphery to the more central airways from where it can be expelled by coughing.

Causes

Any form of malignant lung disease can cause an inflammatory or mechanical stimulus to cough. It may be the direct result of the tumor itself, or a consequence of consolidation associated with bronchial obstruction, aspiration or tracheoesophageal fistulae. In addition, the combination of pain and cachexia diminishes cough effectiveness and increases susceptibility to infection. Some tumors, particularly bronchoalveolar carcinoma, actively secrete mucus and therefore continuously stimulate the cough reflex. Occasionally, cough associated with increasing breathlessness is the result of an interstitial pneumonitis associated with radiotherapy.

There are many nonmalignant causes of chronic cough, which may nevertheless be relevant in palliative care. Smoking is a prime cause in adults and induces both airway inflammation and mucus hypersecretion. Because the mucociliary apparatus is also damaged, there is constant stimulation of the cough reflex. Lung damage due to smoke or persistent infection leads to chronic bronchitis and bronchiectasis, conditions characterized by chronic cough and excessive sputum production. Management is usually directed at treating the underlying cause, i.e. treating infection and increasing cough clearance, rather than cough suppression.

In nonsmoking, immunocompetent patients with a normal chest radiograph, who are not taking an angiotensin-converting enzyme (ACE) inhibitor and who do not have exposure to irritants, the most common causes of cough are postnasal drip syndrome, asthma, and gastroesophageal reflux disease. In 20 percent of patients cough is due to more than one cause.[1]

Assessment

Cough may make an important contribution to symptoms such as pain, nausea, insomnia and breathlessness, and its treatment can therefore have considerable benefits. As well as looking for an underlying cause, care should be taken to determine whether cough frequency or difficulty with expectoration is most troublesome. Once this is established

it helps make the decision as to whether therapy should be curative, protussive, or antitussive. The patient's prognosis should also be taken into account when deciding on management: if cough is severe and the prognosis short, there may be no time to treat infection or reflux, and a powerful opioid antitussive might be more appropriate.

Management strategies

SUPPORTIVE

The severity of a cough may be used as a gauge of disease progression by some patients, particularly if it was the presenting symptom of their cancer. Paroxysms of coughing are distressing to experience, alarming to watch and can lead to a fear that death will occur during an attack. Discussion, reassurance, and the establishment of a management plan to use during a coughing fit are helpful for both patients and carers.

STOP COUGH CAUSING MEDICATIONS

Among approximately 10 percent of users, ACE inhibitors cause a dry cough, which tends to be a class effect and is not dose related. There may be no correlation between the timing of drug usage and the onset of cough. It is important to note that cough of any cause can be aggravated by ACE inhibitors and this effect can take up to 4 weeks to resolve once the drug is stopped.[6**]

PHARMACOLOGIC

Pharmacological therapy can be used to treat an underlying cause or to modify the cough, in which case it is either protussive or antitussive. Protussive therapy makes the cough more effective and therefore less distressing, and is also useful if the cough is providing a useful physiological function, for example clearing a treatable infection. Antitussive therapy involves nonspecific cough suppression.

Treatment of the underlying cause

DECONGESTANTS AND ANTIHISTAMINES

Postnasal drip syndrome is the most common cause of chronic cough. Secretions from the nose or sinuses drip into the hypopharynx and stimulate the cough reflex. Symptoms of nasal congestion or discharge or a history of a recent cold are relatively sensitive but not necessarily specific[5] and ultimately a diagnosis of postnasal drip syndrome is made if cough shows a response to therapy. Sedative antihistamines and decongestants have been shown to be beneficial for both acute[7**] and chronic cough[8*] caused by postnasal drip but the effect is gradual and can take up to 2 weeks.

BRONCHODILATORS

In those with asthma or airway hyperresponsiveness, cough will respond transiently to bronchodilator therapy with

β_2 agonists,[9*] and in the long term has been shown to respond to sodium necrodomil,[10**] antileukotriene agents,[11*] and corticosteroids.[12*] In addition, the bronchodilator ipratropium bromide has been found to be useful as an antitussive in patients with chronic obstructive pulmonary disease by decreasing both sputum production and cough.[13**]

The use of bronchodilators to aid expectoration in chronic lung disease is controversial. They may reduce cough effectiveness because the increase in bronchial compliance causes the airways to collapse during the dynamic compression phase of the cough.[5] However, in one study nebulized terbutaline significantly enhanced the effects of physiotherapy on cough clearance for patients with bronchiectasis.[13*] This may have been because of enhanced ciliary beating and increased mucus hydration.

PROTON PUMP INHIBITORS/ANTACIDS

Cough due to gastroesophageal reflux can take a number of weeks to resolve in healthy subjects treated with antacids.[14] Because cough may aggravate reflux and reflux may then further aggravate cough, treatment with prokinetics and antacids may be worth considering in the palliative care setting for people with particularly troublesome symptoms.

CORTICOSTEROIDS

A dry cough associated with increasing dyspnea in those who have recently received radiotherapy to the lung should raise the suspicion of radiation pneumonitis.[15] Interstitial pneumonitis is also a rare complication of some chemotherapeutic agents.[16,17] If appropriate, radiological imaging should be carried out to confirm the diagnosis, as both are likely to respond to steroids.

RADIOTHERAPY

Radiotherapy can improve cough in nonsmall cell lung cancer in about 50 percent of patients,[18*] and seems to be related to the degree of shrinkage of the tumor. Re-treatment can be beneficial for those with cough who have previously received radiotherapy (palliation lasted for more than 50 percent of their remaining lifespan in one study).[19,20*] Intraluminal brachytherapy for endobronchial lesions improved cough at 6 weeks in 62 percent of patients.[21*]

CHEMOTHERAPY

Patients receiving single agent gemcitabine[22**] or carboplatin and etoposide[23**] for inoperable nonsmall cell lung cancer reported a greater improvement in cough and required less radiotherapy for symptom control than those receiving 'best supportive care'. However, the total number of patients who experienced any palliation of their cough was small and 'best supportive care' was loosely defined and did not necessarily include specialist palliative care.

BRONCHOSCOPIC THERAPIES

These include endobronchial laser therapy, electrocautery, argon plasma coagulation, cryotherapy, with or without intraluminal stent insertion. Their main indication in palliative care is for the relief of malignant central airway obstruction and in the case of the first three, management of hemoptysis. No studies have specifically investigated their use in the palliation of intractable cough. Indeed retention of secretions and cough are known complications of intraluminal stent insertion.[24–26]

Protussive cough enhancers (mucoactive agents)

EXPECTORANTS

Expectorants improve cough effectiveness by increasing airway water or the volume of airway secretions. Simple hydration has not been shown to improve cough and may be detrimental, since overhydration has been shown to decrease airway clearance in some patients with chronic cough.[27*]

HYPERTONIC SALINE

Nebulized hypertonic saline has been shown to enhance mucociliary clearance both *in vitro* and *in vivo*. As well as stimulating mucociliary transport, it is postulated that hypertonic saline breaks the ionic bonds within mucus gel and therefore lowers viscosity and elasticity.[28] It may also induce an osmotic flow of water into the mucus layer and thereby alter the mucus rheology. The effect appears to be concentration dependent: patients with cystic fibrosis were found to have better cough clearance with increasing concentrations of nebulized hypertonic saline.[29*] Therefore more evidence exists for the use of nebulized hypertonic saline as opposed to normal saline, which tends to be administered routinely.

GUAIFENESIN

This expectorant is found in many over-the-counter preparations, although few studies have evaluated its efficacy. One placebo controlled trial showed that patients treated with guaifenesin maintained steady levels of sputum production compared with the decline in sputum volume found with those taking placebo.[30**] In addition, guaifenesin has recently been shown to decrease cough reflex sensitivity in patients with upper respiratory tract infection.[31]

MUCOLYTIC AGENTS

Mucolytic medications increase the expectoration of sputum by depolymerizing either the mucin network (classic mucolytics) or the DNA-actin polymer network (peptide mucolytics), thereby reducing its viscosity and aiding cough clearance.[32]

Classic mucolytics, e.g. *N*-acetylcysteine, carbocysteine

These mucolytics hydrolyze the disulfide bonds that link mucin monomers within sputum. Classic mucolytics are widely used in parts of Europe and Asia for chronic bronchitis. Although they have some benefit in reducing the number and length of exacerbations,[33***] their relevance for patients with advanced cancer is unclear. Oral preparations are gastric irritants while nebulized *N*-acetylcysteine has a sulfurous odor and can cause bronchospasm, making it unsuitable for symptom palliation.

Peptide mucolytics

Recombinant DNAase is approved for use in patients with cystic fibrosis. It reduces the size of DNA molecules within mucus, thereby reducing sputum viscosity and aiding clearance. It has been shown to improve forced expiratory volume in one second (FEV_1), reduce exacerbations and improve quality of life in cystic fibrosis patients, but has shown no benefit for patients with chronic bronchitis and is not generally used for symptom control in other conditions.[32]

CHEST PHYSIOTHERAPY

Advice from a physiotherapist on cough technique is important. 'Huffing', a technique that involves forcible exhalation with the glottis open from a medium-to-low lung volume, can be helpful for weak, breathless patients with extensive disease.

Cough suppression

HOME REMEDIES/OVER-THE-COUNTER PREPARATIONS

Any sweet thickened drink will help relieve cough and many popular 'cough medicines' and herbal remedies rely on the presence of demulcents such as sugars and gum arabic which absorb fluid and produce a soothing covering in the throat. They are probably most useful if the cough is due to receptor irritation in the oropharynx.[34]

ANTITUSSIVES

Relatively little is known about how antitussive drugs act to inhibit cough.[35] Some have a predominantly central mode of action, for example opioids, whereas others are thought to work peripherally. The concept of 'opioid-resistant cough' appears in the literature as a distinct entity,[36–38] and may be due to either peripheral or central sensitization of the cough reflex. Various drugs have been suggested to be beneficial in this situation and are discussed below.

OPIOIDS AND RELATED COMPOUNDS

The antitussive activity of opioids is distinct from their analgesic effect and some opioid-related antitussives have no analgesic effect at all. For palliative care patients, it is often necessary to treat both cough and pain, in which case a strong opioid analgesic is appropriate. If cough persists while a patient is taking a strong opioid for pain relief, it is not currently clear whether it is beneficial to use a separate opioid, that has greater antitussive activity, for cough. If, however, predominantly the antitussive activity is required, codeine or one of its nonanalgesic derivatives can be used.

Codeine

Codeine's antitussive activity is much greater than its analgesic action and has been extensively studied both clinically and experimentally.[39***] A 4-hourly dose of 30–60 mg is known to be effective, but has all the typical opioid side effects such as nausea, drowsiness, and constipation.

Hydrocodone

Hydrocodone is one of the metabolites of codeine and has analgesic and antitussive activity. It was used in a phase II open label study in cancer patients with cough as an alternative to codeine because it had been found to be better tolerated.[40*] A median dose of 10 mg a day was associated with the best response (most patients achieved >50 percent improvement in cough frequency). Most patients were using other opioids for analgesia.

Methadone

The dextroisomer of methadone is particularly active and is a more potent antitussive than codeine or morphine.[39*] Methadone linctus can be given at a dose of 1–2 mg every 4–6 hours, reducing to twice daily with prolonged use. Because of its long half life and potential to accumulate, it should be used with caution and under specialist supervision.

OPIOID-RELATED ANTITUSSIVES WITH NO ANALGESIC ACTIVITY

Pholcodine

This is structurally related to codeine and possibly has greater antitussive activity, but no analgesic action. It has few side effects and does not give rise to tolerance or dependence.[39**] It can be used at a dose of 5–10 mg three to four times per day.

Dextromethorphan

Dextromethorphan is a non-narcotic codeine analog and is the active ingredient in many over-the-counter preparations. It is the most commonly used antitussive in the USA and compares favorably to codeine in patients with chronic cough. In one comparative study, both were effective in reducing cough frequency at a dose of 20 mg, but dextromethorphan was preferred by the majority of patients and had fewer side effects.[41**]

Dimemorfan

Dimemorfan is widely used in Japan. Although an opioid derivative, dimemorfan is thought to have a central antitussive activity which is independent of the narcotic antitussive mechanism. Its action is not affected by levallorphan, an opioid receptor antagonist. In animal experiments its antitussive activity is greater than codeine and it has a stimulant rather than a depressant effect on the respiratory center. It shows marked or moderate efficacy in about 50 percent of

patients treated at doses of 20 mg three times daily. It does not cause dependence and has no analgesic action.[42**]

NONOPIOID ANTITUSSIVE DRUGS

Benzonatate

Benzonatate is chemically related to para-aminobenzoic acid anesthetics and is thought to act peripherally by anesthetizing stretch receptors. It has been described in a case series as useful for opioid-resistant cough in cancer patients at a dose of 100 mg three times daily and has few side effects.[38*]

Levodropropizine

Levodropropizine is also thought to have a peripheral mechanism of action involving modulation of C fiber sensitivity. It is a phenylpiperazinopropane derivative which has been shown to be as effective as dihydrocodeine in patients with malignant involvement of the lung at a dose of 75 mg three times daily. Although adverse effects were low in both groups, there was significantly less somnolence reported in the levodropropizine group.[43**] The side effect profile of levodropropizine was also significantly better when it was compared to dextromethorphan in patients with moderate nonproductive cough, although both had similar antitussive activity.[44**]

Moguisteine

Moguisteine is a peripherally acting non-narcotic antitussive drug. It has been shown to produce a significant reduction in cough when compared with placebo (42 percent vs. 14 percent, respectively). Patients with chronic respiratory disorders and chronic cough, some of whom had lung cancer, were randomized to receive moguisteine syrup, 200 mg three times daily, or placebo over a period of 4 days.[45**] In a separate study a dose of 100 mg three times daily was found to be equally as effective as codeine 15 mg and 30 mg.[46**]

Glaucine

This centrally acting antitussive is mainly available in eastern European countries and should not be confused with a β blocker, metipranolol, which is marketed in Europe under the same name.[5] Antitussive effects and side effect profile were significantly better than codeine in one randomized controlled trial.[47**] Both drugs were taken at a dose of 30 mg three times daily.

Sodium cromoglycate

Sodium cromoglycate may suppress unmyelinated C fibers involved in the afferent pathway of the cough reflex. A trial in patients with neoplastic, irritative cough which had been unresponsive to conventional treatment found there was a significant reduction in cough amongst those receiving inhaled sodium cromoglycate when compared with placebo.[37**]

LOCAL ANESTHETICS

Experimentally, local anesthetics delivered either intravenously or by inhalation have been shown to inhibit the cough response to a variety of stimuli.[35] Nebulized bupivacaine has been used for persistent cough in the palliative care setting, although evidence exists in case reports only.[48*] Its use is limited by its unpleasant taste, risk of aspiration, risk of bronchospasm, and short duration of action and patients also frequently develop tachyphylaxis.

SEROTONIN SELECTIVE REUPTAKE INHIBITORS

It has been postulated that serotonin selective reuptake inhibitors may be beneficial in opioid resistant dry cough based on observations that increased serotonin levels depress the cough reflex in cats.[49] One case series reported paroxetine to be effective for cancer patients with cough for whom codeine had been ineffective.[36*] However, there is known to be a powerful placebo effect with all cough treatment, and therefore, any study which has no placebo control is difficult to interpret.[50]

HICCUP

Chronic hiccup is an infrequent but distressing problem. Whether it occurs in patients with advanced cancer or those who are otherwise healthy, it leads to fatigue, insomnia, depression, and weight loss and can have a significant effect on quality of life.

Physiology

Hiccup may exist as an exercise to coordinate respiratory muscles in the fetus, but serves no known physiological purpose in the adult.[51] The reflex arc consists of:

1 afferent input via the phrenic and vagus nerves and the thoracic sympathetic chain
2 a central mediator thought to be in the cervical spine and brainstem
3 an efferent limb via motor fibers of the phrenic nerve.

The pathophysiology of chronic hiccup is poorly understood but probably results from persistent disturbance of one of the components of the reflex arc. Conditions associated with hiccup can be grouped into three main categories:

- physical causes within the anatomical distribution of the phrenic and vagus nerve
- neurological conditions thought to interfere with central control mechanisms
- metabolic/toxic and drug-induced causes: steroids in particular have been linked with the onset of hiccups and are thought to lower the threshold for synaptic transmission in the midbrain.[52]

Clinical management

It is important to consider the probable etiology (Box 70.1): removal of an underlying cause is more likely to be

successful than medication. However, in most cases the cause is untreatable or cannot be found.

Box 70.1 Conditions associated with intractable hiccup

Physical causes within the anatomical distribution of the phrenic and vagus nerve

- Gastritis
- Gastric distension
- Bowel obstruction
- Gastroesophageal reflux
- Subphrenic and hepatic disease
- Foreign body in external auditory meatus
- Pleural effusion
- Lateral myocardial infarction
- Mediastinal disease
- Thoracic aortic aneurysm

Neurological conditions – structural or functional disorders of the brainstem

- Brainstem infarction
- Multiple sclerosis
- Brainstem tumors
- Tuberculoma
- Sarcoidosis

Metabolic/toxic and drug-induced

- Hyponatremia
- Uremia
- Hypocalcemia
- Addison disease
- Hypocapnia
- Alcohol
- Corticosteroids
- Midazolam

Treatment strategies

Hiccup often occurs in short episodes requiring no specific treatment. As with all symptoms an assessment of the extent and impact of the symptom on the patient and family should be documented to establish the benefit of any

treatments. There are many 'traditional' remedies for hiccups which often involve some form of pharyngeal stimulation or diaphragmatic interruption/splinting:

- Cold key on the back of the neck
- Drinking water from the wrong side of a cup
- Sucking on a spoon of sugar
- Stimulation of the soft palate

These may be more effective for an acute bout of hiccups rather than the chronic, intractable form but may be tried as they are unlikely to cause any harm.

Phrenic nerve crush, cervical phrenic nerve block, and phrenic nerve stimulation have all been used to treat chronic hiccup in an attempt to disrupt the reflex arc. A number of papers have been published on the use of acupuncture and this is worth considering if drug side effects are intolerable.

Pharmacological management

Rare and self-limiting symptoms, such as hiccup, are particularly difficult to research and there are few published trials. Treatments discussed here (Table 70.1) are those for which there is a small amount of evidence, or those which have found their way into general use.

SECRETIONS

Salivary or bronchial secretions can be problematic either because of excessive production (e.g. bronchorrhea) or because of defective clearance (e.g. an ineffective cough or swallow reflex). The volume of bronchial secretions is partly under parasympathetic control: an increase in vagal activity increases the volume of secretions. However adrenergic nerves, cough receptor stimulation, and inflammatory changes also influence secretory output.

Rattle

Prospective studies of terminally ill cancer patients have reported the incidence of death rattle to be between 41 percent and 56 percent.[63–66] Rates in smaller observational studies vary widely.

PATHOPHYSIOLOGY

Noisy, rattly breathing is caused by an accumulation of secretions in a patient who is either weak or tired, has lost their cough and swallowing reflexes, is semi-conscious, unconscious or poorly positioned. The noise occurs when secretions bubble with respiration. It is has been postulated that there may be two types of rattle: type 1, a consequence of pooled salivary secretions that accumulate when the patient is close to death; and type 2, caused mainly by bronchial secretions when the patient has been deteriorating over a few days.[67] Among cancer patients it seems that

Table 70.1   *Drugs used for control of hiccup*

Drug	Evidence	Common side effects
Metoclopramide	Used with success in a case series of 14 patients with a variety of conditions[53*]	Few side effects and not sedative so reasonable to use first line
Haloperidol 3–5 mg nocte (oral or subcutaneous)	Licensed for use in intractable hiccup but evidence for efficacy in case reports only Commonly used in palliative care	Extrapyramidal side effects and sedation (usually at higher doses)
Chlorpromazine 25 mg tds (orally)	Licensed for use in intractable hiccup but scant evidence for efficacy	Hypotension and sedation
Baclofen 5 mg tds (orally), increasing each dose by 5 mg every 3 days until effective	A number of case series and an extremely small randomized controlled trial support its use[54–57*]	Sedation – particularly in renal failure
Gabapentin starting dose 100–300 mg tds	May be beneficial when central cause most likely (e.g., brainstem ischemia/inflammation) Reported to be effective in this situation in a number of case series[58–61*]	Drowsiness, dizziness and ataxia
Nifedipine 30–60 mg/day (orally)	4 patients in a series of 7 gained complete relief and the fifth felt improvement with nifedipine[62*]	Headache, vasodilation, peripheral edema

tds, three times daily.

cerebral tumors and malignant lung involvement predispose to death rattle.[64,67] It is possible that some cases of refractory rattle associated with cerebral tumors are due to neurogenic pulmonary edema. This is described in the literature in association with a variety of neurological conditions and is unresponsive to anticholinergic agents.[68]

MANAGEMENT STRATEGIES

Reassure patient and carers

Good terminal care often implies 'dying peacefully'. Controlling 'death rattle' can be an important component of this but is probably only effective about a third to a half of treated patients.[64,69] Making extreme efforts to control death rattle may not be necessary for patient comfort but it can be very distressing for relatives spending long periods of time at the patient's bedside. It is absolutely vital that time is spent giving explanation and reassurance to relatives, and it is important that nursing staff feel confident to do this.[70]

Positioning

Repositioning the patient to a lateral or more upright position to promote drainage of secretions is often recommended. In one study, nursing interventions such as repositioning and suction improved symptoms in 31 percent of patients.[65*]

Suctioning

This can be appropriate if secretions have accumulated in the pharynx and are easily reachable, but can cause significant distress in some patients.[66*] Assessment should be made on an individual basis according to the extent to which excessive secretions are preventing peace and dignity.

Pharmacological management

Pharmacological management involves reduction of salivary and bronchial secretions and dilatation of airways to allow a more laminar flow. Anticholinergic medications are more effective at reducing saliva secretion and dilating bronchial smooth muscle than reducing bronchial secretions.[67] They have no effect upon secretions which have already accumulated and are therefore more effective in preventing rattle if used early.

Clinical guidelines have been published giving guidance for doses of anticholinergic drugs (see Table 70.2) in death rattle based on one-off doses in healthy volunteers.[71] The choice of drug is less clear from the literature and therefore depends upon knowledge of the side effect profile, cost, and availability. All can cause dry mouth and urinary retention and those that cross the blood–brain barrier are more sedative and antiemetic. Although this can be beneficial they may also cause confusion and agitation, particularly in the elderly.

Bronchorrhea

Bronchorrhea is arbitrarily defined as the production of >100 mL of sputum per day. Excessive sputum production is seen in chronic, benign lung diseases such as bronchiectasis and chronic bronchitis. However, massive bronchorrhea, in which liters of clear frothy sputum are generated, is usually associated with malignancy, and can lead to severe fluid and electrolyte depletion in addition to respiratory distress. It is most commonly associated with bronchoalveolar carcinoma, but has been described in metastatic pancreatic, colonic and cervical adenocarcinoma.[72–74] The mechanism of massive

Table 70.2 *Anticholinergic drugs for death rattle*

	Cross blood–brain barrier[a]	Stat dose (SC)	Continuous SC infusion in 24 hours	Comments
Atropine	Yes	300–600 µg	1.2–2.4 mg	No evidence to support its use, but could be considered if no alternative available
Hyoscine hydrobromide	Yes	400 µg	1.2–2 mg	Available in transdermal patches in doses 0.5–1.5 mg for use over 24–72 hours, multiple patches can be used
Hyoscine butylbromide	No	20 mg	400 mg	Poor oral absorption
Glycopyrrolate	No	400 µg	1.2–2 mg	

[a] Sedation, antiemetic, confusion.
SC, subcutaneous.

fluid production is poorly understood and may differ in benign and malignant conditions.

MANAGEMENT

Bronchorrhea caused by an underlying malignancy will diminish if the tumor responds to therapy. Most cases, however, are due to bronchoalveolar carcinoma which is not very chemoresponsive.

There are a few case reports, in the literature, of the successful treatment of bronchorrhea using indometacin, erythromycin, and furosemide. However, in one randomized, placebo controlled trial, nebulized indometacin at a dose of 2 mL three times daily (1.2 µg/mL) was used to treat bronchorrhea associated with chronic bronchitis, diffuse panbronchiolitis, and bronchiectasis. Sputum production was significantly reduced and breathlessness improved.[75**] Subsequently nebulized indometacin has been reported to have been used successfully to treat bronchorrhea in two patients with bronchioalveolar carcinoma.[76]

Based on evidence that erythromycin inhibits bronchial hypersecretion *in vivo* and from epithelial cells *in vitro*, there are case reports of its successful use in benign and malignant causes of bronchorrhea.[77,78]

SUMMARY

Cough, hiccup, and respiratory secretions are common problems that cause great distress both to patients with advanced disease and to their families and carers. There are few effective evidence-based treatments available for these conditions at present, hence the wide variety of management strategies cited here.

The patient's aims and priorities must guide the treatments used and their prognosis and clinical state will impose limitations on the options available and appropriate. It is important that the patient (and family) understand that it may take time and several therapeutic interventions to improve symptom control and that treatment may involve pharmacological and nonpharmacological approaches.

There is an urgent need for a better evidence base on which to base our treatment decisions.

Key learning points

Cough

- Cough is common but generally not well palliated.

- It is important to decide: if there is a treatable underlying cause; if difficulty with expectoration is the main issue; and if there is associated pain and breathlessness.

- If no analgesia is required, the choice of antitussive depends upon drug availability and side effect profile.

- Some opioids have more antitussive activity than others and can be used in addition to a regular opioid analgesic.

Hiccup

- Establish site of underlying cause (central or peripheral) and treat if possible.

- Nonpharmacological remedies involving vagal or phrenic stimulation can be tried but may be of more use for acute rather than chronic hiccup.

- Metoclopramide is an appropriate first-line drug, particularly if gastric stasis or distension is implicated.

- More sedative drugs have a role, particularly if there is associated distress or insomnia.

- Consider gabapentin if a central cause is most likely.

Rattle

- Secretions can be salivary or bronchial in origin.

- Anticholinergic medications affect saliva production more than bronchial mucus production.

- Pharmacological management of rattle should be instituted early, before secretions have accumulated.

- Reassurance and support for relatives is vital.

Depression/anxiety

MICHAEL J FISCH

INTRODUCTION

The length and quality of life of patients with serious chronic illnesses such as cancer are influenced not only by their malignant disease but also by comorbid medical and psychological conditions, such as depression. The complexity of care for these patients makes it particularly challenging to ascertain whether a patient is struggling with serious depression. Moreover, compared with the statistics on the overall population of general medical patients, there are fewer data to draw upon that would help clinicians determine what treatments are effective for depression in the advanced cancer or other advanced disease settings. This chapter will examine the assessment and treatment of depression in general medical patients and in patients with cancer. Cancer will be used as a paradigm for a serious chronic illness that benefits from good palliative care, and from which available data could be generalized to many other serious chronic diseases. Some of the unique aspects of managing depression in the end-of-life setting will be examined, and the diagnosis and management of anxiety will be distinguished from depression as well.

PREVALENCE, EFFECT, AND ASSESSMENT OF DEPRESSION

General medical patients

To better understand how to recognize and treat depression in patients with cancer, it is useful to first review the existing paradigms for finding and treating depression in the primary care setting. Depression is estimated to affect more than 120 million people worldwide.[1] Large prospective studies have shown that the prevalence of major depression in the outpatient primary care setting is 6–14 percent, and the lifetime incidence of major depression is approximately 15 percent.[2**] The point prevalence of depression in preadolescent children is in the 1–3 percent range, and it is about three times higher in adolescents.[3] Depression is two to three times more common in hospitalized patients and patients with chronic illnesses.[4] Physicians recognize psychological distress in about two-thirds of the general medical patient population and prescribe antidepressants for about half of those distressed patients.[2] Major depressive disorder can cause severe functional impairment and increase the risk of suicide.[5**] Depressive symptoms are associated with a higher-than-normal risk of physical decline and with long-term mortality in older adults;[6*,7*,8*,9*] depression is also a risk factor for coronary heart disease and stroke,[10,11] and it is associated with greater use of healthcare services.[12,13]

The standard paradigm for identifying depression in the primary care setting is to view depression as a syndromal diagnosis made on the basis of patient history and the exclusion of competing diagnoses, using criteria from the Diagnostic and Statistical Manual of Mental Disorders (DSM)-IV.[14] Major depression is defined as depressed mood or anhedonia (loss of interest in pleasurable activities) that lasts for at least 2 weeks plus the presence of three or four other specific psychological or somatic symptoms. If two to four rather than more than five symptoms are present, then the patient may be defined as having minor depression, an unofficial research diagnosis in the DSM-IV.[15] A recent review of case-finding instruments used in primary care showed that at least 11 questionnaires, ranging in length from 1 to 30 questions and ranging in time of administration from 1 to 5 minutes, show reasonable performance characteristics when compared with a semi-structured interview applying standard diagnostic criteria.[15] The US Preventive Services Task Force recommends depression screening in clinical practices that have systems in place to ensure

accurate diagnosis and effective treatment and follow-up.[16] Unfortunately, such systems are not available in most primary care practices or oncology/hematology subspecialty practices.

The decision regarding whether to treat a patient for depression in the primary care setting is not always made on the basis of rigid diagnostic criteria; it often arises from clinical judgment about the severity and duration of symptoms and the likelihood of spontaneous recovery within a supportive environment.[17] Between 50 percent and 60 percent of cases of major depression respond to initial therapy with antidepressants, psychotherapy, or both.[17***] Minor depression and dysthymia have similar response rates to antidepressants or psychotherapy over placebo.[18] Depression may be treated by a patient's primary care physician, who can use either a collaborative care model that involves augmentation with one or more visits with a mental healthcare provider or a stepped-care approach in which patients whose depression does not respond to initial therapy are referred to a mental healthcare provider.[4] Physicians and patients show considerable variability in how they think depression should be treated. This variability arises from not only physician, patient, and spouse or caregiver preferences but also health system variables, such as the availability of mental healthcare providers and reimbursement for mental healthcare.[4] Unfortunately, the vast majority of depressed patients who receive antidepressants are not prescribed an adequate dose for a long enough time.[2] Likewise, the duration of psychotherapy is often too brief; effective therapy requires 6–16 visits.[17*] These data underscore the basis of the US Preventive Services Task Force emphasis on having appropriate systems in place so that patients who have depression detected by screening achieve the best possible outcomes.

Depression is associated with significant morbidity, and the estimated economic impact of depression in the USA alone is more than US\$40 billion annually.[19*] Fortunately, depression is treatable, and thus cost effective interventions to improve the detection and treatment of depression are important. A randomized trial to determine the cost effectiveness of a specific quality improvement program in 46 primary care clinics and six community-based managed care organizations found that the cost per quality-adjusted life year (QALY) associated with the specific quality improvement program was US\$15 000–35 000, comparable with that of other accepted medical interventions.[20] Moreover, employment retention for depressed patients improved over a 1-year period without an overall increase in medical visits.[21]

Cancer: a paradigm for serious chronic illness

In a comprehensive, evidence-based review of the literature of depression in cancer, Pirl[22] reported that despite standardized criteria for diagnosing major depressive disorder in cancer patients, it remains difficult to draw firm conclusions about the prevalence of major depression in this population because of the wide range of reported rates. There were 11 cross-sectional studies of major depression in cancer published between 1983 and 2000, drawing upon nearly 2000 patients.[23–33] The best estimate is that major depression has a point prevalence of 10–25 percent in cancer patients. This prevalence is similar to that seen in patients with other chronic medical illnesses, such as diabetes and heart disease, and slightly lower than that observed for patients with debilitating chronic neurological diseases, such as multiple sclerosis or Parkinson disease.[1]

Although some comprehensive cancer centers have adequate behavioral healthcare resources, most hospitals and oncology clinics rely on general psychiatry and psychology staff and resources. Limited funding for mental healthcare resources is a serious problem, and care is often fragmented among private practitioners, for-profit and not-for-profit clinics, and community mental health centers.[34*] Limited resources in standard areas of care also affect the research environment.

Even though it may be ideal to use a two-stage strategy that combines an assessment of severity with an assessment of the number of depressive symptoms, it is far more common to perform only a short instrument to assess symptom severity in the typical environment where time and resources are limited. Numerous symptom scales have been used to assess depression symptom severity at a specific time or over time. The most commonly reported instruments are shown in Box 71.1.

Box 71.1 Self-report measures used to assess depressive symptoms in cancer patients

- Hospital and Anxiety Depression Scale (HADS)
- Zung Self-Rating Depression Scale (ZSRDS)
- Brief version, Zung Self-Rating Depression Scale (BZSDRS)
- Beck Depression Inventory (BDI)
- Beck Depression Inventory, Short Form (BDI-SF)
- Center for Epidemiologic Studies Depression Scale (CES-D)
- Brief Symptom Inventory (BSI)
- Rotterdam Symptom Checklist (RSCL)
- Geriatric Depression Scale (GDS)
- Profile of Mood States (POMS)
- General Health Questionnaire (GHQ)

The instrument that has been investigated most extensively is the HADS. Since its original publication in 1983 by

Zigmond and Snaith,[35] this instrument has been translated into more than 20 languages and has become one of the most often cited articles in the medical literature. There have been no fewer than 14 published studies of cancer patients assessed with the HADS since 1989, and six of those studies included more than 200 patients each. One of the largest validation studies of the HADS included 514 patients from four sites and found that, using the DSM-III, as the reference standard, the HADS had a sensitivity of 80 percent, a specificity of 76 percent, and a positive predictive value of 41 percent in outpatients with various cancers.[36] In a large primary care population, the HADS had a positive likelihood ratio of 7.0 (95 percent CI 2.9 to 11.2) and a negative likelihood ratio of 0.3 (95 percent CI 0.3 to 0.4).[37] When symptom scales are used, the prevalence of depression is usually found to be in the 15–35 percent range, which is slightly higher than the prevalence of major depression assessed by a diagnostic interview.

Challenges in the assessment of depression in cancer patients

Patients, family members, and healthcare providers sometimes believe that feeling down, depressed, or hopeless is perfectly natural and understandable in the context of living with cancer. Clinicians are encouraged to acknowledge the difficulty and disappointment that often confront cancer patients and their families,[38] but depression and hopelessness are not accepted by expert clinicians as an inevitable consequence of living with cancer. In addition, cancer patients often have physical symptoms of depression (so-called neurovegetative symptoms), such as sleep disturbance, psychomotor retardation, appetite disturbance, poor concentration, and low energy, as a consequence of their underlying illness or treatment, thus confounding the diagnosis of depression. Indeed, depression is just one of many symptoms that clinicians must recognize and manage in inpatients and outpatients with cancer. For example, roughly two-thirds of outpatients with cancer experience pain, and more than a third report significant disruption in daily function associated with the pain.[39**] For patients with advanced cancer, the median number of symptoms (e.g. pain, trouble sleeping, fatigue, and anhedonia) expressed by self-report is generally five or more.[40*,41*,42*] It may be that the problem of concurrent symptoms is the most relevant difference between depression in the general medical setting and in the cancer care setting. Relatively few cancer care providers have sufficient knowledge and skill to assess and treat depression in this context, and it is often difficult to decide whether the depressive symptoms should be the primary focus of treatment or whether these symptoms may improve if other problems are better managed. Clinicians sometimes use verbal or nonverbal cues to focus on symptoms for which they have a broader comfort zone for assessing and treating. Currently, many cancer providers

are most comfortable treating somatic symptoms, such as pain, nausea, constipation, or dyspnea.

The large number of instruments and techniques used to assess cancer patients for depression does not seem to translate into an overall improvement in the assessment of depression in this complex population of patients. A 'Don't ask, don't tell' policy appears to be in place all too often.[34] A list of nine of the most significant barriers to the assessment of depression is presented in Box 71.2. With a growing appreciation for the need to simplify the starting point in assessing depression, the use of 1- or 2-item screening techniques has become popular (Box 71.3). Chochinov et al.[43] have studied a simple 1-item survey and found it to have acceptable psychometric properties in patients with advanced cancer. Akizuki et al.[44] have described a clever 1-item survey that was tested in 275 patients and was found to correlate well with both the HADS ($r = 0.66$) and the Distress Thermometer ($r = 0.71$). At optimal cutoffs, the sensitivity (80 percent) and specificity (61 percent) for diagnosing major depression and adjustment disorders for this 1-item survey were similar to those of the HADS and Distress Thermometer. Finally, Whooley and colleagues[45] have used 2-item screening in medically ill patients who did not have cancer with an approach that targeted depressed mood and anhedonia. This 2-item screening approach has been endorsed by the US Preventive Health Task Force for use in primary care settings.[16,46] Once again, this simple approach appears to be about as effective as the more complex instruments for decision-making purposes,

---

Box 71.2 Common barriers to the assessment of depression in patients with cancer

- Time constraints in busy oncology settings

- Cost constraints limiting access to professionals with behavioral health training

- Overlap of physical symptoms of depression and symptoms of cancer or its treatment

- Stigma concerning mental illness or weakness perceived by the patient/family

- Patient/family fear that revealing depression will lead to undertreatment of the cancer

- Clinician underrecognition of hopelessness, feelings of worthlessness, or suicidal ideation

- Clinician uncertainty about how to interpret screening instrument cut-offs

- Poor continuity of care over the trajectory of illness

- Limited understanding by cancer professionals regarding which patients are most at risk

Box 71.3 Examples of 1– or 2–question screening methods for depression

One question

- 'Are you depressed?' (Chochinov et al.[43])

- 'Please grade your mood during the past week by assigning it a score from 0 to 100, with a score of 100 representing your usual relaxed mood. A score of 60 is considered a passing grade.' (Akizuki et al.[44])

Two questions

- 'Have you often been bothered by feeling down, depressed, or hopeless?'

- 'Have you often been bothered by having a lack of interest or pleasure in doing things?' (Whooley et al.[45])

and this 2-item screening approach has also been used in cancer patients.[47*]

In addition to brief screening approaches specific to depression, a more global approach to distress screening has been developed by Holland[48,49] and endorsed by the National Comprehensive Cancer Network. This approach involves a thermometer with a numerical scale ranging from 0 to 10 for the patient to indicate 'How much distress you have been experiencing in the past week, including today?' This is coupled with a 34-item checklist organized into practical areas, family issues, emotional issues, spiritual/religious issues, and physical symptoms. This approach embeds depression screening in a broad context that can be less stigmatizing to some patients. The drawback of this approach is that it is not easy to use in face-to-face discussions between the physician and patient. Rather, it is well suited to a practice setting in which other providers are available to do the screening and initiate an appropriate response to the patient on the basis of the information provided. In general, the distress screening approach works best in a resource-rich environment. In the USA, support for psychosocial services is expected to be hindered even more by reduced payments for oncology care through the Medicare Prescription Drug, Improvement, and Modernization Act of 2003.

TREATMENT OF DEPRESSION

General medical patients

Antidepressant therapy and psychotherapy seem to be equally effective for treating mild-to-moderate depression in the general medical population.[4,50*] For treating severe depression, antidepressant therapy combined with

psychotherapy may be better than psychotherapy alone.[51**] Antidepressants are also effective for treating depression in patients with concomitant physical illnesses. In 1998, a systematic review of randomized trials comparing antidepressants with placebo to treat depression in physically ill patients was published; the review comprised 18 studies including more than 800 patients with a variety of chronic diseases.[52***] Depression treated with antidepressants was significantly more likely to improve than that treated with placebo (odds ratio = 0.37; 95 percent CI 0.27 to 0.51). However, the study also showed that approximately four patients would need to be treated to produce one recovery that would not have occurred with placebo alone (number needed to treat = 4.2; 95 percent CI 3.2 to 6.4). Approximately 10 cases of depression needed to be treated with antidepressants to cause one treatment dropout relative to placebo.[52***]

Interestingly, the response rates to both antidepressants and placebo are substantial, having increased considerably over the past 20 years.[53*] This may reflect a 'stage migration' effect, wherein the study cohorts at inception have tended to have less severe depressive symptoms over time. Evidence suggests that severe depression is less likely than mild or moderate depression to respond to placebo.[54,55] Of note, the widely used herbal remedy St John's wort (*Hypericum perforatum*) has not been found to be effective compared with placebo for treating moderately severe depression.[56]

More than 24 antidepressants that work by at least seven distinct mechanisms of action are available.[57] However, no single drug or category of drugs has proved most effective for relieving depressive symptoms or treating the syndrome of major depression (see Box 71.4 for summary of antidepressant agents).[17,58] In the USA, many adults take medications to improve their health and wellbeing; in any given week, most American adults take at least one medication, and 7 percent take five or more.[59] This growing affinity for taking medication also is manifested in a national trend in the outpatient treatment of depression. Specifically, the proportion of depressed patients receiving antidepressant medications nearly doubled between 1987 and 1997 (from 37.3 percent to 74.5 percent), whereas the proportion of depressed patients receiving psychotherapy declined (71.1 percent to 60.2 percent).[60*]

Cancer patients

CHOOSING PATIENTS FOR TREATMENT

The largest barrier to the effective treatment of depression in patients with cancer is the difficulty recognizing which patients are depressed and need treatment. The factors associated with increased risk of depression in cancer patients are shown in Box 71.5. Because of the complexity of assessing patients in modern cancer care environments, many cases of depression are missed, and the patients with more severe

---

Box 71.4 Commonly used antidepressants grouped by mechanism of action

Selective serotonin reuptake inhibitors (SSRIs)

- Fluoxetine

- Paroxetine

- Sertraline

- Citalopram

- Escitalopram

Comment: These agents have few anticholinergic or cardiovascular side effects, and they are not fatal in overdose. Sexual dysfunction, insomnia, headache, or nausea may occur with any of these agents.

SSRI and presynaptic α_2-receptor antagonist

- Mirtazapine

Comment: This agent may cause sedation and weight gain. For this reason, it can be dosed at night to improve sleep and given to patients who have poor appetite. It can cause constipation, edema, hypertension, or orthostatic hypotension.

SSRI and norepinephrine reuptake inhibitor

- Venlafaxine

Comment: In addition to its effect on depression, this agent has been used to decrease the frequency and intensity of hot flashes in cancer patients. Dose-related sustained hypertension is an important possible side effect to monitor. May cause sexual dysfunction, insomnia, headache, constipation, or nausea.

Dopamine and norepinephrine reuptake inhibitor

- Bupropion

Comment: This agent is also indicated to improve rates of successful smoking cessation. Sometimes used to avoid the sexual dysfunction seen with other agents. Does not treat anxiety. Known to lower the seizure threshold. May cause insomnia, agitation, confusion, headache, or weight loss.

Psychostimulants

- Methylphenidate
- Dextroamphetamine

Comment: These agents are known for the rapid onset of action in terms of antidepressant efficacy. They are activating agents also used to counteract opioid-induced sedation. Generally given in the waking hours (morning and early afternoon). Should be avoided in patients with unstable ischemia or cardiac arrhythmias. Drug tolerance, abuse, and dependence can occur. May cause nervousness, agitation, or insomnia.

Tricyclic antidepressants

- Nortriptyline

- Amitriptyline

- Doxepin

- Desipramine

Comment: These agents can cause cardiac arrhythmias, and overdoses are lethal. Baseline electrocardiography is recommended. Often used as adjuvant analgesics at doses subtherapeutic for depression. May cause sexual dysfunction, weight gain, anticholinergic effects (dry mouth, sedation, or constipation), or orthostatic hypotension.

---

symptoms, ironically, are more easily overlooked. Investigators in Indiana, USA, working in the community setting[61] evaluated 1109 outpatients with cancer and found that physicians were most accurate at correctly identifying the absence of depression. However, when depression was severe, only 13 percent of affected patients were correctly classified by their oncologists. In general, oncologists and oncology nurses appear to be most responsive to sad, tearful patients with

minor depression rather than patients with a flat affect, feelings of pervasive guilt or worthlessness, or suicidal thoughts. In a sense, sicker patients may create thicker smokescreens that impede easy recognition of the underlying problem. These patients are particularly vulnerable, and their inability to advocate for themselves may be part of the illness.[34]

Box 71.5 Risk factors for depression in cancer

Social factors

- Recent losses
- Financial stressors
- Poor social support
- Sexual and/or physical abuse
- Childhood trauma or parental loss
- History of substance abuse

Genetic factors

- Family history of depressive disorder

Cancer-related factors

- Advanced stage of disease
- Poor performance status
- Poor pain control
- Pancreatic cancer

Cancer treatment factors

- Corticosteroids
- Interferon alfa
- Interleukin-2
- Amphotericin-B
- Procarbazine
- L-Asparaginase

Symptom research is an emerging interest within the discipline of academic general medicine.[61–63] Within this new paradigm, symptoms are conceptualized in terms of a functional disturbance of the nervous system. There is a growing appreciation for the physical changes in the nervous system associated with depression and its treatment.[64,65] Understanding depressive symptoms in the context of symptom science rather than solely within the standard psychiatric paradigm is being explored in the context of cancer care to try to overcome some of the barriers to recognition and management of depression in this population.

TREATMENT OPTIONS

Drugs used to treat depression in cancer patients are quite similar to those used in the primary care setting; these include tricyclic antidepressants, SSRIs, newer antidepressants, and psychostimulants. Specific examples of commonly used antidepressants grouped by mechanism of action are presented in Box 71.4. The National Institutes of Health consensus statement regarding symptom management in cancer states that 'depression related to cancer is not substantially different from depression in other medical conditions, but treatments may need to be adapted or refined for cancer patients'.[66] One refinement for patients with cancer, particularly in the palliative care setting, is the growing interest in the use of psychostimulants to treat depression.[67*,68,69*,70*] This interest is driven by the potential of these agents to rapidly produce clinical effects and to alleviate concomitant symptoms, such as fatigue, sedation, and poor concentration. Another refinement that is often important to cancer patients is being mindful of potentially important drug interactions that can occur with antidepressants that are metabolized using the cytochrome P450 (CYP) enzyme system of the liver. In particular, agents such as fluoxetine and nefazodone that inhibit the CYP 3A4 enzyme system may increase the effects of some commonly used chemotherapeutic agents. Moreover, because many patients with cancer are older adults with complex medical problems, other coadministered drugs may be influenced by the antidepressants. Although the clinical relevance of these potential interactions is not well described or understood, it is useful for clinicians to be aware of this issue. Selected CYP interaction possibilities are summarized in Table 71.1.

Psychological therapies include psychoeducational interventions, cognitive behavioral therapy, interpersonal therapy, and problem-solving therapy. Although these therapies are often used to treat depression in patients with cancer, there is a barrier to their use: the sheer complexity of patient care (multiple providers, laboratory and radiographic tests, and scheduled treatments such as radiation or infusions) makes scheduling psychological interventions difficult. Electroconvulsive therapy, an invasive modality known to be effective for severe depression, is rarely used and has not been studied for depression in the context of cancer care.

Difficult issues in designing interventions for cancer-related depression include identifying an acceptable standard for depression treatment in cancer, choosing an appropriate duration of therapy, and finding a feasible strategy to assess compliance with the intervention. In addition, assessment of outcomes is particularly challenging because the researcher must choose feasible numbers and types of outcome measures and decide the importance of depression-specific outcomes relative to secondary outcomes, such as quality of life. Other difficulties in researching depression in cancer patients include the lack of a standard primary endpoint; the high frequency of missing data; the clash of expectations and paradigms inherent to interdisciplinary review of depression

Table 71.1 *Selected cytochrome P450 drug interactions*

Agents	2C9	2C19	2D6	3A4
Substrates	Fluoxetine	Tricyclic antidepressants	Tricyclic antidepressants	Benzodiazepines
	Celecoxib	Benzodiazepines	Venlafaxine	Theophylline
	Warfarin		Fluoxetine	Methadone
	Trimethoprim/sulfameth		Haloperidol	Cyclosporine
	Oxazole		Phenothiazines	Tacrolimus
	Cyclophosphamide		Oxycodone	Tamoxifen
			Hydrocodone	Etoposide
			β Blockers	Vinca alkaloids
			Ondansetron	Paclitaxel
			Tamoxifen	Gefinitib
				Imatinib
				Calcium channel blockers
Inhibitors	Paroxetine	Fluoxetine	Fluoxetine	Nefazodone
	Sertraline	Paroxetine	Paroxetine	Fluoxetine
	Fluconazole	Omeprazole	Sertraline	Quinolones
	Amiodarone		Methadone	Macrolide antibiotics
			Doxorubicin	Ketoconazole
			Vinblastine	Amiodarone
				Grapefruit juice
				HIV protease inhibitors
Inducers		Corticosteroids		St John's wort
				Barbiturates
				Phenytoin
				Corticosteroids
				Rifampin

Note: This table highlights some of the most serious known P450 drug interactions. Appropriate, updated reference material should be consulted to establish the presence or absence of important P450 interactions before prescribing.

research proposals; the shortage of patient access to behavioral health specialists; and the relative aversion of patients, family members, and some healthcare providers to placebo controlled study designs.

RANDOMIZED TRIALS

With all of these challenges in mind, it is not surprising that data from controlled trials regarding the efficacy of treatment of depression in cancer patients is sparse. Only eight published placebo controlled randomized trials have compared an antidepressant drug (a tricyclic antidepressant or serotonin reuptake inhibitor) with a placebo in cancer patients (Table 71.2). Fewer than 1000 patients were included; none of these studies included children, and three of the studies[71**,72**,73**] included women only. The trend in these studies was in favor of the treatment arm, but the small sample size of the individual trials, short follow-up duration, and heterogeneity of outcome measures limit the conclusions that can be made from this body of research.

The handful of other randomized, controlled trials involving patients with cancer and assessment of depression outcomes are equally difficult to interpret. Three randomized,

placebo controlled trials assessed depression outcomes but studied drugs (methylprednisolone, thioridazine, and mazindol) that are not typically used to treat depression.[78**,79**,80**] These studies included a total of 116 patients. There are also three published double-blind, randomized trials comparing two interventions without a placebo control.[81–83] These trials compared alprazolam versus muscle relaxation,[81] fluoxetine versus desipramine,[82] and trazadone versus clorazepate[83] in a total of 211 patients. Overall, research related to drug therapy for depression in patients with cancer spans 30 years. Unfortunately, these studies include a myriad of different endpoints, and most of the trials had small sample sizes and short durations of follow-up. The trend in these trials suggested that antidepressants alleviate depression in cancer patients much as in other medically ill patients. Further research is needed to better define the magnitude and duration of the treatment effect and to improve the precision of the estimate of this effect. In addition, the toxicities and costs of drug therapy for cancer patients who have depressive symptoms have not been adequately studied.

Psychological therapies are most often applied in addition to drug treatments for depressed patients, but this kind of

Table 71.2 *Clinical trials comparing antidepressant with placebo in patients with cancer*

Author(s)	Intervention (No. of subjects)	Patient description	Inclusion criteria for depression	Outcome measures	Measures improved compared with placebo
Purohit *et al.*, 1978[74]	Imipramine (39)	Hospitalized patients receiving radiation therapy	Not stated	HDRS	No statistical evaluation
Costa *et al.*, 1985[73]	Mianserin (73)	Adult women with cancer	Major depression: HDRS ⩾ 16 ZSDRS ⩾ 41	CGI, HDRS, ZSDRS	CGI (77% vs. 50%), HDRS at days 7, 21, and 28, ZSDRS at days 7 and 28
Eija *et al.*, 1996[72]	Amitriptyline (15)	Patients with breast cancer and neuropathic pain	None	2 questions about depression on a 4-point scale	No statistical evaluation
Van Heeringen and Zivkov, 1996[71]	Mianserin (55)	Adult women with early-stage breast cancer treated with radiation	DSM-III depressive disorder	HDRS	HDRS at 4 weeks and 7 weeks
Razavi *et al.*, 1996[75]	Fluoxetine (91)	Adults with depression or adjustment disorder in relation to cancer	DSM-III depression or adjustment disorder, HADS ⩾ 13	HADS, MADRS, SCL-90-R, HAS, SQOLI	SCL-90-R at 5 weeks
Musselman *et al.*, 2001[76]	Paroxetine (40)	Adults beginning high-dose interferon alpha for melanoma	None	HDRS, HAS, DSM-IV criteria	HDRS and HAS at 8 and 12 weeks, major depression (11% vs. 45%)
Fisch *et al.*, 2003[47]	Fluoxetine (163)	Adults with advanced solid tumors and expected survival of 3–24 months	Depressed mood and/ or anhedonia revealed by 2-question survey	FACT-SP, Brief ZSRDS	FACT-G, Brief ZSRDS (12-week study)
Morrow *et al.*, 2003[77]	Paroxetine (479)	Adults with cancer beginning chemotherapy	None	CES-D, POMS D/D	CES-D and POMS D/D at 12 weeks, POMS D/D at 9 weeks

therapy can also be used alone to treat moderate to severe depression.[4] There are no data regarding the added value of psychological therapies plus antidepressants compared with antidepressants alone specifically in cancer patients. In fact, there are very few studies in the medically ill in which the effect of psychotherapy has been described with sufficient methodological detail.[84] There are several published meta-analyses of controlled trials of psychological interventions for decreasing psychological distress in cancer patients. Sheard and Maguire[85] reported the results of two meta-analyses and found 20 trials with sufficient data to show a combined effect size of 0.36 (95 percent CI 0.06 to 0.66; 1101 patients). This study did not reveal a difference in the efficacy of group therapy compared with individual therapy in patients with cancer. A recent systematic review of psychological therapies for cancer patients was completed by the New South Wales

Cancer Council Cancer Education Research Program.[86***] This review evaluated 627 eligible papers published since 1954, and 129 trials were identified that involved psychosocial outcomes. The data from this systematic review regarding depression are summarized in Table 71.3. Only 21 percent of the 114 studies showed an advantage for the therapies in terms of the endpoint of depression. Similar to the situation with antidepressant trials, the data regarding the efficacy of psychological interventions for the treatment of depressive symptoms in cancer patients remain equivocal.

It is useful to note that application of unwanted (but received) support or counseling has been uniquely associated with poor psychosocial adjustment.[87*] As such, clinicians would do well to make counseling and support available to cancer patients but to respect the boundaries that some patients set regarding such services.

Table 71.3 *Psychological intervention trials with depression as an endpoint*

Description of intervention	Significant benefit found/ total trials
Individual therapy	2/18
Therapist-delivered	4/24
Significant-other involvement	1/5
Information and education	4/13
Unstructured counseling	1/5

UNIQUE ISSUES IN END–OF–LIFE CARE

The prevalence of significant depression in palliative care settings is similar to those described for cancer settings above, as most palliative care cohorts are dominated by patients with advanced cancer. Ambiguity surrounding the definition of end-of-life care makes this particular literature difficult to interpret and apply. The 1-item screening question 'Are you depressed?' explored by Chochinov involved a cohort of 197 palliative care inpatients and had perfect sensitivity and specificity of 1.0 in this single study.[43] However, in a palliative care cohort of 74 patients in the UK receiving only palliative and supportive day care, Lloyd-Williams and colleagues found that 27 percent of patients had depression by semi-structured interview criteria, and the single-item screening question had a sensitivity of 55 percent, a specificity of 74 percent, a positive predictive value of 44 percent, and a negative predictive value of 82 percent.[88] Nevertheless, even use of the 14-item HADS had significant limitations in another UK study in a hospice population, as the positive predictive value of this instrument using a cut-off threshold of 20 was only 48 percent with a sensitivity of 77 percent and specificity of 89 percent.[89] Overall, there are insufficient data in end-of-life patient populations to distinguish the assessment issues from those that have been described for cancer patients in general. It should be noted, however, that the occurrence of counter-transference of hopelessness on the part of families and clinicians may discourage dying patients from seeking assessment and treatment for depression.[90]

Regarding the treatment of patients with depression toward the end of life, several consensus statements have been published.[90–92] These statements are limited by the paucity of evidence, but several themes emerge across these statements. First, there should be a low threshold for treating patients with suspected depression using short-term therapeutic trials of carefully selected interventions.[84***,92] In addition, the rapid onset of action of psychostimulants make this class of drugs particularly appealing in patients toward the very end of life. Moreover, psychotherapeutic interventions focused on issues related to meaning and/or dignity[93,94] have shown promising results in the terminally ill.

Finally, one of the more dreaded issues in managing patients with serious illness toward the end of life is the problem of patients who express desire for death. Desire for death statements may indicate that a patient is depressed or suicidal, but may also be a way of coping or expressing suffering.[95*] The prevalence of desire for death statements in terminally ill patients varies widely, ranging from less than 2 percent to 30 percent, depending on the patient population and how patients are identified.[96*,97*,98*] Depressive disorders and delirium are clearly the most common underlying cause of suicidal ideation in patients with potentially fatal illnesses.[99*,100*,101*,102*] However, the presence of a potentially fatal illness, by itself, only carries a modest two- to fourfold increased risk for suicide.[103*] Challenging aspects of assessing patients with desire for death include evaluation and treatment of depression and delirium, assessing the adequacy of palliative care overall, and dealing with broader issues such as personality, family dynamics, as well as important ethnic and cultural issues.[104,105***] It is important to understand that most patients appreciate being asked about their mood in depth, including questions about desire for death or suicide.[106]

MANAGING ANXIETY

It is the rare patient living with cancer or a serious chronic illness who does not confront anxiety. Most patients adapt readily with reassurance from friends, family, and providers. However, some patients have comorbid psychiatric conditions that may manifest with anxiety such as depressive disorders, delirium, or underlying anxiety disorders. Moreover, there may be other underlying causes of anxiety that need to be explored and treated. The common causes of anxiety in palliative care are outlined in Box 71.6.

Symptoms that are uniquely attributable to anxiety include physical symptoms such as tremor, sweating, tachycardia, hyperventilation, and restlessness. Psychological symptoms of anxiety include worry, rumination, and fear.[107] These symptoms may cause patients to flee their environment or display avoidant behaviors. Anxiety symptoms often co-exist with depression and delirium.[108] It is important to consider the diagnosis of delirium in anxious patients, for use of benzodiazepine therapy in patients with subtle manifestations of disordered attention and confusion may lead to an exacerbation of the delirium. Assessment tools that are used to screen for delirium in patients with anxiety who are also at risk for cognitive disturbance are described in Chapter 74.

Box 71.6 Common causes of anxiety symptoms in palliative care

Situational

- Recent diagnosis of serious illness
- Impending surgery or chemotherapy
- Impending diagnostic imaging
- Perceived risk for receiving bad news
- Fear of death/existential anxiety

Symptom-related

- Pain
- Dyspnea
- Palpitations
- Nausea

Metabolic disturbances

- Hypercalcemia
- Hypoglycemia
- Carcinoid syndrome

Drug-associated

- Akathisia due to phenothiazines
- Thyroid replacement
- Allergic reactions

Psychiatric disorders

- Delirium
- Depressive disorders
- Panic disorder
- Posttraumatic stress disorder
- Phobias
- Generalized anxiety disorder

For patients with pervasive worry and autonomic hyperreactivity, pharmacotherapy may be indicated. The categories of medications used to treat anxiety are listed in Box 71.7. Unfortunately, there is an overall lack of evidence on the role of benzodiazepines and most other anxiolytics in palliative care patients.[109] Benzodiazepines are the most commonly prescribed agents and they are effective first-line agents. These medications may cause significant sedation or trigger delirium in patients who are on other psychoactive medications (including opioids) or who are particularly frail. These drugs should be used cautiously and, when feasible, should be discontinued. The short-acting benzodiazepines

lorazepam and alprazolam are used most frequently. For patients with panic disorder, alprazolam is effective as are several antidepressants (imipramine, sertraline, paroxetine). For patients with coexisting delirium or possible opioid toxicity, haloperidol or other neuroleptic agents are useful for management of symptoms while the underlying problem is addressed. In particular, the newer antidepressants are being explored with increasing frequency to treat patients who have complex symptoms including anxiety.[110] Antihistamines and other sedative hypnotic agents can also provide useful anxiolysis, particularly at night when insomnia is an issue. Finally, counseling is effective for treatment of anxiety and it generally involves substitution of more adaptive behaviors and problem-solving approaches for expression of anxiety (which is less adaptive). Counseling may be psychoeducational, behavioral, cognitive – behavioral, or group oriented.

Box 71.7 Drug therapy of anxiety

Benzodiazepines

- Clonazepam
- Alprazolam
- Diazepam
- Lorazepam

Antidepressant agents

- SSRI and newer antidepressants
- Tricyclic antidepressants

Neuroleptic agents

- Haloperidol
- Atypical antipsychotics

Other drug therapies

- Buspirone
- β blockers (for autonomic symptom relief)
- Sedative hypnotics (for relief of insomnia)

Key learning points

- Depression and anxiety are common in patients with serious illness.
- Despite a body of research that spans several decades and includes hundreds of clinical trials, one can make no strong recommendations about the effectiveness of antidepressants or psychological interventions at improving

depression or anxiety outcomes for patients with cancer and other serious chronic illnesses.

- Simple, direct questions to explore issues about mood, anxiety, or desire for death are important and appreciated by patients.

- An awareness of the potential for drug interactions with antidepressants and some other drugs commonly used in palliative care is important.

- Patients with serious chronic illnesses would benefit from multidisciplinary care that includes access to specialists in behavioral health when needed.

Confusion/delirium

WILLIAM BREITBART, MIRIAM FRIEDLANDER

INTRODUCTION

Cognitive failure is unfortunately all too common in patients with advanced illness. The Diagnostic and Statistical Manual of Mental Disorders (DSM)-IV[1] divides cognitive disorders into the subcategories of:

- Delirium, dementia, amnesic and other cognitive disorders
- Mental disorders due to a general medical condition (including mood disorder, anxiety disorder and personality change due to a general medical condition)
- Substance-related disorders.

While virtually all of these mental syndromes can be seen in the patient with advanced disease, the most common include delirium, dementia, and mood and anxiety disorders due to a general medical condition. Lipowski categorized organic mental disorders into those that were characterized by general cognitive impairment, (i.e. delirium and dementia) and those where cognitive impairment was rather selective or limited (i.e. amnesic disorder, organic hallucinosis, organic mood disorder, etc.).[2] With organic mental disorders where cognitive impairment is selective, limited, or relatively intact, the more prominent symptoms tend to consist of either anxiety, mood disturbance, delusions, hallucinations or personality change. For instance, the patient with mood disturbance meeting criteria for major depression, who is severely hypothyroid or on high-dose corticosteroids is most accurately diagnosed as having a mood disorder due to a general medical condition or substance-induced mood disorder, respectively (particularly if organic factors are judged to be the primary etiology related to the mood disturbance). Similarly, the patient with hyponatremia, or the patient on aciclovir for central nervous system (CNS) herpes who is experiencing visual hallucinations but has an intact sensorium with minimal cognitive deficits, is more accurately diagnosed as having a psychotic disorder due to a general medical condition or a substance-induced psychotic disorder, respectively.

In spite of very little being known about the neuropathogenesis of delirium, its symptoms suggest that it is a dysfunction of multiple regions of the brain.[3] Delirium has been characterized as an etiologically nonspecific, global, cerebral dysfunction characterized by concurrent disturbances of level of consciousness, attention, thinking, perception, memory, psychomotor behavior, emotion, and the sleep–wake cycle. Disorientation, fluctuation, or waxing and waning of these symptoms, as well as an acute or abrupt onset of such disturbances are other critical features of delirium. Delirium, in contrast with dementia, is conceptualized as a *reversible* process. Reversibility of the process of delirium is often possible even in the patient with advanced illness; however it may *not* be reversible in the last 24–48 hours of life. This is most likely due to the fact that irreversible processes such as multiple organ failure are occurring in the final hours of life. Delirium occurring in these last days of life is often referred to as terminal restlessness or terminal agitation in the palliative care literature.

At times it is difficult to differentiate delirium from dementia since they frequently share such common clinical features as impaired memory, thinking, and judgment, and disorientation. Dementia appears in relatively alert individuals with little or no clouding of consciousness. The temporal onset of symptoms in dementia is more subacute or chronically progressive, and the sleep–wake cycle seems less impaired. Most prominent in dementia are difficulties in short-term and long-term memory, impaired judgment, and abstract thinking as well as disturbed higher cortical functions (such as aphasia and apraxia). Occasionally, delirium superimposed on an underlying dementia is encountered such as in the case of an older patient, a patient with

acquired immune deficiency syndrome (AIDS), or a patient with a paraneoplastic syndrome. Clinically, a number of scales or instruments aid clinicians in the diagnosis of delirium, dementia, or cognitive failure.

DELIRIUM IN THE TERMINALLY ILL PATIENT

Prevalence of delirium

Delirium is the most common and serious neuropsychiatric complication in the patient with advanced illness. Cognitive disorders and delirium in particular, have enormous relevance to symptom control and palliative care. Delirium is highly prevalent in cancer and AIDS patients with advanced disease, particularly in the last weeks of life, with prevalence rates ranging from 25 percent to 85 percent.[4–11] Delirium is one of the most common mental disorders encountered in general hospital practice. Knight and Folstein estimated that 33 percent of hospitalized medically ill patients have serious cognitive impairments.[12] Massie and coworkers found delirium in 25 percent of 334 hospitalized cancer patients seen in psychiatric consultation and in 85 percent (11 of 13) of terminal cancer patients.[5] Pereira and coworkers found the prevalence of cognitive impairment in cancer inpatients to be 44 percent, and just prior to death, the prevalence rose to 62.1 percent.[13] Delirium also occurs in up to 51 percent of post-operative patients.[14,15] The incidence of delirium is currently increasing, which reflects the growing numbers of older patients, who are particularly susceptible.[14] Studies of older patients admitted to medical wards estimate that between 30 and 50 percent of patients age 70 years or more showed symptoms of delirium at some point during hospitalization.[16–20] Older patients who develop delirium during hospitalization have been estimated to have a 22–76 percent chance of dying during that hospitalization.[21]

Delirium is associated with increased morbidity in the terminally ill, causing distress in patients, family members, and staff.[22–24] In a recent study of the 'Delirium Experience' of terminally ill cancer patients, Breitbart and colleagues found that 54 percent of patients recalled their delirium experience after recovery from delirium.[22] Factors predicting delirium recall included the degree of short-term memory impairment, delirium severity, and the presence of perceptual disturbances (the more severe the less likely recall). Distress related to the episode of delirium was rated by patients, spouses/caregivers, and nurses on a 0–4 numerical rating scale (with 4 being most severe). Patients scored an average rating of 3.2, spouses 3.75, and nurses 3.2. The most significant factor predicting distress for patients was the presence of delusions. Patients with hypoactive delirium were just as distressed as patients with hyperactive delirium. Predictors of spouse distress included the patients' Karnofsky Performance Status (the lower the Karnofsky, the worse the spouse distress), and nurse distress included delirium

severity and perceptual disturbances. Delirium can interfere dramatically with the recognition and control of other physical and psychological symptoms such as pain in later stages of illness.[23,25,26]

A recent retrospective study of 284 hospice patients sought to identify factors that contribute to impairment of communication capacity in terminally ill cancer patients.[27] The study demonstrated that communication capacity was frequently impaired in terminally ill cancer patients and the degree of impairment was significantly associated with higher doses of opioids. Patients who did not require high doses of opioids were able to retain complex and simple communication capacity longer than those who required high doses of opioids prior to death. Delirium was present in 20 percent of patients in this study which emphasized the importance of further investigations to explore new strategies for maintaining communication capacity in this population.

Often a preterminal event, delirium is a sign of significant physiological disturbance, usually involving multiple medical causes, including infection, organ failure, medication side effects (including opioids), as well as extremely rare paraneoplastic syndromes.[11,28–31] Lawlor and colleagues recently reported on their experience in the management of delirium in advanced cancer patients in a palliative care unit.[32] Whereas 42 percent of patients had delirium upon admission to their palliative care unit, terminal delirium occurred in 88 percent of the deaths. Unfortunately, delirium is often underrecognized or misdiagnosed and inappropriately treated or untreated in terminally ill patients. Impediments to progress in the recognition and treatment of delirium have included confusion regarding terminology and lack of consistency in the use of diagnostic classification systems. In addition, the signs and symptoms of delirium can be diverse and are sometimes mistaken for other psychiatric disorders such as mood or anxiety disorders. Practitioners caring for patients with life-threatening illnesses must be able to diagnose delirium accurately, undertake appropriate assessment of the etiologies, and be knowledgeable about the benefits and risks of the pharmacological and nonpharmacological interventions currently available in managing delirium among the terminally ill.

Diagnosing delirium

The clinical features of delirium are quite numerous and include a variety of neuropsychiatric symptoms that are also common to other psychiatric disorders such as depression, dementia, and psychosis.[33] Clinical features of delirium include prodromal symptoms (restlessness, anxiety, sleep disturbance, and irritability); rapidly fluctuating course; reduced attention (easily distractible); altered arousal; increased or decreased psychomotor activity; disturbance of sleep–wake cycle; affective symptoms (emotional lability, sadness, anger, and euphoria); altered perceptions (misperceptions, illusions, delusions, and hallucinations);

disorganized thinking and incoherent speech; disorientation to time, place, or person; and memory impairment (cannot register new material). Neurological abnormalities can also be present during delirium, including cortical abnormalities (dysgraphia, constructional apraxia, dysnomia, aphasia); motor abnormalities (tremor, asterixis, myoclonus, and reflex and tone changes); and electroencephalographic (EEG) abnormalities (usually global slowing). It is this protean nature of delirious symptoms, the variability and fluctuation of clinical findings, and the unclear and often contradictory definitions of the syndrome that have made delirium so difficult to diagnose and treat.

Box 72.1 lists the DSM-IV[1] criteria for delirium. The essential defining features of delirium, based on DSM-IV criteria, have shifted from the extensive list of typical symptoms and abnormalities described above, to a focus on the two essential concepts of disordered attention (arousal) and cognition while continuing to recognize the importance of acute onset and organic etiology. Associated phenomena such as psychomotor behavioral changes, perceptual disturbances, hallucinations or delusions are no longer viewed as essential to the diagnosis of delirium. Delirium is now conceptualized primarily as 'a disorder of arousal and cognition'[3] in contrast with dementia, which is a disorder of cognition without an arousal disturbance. It is this disorder of the arousal system, with consequent disturbances in level of consciousness and attention that is pathognomonic of delirium and is, in part, the basis for classifying delirium into several subtypes.

Box 72.1 DSM–IV criteria for delirium

Delirium due to a general medical condition:

A Disturbance of consciousness (that is, reduced clarity of awareness of the environment) with reduced ability to focus, sustain, or shift attention.

B Change in cognition (such as memory deficit, disorientation, language disturbance, or perceptual disturbance) that is not better accounted for by a preexisting, established, or evolving dementia.

C The disturbance develops over a short period of time (usually hours to days) and tends to fluctuate during the course of the day.

D There is evidence from the history, physical examination, or laboratory findings of a general medical condition judged to be etiologically related to the disturbance.

SUBTYPES OF DELIRIUM

Three clinical subtypes of delirium, based on arousal disturbance and psychomotor behavior, have been described. These subtypes included the 'hyperactive' (hyperaroused, hyperalert, or agitated) subtype, the 'hypoactive' (hypoaroused, hypoalert, or lethargic) subtype, and a 'mixed' subtype with alternating features of hyperactive and hypoactive delirium.[2,3] Research suggests that the hyperactive form is most often characterized by hallucinations, delusions, agitation, and disorientation, while the hypoactive form is characterized by confusion and sedation, but is rarely accompanied by hallucinations, delusions, or illusions.[34] In addition, there is evidence suggesting that specific delirium subtypes may be related to specific etiologies of delirium, may have unique pathophysiologies, and differential responses to treatment.[35,36] It is estimated that approximately two-thirds of deliria are either of the hypoactive or mixed subtype, hence, the prototypically agitated delirious patient most familiar to clinicians is actually a minority of the deliria which occur.[2,34,37]

DIFFERENTIAL DIAGNOSIS

Many of the clinical features and symptoms of delirium can be also be associated with other psychiatric disorders such as depression, mania, psychosis, and dementia. For instance, delirious patients, not uncommonly, exhibit mood disturbances such as anxiety, fear, depression, irritability, anger, euphoria, apathy, or lability. Delirium, particularly the 'hypoactive' subtype, is often initially misdiagnosed as depression. Symptoms of major depression, including altered level of activity (hypoactivity), insomnia, reduced ability to concentrate, depressed mood, and even suicidal ideation, can overlap with symptoms of delirium making an accurate diagnosis more difficult. In distinguishing delirium from depression, particularly in the context of advanced disease, an evaluation of the onset and temporal sequencing of depressive and cognitive symptoms is particularly helpful. Importantly, the degree of cognitive impairment in delirium is much more severe and pervasive than in depression, with a more abrupt temporal onset. Also, in delirium the characteristic disturbance in arousal or consciousness is present, while it is usually not a feature of depression. Similarly, a manic episode may share some features of delirium, particularly a 'hyperactive' or 'mixed' subtype of delirium. Again, the temporal onset and course of symptoms, the presence of a disturbance of consciousness (arousal) as well as of cognition, and the identification of a presumed medical etiology for delirium are helpful in differentiating these disorders. Delirium that is characterized by vivid hallucinations and delusions must be distinguished from a variety of psychotic disorders. In delirium, such psychotic symptoms occur in the context of a disturbance in consciousness or arousal, as well as memory impairment and disorientation, which is not the case in other psychotic disorders. Delusions in delirium tend to be poorly organized and of abrupt onset, and hallucinations are predominantly visual or tactile rather than auditory as is typical of schizophrenia. Finally, the development of these psychotic symptoms in the context of advanced medical illness makes delirium a more likely diagnosis.

The most common differential diagnostic issue is whether the patient has delirium, or dementia, or a delirium superimposed upon a preexisting dementia. Both delirium and dementia are cognitive impairment disorders and so share such common clinical features as impaired memory, thinking, judgment, and disorientation. The patient with dementia is alert and does not have the disturbance of consciousness or arousal that is characteristic of delirium. The temporal onset of symptoms in dementia is more subacute and chronically progressive, and the sleep–wake cycle is less impaired. Most prominent in dementia are difficulties in short-term and long-term memory, impaired judgment, and abstract thinking as well as disturbed higher cortical functions (such as aphasia and apraxia). Occasionally, delirium superimposed on an underlying dementia is encountered such as in the case of an older patient, an AIDS patient, or a patient with a paraneoplastic syndrome. Delirium, in contrast with dementia, is conceptualized as a reversible process. Reversibility of the process of delirium is often possible even in the patient with advanced illness. However, delirium may not be reversible in the last 24–48 hours of life. This is most likely due to the fact that irreversible processes such as multiple organ failure are occurring in the final hours of life. Delirium occurring in these last days of life is sometimes referred to as 'terminal delirium' in the palliative care literature.

DELIRIUM SCREENING/DIAGNOSTIC SCALES

A number of scales or instruments have been developed which can aid the clinician in rapidly screening for cognitive impairment disorders (dementia or delirium), or in establishing a diagnosis of delirium[38–46] (see Box 72.2). Such scales have been described and their relative strengths and weaknesses reviewed elsewhere.[43,47] Perhaps most helpful to clinicians are the Mini-Mental State Examination (a cognitive impairment screening tool) and several delirium diagnostic and rating scales, including the Delirium Rating Scale, the Delirium Rating Scale–Revised–98, the Confusion Assessment Method, the Abbreviated Cognitive Test for Delirium, and the Memorial Delirium Assessment Scale. These tools are described briefly below.

Box 72.2   Assessment methods for delirium in cancer patients

Diagnostic classification systems

- DSM-IV

- Internation Classification of Diseases (ICD)-9, ICD-10

Diagnostic interviews/instruments

- Delirium Symptom Interview (DSI)

- Confusion Assessment Method (CAM)

Delirium rating scales

- Delirium Rating Scale (DRS)

- Delirium Rating Scale–Revised–98 (DRS-R-98)

- Confusion Rating Scale (CRS)

- Saskatoon Delirium Checklist (SDC)

- Memorial Delirium Assessment Scale (MDAS)

- Abbreviated Cognitive Test for Delirium (CTD)

Cognitive impairment screening instruments

- Mini-Mental State Examination (MMSE)

- Short Portable Mental Status Questionnaire (SPMSQ)

- Cognitive Capacity Screening Examination (CCSE)

- Blessed Orientation Memory Concentration Test (BOMC)

Mini–Mental State Examination

The MMSE is useful in screening for cognitive failure, but does not distinguish between delirium and dementia.[45] The MMSE provides a quantitative assessment of the cognitive performance and capacity of a patient, and is a measure of severity of cognitive impairment. It is also most sensitive to cortical dementias such as Alzheimer disease, and less sensitive in detecting subcortical deficits such as those found in AIDS dementia. The MMSE assesses five general cognitive areas including orientation, registration, attention and calculation, recall, and language. Although a score of 23 or less has generally been considered the cut-off score for cognitive impairment, a three tiered system is now often used suggesting that a score of 24–30 indicates no impairment, 18–23 indicates mild impairment, and 0–17 indicates severe impairment.

Delirium Rating Scale

The DRS, developed by Trzepacz and colleagues is a 10-item clinician-rated symptom rating scale for diagnosing delirium.[47] The scale is based on DSM-III-R diagnostic criteria for delirium and is designed to be used by the clinician to identify delirium and distinguish it reliably from dementia and other neuropsychiatric disorders. Each item is scored by choosing the appropriate rating which carries a numerical weight selected to distinguish the phenomenological characteristics of delirium. A score of 12 or greater is diagnostic of delirium.

Delirium Rating Scale–Revised–98

The DRS-R-98 is a revision of the DRS. The DRS-R-98 has 13 severity and three diagnostic items with descriptive anchors for each rating level. It includes more items than

the DRS and was designed for phenomenological and treatment research although it may be used clinically. The DRS-R-98 is a valid, sensitive, and reliable instrument for rating delirium severity. It has advantages over the original DRS for repeated measures and phenomenological studies due to its enhanced breadth of symptoms and separation into severity and diagnostic subscales.[48]

Confusion Assessment Method

The CAM is a 9-item delirium diagnostic scale that uses the DSM-III-R criteria for delirium, and can be administered quickly by a trained clinician.[49] A unique and helpful feature of the CAM is that it has been simplified into a diagnostic algorithm that includes only four items of the CAM designed for rapid identification of delirium by nonpsychiatrists. The 4-item algorithm requires the presence of: (i) acute onset and fluctuating course, (ii) inattention, and either (iii) disorganized thinking or (iv) altered level of consciousness.

Abbreviated Cognitive Test for Delirium

The abbreviated CTD was developed as a tool to help identify delirium in patients in the intensive care unit setting who have limited ability to communicate verbally.[50] This brief tool uses visualization span and recognition memory for pictures as two of nine content scores that produces a total score that reliably identifies delirium and discriminates delirium from dementia, depression, and schizophrenia.

Memorial Delirium Assessment Scale

The MDAS is a 10-item delirium assessment tool (see Box 72.3), validated in hospitalized inpatients with advanced cancer and AIDS.[38] The MDAS is both a good delirium diagnostic screening tool as well as a reliable tool for assessing delirium severity among patients with advanced disease. A cut-off score of 13 is diagnostic of delirium. The

MDAS has advantages over other delirium tools in that it is both a diagnostic as well as a severity measure that is ideal for repeated assessments and for use in treatment intervention trials. Recently, Lawlor and colleagues further examined the clinical utility and validation of the MDAS in a population of advanced cancer patients in a palliative care unit.[51] These investigators found the MDAS to be useful in this population, and found that a cut-off score of 7 out of 30 yielded the highest sensitivity (98 percent) and specificity (76 percent) for a delirium diagnosis in this palliative care population.

MANAGEMENT OF DELIRIUM IN THE TERMINALLY ILL PATIENT

The standard approach to the managing delirium in the medically ill, and even in those with advanced disease, includes a search for underlying causes, correction of those factors and management of the symptoms of delirium. The desired and often achievable outcome is a patient who is awake, alert, calm, cognitively intact, not psychotic, and communicating coherently with family and staff. In the terminally ill patient who develops delirium in the last days of life ('terminal' delirium), the management of delirium is unique, presenting a number of dilemmas, and the desired clinical outcome may be significantly altered by the dying process (see Fig. 72.1).

Assessment of etiologies of delirium

When confronted with delirium in the terminally ill or dying patient, a differential diagnosis should always be formulated as to the likely etiology or etiologies. There is an ongoing debate as to the appropriate extent of diagnostic evaluation that should be pursued in a dying patient with a terminal delirium.[52,53] Most palliative care clinicians would undertake diagnostic studies only when a clinically suspected etiology can be identified easily, with minimal use of invasive procedures, and treated effectively with simple

---

Box 72.3 Items from the Memorial Delirium Assessment Scale (MDAS)

1 Reduced level of consciousness (awareness)

2 Disorientation

3 Short-term memory impairment

4 Impaired digit span

6 Disorganized thinking

7 Perceptual disturbance

8 Delusions

9 Decreased or increased psychomotor

10 Sleep–wake cycle disturbance (disorder of arousal)

Figure 72.1 *Overview of delirium management.*

interventions that carry minimal burden or risk of causing further distress. Diagnostic workup in pursuit of an etiology for delirium may be limited by either practical constraints such as the setting (home, hospice) or the focus on patient comfort, so that unpleasant or painful diagnostics may be avoided. Most often, however, the etiology of terminal delirium is multifactorial or may not be determined. Bruera and colleagues report that an etiology is discovered in less than 50 percent of terminally ill patients with delirium.[6] When a distinct cause is found for delirium in the terminally ill, it is often irreversible or difficult to treat. Studies, however, in patients with earlier stages of advanced cancer have demonstrated the potential utility of a thorough diagnostic assessment.[6,25] When such diagnostic information is available, specific therapy may be able to reverse delirium. One study found that improvement could be achieved in 68 percent of delirious cancer patients, despite a 30-day mortality of 31 percent.[54] Another found that a third of the episodes of cognitive failure improved following evaluation that yielded a cause for these episodes in 43 percent.[6]

In a recent prospective study of delirium in patients on a palliative care unit, investigators reported that the etiology of delirium was multifactorial in the great majority of cases.[32] Even though delirium occurred in 88 percent of dying patients in the last week of life, delirium was reversible in approximately 50 percent of episodes. Causes of delirium that were most associated with reversibility included dehydration and psychoactive or opioid medications. Hypoxic and metabolic encephalopathies were less likely to be reversed in terminal delirium.

The diagnostic evaluation includes an assessment of potentially reversible causes of delirium. A full physical examination should assess for evidence of sepsis, dehydration, or major organ failure. Medications that could contribute to delirium should be reviewed. A screen of laboratory parameters will allow assessment of the possible role of metabolic abnormalities, such as hypercalcemia, and other problems, such as hypoxia or disseminated intravascular coagulation. Imaging studies of the brain and assessment of the cerebrospinal fluid may be appropriate in some instances.

Delirium can have multiple potential etiologies (see Box 72.4). In patients with advanced cancer, for instance, delirium can be due either to the direct effects of cancer on the CNS, or to indirect CNS effects of the disease or treatments (medications, electrolyte imbalance, failure of a vital organ or system, infection, vascular complications and preexisting cognitive impairment or dementia).[6,32] Given the large numbers of drugs cancer patients require, and the fragile state of their physiological functioning, even routinely ordered hypnotics are enough to tip patients over into a delirium. Narcotic analgesics such as levorphanol, morphine sulfate, and meperidine, are common causes of confusional states, particularly in older patients and the terminally ill. Chemotherapeutic agents known to cause delirium include methotrexate, fluorouracil, vincristine, vinblastine, bleomycin, BCNU, cis-platinum, asparaginase,

Box 72.4 Causes of delirium in patients with advanced disease

Direct CNS causes

- Primary brain tumor
- Metastatic spread to CNS
- Seizures

Indirect causes

- Metabolic encephalopathy due to organ failure
- Electrolyte imbalance
- Treatment side effects from chemotherapeutic agents: steroids; radiation; narcotics; anticholinergics; antiemetics; antivirals
- Infection
- Hematological abnormalities
- Nutritional deficiencies
- Paraneoplastic syndromes

---

procarbazine, and corticosteroids.[7,11,28,55–60] Most patients receiving chemotherapeutics will not develop prominent CNS effects unless dexamethasone or prednisone is included in the regimen. The spectrum of mental disturbances related to steroids includes minor mood lability, affective disorders (mania or depression), cognitive impairment (reversible dementia), and delirium (steroid psychosis). The incidence of these disorders ranges from 3 percent to 57 percent in the noncancer populations, and they occur most commonly on higher doses.[25] Symptoms usually develop within the first two weeks on steroids, but in fact can occur at any time, on any dose, even during the tapering phase.[25] These disorders are often rapidly reversible upon dose reduction or discontinuation.[25]

Nonpharmacological interventions

In addition to seeking out and potentially correcting underlying causes of delirium, symptomatic and supportive therapies are important.[8,24,26,52] In fact, in the dying patient they may be the only steps taken. Fluid and electrolyte balance, nutrition, vitamins, measures to help reduce anxiety and disorientation, interactions with and education of family members may be useful. Measures to help reduce anxiety and disorientation (i.e. structure and familiarity) may include a quiet, well-lit room with familiar objects, a visible clock or calendar, and the presence of family. Judicious use of physical restraints, along with one-to-one nursing observation may also be necessary and useful.

Recently, Inouye and colleagues reported on a successful multicomponent intervention program to prevent delirium in hospitalized older patients.[61] They focus on a set of risk factors that were highly predictive of delirium in older patients which included: preexisting cognitive impairment, visual impairment, hearing impairment, sleep deprivation, immobility, dehydration and severe illness. Interventions directed at constant reorientation, correction of hearing and visual impairment, reversal of dehydration and early mobilization appeared to significantly reduce the number and duration of episodes of delirium in hospitalized older patients. The applicability of these interventions and the likelihood that they would prevent delirium in the terminally ill, particularly in the last days of life, is likely minimal.

Pharmacological interventions in delirium

Supportive techniques alone are often not effective in controlling the symptoms of delirium, and symptomatic treatment with neuroleptics or sedative medications are necessary (see Table 72.1). Neuroleptic drugs (dopamine-blocking drugs) such as haloperidol, are utilized frequently as antiemetics in the medical setting, however, only 0.5 percent to 2 percent of hospitalized cancer patients, for instance, receive haloperidol for the management of the symptoms of delirium.[62,63] Among terminally ill patients, only 17 percent receive an antipsychotic for agitation or psychological distress, despite an estimated prevalence of delirium ranging from 25 percent in the hospitalized cancer patient to 85 percent in the terminally ill.[64,65]

NEUROLEPTICS

Haloperidol, a neuroleptic drug that is a potent dopamine blocker, is often the drug of choice in the treatment of delirium in patients with advanced disease.[65–73] Haloperidol in low doses, 1–3 mg/day, is usually effective in targeting agitation, paranoia, and fear. Typically 0.5–1.0 mg haloperidol (per oral [PO], intravenous [IV], intramuscular [IM], subcutaneous [SC]) is administered, with repeat doses every 45–60 minutes titrated against target symptoms.[53,74] An IV route can facilitate rapid onset of medication effects. If IV access is unavailable, start with IM or SC administration and switch to the oral route when possible. The majority of delirious patients can be managed with oral haloperidol. Parenteral doses are approximately twice as potent as oral doses. Haloperidol is administered by the SC route by many palliative care practitioners.[6,75] Low doses of neuroleptic medication are usually sufficient in treating delirium in elderly terminally ill patients. In general, doses need not exceed 20 mg of haloperidol in a 24-hour period. However, a few clinicians have advocated high doses (up to 250 mg/24-hour of haloperidol intravenously) in selected cases.[73]

A common strategy in the management of symptoms related to delirium is to add parenteral lorazepam to a regimen of haloperidol.[76,77] Lorazepam (0.5 mg to 1.0 mg every 1–2 hours PO or IV) along with haloperidol may be more effective in rapidly sedating the agitated delirious patient and may minimize extrapyramidal side effects associated with haloperidol.[77] An alternative strategy is to switch from haloperidol to a more sedating neuroleptic such as chlorpromazine (see Fig. 72.2 later). In a double blind, randomized

Table 72.1 *Medications used in the management of delirium in patients with advanced disease*

Generic name	Approximate daily dosage range	Route
Neuroleptics		
Haloperidol	0.5–5 mg every 2–12 hours	PO, IV, SC, IM
Thioridazine	10–75 mg every 4–8 hours	PO
Chlorpromazine	12.5–50 mg every 4–12 hours	PO, IV, IM
Methotrimeprazine	12.5–50 mg every 4–8 hours	IV, SC, PO
Molindone	10–50 mg every 8–12 hours	PO
Droperidol	0.625–2.5 mg every 4–8 hours	IV, IM
Atypical neuroleptics		
Olanzapine	2.5–20 mg every 12–24 hours	PO
Risperidone	0.5–3 mg every 12–24 hours	PO
Quetiapine	12.5–200 mg every 12–24 hours	PO
Ziprasidone (note max IM daily dose 40 mg)	10–80 mg every 12–24 hours	PO, IM
Benzodiazepines		
Lorazepam	0.5–2.0 mg every 1–4 hours	PO, IV, IM
Midazolam	30–100 mg every 24 hours	IV, SC
Anesthetics		
Propofol	10–70 mg every hour	IV
	Up to 200–400 mg/h	

PO, per oral; IM, intramuscular; IV, intravenous; SC, subcutaneous.

comparison trial of haloperidol versus chlorpromazine versus lorazepam, Breitbart and colleagues demonstrated that lorazepam alone, in doses up to 8 mg in a 12-hour period, was ineffective in the treatment of delirium and contributed to worsening delirium and cognitive impairment.[4**] Both neuroleptic drugs however, in low doses (approximately 2 mg of haloperidol equivalent/per 24 hours), were highly effective in controlling the symptoms of delirium (dramatic improvement in DRS scores) and improving cognitive function (dramatic improvement in MMSE scores). In addition, both haloperidol and chlorpromazine were demonstrated to significantly improve the symptoms of delirium in both the 'hypoactive' as well as the 'hyperactive' subtypes of delirium.[4**] Methotrimeprazine, a phenothiazine neuroleptic with properties similar to chlorpromazine, is often used parenterally (IV or by SC infusion) to control confusion and agitation in terminal delirium.[78*] Dosages range from 12.5 mg to 50 mg every 4–8 hours up to 300 mg per 24 hours for most patients, including the elderly where doses at the lower end of the range are preferable. Hypotension and excessive sedation are potential limitations of this drug; however, methotrimeprazine has the advantage of also being an analgesic, equipotent to morphine, through nonopioid mechanisms.[78]

ATYPICAL NEUROLEPTICS

Several new, atypical, antipsychotic agents with less or more specific dopamine-blocking effects (less risk of extrapyramidal side effects or tardive dyskinesia) are now available and include such agents as risperidone, olanzapine, quetiapine, and ziprasidone.[79–83] Risperidone has been useful in the treatment of dementia and psychosis in AIDS patients at doses of 1–6 mg daily, suggesting safe use in patients with delirium.[82] Until recently, there have been only a limited number of published studies of the use of these agents in the treatment of delirium.[80–83] Schwartz and Massand's review of the use of atypical antipsychotics in delirium in 2002 included mostly case reports and retrospective studies.[84] In the interval, a number of additional studies have been published.

A retrospective analysis of 77 patients who received either haloperidol or risperidone for delirium indicated that both were effective in reducing symptoms of delirium and suggested that risperidone reduced the need for prescribing anticholinergic agents to treat extrapyramidal effects.[85*] Two small open prospective studies supported the use of risperidone for the treatment of symptoms of delirium with minimal risk of sedation or extrapyramidal side effects.[86*,87*] In a third larger open label study of 64 patients, patients with a risperidone intervention achieved a significant reduction in DRS scores during a 7-day observation period with minimal sedation or extrapyramidal effects.[88*] In a recent double blind, comparative delirium intervention study assessing the efficacy of haloperidol versus risperidone, Han and Kim demonstrated in a small sample of 24 oncology patients that

there was no significant difference in clinical efficacy or response rate.[89*]

Breitbart and colleagues recently published the results of a large (N = 82) open trial of olanzapine for the treatment of delirium in hospitalized patients with advanced cancer.[83*] Olanzapine was highly effective in the treatment of delirium, resolving delirium in 76 percent of patients with no incidence of extrapyramidal side effects. Several factors were found to be significantly associated with poorer response to olanzapine treatment for delirium, including age over 70, history of dementia, and hypoactive delirium. The average starting dose was in the 2.5–5 mg range and patients were given up to 20 mg per day of olanzapine. Sedation was the most common side effect. A small comparative study of haloperidol versus olanzapine for the treatment of delirium in 11 patients suggested equivalent efficacy and a favorable side effect profile for olanzapine.[81*] In another open label study, olanzapine significantly reduced DRS scores in 20 patients with lymphoma who experienced delirium, however, side effects were not systematically assessed.[90*] Most recently, a study compared olanzapine to haloperidol in a critical care setting over a 5-day observation period. The authors demonstrated significant improvement in both groups.[91*] Thirteen percent of the patients receiving haloperidol experienced mild parkinsonian side effects while none of the patients receiving olanzapine experienced extrapyramidal side effects.[91]

As a result of increasing clinical experience, more palliative care clinicians are using risperidone in low doses (e.g. 0.5–1.0 mg twice a day, orally) as well as olanzapine (2.5–20 mg/day in divided doses) in the management of delirium in terminally ill patients, particularly in those who have a demonstrated intolerance to the extrapyramidal side effects of the classic neuroleptics.[92] Currently, a limitation on the use of these new agents is the lack of availability of these agents in parenteral formulations. Figure 72.2 illustrates an algorithm that has been developed for use by the Memorial Sloan–Kettering Cancer Center Psychiatry Service for the management of delirium in hospitalized cancer patients.

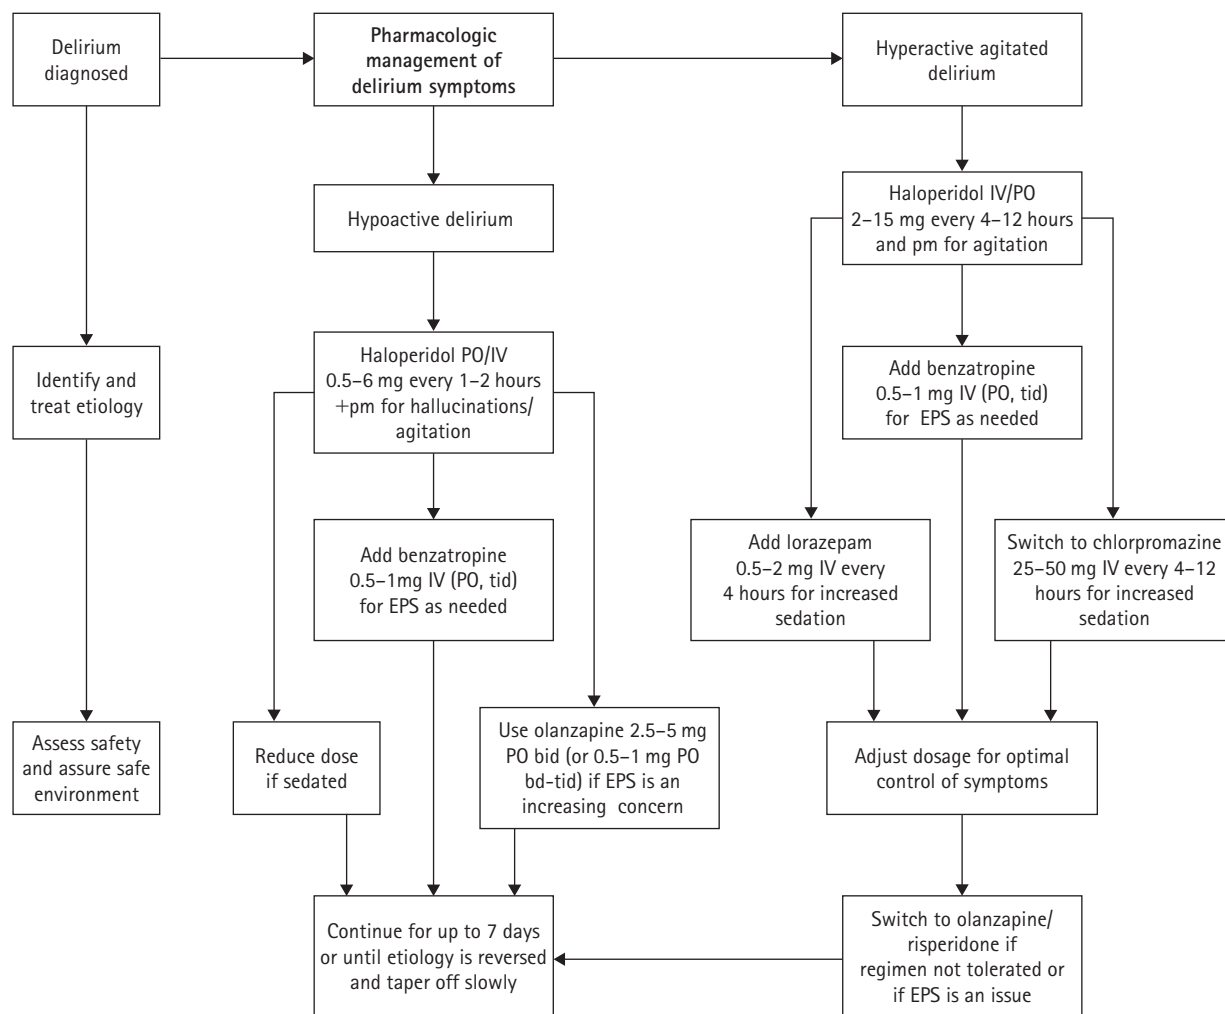
Clinicians are beginning to examine the efficacy and tolerability of even newer atypical antipsychotics, quetiapine and ziprasidone. A few authors have published their experience with quetiapine for the treatment of delirium. Schwartz and Massand's retrospective review of 11 patients treated with quetiapine compared with patients who received haloperidol demonstrated a significant decline in DRS scores in 10/11 patients with only two patients experiencing sedation with an average dose of quetiapine 200 mg daily.[93*] None of the patients in the quetiapine group demonstrated evidence of extrapyramidal effects in contrast with two patients in the haloperidol group experiencing extrapyramidal side effects.[93] Kim et al. reported on a case series of 12 elderly patients with delirium who received quetiapine for delirium.[94*] There was a significant decline in the DRS scores, however, the authors were unable to determine if


Figure 72.2 *The delirium algorithm. pm, evening; IV, intravenous; PO, per oral; tid, three times daily; EPS, extrapyramidal side effects; bd, twice daily.*

quetiapine treatment or effective resolution of the underlying etiology accounted for a reduction in symptoms.[94] Sasaki *et al.* published a prospective open label trial of 12 patients with postoperative delirium of diverse etiologies who had already received other antipsychotics and/or benzodiazepines without efficacy prior to the introduction of quetiapine.[95*] Although DRS scores significantly improved, the efficacy of quetiapine was difficult to determine as patients continued to receive haloperidol and benzodiazepines for severe agitation.[95] Pae *et al.*'s open label trial in 22 Korean patients with delirium demonstrated significant DRS score reduction in 85 percent of patients.[96*] Three patients experienced sedation and two patients were unable to complete the study (one due to lack of efficacy and one due to oversedation). No patient experienced extrapyramidal side effects.[96] Leso and Schwartz published the first case report of ziprasidone in the treatment of delirium.[97*] A young, human immunodeficiency virus (HIV)+ patient with delirium due to cryptococcal meningitis responded with a reduction in DRS score from 26 to 14

with a total daily dose of ziprasidone 100 mg.[97*] Ziprasidone treatment was discontinued due to hypokalemia and hypomagnesemia and ECG premature ventricular contractions and a calculated 8.4 percent prolongation in QTc interval.[97] Young and Lujan published the first case report of intravenous ziprasidone in the treatment of delirium in a postoperative patient in the intensive care unit who failed to respond to standard haloperidol treatment.[98*] The authors described an effective reduction in dangerous agitation but did not report which measurement scale was used to rate delirium symptoms.[98]

While neuroleptics are most effective in diminishing agitation, clearing the sensorium and improving cognition is not always possible in delirium which complicates the last days of life. Processes causing delirium may be ongoing and irreversible during the active dying phase. Ventafridda and colleagues[99] and Fainsinger and colleagues[26] have reported that 10–20 percent of terminally ill patients experience delirium that can only be controlled by sedation resulting in a significantly decreased level of consciousness.

Lawlor and colleagues report that at least 50 percent of terminal delirium is reversible.[32] The goal of treatment with agents such as midazolam, propofol, and methotrimeprazine is quiet sedation. Midazolam, given by SC or IV infusion in doses ranging from 30 mg to 100 mg per 24 hours, can be used to control agitation related to delirium in the terminal stages.[100*] Propofol, a short-acting anesthetic agent, has also begun to be used primarily as a sedating agent for the control of agitated patients with 'terminal' delirium. In several case reports of propofol used in terminal care, an IV loading dose of 20 mg of propofol was followed by a continuous infusion of propofol with initial doses ranging from 10 mg/h to 70 mg/h with titration of doses up to as high as 400 mg/h over a period of hours to days in severely agitated patients.[101*,102*] Propofol has an advantage over midazolam in that the level of sedation is more easily controlled and recovery is rapid upon decreasing the rate of infusion.[101]

Controversies in the management of terminal delirium

Several aspects of the use of neuroleptics and other pharmacological agents in the management of delirium in the dying patient remain controversial in some circles. Some have argued that pharmacological interventions with neuroleptics or benzodiazepines are inappropriate in the dying patient. Delirium is viewed by some as a natural part of the dying process that should not be altered. In particular, there are clinicians who care for the dying who view hallucinations and delusions which involve dead relatives communicating with, or in fact welcoming dying patients to heaven, as an important element in the transition from life to death. Clearly, there are many patients who experience hallucinations and delusions during delirium that are pleasant and in fact comforting, and many clinicians question the appropriateness of intervening pharmacologically in such instances. Another concern that is often raised is that these patients are so close to death that aggressive treatment is unnecessary. Parenteral neuroleptics or sedatives may be mistakenly avoided because of exaggerated fears that they might hasten death through hypotension or respiratory depression. Many are unnecessarily pessimistic about the possible results of neuroleptic treatment for delirium. They argue that since the underlying pathophysiological process often continues unabated (such as hepatic or renal failure), no improvement can be expected in the patient's mental status. There is concern that neuroleptics or sedatives may worsen a delirium by making the patient more confused or sedated.

Clinical experience in managing delirium in dying patients suggests that the use of neuroleptics in the management of agitation, paranoia, hallucinations and altered sensorium is safe, effective and often quite appropriate.[76] Management of delirium on a case by case basis seems wisest. The agitated, delirious dying patient should probably be given neuroleptics to help restore calm. A 'wait and see'

approach, prior to using neuroleptics, may be appropriate with some patients who have a lethargic, or somnolent presentation of delirium, or those who are having frankly pleasant or comforting hallucinations. Such a 'wait and see' approach must, however, be tempered by the knowledge that a lethargic or 'hypoactive', delirium may very quickly and unexpectedly become an agitated or 'hyperactive' delirium that can threaten the serenity and safety of the patient, family and staff. An additional rationale for intervening pharmacologically with patients who have a lethargic or 'hypoactive' delirium is recent evidence that neuroleptics (i.e. haloperidol, chlorpromazine) are effective in controlling the symptoms of delirium in both 'hyperactive' as well as 'hypoactive' subtypes of delirium.[4] In fact neuroleptics improved both the arousal disturbance, as well as cognitive functioning in patients with 'hypoactive' delirium. Also, some clinicians suggest that 'hypoactive' delirium may respond to psychostimulants or combinations of neuroleptics and stimulants.[54] Similarly, hallucinations and delusions during a delirium that are pleasant and comforting can quickly become menacing and terrifying. It is important to remember that by their nature, the symptoms of delirium are unstable and fluctuate over time.

Finally, perhaps the most challenging of clinical problems is management of the dying patient with a 'terminal' delirium that is unresponsive to standard neuroleptic interventions, whose symptoms can only be controlled by sedation to the point of a significantly decreased level of consciousness. Before undertaking interventions, such as midazolam or propofol infusions, where the best achievable goal is a calm and comfortable but sedated and unresponsive patient, the clinician must first take several steps. The clinician must have a discussion with the family (and the patient if there are lucid moments when the patient appears to have capacity) eliciting their concerns and wishes for the type of care that can best honor their desire to provide comfort and symptom control during the dying process. The clinician should describe the optimal achievable goals of therapy as they currently exist. Family members should be informed that the goal of sedation is to provide comfort and symptom control, not to hasten death. They should also be told to anticipate that sedation may result in a premature sense of loss and that they may feel their loved one is in some sort of limbo state, not yet dead, but yet no longer alive in the vital sense. The distress and confusion that family members can experience during such a period can be ameliorated by including the family in the decision making and emphasizing the shared goals of care. Sedation in such patients is not always complete or irreversible; some patients have periods of wakefulness despite sedation, and many clinicians will periodically lighten sedation to reassess the patient's condition. Ultimately, the clinician must always keep in mind the goals of care and communicate these goals to the staff, patients and family members. The clinician must weigh each of the issues outlined above in making decisions on how to best manage the

dying patient who presents with delirium that preserves and respects the dignity and values of that individual and family.

Key learning points

- Delirium occurs in up to 85 percent of patients prior to death.

- Delirium is categorized into subtypes based on arousal or motoric disturbance. Hypoactive delirium is as common and as distressing as hyperactive delirium.

- There are typically three or more etiologies for delirium in the palliative care setting.

- In the terminally ill, delirium is reversible in only 50 percent of cases compared with 95 percent of cases in patients with earlier stage disease.

- The management of delirium involves the concurrent search for and treatment of the underlying etiology while actively controlling the symptoms of delirium.

- Delirium often is a harbinger of impending death. Issues of end-of-life care treatment preferences are ideally dealt with prior to the onset of delirium.

- Delirium is associated with high levels of distress in patients, family members, and nurses. Education of family members and nurses in the palliative care setting is important.

- Neuroleptics are effective in controlling the symptoms of delirium.

- Atypical neuroleptics are demonstrating efficacy in controlling the symptoms of delirium with less extrapyramidal side effects.

- Sedation may be necessary in up to 30 percent of patients with delirium unresponsive to neuroleptics.

Sleeping disorders

FRITZ STIEFEL, DANIELE STAGNO

INTRODUCTION

Sleeping disorders are common in palliative care patients.[1***] The prevalence of insomnia – the most common sleep disorder in palliative care – is reported to range from 23 percent[2] to 70 percent;[3*] the latter percentage has been observed in a recent study, which actively searched for insomnia. Poor sleep affects quality of life and increases perception of symptoms, such as pain, and is therefore an important target of palliative care treatments.[4,5] Both patients and clinicians often consider poor sleep as inevitable in the context of a terminal illness[6*] and there is a trend to prescribe hypnotic drugs with unclear benefits. On the other hand, little attention is paid to the underlying causes of sleep disturbances.[7*]

Sleep disorders can be classified using two diagnostic systems: the International Classification of Sleep Disorders[8] and the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR)[9] (see Box 73.1).

Box 73.1 Classification of sleep disorders according to DSM–IV

Primary sleep disorders

Dyssomnias

- Primary insomnia
- Primary hypersomnia
- Narcolepsy
- Breathing-related sleep disorders
- Circadian rhythm sleep disorders
- Dyssomnias NOS (not otherwise specified)

Parasomnias

- Nightmare disorders
- Sleep terror disorders
- Sleepwalking disorders
- Parasomnias NOS (not otherwise specified)

Sleep disorder related to another mental disorder

Other sleep disorders

- Sleep disorders due to a general medical condition
- Substance-induced sleep disorders

These classification systems may be helpful for the clinician in diagnosing specific sleep disorders and during adjusting management. In palliative care, insomnia due to multiple etiologies – due to the general medical condition, substance-induced and related to another mental disorder – is the most frequently encountered sleep disorder.[1–3] Other forms of primary sleep disorders are relatively rare; this chapter therefore focuses on insomnia.

MEDIATING VARIABLES OF INSOMNIA IN PALLIATIVE CARE

The most important mediating variables of insomnia in palliative care are pain and depression.[10***] Sleep disorders and pain are closely related phenomena. Most epidemiological studies of the impact of pain on sleep are based on self-report; since the definition of normal sleep is not well established, the prevalence of insomnia varies widely. Nevertheless, sleep disorders occur in up to 27 percent of primary care populations[11]

and more frequently in the elderly and in patients with advanced medical illness.[12] Pain certainly promotes insomnia, but it is also the individual's emotional, cognitive, and behavioral response that lead to its chronic development.[13] From a clinical point of view, the relation between insomnia and pain appears to be straightforward: pain causes arousal and arousal interferes with the ability to initiate and maintain sleep.[14] However, the few studies investigating this relationship showed a significant, but only moderate positive relationship between pain severity and sleep complaints. Smith *et al.* therefore suggested that the relation may be more complex and not unidirectional; their hypothesis is that pain-related arousal is different from the somatic and/or cognitive arousal of insomnia, even if mediating variables are likely to exist.[15]

One of the best-studied mediating variables in insomnia is depression, but this literature also remains controversial. For example up to 87 percent of chronic pain patients show depressive disorders;[16***] moreover sleep complaints correlate stronger with severity of depression than pain severity.[17–19] On the other hand, Morin *et al.* showed that rating of depression and anxiety did not distinguish patients with chronic pain with or without sleep disturbances.[20*] They suggested that sleep disturbance in patients with chronic pain does not necessarily reflect an underlying emotional disorder. Thus psychiatric morbidity associated with chronic pain seems to be more often a consequence than a cause of pain.[20*,21*]

Many other somatic symptoms (e.g. nausea, dyspnea, or urinary disturbances) and psychiatric disorders (e.g. anxiety, delirium, or substance abuse and withdrawal) may be mediating variables of insomnia. Since the relationships between somatic and psychiatric disturbances and insomnia often remain unsolvable in the individual patient, palliative care physicians have to ensure that both physical and psychiatric disturbances are evaluated and treated.

In recent years there has been increasing emphasis on the relationship between sleep disorders and alterations of immunity.[1] Interferon α (endogenous or exogenous) has now long been incriminated as a causative factor for depression, psychotic disorders, and sleep disorders. Those symptoms are probably mediated by the release of proinflammatory cytokines and an activation of the hypothalamic–pituitary–adrenal (HPA) axis.[22] Insomnia is also negatively correlated with the activity of natural killer cells.[23] Activity of proinflammatory cytokines is increased in people with chronic sleep disturbances[24] and cancer patients especially those with pancreatic cancer.[25,26] Patients receiving antineoplastic drugs as well as radiotherapy show increased sleep disturbances.[1] The mechanisms are unknown, although not surprisingly the immune system may be concerned.

ASSESSMENT

Insomnia is best defined as a complaint by the patient – similar to the definition of pain – of poor or unsatisfactory sleep; this complaint may include different aspects, such as the difficulty to initiate sleep, repeated or lengthy awakenings, early awakening, inadequate total sleep time, poor quality of sleep, or daytime dysfunction such as change of alertness, loss of energy or cognitive, behavioral and emotional changes.[27] A systematic evaluation of insomnia is the key to its adequate management (see Box 73.2).[11]

Box 73.2 Recommendations for the assessment of insomnia in the palliative setting

- Avoid a nihilistic attitude leading to an inadequate prescription of hypnotics
- Try to evaluate the complaints as accurately as possible and identify mediating factors and maladaptive responses to insomnia
- Establish a diagnosis of insomnia if residual daytime effects are present
- Identify possible links between insomnia and somatic and psychological state
- Evaluate if mediating factors of insomnia can be influenced
- Introduce sleep hygiene measures and give the patient written instructions
- Teach nonpharmacological interventions with which you are familiar
- Consider pharmacological treatment if the above mentioned interventions are not successful
- Think about alternatives to benzodiazepines, especially in patients with psychiatric comorbidity and older patients
- Use benzodiazepines, following the recommendations for their use in patients with somatic diseases
- Monitor treatment and continue to offer a therapeutic relationship

---

The first step is an accurate evaluation of the reported symptoms. Although this may be considered as common sense, it has to be remembered that 53 percent of physicians evaluating older patients neglect eliciting any sleep history.[28***] An adequate sleep history – sleep and wakefulness patterns, history of the bed partner, family history of sleep disorders and previous treatments – should be obtained first. Complaints of inadequate sleep in the absence of any residual daytime effects or distress do not indicate significant insomnia.[27] Insomnia causes psychosocial, physical and occupational disturbances, commonly reported as fatigue/lethargy, mood disturbances, cognitive inefficiency,

motor impairments, social discomfort, and nonspecific physical symptoms.[29]

Tools have been developed to promote a structured evaluation of insomnia by clinicians; among these is the interview for sleep disorders according to the DSM-III-R,[30] which shows a good interrater reliability and concordance with the electroencephalogram (EEG) (the gold standard to assess sleep disturbances). Another instrument is the Pittsburgh Sleep Quality Index (PSQI),[31,32] a 19-item self-report questionnaire measuring sleep quality. A more specific tool is the Audit of Insomnia In Palliative Care.[3] This 15-item questionnaire is based on key features related to insomnia in the palliative care setting. Questions refer to the presence of sleep disturbance, its physical or psychological causes, sleep pattern, medication, previous and current use of hypnotics, and patients' own suggestions as to what measures may improve their insomnia.

Once the diagnosis of insomnia has been established, mediating somatic and psychiatric disturbances should be identified, since treatment will first attempt to target these factors. Finally, the individual's maladaptive cognitive, behavioral and emotional responses, which may be responsible for a chronic development of insomnia, have to be assessed. Maladaptive responses consist for example of anticipation of insomnia towards bedtime (cognition), excessive time spent in bed without sleeping (behavioral) or irritation upon nighttime wake ups (emotional). Identification of these responses is important to explain sleep hygiene measures and to motivate the patient for nonpharmacological interventions.

MANAGEMENT

Whenever possible, a treatment should target mediating somatic and psychiatric factors. If identification of such factors is not possible or if they are not present (anymore), symptomatic treatment of insomnia will be necessary. Before prescribing hypnotics, sleep hygiene measures and basic behavioral interventions should be considered.

Nonpharmacological management

Recognition of maladaptive psychological and behavioral responses to insomnia has led to the development of nonpharmacological interventions,[33,34] which can also be used in the palliative care setting. Although these interventions are easy to implement, they remain unknown and underused. Among them, sleep hygiene measures are most important and should always be part of the management of insomnia. After verbal discussion, instructions should be given in a written form to the patient and checked during follow-up visits. Sleep hygiene measures have considerable face validity but have not been tested for efficacy in alleviating insomnia.[35***]

SLEEP HYGIENE MEASURES

- Wind down during the second half of the evening; rest for 60–90 minutes before bedtime; avoid intense thinking, discussions, and actions.
- Introduce a pre-sleeping routine.
- Practice relaxation techniques during the day and before bedtime.
- Create an adequate sleeping environment (bed, mattress, external sounds, temperature).
- Keep regular sleep hours, use bed for sleep (and sexual activity) only, avoid excessive time in bed and have a regular getting up time (regardless of the quality of the sleep).

BEHAVIORAL INTERVENTIONS

The American Academy of Sleep Medicine has provided interesting recommendations with different levels of evidence for the nonpharmacological treatment of chronic insomnia.[27] We describe those interventions which can easily be implemented in the palliative care setting; for other, more sophisticated interventions, such as biofeedback, paradoxical intention and cognitive therapy, the reader is referred to the literature.

- **Stimulus control** consists of providing a set of instructions that curtail behaviors incompatible with sleep and ensures that the patient does not spend time in bed awake.[35***] Since the patient may have developed a conditioned response associating the bedroom with poor sleep, the objective is to reassociate the bed and the bedroom with rapid sleep onset. The core instructions are similar to the sleep hygiene measures:
  - Lie down to sleep only when sleepy.
  - Use the bed only for sleep and sex.
  - If unable to fall asleep, get up and go to another room. Stay as long as needed, but when sleepy return to the bedroom to sleep.
  - When in bed and awake for longer than 10 minutes repeat previous step.
- **Imagery training** involves visualization, focusing on pleasant and neutral images. Patients with poor fantasy can remember joyful or peaceful moments of the past.[36]
- **Progressive muscle relaxation** consists of tensing and relaxing different muscle groups throughout the body. These techniques are easy to teach and to learn and are especially helpful for patients with chronic pain who display high levels of arousal.[37]

PHARMACOLOGICAL MANAGEMENT

More than 45 percent of clinicians investigating sleep disorders prescribe a medication after asking a mean of only 2.5 questions.[38] Hypnotic agents are routinely prescribed, but the rational for this practice has not been established.

The current opinion on the use and safety of hypnotics in the treatment of insomnia underlines the lack of strong evidence of major benefits and the existing evidence for potential harm.[38] Hypnotics should be considered only after sleep hygiene measures and nonpharmacological interventions have not been successful. Two consensus conferences[39***],[40***] have concluded that their short-term usage may be useful for acute and situational insomnia, but long-term use remains controversial. For example behavioral therapy and pharmacotherapy produce similar short-term outcomes as recently shown in a comparative meta-analysis of the treatment of persistent insomnia.[41***]

Hypnotics

Nearly half of chronic insomniac individuals who take sleeping pills derive little or no subjective benefits from the medication, although they continue to take the medication for years.[42*]

Benzodiazepines effectively suppress insomnia,[41***] but their use for this indication is a controversial issue. A careful evaluation of the patient, treatment of mediating factors, if possible, and nonpharmacological alternatives to the use of benzodiazepines is therefore mandatory.[43,44] If benzodiazepines are indicated, the following recommendations should be considered: use benzodiazepines only with lowest dosage and short periods (maximum 4 weeks); monitor side effects and do not interrupt their use abruptly.[28,38,43] The most relevant general aspects of the pharmacokinetics of benzodiazepine are summarized in Box 73.3.[43] The box indicates a high interindividual variation and shows that onset, distribution, and excretion are influenced by liver disease or decreased absorption in the gastrointestinal tract. Long-acting substances such as diazepam, nitrazepam or flurazepam can cause hangover, daytime drowsiness, dizziness

---

Box 73.3 Relevant pharmacokinetics of benzodiazepines with regard to their use in patients with an underlying medical condition

- Up to 10-fold interindividual variation

- Age, smoking, liver disease, physical illness, gender, and concomitant drugs influence distribution and elimination

- Long-acting substances associated with daytime side effects, short-acting substances with time-limited effects, amnesia, rebound and withdrawal difficulties

- Most substances metabolized by oxidation (more impaired by physical illness, liver disease, age, and other drugs), few by conjugation

- Most substances with active metabolites

---

and prolonged sedation, especially in terminally ill patients; these side effects are less important with intermediate-acting substances, which are conjugated and without active metabolites (e.g. lorazepam, oxazepam). Short-acting benzodiazepines can lead to early morning insomnia, daytime anxiety, tension or panic, amnesia, rebound and withdrawal difficulties.[45–47] With regard to drug interactions in patients experiencing pain, benzodiazepines have additive effects with morphine and other opioids (e.g. sedation, confusion).

Zolpidem for sleep induction and zopiclone for night awakening, although not belonging to the chemical class of benzodiazepines, share many pharmacological features with this group of drugs. These agents can be prescribed as an alternative to classical benzodiazepines, with similar indications and safety warnings.[48***] Nevertheless, with regard to prescription of zolpidem, zopiclone, and zaleplon no reliable data are available.[49***]

Barbiturates are used rarely; these drugs have a greater tendency to depress respiration and are generally less effective than benzodiazepines. Barbiturates have a high abuse potential and a narrow therapeutic margin, and therefore have been withdrawn from the market in several countries.

A careful evaluation of the risk–benefit ratio should precede a treatment with benzodiazepines. The problem with prescribing benzodiazepines is not the potential abuse, withdrawal symptoms, and drug interactions, but rather the mishandling by clinicians who prescribe them without clear-cut indication or those who use them to get rid of an embarrassing problem.[48]

Antidepressants, neuroleptics, and other psychotropics

Sedative antidepressants such as amitriptyline, trimipramine, doxepin, mianserin, mirtazapine, nefazodone or trazodone are first choice in depressed patients with insomnia.[50–53] Antidepressants are also adjuvant analgesics, drugs with a primary indication other than pain. Although antidepressants have been found to have an analgesic effect independent of the effect on concomitant depression,[54] depression and other symptoms such as insomnia often coexist with pain and have a negative influence on pain perception.[51***] Sedative antidepressants have anticholinergic and other side effects and should therefore be used with caution in patients with somatic diseases; they may also induce or trigger confusional states.

Sedative neuroleptics (such as chlorprothixene, levopromazine, promazine, or thioridazine) are potentially harmful because of adverse effects such as hypotension. For example, levopromazine produces cardiovascular side effects even in young patients.[52,55] In demented patients, pipamperone, clomethiazole or chloral hydrate may be helpful.[52]

Clomethiazole, primarily introduced for the treatment of alcohol withdrawal syndrome[56] can be considered as effective in patients with insomnia due to nocturnal agitation associated with cognitive impairment.[57–60] Clinical experience

suggests that sedating antihistamines, such as diphenhydramine, hydroxyzine, doxylamine, and promethazine may be of help in some patients, but their efficacy for the treatment of insomnia is not well established and their potential to cause delirium or hypotension make these agents of questionable value. Melatonin, not registered in most European countries, may have some beneficial sleep-regulating activity[61,62] and analgesic adjuvant effects.[63] Compared to the previously mentioned compounds, the sleep-inducing activity of melatonin is relatively scant; however, its excellent tolerability can make it acceptable to patients reluctant to take potent psychotropic drugs.[48] There is a growing literature reporting some benefit of cannabinoids[64] in sleep disorders, but to our knowledge no methodologically sound study has been conducted in palliative care. The same holds for molecules whose purpose is to diminish the expression or the effects of proinflammatory cytokines (tumor necrosis factor, interleukin [IL]-1α/β, IL-6); non-steroidal anti-inflammatory drugs (NSAIDs)[22] and thalidomide[65,66] are under observation.

CONCLUSIONS

Management of insomnia in palliative care is a considerable challenge for the clinician. It requires a careful evaluation, diagnostic skills, familiarity with nonpharmacological interventions and a sound knowledge of pharmacotherapy. In front of patients who are angered and/or saddened by their condition, clinicians are tempted to prescribe psychotropics to offer quick relief. While this may reduce the pressure felt by both the patient and the clinician, it may become a problem, because of the side effects. We therefore would like to invite readers to follow the above mentioned diagnostic and therapeutic strategies.

Key learning points

- Assessment of insomnia and its mediating factors
- Classification systems and specific assessment tools
- Recommendations for clinical evaluation
- Sleep hygiene measures and behavioral interventions
- Pharmacological management of insomnia
- Hypnotics in the palliative care setting

Counseling in palliative care

KIMBERLEY MILLER, DAVID W KISSANE

INTRODUCTION

Psychotherapeutic interventions and support may be offered to the individual patient living with advanced cancer, but palliative care also recognizes the needs of the 'second order'[1] or 'hidden'[2] patients among families and caregivers. Although the incidence of distress found in studies varies, approximately 15–40 percent of cancer patients will develop significant anxiety and/or depression,[3–5] rates being less for true major depression.[6] Among caregivers of terminally ill patients, one study using structured psychiatric interviews found that 33 percent had psychiatric morbidity,[7] most commonly major depression, anxiety, or adjustment disorders. When self-report questionnaires are used, these frequencies become higher.[8–10] A systematic review has shown that those experiencing or at risk of psychological distress show a greater effect size in responding to psychological treatments compared with those with minimal or no distress.[11***] Therefore, identifying and intervening with patients and families at high risk is an important therapeutic and cost minimizing principle.

The approach to counseling will vary according to needs and clinical indications.[12] Services may be delivered individually, some will be more effective when targeting a couple, and meeting with the immediate or extended caregiving family is both helpful and cost-effective. Self-help or professionally led groups are beneficial in promoting support, while focused family therapy and multifamily groups present other options.

In this chapter, the indications for counseling, varied models of intervention, issues for therapists and process challenges in the delivery of the counseling will be reviewed alongside the evidence for effectiveness of outcome.

WHAT ISSUES PRESENT FOR COUNSELING?

Patients present often with a concern or worry, sometimes with a symptom and rarely with a labeled disorder. The concern may be phrased as a question, buried in a bewildered maze of thoughts and feelings or projected as a problem onto another family member. Whatever the presentation – whether emotional, attitudinal, behavioral or conative – each request for help challenges the clinician to recognize what is relevant and organize this meaningfully. Understanding the person with their gamut of life's experiences and influences, successes and failures, accomplishments and omissions, shame and secrets, health or illness is at the heart of being able to respond to the whole person as an unique individual within their culture, family, and social world.[13]

Clinicians respond to such complexity with organizational schemata that structure the phenomena into recognizable patterns and hierarchies. Training, skill, and experience are crucial here if order is to emerge from potential chaos and be channeled constructively towards improved coping and beneficial outcome. Nevertheless, health professionals need to suspend any preconceptions and listen intently, lest the real needs of the patient are ignored with an inherent inability to heal, even if the disease is being treated. During the final weeks and days of life, matters existential, relational and spiritual come to the fore and may be more important ultimately than physical symptom management.[14]

How do clinicians organize patients' concerns to aid comprehension and plan consequent intervention? While listening to the narrative of illness, themes are identified and clustered into groups. Common themes include (i) loss, (ii) emotional response, (iii) meaning, and (iv) coping. Loss is myriad in its presentations during the course of illness,

Table 74.1   *A biopsychosocial and spiritual orientation to common issues that may arise in counseling during palliative care*

Biologic	Psychological	Social	Spiritual
Specific somatic symptoms, e.g. pain, fatigue, insomnia	Emotional responses, e.g. sadness, anger, fear	Instrumental care, e.g. nursing, pharmacy	Meaning of illness, e.g. aging, dying, punishment
Reduced physical function, e.g. frailty, impairment, disability	Adaptation, e.g. courage, acceptance, rejection	Occupational and physical therapies, e.g. respite, aides	Dignity of person, e.g. respect, valuing accomplishments
Altered bodily appearance, e.g. disfigurement	Sense of self, e.g. self-esteem, shame, stigma	Relational, e.g. marital, family, sexual, intimacy	Freedom and control, e.g. choice, mastery
Treatment processes, e.g. radiation, chemotherapy	Decision making, e.g. quality of life and treatment adherence	Financial and supportive e.g. burden, withdrawal	Rituals, e.g. prayer, connection with the sacred

and unless normalized as universal yet forever challenging, grief may not be well supported. When loss corresponds with expectations consonant with the life cycle, acceptance results readily; when illness is out of step with this natural order, distress, resentment, and profound grief develop easily. Identifying relevant emotions and any meaning attributed to illness is pertinent. Concepts of the inevitability of change or transitions associated with aging prove helpful, whereas adaptation as a response invokes some form of coping to optimize outcome and sustain quality of life.

The biopsychosocial and existential/spiritual model is one framework for organizing common issues that present for counseling during palliative care. Its value lies in its integration of the somatic with psychologic, social, and spiritual concerns. Table 74.1 illustrates typical issues without seeking to be exhaustive in its coverage of potential themes.

WHAT DIAGNOSES POTENTIALLY UNDERPIN THESE CONCERNS?

Sometimes therapists offer counseling about specific issues or focused requests like 'What do I say to my children?'. In these circumstances, direct exploration of options and role play will assist readily. Generally, however, the process of making a clinical diagnosis is pivotal to considering all of the therapeutic options available to ease distress and promote healing. The beauty of diagnosis is that it should trigger a comprehensive treatment plan, one based on experience, clinical wisdom, indeed, evidence of effectiveness. In this sense, no counseling should occur in palliative care without a competent, thorough clinical assessment leading to a thoughtful management plan. The clinician is thus always the professional.

Moreover, just as each physical symptom should lead to an assessment, examination, differential diagnosis and continued reevaluation of response to treatment, so too should each emotional theme generate its differential and continued exploration. Thus:

- Is the sadness an expression of grief or depression?
- Is the fear grounded in reality or excessive because of coping style?

- Does a pattern of low self esteem increase embarrassment or sense of stigma?
- Does the loss of meaning constitute demoralization or depression?
- Is concern about being a burden driven by altruism, independence or shame at loss of control?

Before considering what the applicable model of intervention is, these golden rules are vital: always take a careful history, examine the mental state, understand what has predisposed to, precipitated or perpetuated such distress, and formulate why this person is ill in this manner and at this time.

Box 74.1 overviews the common clinical diagnoses that are suitable for counseling. In terms of psychiatric nosological systems, these fall into grief reactions, situational or adjustment disorders, anxiety and depression, existential concerns, relational and V-code categories. Other common diagnoses such as delirium, dementia, psychoses, and a range

---

Box 74.1 Common psychiatric diagnoses that lead to counseling therapies

- Adjustment disorder, e.g. coping with intense grief, social withdrawal

- Anxiety disorder, e.g. panic attacks, nightmares, insomnia

- Depressive disorder, e.g. anhedonia, suicidality

- Demoralization disorder, e.g. loss of meaning, loss of hope

- Relational disorder, e.g. marital and family dysfunction, personality disorders, sexual dysfunction

- Existential disorder, e.g. spiritual despair, concern about being a burden, need to be in control, profound aloneness

- Organic psychiatric disorder, e.g. delirium, medication side effects, alcohol and substance abuse

of other organic states are not suitable for psychotherapy primarily, pharmacotherapy being the mainstay of treatment. For a number of conditions including anxiety and depressive disorders, combinations of psychotropic and psychotherapeutic treatment are indicated.[15]

INDICATIONS FOR COUNSELING

Distress, formal psychiatric disorder, concern about coping, and lack of sufficient social supports are the common indications for counseling.[16] Sometimes it can be as simple as unmet information needs but, in general, we try to distinguish those who can be supported by all members of the multidisciplinary care team from those who warrant referral for specialist counseling. The latter involves particularly clinicians trained in social work, psychology, or psychiatry. Risk factors for poorer coping include:

- *Factors in the person*: past history of depression or psychiatric disorder; cumulative life events; high levels of perceived stress or poor coping.
- *Factors in the illness*: onset at a young age; delay in diagnosis; recent diagnosis with rapid disease progression; long, intensive treatments or complications of treatment; specific cancers – pancreatic, neuroendocrine, lymphomas.
- *Factors in the environment*: poor social supports; family dysfunction; socio-economic deprivation; potential to leave young children behind.

Whenever one or more of these factors are present, consideration of the benefits of supportive counseling proves worthwhile.[17] Once an established psychiatric disorder exists, referral should be axiomatic.

Because of the large research literature showing that psychiatric disorders are often missed (for instance see references 18*, 19*, and 20*), usually through normalization of distress as what is expected, many services utilize a model of screening to assist recognition of those in greater need of psychosocial care.[21,22*] A randomized controlled trial of computer-assisted screening and referral for intervention has demonstrated an ability to reduce depressive disorders in oncology patients.[23**] Many services today use a triage mechanism to refer patients with milder levels of distress to social workers, and those with more severe distress to psychologists or psychiatrists.

MODELS OF COUNSELING

A number of schools of psychotherapy exist, many developed originally for specific clinical circumstances, but generally these are applied eclectically by counselors so that aspects of these different models are combined to suit the clinical predicament of the patient or family. Table 74.2

Table 74.2 *Models of psychotherapy*

Targets of therapy	Categories of therapy
Individual	Psychoeducational Supportive-expressive Grief therapy
Couple	Existential psychotherapy Cognitive–behavioral therapy
Group	Interpersonal psychotherapy Psychodynamic therapies
Family	Narrative and dignity therapies Spiritual and meaning-centered therapies
Community	Systemic therapies

summarizes the common models of psychotherapy. The following case example will illustrate how each psychotherapeutic model can be used.

Soon after moving back to his hometown with Sue, his girlfriend of 9 years, George, a 29-year-old man was diagnosed with stage IV renal cell carcinoma, involving extensive retroperitoneal and paraaortic lymphadenopathy. They had both just completed their education, and hoped to marry and start a family, while beginning their careers and living closer to their families. Sadly, George's cancer was found to have metastasized quickly to his lungs, bones, and liver. As the cancer progressed, George required regular subcutaneous injections of hydromorphone (Dilaudid) for pain control. He began to feel more helpless and worried that he was placing too large a burden on Sue, who was giving him the injections around the clock, with help from a visiting nurse service. George's underlying fear was that Sue would grow weary of this, her view of him would shift from partner to patient, and that they would drift apart as his health deteriorated.

Psychoeducational interventions

Whether delivered individually, to groups or families, the provision of information about the illness and its treatment is foundational, and a counseling component of all clinical encounters. In their meta-analysis of 116 studies, Devine and Westlake[24***] proved that psychoeducational models have a large effect size, which should not surprising, as the outcome measure in such studies is simply the acquisition of new knowledge. Studies of unmet needs have nevertheless identified information provision as a major concern of patients with cancer,[25*] highlighting its importance at all stages of illness.

In George's case, nursing education covered pain and other symptom management, the nature of his cancer and its treatment, the anticipated process of dying, and how Sue could optimize her role and coordinate care with other members of George's family.

Supportive psychotherapy

Supporting a patient and family through cancer is best done by listening to the story of illness and its treatment, exploring the meaning of the diagnosis and prognosis, allowing the therapist to convey a level of understanding, and thereby developing a trusting relationship with them.[26] The counselor employs typically a range of therapeutic techniques including questions that seek clarification and invite sharing of emotions, comments that affirm, reassure, encourage or explain and suggestions that guide, promote acceptance and optimize support. This approach is the most generic form of counseling and its techniques are found in all other models of psychotherapy. Although cited in group work, the following goals are also pursued in individual supportive therapy: building bonds, expressing emotions about the illness and its impact on relationships, detoxifying death and dying, redefining life priorities, mobilizing supports, and improving coping and communication.[27**,28**,29**] Evidence for its effectiveness in advanced cancer is strongest for supportive-expressive group therapy (SEGT)[30] where randomized controlled trials have demonstrated its ability to reduce emotional distress, anxiety, and depression.[31**]

The unfairness of George's illness occurring out of step with his expected life cycle was acknowledged, their grief at the many losses normalized, their courage affirmed, and their commitment to each other understood. Helping George and Sue to share their feelings and consider how best to support one another led to affirmation of their greater sense of closeness that this tragedy brought. Accompaniment and commitment were key principles in sustaining continuity of care for them.

Grief therapy

Loss is found universally in illness and is experienced through disease, disfigurement, disability, dependency, depression, and death.[32] Although a variant on supportive psychotherapy, the model of counseling developed for the bereaved[33,34] serves well also as a response to the cumulative experience of loss during any journey with advanced disease. Grief is the interest owed on the debt of investment.[35] The tasks involved

include promoting the sharing of emotion, normalizing the sadness, educating about the pattern of distress (waves of emotionality) and time course of mourning, interpreting any displacement of anger and encouraging adaptive coping responses. Such counseling techniques should be applied by all clinicians working in palliative medicine.

Counseling the bereaved becomes an important dimension of comprehensive palliative care, those at high risk being identified through recognition of (i) personal vulnerability, such as past history of psychiatric disorder, (ii) relational problems like dependence or ambivalence, (iii) a death experienced as in some way shocking, unexpected or traumatic, and (iv) the presence of family dysfunction or perception of being unsupported or disenfranchised. Group work is especially helpful for the isolated.[36]

Existential psychotherapy

Bred from existentialism, 'the study of the experience of living life to its fullest',[37] concepts of self awareness, freedom and responsibility in making choices in one's life, ultimate aloneness and our human need for relatedness, the meaning of life and the inevitable reality of death[38] are explored and confronted in the dying population. The common sources of existential distress are summarized in Table 74.3 with suitable models of counseling for specific challenges.[39] The counselor helps to define the particular existential challenge that each patient perceives and invites consideration of realistic ways of responding. Built upon processes of confrontation, reaction formation, and inviting choice about those aspects of life that should be most valued, patients are helped to live authentic and purposeful lives with a particular focus on living in the present moment. Many recent end-of-life models of therapy have developed from existential psychotherapy.[40]

In George's case, questions were asked about the meaning of their relationship, what they valued in life and each other, what priorities they had in living life out fully and what benefits Sue found in caring for George. Open acknowledgement of the potential for death helped identify the preciousness of each moment. Grief was checked to the extent that it risked spoiling continued living; the random nature of George's illness was contrasted with their spiritual wonder about life's mysteries.

Cognitive–behavioral therapy

Cognitive–behavioral therapy (CBT) involves teaching the patient to make connections between emotional events or triggers, associated automatic thoughts or beliefs, and resultant feelings or behaviors. This model, well known in

Table 74.3 *Adaptive and maladaptive responses to existential challenges and relevant counseling*

Nature of existential challenge	Features of successful adaptation	Form of existential distress when problematic	Common symptoms experienced	Related psychiatric disorders	Suitable model of therapy
Death	Courageous awareness of and acceptance of dying; saying goodbye	Death anxiety	Fear of the process of dying or the state of being dead; panic at somatic symptoms; distress at uncertainty	Anxiety disorders, panic disorder, agoraphobia, generalized anxiety disorder, acute stress disorder, adjustment disorder with anxious mood	Psychoeducational, cognitive–behavioral therapy, existential psychotherapy, psychodynamic therapy
Loss	Sad at reality of loss yet resigned to the occurrence of illness	Complicated grief	Intense tearfulness, grief and waves of emotionality, progressing into symptoms of depression	Depressive disorders	Supportive psychotherapy, grief therapy, interpersonal psychotherapy
Aloneness	Accompanied and supported by family and friends	Profound loneliness	Isolated, alienated and sense of complete aloneness in life	Dysfunctional family, absence of social support, relationship problems	Interpersonal psychotherapy, family focused therapy, supportive group therapy
Freedom	Acceptance of frailty and reduced independence	Loss of control	Angst at loss of control; obsessional mastery; indecisive, nonadherence to treatments; fear of dependency	Phobic disorders, obsessive-compulsive disorders, substance abuse disorders	Supportive psychotherapy, interpersonal psychotherapy, psychodynamic therapy
Meaning	Sense of fulfillment	Demoralization	Pointlessness, hopelessness, futility, loss of role, desire to die	Demoralization syndrome, depressive disorders	Interpersonal psychotherapy, narrative and dignity-conserving therapies, meaning-centered therapies, existential therapy
Dignity	Sense of worth despite disfigurement or handicap	Worthlessness	Shame, horror, body image concerns, fear of being a burden	Adjustment disorders	Narrative and dignity conserving therapies, supportive psychotherapy, grief therapy
Mystery	Reverence for the unknowable and sacred	Spiritual doubt and despair	Guilt, loss of faith, loss of connection with the transcendent	Adjustment, anxiety and depressive disorders	Meaning-centered therapy, life narrative therapies

the general psychiatry literature for successfully treating anxiety and depressive disorders,[41***,42***,43***] has been further developed specifically for cancer patients.[44,45,46**,47**] Homework is assigned between sessions, allowing the patient to practice identifying thought patterns that accompany distressing experiences associated with their illness. This is reviewed in the session, where cognitive reframing and disputing of negative automatic thoughts is taught, placing a more realistic framework in place. In working with advanced cancer patients, their concerns should not be simply dismissed, shifting to an unrealistic positive stance. Rather, validating their experience remains paramount, while helping them to understand that their pattern, for example that of catastrophizing or overgeneralizing, likely contributes to further psychological distress. In the palliative population, existential themes may be understood through cognitive

therapy.[48] Such themes as guilt about prior lifestyle choices, feelings of burden, anxiety about disfigurement, perceived rejection by friends and fear of the dying process are explored and examined.

A focus on problem solving, active coping, including assertiveness training and anger management may also be employed. Additional behavioral interventions include relaxation training through progressive muscular relaxation, guided imagery,[49**,50**] massage,[51**] hypnosis or meditation,[52*] together with activity scheduling, exposure and systematic desensitization as commonly used in the general psychiatry to treat depression and anxiety.

Mind reading and negative predictions were identified as the cognitive distortions being used and alternative explanations were suggested to George. As well, he was urged to clarify this with Sue, who was devastated to learn that he was feeling this way. She explained that providing him with pain relief was a privilege, and that it made her feel helpful. Sue acknowledged that she was tired, but suggested that she was no more tired than he was, and that they were in this together for the long haul. She felt, more than ever before in their relationship, that they were very much partners in this, and reassured him that this was only going to continue to bring them closer together.

Interpersonal psychotherapy

Interpersonal psychotherapy (IPT) focuses pragmatically on one or two of four key domains common to most counseling: grief, role transitions, interpersonal disputes, and interpersonal sensitivity or deficits.[53,54] Therapists help facilitate the mourning process relating to the various losses experienced by patients and families during the cancer illness. This may also occur in the context of role transitions as individuals are aided in coming to terms with the loss of their old roles, while learning to accept the new, generally a movement from health to sickness. Negative attitudes about the new role are disputed and reframed, while self-esteem and mastery over the transition are emphasized.

In examining disputes, expectations in relationships as well as patterns of communication are explored, while parallels to other relationships are made, where appropriate. Often conjoint sessions are needed. Prior to this, role playing or modeling may occur. Interpersonal sensitivity and deficits are generally more entrenched in the personality of the individual, and therefore may not be as workable as other areas in the advanced cancer population. In the general psychiatry population, exploration into social development, specifically issues of trust, occurs and treatment efforts focus on building a therapeutic alliance and minimizing isolation.

George had always been an athlete, playing competitive racket sports, including badminton and tennis, as well as soccer. Determined to continue his active lifestyle for as long as possible into the illness, he did just that. He also began coaching at a local middle school. However, both the pain and fatigue began to interfere with his ability to be active, and he had to stop. A large part of his identity was being an athlete. Now unable to continue an active lifestyle, George felt frustrated and described losing a large part of himself. He felt 'weak', lacked purpose, and became agitated by the lack of distraction these activities provided. The therapist helped clarify the positive and negative aspects of both the old and the new roles, while validating his feelings about the transition. George was able to attend training as an assistant coach, giving more verbal direction than physical. His contribution was affirmed and he was urged to also develop new interests and hobbies, ones that involved less physical activity. George chose to continue coaching from the sidelines, and received great support from others in continuing in the face of advanced disease. The players asked him one day why George was not playing with them anymore, which led to a meaningful discussion about cancer and its limitations, while modeling great courage. He came to enjoy his free time, no longer feeling agitated by it, but blessed that it gave him more time with friends and family. Although he would gladly have turned in his diagnosis for a return to health, George grew to accept that he had purpose in this new role, resulting in feelings of peace and acceptance.

Psychodynamic psychotherapy

Principles from psychodynamic and psychoanalytic psychotherapy are commonly used indirectly in working with advanced cancer patients.[55] Patterns of prior coping and relationship difficulties may play out in the threat of loss, and recognition of such patterns in earlier life may increase understanding and aid resolution of conflicts. Straker recommends identifying and exploring defenses, examining core conflicts, and working with transference and countertransference issues in the cancer population.[56] Defenses such as denial and regression may, in fact, be adaptive and promote functioning. They may serve to alleviate distress such as depression, anxiety or helplessness, assuming they do not result in disruption of appropriate medical treatment or fulfillment of goals, including the organization of one's final affairs. Projected feelings of helplessness may develop in therapists treating patients facing the terminal phase of illness. Making sense of these as a countertransference response increases understanding of what the

patient is experiencing, guiding what the focus of therapeutic work might therefore be.

> In reminiscing about his childhood, George recalled how often his mother complained about the extra washing his sporting clothes caused, and how when the washing was not done, he had to miss his beloved events. He felt abandoned by his mother at such times, but retreated from any argument as her verbal lashings were fierce. When George asked the therapist if the sessions were too upsetting for her, she drew a comparison between his fears of being a burden to the therapist and to Sue, akin to how he felt a burden to his mother in childhood. It dawned on George that his fear of Sue retreating from his care was based on his old pattern of relating and not something coming from Sue.

Life narrative and dignity-conserving therapies

The narrative account of the person's life aims to generate an understanding of the patient's reaction to and meaning attributed to their illness from the perspective of their overall philosophy and approach to life.[57–59] Links are made between prior coping during early life experiences and current responses to their cancer experience. The therapist summarizes his or her understanding of the coherent developmental story to promote a sense of accomplishment, fostering celebration and sense of fulfillment while highlighting roles, relationships and any apparent purpose of the patients' life. A shared consensus is sought about all that has been accomplished.[60]

Chochinov has developed a model of dignity-conserving care for patients approaching death (see also Chapter 13 in this book).[61,62] Efforts to improve their self-worth and promote respect are at its core. Each person's illness-related concerns, independence, spiritual, and psychological concerns and how these impact on their sense of dignity are explored. A key goal is to promote hope, autonomy and sense of control, while also addressing spiritual concerns. Dignity-conserving psychotherapy invites the patient to give a narrative account on tape of important aspects of their life that they would most want remembered. This is transcribed, edited and given to the patient, as well as being a legacy for their family. Topics that prompt this life review in the dignity-conserving model include: the individual's life story; how they want their families to remember them; vital roles they have played within their family, job and community; accomplishments they are most proud of; hopes and dreams for relatives and friends; words of advice to pass along to others; things they want to say to family that have not been said before, or that they want to say again; words that might provide comfort to their family and friends.

Meaning-centered psychotherapy

Spiritual suffering arises from doubt about earlier beliefs and religious practices and whether there is any greater meaning to life and death. For the religious, loss of connectedness with the transcendent is problematic; for the atheist, the absence of meaning in the chaos of 'life-considered-random' can render existence pointless. Breitbart and colleagues have developed meaning-centered psychotherapy as a model that promotes a sense of meaning and purpose,[63–65] (and also Gibson CA, Breitbart W. Individual meaning-centered psychotherapy treatment manual. Unpublished document. New York: Memorial Sloan-Kettering Cancer Center, 2004), adopting many principles from Viktor Frankl's 'logotherapy'.[66] Patients are active members in their own treatment, sharing experiences that have helped promote a sense of meaning, peace, and purpose. Exercises are assigned as homework and reviewed at subsequent meetings. The model is being tested in individual and group formats. Sense of personal responsibility, attitudes, creative and experiential values, and the meaning they bring to life are explored.[67]

> George identified the joy that Sue had brought into his life as giving him a special sense of purpose through their relationship together. He lamented nonetheless that they wouldn't reproduce now and that he would not leave a child behind. He told Sue that he wanted her to find someone else after his death and that she should have children early on in this next relationship. Sue told George that she would take some of his gentleness into any future parenting she did, so that he would live on through his influence on her.

Systemic therapies

Whether focused on the marital, parental, or sibling systems, the family-of-origin or current nuclear family, the mutual and reciprocal influence of one party upon another can be an important consideration therapeutically. Furthermore, insight into recurring patterns across generations helps families to vary these 'scripts' and choose a new direction in their relationships. While family therapy is the classical example of a systemic therapy, the concept can also be applied in individual counseling. Family Focused Grief Therapy (FFGT) is one preventive model that targets at risk families during palliative care and continues with the bereaved post death, aiming to optimize family functioning so that complicated grief is reduced.[68] Families with poor communication, reduced cohesion and a muted style of dealing with anger, the so-called sullen families, respond best to FFGT.[69*,70**] Care needs to be

exercised with the most dysfunctional or hostile families to respect any salutary solution to family conflict through separations and distance, so that conflict is not rekindled by family meetings. Thus modest goals are set with these very dysfunctional families; FFGT has much to offer families at risk in palliative care, its brief and focused approach delivering cost effectiveness alongside continuity of care into bereavement.

> George and Sue were brought together with their parents and siblings, the broader family rallying to support the young couple. Open communication about the cancer and its treatment ensured their grief was shared, hope fostered, and respite was organized to protect Sue from exhaustion. As teamwork grew, each family's sense of celebration of George's life became apparent, and support was sustained for Sue throughout the subsequent period of bereavement.

THERAPIST AND PROCESS ISSUES

Professionals working with palliative care patients and their families generally include medical practitioners, nurses or nurse practitioners, social workers, psychologists, psychiatrists, pastoral care workers and other integrative medicine or allied health clinicians. Trained volunteers and healthcare aides also play a supportive role. All disciplines should have broad knowledge about palliative medicine, specifically in the understanding of the diagnosis, treatments, and prognosis, as well as a general ability to support dying patients and their families compassionately. The whole of the multidisciplinary treatment team makes a contribution to psychosocial care.

When it comes to developing skill and expertise in the specific models of counseling described in this chapter, formal training is needed. Research confirms that patients respond better to brief interventions provided by well-trained and skilled therapists compared to longer courses of treatment given by less psychologically trained staff.[11***]

The core elements of any counseling comprise the relationship that is established, the explanatory model of intervention used, the procedure for promoting change and the healing that in turn induces further benefit. A number of therapeutic factors are common to all models of intervention. For instance, developing a strong working relationship, often termed a therapeutic alliance, with the patient and their caregivers is foundational. Other key factors include engaging in active listening, allowing patients to ventilate their feelings about their experience, validating their concerns, providing support, and building trust and respect.[71] Exploration of prior losses, especially deaths in the family, and how members coped with their related grief is illuminating.

Irrespective of the model of intervention, some degree of emotional and cognitive learning occurs as each patient is invited to take responsibility for change and well-being. Jerome Frank[72,73] emphasized the restoration of hope and sense of mastery over whatever one can accomplish as being at the heart of all therapeutic improvement. As gains are achieved, consolidation grows from renewed confidence, while response prevention strategies are generally worthwhile. For much of this work, a delicate balance is needed between promoting hope and supporting grief, these two themes often evolving in parallel. Availability, particularly at a time when patients are being told that life-prolonging treatment is no longer an option, can decrease any sense of abandonment. As well, psychological intervention may help patients to adhere to supportive care measures in a way that will improve the quality of life remaining.

Winnicott's model of a facilitating environment is helpful, in which the counselor provides a secure relationship, whose structure creates an experience in which 'holding' and 'containment' of distress are achieved.[74,75] In palliative care, the boundaries under which this structure would be established ordinarily are modified, so that appropriate and compassionate touch is permitted, access and responsiveness are the norm, and the therapist's warmth, empathy and unconditional regard help create the holding frame. Nevertheless, an emphasis still exists on appropriate restriction of therapist self disclosure, here and now feelings being sensitively shared while greater caution is exercised over one's personal life. Disclosure of a gay orientation may be helpful to homosexual patients, but disclosure of personal cancer or illness experiences is generally unwise, the focus of the therapy being truly directed toward the patient.

In the setting of medical illness, most counseling needs to be brief and focused for pragmatic reasons. Given this, the skill and experience of the therapist is especially pertinent, with clinical judgments determining what is worthy of constructive focus and what is wisely left as a long-term or irremediable pattern of behavior. Personality disorders would not be addressed at the individual therapy level and entrenched family conflict might be respected as ultimately a difference of opinion best resolved by accepting distance between relatives. Selection of a model of therapy is usually eclectic and based on clinical experience, combining elements from several models in response to the prevailing symptoms or predicaments that the patient presents.

Flexibility in number, frequency and duration of sessions, location of appointments, and modality of treatment used is a necessary part of working with the palliative care population. Telephone support may substitute for direct patient care. Physical symptoms, side effects of treatments and stage of illness all significantly impact on delivery of services and a change in medical status may necessitate a shift in therapeutic focus. An open flexible approach is best maintained throughout the course of treatment. The potential for psychopharmacological treatment is

always considered alongside any counseling and its need monitored.

EFFECTIVENESS OF COUNSELING AND LIMITATIONS

Strong evidence exists from meta-analyses about the effectiveness of psychological interventions for the treatment of anxiety and depression in the medically ill such as those with cancer.[11***,24***,76***] When selectivity is exercised over studies with greater methodological rigor, effect size for anxiety reduction was 0.42 standard deviations (95 percent confidence interval [CI]) 0.08 to 0.74, total sample size 1023 patients) and for depression was 0.36 (95 percent CI 0.06 to 0.66, sample size 1101 patients).[24***] These findings are more robust for anxiety than depression, where treatment with antidepressants is also indicated.

Group therapy is at least as effective as individual counseling. Length of treatment is important, with more than 8 hours of counseling generating an effect size of 1.01 for anxiety compared with 0.41 when only 4–7 hours is given ($P = 0.002$).[24***] Similarly, length of therapy improves outcome in treating depression. More experienced therapists increase the effect size for both anxiety ($d = 0.57$ versus 0.10, $P = 0.054$) and depression ($d = 0.43$ versus -0.18, $P = 0.038$) compared with less experienced counselors.[24***] These findings challenge palliative care services to hire appropriately skilled counselors.

The latter concept may have relevance when one seeks to understand the findings from systematic analyses that palliative care service interventions do not significantly improve the outcome for caregivers of the dying patient.[77***,78***] Community programs the world over have saved costs through engaging unskilled counselors. Another explanation for the apparent absence of proved impact on carers is the absence of targeting 'at risk' carers with preventive interventions. Unless services employ screening to identify high risk individuals and families, many delightful folk, who will otherwise cope admirably, receive expensive therapies and hide the benefit in studies available to those with more limited coping.

Finally, a caveat is needed about the risks of counseling. Just as pharmacotherapy can induce side effects, sometimes with deleterious consequences, so also can counseling cause harm. Research suggests that about 10 percent of counseling interventions generate untoward effects, such as worsening anxiety, depression, or marital and family conflict. This limitation calls for skill and experience being derived from formal training in the models of intervention and in one of the basic psychosocial disciplines, so that therapists can identify any deterioration and introduce corrective strategies. When counseling is delivered by trained and experienced professionals, it has much to offer in ameliorating distress and suffering.

Key learning points

- High rates of distress exist among patients, caregivers and family members during palliative care.

- Counseling interventions have proved efficacy in relieving distress, anxiety, and depression.

- The training and experience of the therapist strongly influences the effectiveness of interventions.

- Outcome is progressively improved by longer interventions.

- Group interventions are at least as efficacious as individual therapies; family group counseling may be more cost effective when applicable.

- Whereas psychoeducational, supportive and grief therapies are the mainstay of psychotherapeutic approaches, interpersonal, narrative and meaning-centered models offer promise in ameliorating existential distress.

Hope in end-of-life care

CHERYL L NEKOLAICHUK

October 29, 2004

the biggest pain to go through in the end . . .
is the gradual drop-away of visitors.
I hope my friends keep their promises.
Promises about sitting with me
and being with me when that time comes . . .

(A patient receiving palliative care. From Nekolaichuk CL.
Understanding the experience of hope in palliative care.
Manuscript in preparation)

INTRODUCTION

The progressive nature of a terminal illness challenges patients to search for the elusive experience of hope. The unpredictable nature of the illness course, marked by debilitating symptoms, body image distortions and multiple losses, propels the terminally ill and their families onto a pathway of uncertainty, fear and, for some, despair. Traditional roles may be reversed or erased, as patients struggle to maintain connections from marginalized positions in society. External messages of 'There is no cure' become internal messages of 'There is no hope', as patients wrestle with their own mortality. In a recent study involving advanced cancer patients, 47.8 percent of participants reported at least some sense of hopelessness,[1] which is not surprising given the adversities many patients face.

Despite these enormous challenges, people who are terminally ill strive to include hope within their caring circles. In interviews with 120 terminally ill cancer patients, 99 percent of respondents rated *having a sense of hope* as a very important existential concern.[2] Based on a review of research studies, Lin and Bauer-Wu[3] identified *living with meaning and hope* as one of six essential themes of psychosocial spiritual

wellbeing in patients with advanced cancer. In a recent qualitative study focusing on information needs, patients with advanced cancer identified the *provision of hope and need for hopeful messages* as one of two most important concerns regarding information content.[4]

Healthcare professionals have equally emphasized the importance of hope in the delivery of palliative care. Numerous position papers and literature reviews highlight the need for intentionally incorporating hope within end-of-life care.[5–12] Janssens and colleagues[13] have further embedded the concept within a philosophy of care framework for palliative care. This framework consists of three realms – medical, psychosocial, and spiritual – with hope as a central existential phenomenon within the spiritual realm.

Although these endorsements are substantive, an intentional integration of hope within end-of-life care remains relatively underdeveloped. To begin to address this issue, we need to consider the following questions:

- What is the nature of hope in palliative care?
- How can we enhance our approaches for assessing hope in people who are terminally ill?
- What types of hope-enhancing strategies and interventions would be most appropriate for this unique population?

Beginning with an overview of the therapeutic value of hope, this chapter will address these three key questions for end-of-life care.

THERAPEUTIC VALUE OF HOPE IN ILLNESS

The therapeutic value of hope in dealing with chronic and life-threatening illnesses is well documented. Hope has been positively linked to effective coping,[14,15] enhanced

quality of life,[16,17] spiritual wellbeing,[18] and healing.[19–21] In contrast, hopelessness may be associated with low levels of perceived emotional support,[22,23] depression,[23,24] suicidal intent,[25] desire for hastened death,[26] and pain.[27] Similar to studies in psychiatric populations,[26] recent studies in terminally ill patients identified hopelessness as a strong predictor of suicidal intent.[28,29]

Although these findings are significant, some caution is warranted in making cross-study comparisons. Study samples were quite diverse, including patients with human immunodeficiency virus (HIV)/acquired immune deficiency syndrome (AIDS)[18,22,23,27] and cancer,[14,16,28,29] depressed patients,[20,21,24,25] patients with long-term disabilites,[15,19] and older patients,[17] and were not entirely limited to the terminal illness phase. The use of different measures to assess hope or hopelessness across studies further limits meaningful comparisons. Future research studies, focusing on relationships between hope, symptom expression, and positive health indicators, such as quality of life, wellbeing and coping, need to specifically target the terminally ill, using consistent measurement approaches appropriate for this population.

Nature of hope in palliative care

> What does hope mean to you as a healthcare provider?
> What does hope mean to the patients for whom you provide care?

Traditionally, within healthcare communities, the concept of hope has been closely linked with treatments and cures.[30,31] When hope for a cure is no longer viable, healthcare professionals and patients may give up hope. Although the situation may be hopeless, there is always hope for the individual.[32] A key challenge is to understand the nature of hope in palliative care. To do so, it is important to begin by understanding the concept of hope in general.

A diversity of definitions and conceptual frameworks for hope exist in the literature. Currently, there is no universal definition for hope. In a recent critique of the hope literature, Nekolaichuk[33] identified seven themes associated with differing perspectives about hope (see Fig. 75.1). Based on these seven themes, the following assumptions about hope were generated:

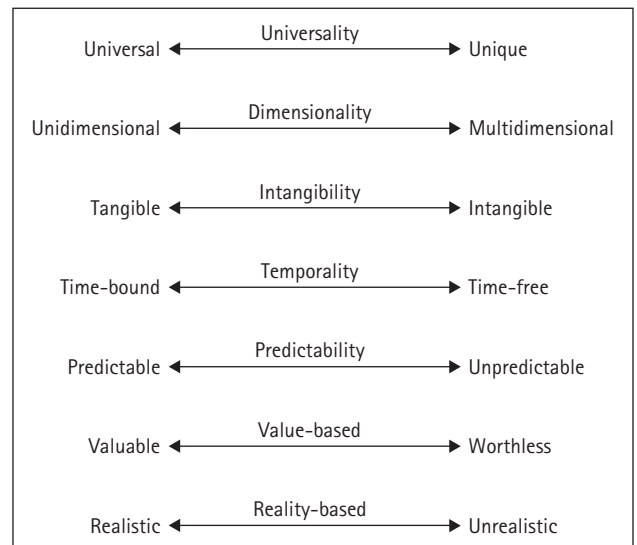
- *Universality*: Hope is both a universal and an intensely personal experience.
- *Dimensionality*: Hope is a complex concept, ranging from unidimensional to multidimensional aspects of a person's experience.
- *Intangibility*: Hope has both tangible and intangible components, some of which may never be elucidated.
- *Temporality*: Hope appears to imply some sense of temporality, although this may not necessarily be limited to a future orientation. It is also possible that some components of hope may not be bound by time.


Figure 75.1 *Thematic analysis of the concept of hope.*

- *Predictability*: Hope may have both predictable and unpredictable components to the experience.
- *Value-based*: The value of hope appears to be embedded in personal experience.
- *Reality-based*: Hope appears to be connected with some sense of realism, although the viewpoints of reality remain unclear.

These seven themes provide a helpful framework for understanding the nature of hope in palliative care.

Universality

Although hope is a universal human experience, it is also intensely unique. Thus, it is important to understand the experience from the patient's perspective. A number of qualitative studies, focusing on the terminally ill patient's experience of hope, have been conducted in diverse settings, such as palliative home care,[34,35] inpatients,[36,37] outpatient clinics other than home care,[36,38,39] and nonmedical settings.[32,40–43] The types of sample varied, including people with cancer,[34–37] HIV/AIDS,[32,40–43] and end-stage renal disease.[38] Although most of these studies involved patients directly, one study attempted to understand the experience by interviewing nurses about their perceptions of hope in palliative care patients with cancer.[39]

Dimensionality

A diversity of conceptual frameworks for hope has emerged, ranging from unidimensional to multidimensional models. Of the many diverse frameworks, Dufault and Martocchio's model,[44] qualitatively derived from a sample of older cancer and terminally ill patients, continues to provide a useful initial framework for understanding hope in the terminally ill.

Dufault and Martocchio proposed a multidimensional framework for hope, consisting of six dimensions: cognitive, affective, behavioral, affiliative, contextual, and temporal. Each of these dimensions may be impacted in different ways when a person is facing a terminal illness.

Intangibility

The experience of hope may have both tangible and intangible components. Dufault and Martocchio[44] described these two types of hope as particularized and generalized hopes. Particularized hopes are hopes that are directed towards specific goals. For the terminally ill, particularized hopes may vary as the disease progresses. Patients often describe how their hopes may change over time,[5,45] for example, from a hope for a cure, to a hope for symptom relief, to a hope for special time with family, to a hope for a peaceful death. In contrast, generalized hopes represent an intangible inner experience of hope that is not connected to any specific goal or object. This invisible part of hope, which may be difficult to articulate, is often experienced at a deep, spiritual level.

Temporality

Although most definitions for hope include a future orientation, this may not always be appropriate for the terminally ill.[7] For some people, with strong faith beliefs, hope may be tied to a future beyond this life. For others, however, the experience of hope may be interwoven with past, present and future experiences;[7,44,46,47] may be lived in the present;[16] or may transcend time.[44,48] It is important to have some understanding of how patients view hope in terms of time, potentially deemphasizing the future component.

Predictability

The uncertainty of advancing disease raises fears in most patients who are terminally ill. Although frameworks do differ, some models have included uncertainty as an inherent part of the hope experience.[46,49] Exploring a person's fears, as well as focusing on predictable aspects of a person's life, helps buffer the uncertainties of progressive illness.

Value-based

Few could argue with the potential therapeutic benefits that hope offers to the dying. It is important to acknowledge, however, that not everyone may place a positive value on the experience, particularly if people have been disappointed by hope in the past. For example, this may become an issue when patients place all of their hopes into finding a cure, only to be devastated when they are given the bad news that

their condition is incurable. The challenge is to be able to help patients develop a broad hoping repertoire, including hopes beyond a cure.[7]

Reality-based

Often, people may concurrently hold two opposing hopes, such as a hope for a cure and a hope for a peaceful death.[34] This may be troubling for some caregivers and family members, who might view this as unrealistic or unhealthy denial. In contrast, Jevne and Nekolaichuk[50] describe this phenomenon as a normal way for patients to prioritize their hopes:

> It is important to listen to the descriptive words that they [patients] attach to their hopes, acknowledging the range (and depth) of their hopes. One elderly patient who was forced to stop traveling due to a progression of his disease described his hope to travel as a 'forlorn' hope. Another palliative patient who expressed a hope for peace in the world described that particular hope as a 'big' hope. Yet another patient who hung onto a hope for a cure, despite being told that her cancer was incurable, suggested that it 'may not be a very realistic' hope, but that 'miracles do happen.' For a patient who believed in life after death, her hope to be united with God was her 'ultimate' hope. (p. 195)

ASSESSMENT OF HOPE

> How can you tell how hopeful a person is?
> What do you need to know to understand a person's experience of hope?

Although a variety of approaches have been developed for assessing hope in clinical practice (see Farran et al.[49] for an excellent review), few of these approaches have been developed specifically for palliative care.[7,12] Given the frailty of the terminally ill population, assessments need to be relatively brief, psychometrically sound in terms of quantitative measures, and include combined quantitative and qualitative approaches. They also need to be continuous and closely linked with the development of hope-enhancing strategies and interventions. In some cases, the assessment itself may be a type of intervention.

In terms of quantitative assessments, there are two hope measures that show promise. The Herth Hope Index[51] is a well-validated measure that has been used in the terminally ill, most recently being validated in a Swedish sample of palliative patients.[52] Although psychometric findings were favorable, the authors cautioned against its use in Swedish clinical palliative settings, however, due to linguistic, conceptual, and cultural translation difficulties. The Hope Differential-Short, a relatively new measure for capturing the personal experience of hope, was recently validated in a sample of advanced cancer patients.[53] Although further

Table 75.1   *A hope assessment framework for terminally ill patients*

Theme	Questions for the healthcare professional	Questions for the patient
Personal spirit	What is meaningful in this person's life?	What is meaningful in your life? What would give you meaning in your life?
	What is this person's relationship with time?	How has your hope changed over time?
	How might past, present, and future experiences influence this person's experience of hope?	Tell me about a time in your past that has informed you about your hope in some way.
Risk	What is this person's tolerance for uncertainty?	How have you handled times of uncertainty in the past? What are you most afraid of?
	How can I enhance this person's hope, beyond a hope for a cure?	Without taking away your hope for a cure, what else might keep you going in the event that a cure is not possible?
Authentic caring	Who authentically cares about this person?	Who in your world cares about you?
	How can I provide truthful information to this person without destroying all hope?	Who do you care about?

Adapted from Nekolaichuk and Bruera.[7]

validation studies are warranted, this measure provides an innovative approach for individual patient assessments.

Given the complexity of the hope experience, quantitative measures need to be combined with qualitative assessments. One example of a qualitative assessment is Nekolaichuk and Bruera's hope framework for palliative care.[7] This framework is based on an empirically derived model of hope, consisting of three dimensions: personal spirit, risk, and authentic caring.[54] Personal spirit is a predominant personal dimension, represented by a core theme of meaning. Risk, a situational dimension, is primarily represented by an underlying theme of uncertainty. Authentic caring, a relational dimension, is characterized by the complementary themes of credibility and caring. Thus, a person's experience of hope may be associated with finding meaning in life, taking risks in spite of uncertainty and developing caring, credible relationships. An example of how this framework could be used for hope assessment appears in Table 75.1.

HOPE–ENHANCING STRATEGIES AND INTERVENTIONS

> How do you enhance hope for someone who appears to have given up?
> How do you help repair a patient's hope that others may have inadvertently damaged?

Many people have offered suggestions for hope enhancing strategies and interventions for the terminally ill, based on literature reviews,[55] research studies,[10,45,56–59] theoretical perspectives[60] and clinical experience.[61–63] In a systematic review of nursing literature, Holt[64***] identified 14 hope intervention themes, the six most common being positive relationships, patient self-worth, patient control, goal setting, use of distraction and family support. Many of these

interventions have not been empirically tested, however, particularly in terminally ill patients.

To date, very few intervention studies have focused on hope. Based on a quasi-experimental design, Tollett and Thomas[65*] studied the effect of rational thought on levels of hope in a sample of homeless veterans. Similarly, Rustoen *et al.*[66*] conducted a quasi-experimental study to evaluate the effect of a nursing-based intervention on hope and quality of life in patients with newly diagnosed cancer. Using a quasi-experimental design, Herth[67*] evaluated the effect of a 7-session hope-enhancing nursing intervention program on levels of hope and quality of life in a convenience sample of people with first recurrence of cancer. A follow-up evaluation of this intervention program was also conducted with the treatment group.[68*] Breitbart and Heller[69**] reported on preliminary findings of a meaning-centered psychotherapeutic intervention, suggesting that people in the meaning-centered group had less hopelessness and desire for death, and greater spiritual wellbeing and a sense of meaning, than those in the control group.

Specific hope-enhancing interventions for the terminally ill need to be developed and evaluated. As an example, Jevne and Nekolaichuk[50] developed a hope intervention framework for cancer patients, based on clinical experience, patient interviews and a thematic analysis of the literature. This framework consists of seven hope-enhancing themes: caring, communication, commitment, coping, creating, community, and celebrating. Within each theme, specific strategies for enhancing hope are proposed. An outline of this framework appears in Table 75.2, with sample questions that could be asked of patients (see Jevne and Nekolaichuk[50] for detailed descriptions of additional strategies). Although this framework was developed for cancer patients, many of these strategies could potentially be applied to the terminally ill. Further research is needed to extend its use in this population.

Table 75.2 *The seven Cs: a hope intervention framework*

Theme	Questions for the patient
Caring	Tell me about a time in your life when you experienced a moment of caring.
Communication	Tell me about what it is like to be ill. How has your hope changed since you have become ill?
Commitment	What would be one small thing that you might do on a regular basis to help strengthen your hope?
Coping	What has helped you through difficult times in the past?
Creating	If you were to create a 'hope kit', then what things would you put in it?
Community	How is hope experienced in your community (culture)?
Celebrating	If you were to plan a celebration of hope, then what might you do?

Adapted from Jevne and Nekolaichuk.[50]

SUMMARY

How might we create a space for hope in end-of-life care?

This chapter highlighted three specific challenges for intentionally integrating hope within clinical practice:

- the need to understand the nature of hope in the terminally ill
- the need to develop brief, psychometrically sound and appropriate assessment approaches for a palliative population
- the need to develop and evaluate specific hope-enhancing interventions for the terminally ill.

The lack of well-developed assessment approaches and effective hope-enhancing interventions, targeted specifically for the terminally ill, have impeded progress in this area. Through collaborative efforts involving patients, clinicians, and researchers, appropriate hope assessment frameworks and hope-focused interventions need to be developed and eventually become part of routine end-of-life care.

Key learning points

- Patients, healthcare providers and health researchers have all acknowledged the important role of hope in terminal illness.

- Hope is an inherent part of being human. Although it is a universal human experience, it is also an intensely personal one. It is important to understand what hope means to each person with a terminal illness.

- Hope assessments and interventions are closely intertwined. Assessment is a continuous process and may be a type of intervention. Interventions are closely linked to the types of assessments that are conducted.

- Although many assessment and intervention approaches for hope have been proposed, few have been developed for and validated in the terminally ill.

- Systematic approaches for hope assessment and intervention need to be developed and integrated into routine clinical practice in end-of-life care.

Dehydration and rehydration

ROBIN L FAINSINGER

INTRODUCTION

There are many facets to the often complicated and controversial topic of dehydration and rehydration of palliative care populations. The ongoing divergent opinion is well illustrated by the following recent statements:

> Research is limited but suggests that artificial hydration in imminently dying patients influences neither survival nor symptom control.[1]
>
> The best available evidence suggests that hydration of advanced cancer patients plays an important role in maintaining cognitive function and is therefore an important factor in the prevention and reversal of delirium in this population.[2]

Superimposed on these conflicting medical comments are other complex issues:

> terminal dehydration is a controversial topic, weighted heavily with historic symbolism, and strong religious, societal, and cultural conflicts.[3]

Some of these issues can be illustrated with the following examples.

SCENARIO 1

A 70-year-old woman living in an isolated rural community in southern Africa develops increasing abdominal discomfort. She has been active and in good health, although she has lost approximately 3 kg of weight over the last 2 months. She develops severe nausea and vomiting and inability to maintain an adequate oral intake. The family's access to transportation that would enable them to travel to the nearest hospital 10 km away is limited. Her extended family nurses her at home and after a few days she is able to resume a reasonable oral intake, her strength improves and she resumes her role with household maintenance and care of her grandchildren.

SCENARIO 2

A 70-year-old woman living in a wealthy country with universal healthcare develops increasing abdominal discomfort. She has been active and in good health, although she notes that she has lost approximately 3 kg of weight over the last few months. Extensive diagnostic imaging and subsequent liver biopsy confirm pancreatic cancer with liver metastases. She develops severe nausea and vomiting and presents to the emergency department of her local hospital with clinical evidence of dehydration. She is rehydrated with intravenous fluids and admitted for investigation. No evidence of bowel obstruction is found on diagnostic imaging. The patient improves, resumes a reasonable oral intake and is discharged home.

SCENARIO 1

Over the course of the next few weeks the woman develops increasing abdominal pain, poor appetite and loss of weight, and intermittent nausea and vomiting. She is fortunate that a mobile health clinic has now started to visit her isolated community on a monthly basis. The nurse practitioner doing the examination notes that the patient looks cachectic and has a very enlarged, tender liver. She suspects that the patient is dying from an unknown gastrointestinal primary with extensive intraabdominal metastatic disease. The family and patient are provided with an explanation of the suspected diagnosis and prognosis. The clinic is able to provide a free prescription of morphine liquid, and an explanation of dietary supplements they could use to prevent constipation.

The nurse practitioner is aware of the options for hydration supplementation including intravenous, hypodermoclysis, and rectal hydration. However for a variety of reasons, including economic and the increased burden this would place on the family caregivers, all of these options are rejected. Instead the family is given suggestions to assist the patient to continue to drink as long as this is comfortable for her, as well as some suggestions to provide mouth care. The nurse practitioner wishes the patient and family well and indicates that they should return for a follow-up visit when the mobile clinic is back in their community. The nonverbal communication in the room indicates that all of them understand that the nurse practitioner does not really expect to see them for a follow-up visit.

SCENARIO 2

Over the next few weeks increasing abdominal pain requires escalating morphine doses to achieve good control. The patient expresses a preference to remain at home as she deteriorates. However the patient and her husband indicate to the family physician that their religious beliefs are that everything possible should be done to maintain life for as long as possible. Intermittent nausea and vomiting results in the oral morphine being changed to the subcutaneous route, and increasing abdominal pain requires increasing the morphine to 100 mg subcutaneously per day. The family physician discusses the option of parenteral hydration. Hypodermoclysis at 1 L overnight is instituted. A daughter and son now arrive to assist and support their father in caring for their mother. The son has worked as a hospice nurse and questions the value of ongoing hydration at this point. The daughter is a nephrologist who believes that hydration is necessary to maintain normal renal function, and avoid the accumulation of morphine metabolites that may cause side effects. The patient and her husband have had extensive discussions over the years with their family physician who has a good understanding of how their spirituality affects their decision making. Although respecting their children's opinions, the couple rely heavily on their family physician to provide information and direction on appropriate management.

These scenarios highlight some of the complexity that surrounds this widely debated and controversial topic. At the center of the discussion, irrespective of the setting and circumstances, is the desire to keep patients as comfortable as possible while avoiding unnecessary management or procedures. However there is no doubt that the definition of 'unnecessary' will have great international variation. Clinicians with the responsibility to make these decisions will need to sort through expressions of opinion, information on pathophysiology and biochemical changes, research looking at a variety of outcomes, differing family and cultural expectations, and consensus statements. This diverse information then has to be individually applied to the specific trajectory and circumstances of patients and their families.

WHAT IS DEHYDRATION?

As has been pointed out in recent reviews, use of the term dehydration in considering this issue, is often inaccurate.[2,4] Fluid deficit is the state of water loss with or without electrolytes, that includes the subtypes of volume depletion and dehydration. Dehydration should be understood as total body water deficit that is predominantly intracellular and associated with hypernatremia. Volume depletion implies a deficit in the intravascular fluid volume and can be isotonic, hyponatremic, or hypernatremic (Fig. 76.1).

A variety of factors can be associated with fluid deficits (Table 76.1). Any of these etiologies for fluid deficit can occur at any stage of a palliative care illness and multiple possible mechanisms can occur simultaneously.

The assessment of risk or presence of fluid deficits is based on a variety of factors that can be determined by history, physical examination, and laboratory findings. The history is of obvious value in determining the possible risk factors listed in Table 76.1. There are sometimes practical difficulties in estimating the accuracy of fluid intake estimates and potential fluid loss through urine and fecal incontinence. Symptoms of fluid deficit can include behavior and cognitive changes, fatigue, thirst, nausea, and a dry mouth. The classic signs of fluid deficit include dry mouth, reduced skin turgor, postural hypotension, tachycardia, reduced jugular venous pressure, sunken eyes, and reduced sweating. However all of these problems need to be interpreted with caution as they can be associated with other causes present in aging, cachexia, advanced cancer, and side effects due to commonly used medications.
Figure 76.1   *Types of fluid deficit.*

Table 76.1   *Factors associated with fluid deficits*

Decreased intake	Increased fluid loss
Asthenia	Bowel resection
Anorexia	Diarrhea
Coma	Diuretics
Delirium	Diabetes mellitus/insipidus
Dementia	Fistulas
Depression	Fever/sweating
Dysphagia	Hypercalcemia
Nausea	Vomiting

Laboratory evaluation can provide some helpful information in evaluating fluid deficits, but will obviously depend on the setting of care and whether such investigations are acceptable to the patient, family and healthcare team. The common findings present in volume-depleted patients include elevated levels of urea, creatinine, plasma proteins, hematocrit, and sodium. It is worth noting that a systematic review attempted to clarify the physical diagnosis of hypovolemia in adults.[5***] The authors concluded that in patients with vomiting, diarrhea, or deceased oral intake, few findings, with the exception of serum electrolytes, urea, and creatinine values, have proven value.

THE HYDRATION CONTROVERSY

There is no controversy that palliative care populations should be encouraged to maintain an adequate oral intake to prevent fluid deficit. However there are many literature reports illustrating opposing viewpoints on the use of supplemental parenteral hydration. These have been considered from both clinical and ethical viewpoints.[6–16] Historical reviews on this topic have referenced a similar collection of clinical anecdotes and opinions. The arguments for and against hydrating palliative care populations are summarized in Box 76.1.[11,12]

It would appear that the arguments for initiating or maintaining parenteral hydration in palliative care populations originate from the standard medical approach to fluid deficits. Thus it would be reasonable to expect that most patients dying in hospitals will have an intravenous line unless they have undergone rapid deterioration or unanticipated demise. This was originally demonstrated by a Canadian report[17] where 73 of 106 cancer patients dying in a tertiary care hospital were noted to have intravenous fluids administered. A more recent retrospective study on the use of artificial hydration in an acute care hospital in England[1] noted that of 111 patients, 65 percent were hydrated during the last week of life and 46 percent were being hydrated at the time of death. The mean rate of parenteral hydration was 2000 mL/day. The results suggest that artificial hydration is no longer necessarily considered routine hospital practice for dying patients in this setting.

In order to clarify routine practice of physicians involved in end-of-life care in Edmonton, Canada, the routine management of parenteral hydration for patients dying in a palliative care unit, and acute care hospital while receiving or not receiving consult advice from the palliative care program was reported.[18] A retrospective chart review of 50 consecutive patients dying at each of the three sites was included. The majority of patients at all sites received hydration ranging from 66 percent to 98 percent of patients during the last week of life. However the volume of hydration was noted to be significantly lower in the palliative care unit site.

Box 76.1 Hydration in palliative care

Against parenteral hydration

- Symptom distress is not experienced by comatose patients
- Dying is prolonged by parenteral fluids
- There is less urine and thus less problem with incontinence and catheter use
- Decreased gastrointestinal fluid associated with dehydration results in less nausea and vomiting
- Decreased respiratory secretions will result in less cough and pulmonary edema
- The severity of edema and ascites is decreased
- Dehydration can act as a natural anesthetic for the central nervous system
- Parenteral hydration is uncomfortable and limits patient mobility

For parenteral hydration

- Parenteral hydration assists in making dying patients more comfortable
- There is no evidence that parenteral hydration prolongs life
- Fluid deficits can cause restlessness, confusion, and neuromuscular irritability
- Oral hydration is provided to dying patients complaining of thirst, and therefore parenteral hydration should be an option
- Emphasis on the poor quality of life of palliative care populations detracts from efforts to improve comfort and life quality
- Parenteral hydration is considered a minimum standard of care
- Withholding parenteral fluid from palliative care populations may result in withholding therapies to other compromised patient groups

A survey questionnaire of Japanese physicians attempted to clarify attitudes towards terminal dehydration. Results revealed that physicians with more positive attitudes toward intravenous hydration were less involved in end-of-life care and more likely to regard fluid as a necessary physiological requirement, consider it a minimum standard of care, and believe that this was beneficial for palliating symptoms.[19] A Canadian study distributed a questionnaire to 18 palliative care physicians in major Canadian centers in an attempt to clarify the routine practice of physicians involved

in end-of-life care.[20] Results demonstrated a wide range of practice. Physicians estimated that they ordered parenteral hydration in a median of 6–10 percent of patients (range 0–100 percent). The route of parenteral hydration was: intravenous hydration, a median of 30 percent (range 0–100 percent), and hypodermoclysis, a median of 70 percent (range 0–100 percent). The estimated average volume range per 24 hours was between 200 mL and 2400 mL.

It is easy to imagine the problems inflicted on advanced palliative care populations by a policy of maintaining intravenous hydration with volumes in excess of 3 L/day. Under this circumstance complications such as increased respiratory and gastrointestinal symptom distress can be anticipated. The literature reports against parenteral hydration would suggest that healthcare professionals looking after palliative care populations have reacted to overuse of intravenous fluids and concluded that no parenteral hydration is the preferred approach. This has been reinforced by anecdotal literature reports noting that many palliative care patients appear to die comfortably without parenteral hydration. Nevertheless a review of the literature indicates that these reports are mostly based on unsubstantiated data.[12] There are other issues worth considering:[11,12,21–24]

- Fluid deficit as a cause of confusion and restlessness in nonterminally ill patients is well recognized. The problems of delirium and agitation have been well reported in palliative care populations.[2]
- Reduced intravascular volume and glomerular filtration rate caused by fluid deficits are well accepted as a cause of prerenal failure.[2,4] Opioid metabolite accumulation in the presence of renal failure, resulting in confusion, myoclonus and seizures, has been well documented.

Reports with regard to agitated delirium and terminal restlessness have frequently appeared in the palliative care literature. Discussion of these problems has generally centered on the need for pharmacological management which often includes sedation.[25–27] Ventafridda et al.[28] reported 9 percent of patients requiring sedation for agitated delirium in a study of unendurable symptoms experienced by patients with cancer during their last days of life. This prompted a report by our group[29] that agitated delirium was the most frequent problem requiring sedation in the last week of life in 10 percent of our patients. A later report noted that the severity of agitated delirium requiring sedation had decreased to 3 percent in our palliative care unit.[30] We speculated that this resulted from a change in our practice to include more frequent use of hypodermoclysis for hydration, switching opioids earlier when toxicity developed, and the use of less sedating treatments such as haloperidol for delirium, decreasing the prevalence and difficulty of managing agitated delirium in this setting.[31]

Reports in the palliative care literature have continued to note innovative approaches to the pharmacological management of symptoms associated with agitated delirium, including the use of intravenous propofol.[32–34] A retrospective chart review of 76 consecutive patients dying at St Luke's Hospice in Cape Town, South Africa, found that 29 percent of patients required sedation for agitated delirium. Although none of these patients were treated with parenteral hydration, patients requiring sedation were noted to require significantly higher doses of opioids during a longer admission.[35]

Further reports on the use of sedation have suggested that agitated delirium appears to be less problematic in a number of different settings in Edmonton,[36] where parenteral hydration is more common practice,[18] compared with requirements for sedation in a number of other international settings.[37] As a result it has been suggested that dehydration could be a reversible component of agitated delirium, that may be ignored by an approach that focuses on a sedative pharmacological solution to this apparently common and certainly distressing situation.[38*] Thus it may be illogical for a patient to receive medications for agitated delirium, myoclonus, and seizures, if in some circumstances these problems could be prevented or corrected by the use of parenteral hydration.

HYDRATION RESEARCH

Research into the use of hydration in palliative care settings has focused on three dimensions:[39]

- The association between biochemical findings and hydration status
- The association between biochemical findings and clinical symptoms
- The association between hydration status and clinical symptoms.

Biochemical findings and hydration status

There is no controversy that dehydration is a cause of renal failure.[40–42] However while parenteral hydration is accepted standard management in many settings, the impact of fluid deficit and rehydration on the renal function and electrolyte balance of palliative care populations is still questioned.[10,43–46]

Ellershaw et al.[47] undertook biochemical investigation in 82 patients with advanced cancer. The patients were taking oral sips of fluid and no longer able to tolerate oral medication. Our group[48] reported biochemical investigation of 100 consecutive patients, 69 of whom received hypodermoclysis at an average volume of 1203 ± 505 mL/day. A comparison of these two reports[49] has been published (Table 76.2). Morita et al.[50] published further results on the biochemistry of terminally ill cancer patients, and concluded that relatively small amounts of parenteral hydration may result in less abnormal biochemistry, particularly with regard to renal function.

Table 76.2 *Comparison of biochemical findings in patients taking oral fluids (sips)[47] and those receiving hypodermoclysis[48]*

| | Fainsinger et al.[48] | | Ellershaw et al.[47] | |
	Mean	Normal range	Mean	Normal range
Urea (mmol/L)	8.8	3.2–8.2	15.5	2.5–6.5
Creatinine (μmol/L)	101	62–133	177	60–120

Biochemical findings/hydration status and clinical symptoms

Much of the early literature on this issue was based on anecdotal opposing viewpoints and case reports.[51,52] However many reports have now attempted to study this issue more carefully. Burge[45] reported a cross-sectional survey studying the quantitative assessment of the dehydration experience in patients with advanced cancer. The study concluded that parenteral hydration on the basis of fluid intake and laboratory measures were not helpful if the aim was to reduce thirst. McCann et al.[53] studied 48 consecutive patients with regard to symptom prevalence and management of hunger and thirst in terminally ill patients not receiving parenteral hydration. Symptoms of hunger, thirst, and dry mouth were apparently well managed with oral sips and mouth care.

Ellershaw et al.[47] investigated the relationship between symptoms and dehydration in 82 patients not provided parenteral hydration. No significant association was demonstrated between the level of hydration and respiratory tract secretions, thirst, and dry mouth. However they did acknowledge that the effect of renal failure and possible consequences of agitation and confusion were not assessed. Musgrave et al.[54] studied the effect of intravenous fluids on a group of patients with advanced cancer dying in a hospital oncology unit. No relationship was demonstrated between level of thirst, intravenous fluids, and biochemical parameters. A subsequent study[55] also failed to demonstrate any relation between intravenous fluids, fluid balance, and the prevalence of crepitations, ascites, and leg edema. A retrospective chart review of 117 and 162 patients admitted to a palliative care unit in 1988–89 and 1991–92 assessed the impact of a change in practice with regard to management of dehydration and cognitive impairment.[56*] The authors concluded that the data suggested that routine cognitive assessment, opioid rotation and hydration may reduce the frequency of agitated confusion in terminally ill cancer patients. Although hydration may have had a role, it was not possible to determine the relative contribution. A partial replication of this study considered the role of hydration and an incomplete opioid substitution on the prevalence of agitated delirium.[57] However no significant decrease in the occurrence of agitated delirium was noted.

Ashby et al.[58] measured plasma concentrations of morphine and metabolites in 36 hospice patients. They concluded that morphine metabolites may be a causal aggravating factor in nausea and vomiting and cognitive impairment in palliative care patients with significant renal impairment. Lawlor et al.[59*] completed prospective serial assessments of 113 patients with advanced cancer in a delirium study. Univariate analysis demonstrated reversibility associated with psychoactive medications and dehydration. They concluded that although delirium is multifactorial, hydration using hypodermoclysis may be one of the potential useful measures to consider.

A review by Burge[60***] concluded that there is little clinical evidence to guide patients, families, and clinicians in treatment decisions regarding fluid intake during the terminal phase of life. A subsequent systematic review by Viola et al.[61***] summarized existing evidence regarding fluid status effects and fluid therapy. Six studies where selected for inclusion and the authors concluded that given the study limitations it was impossible to draw firm conclusions regarding clinical care.

SOCIAL AND CULTURAL CONSIDERATIONS

There are other important issues to consider in regard to the use of parenteral hydration.[62] Patient and family attitudes, level of comfort with the situation, and education, and healthcare workers' attitudes, level of education and biases in presentation all influence the decision-making process.

Morita et al.[63] studied patients' and family members' perceptions about rehydration to identify factors contributing to decision making. The survey included 121 Japanese hospice patients with insufficient oral intake. Patient performance status, fluid retention symptoms, denial, physician recommendations, patients and family members' beliefs with regard to hydration effect on patient distress, and family anxiety about withholding rehydration were significantly associated with decision making. The main determinants for rehydration were the patient performance status, fluid retention symptoms, denial, and care receiver's beliefs about the effects of rehydration on patient distress.

A Canadian study[64] identified issues of importance to family caregivers with regard to administering parenteral hydration to patients with advanced cancer. Factors influencing caregivers including symptom distress issues, ethical and emotional considerations, information exchanged between health professionals and families, and culture. Perceived benefits of artificial hydration were central to the ethical, emotional, and cultural considerations involved in caregivers' decision making. An article presenting the values of the Jewish faith with regard to terminal dehydration[65] illustrates the difficulty of applying cultural and ethnic research and opinion. Letters in response varied from describing this as an 'excellent article'[66] to 'extremely offensive in its references to Jewish people'.[67]

It has been proposed that terminal dehydration or voluntary cessation of drinking may provide an alternative to

physician-assisted suicide. Miller and Meier[68] suggested that terminal dehydration accompanied by standard palliative care management, offers patients a way to escape agonizing, incurable conditions that they consider to be worse than death, without requiring transformation of the law and medical ethics'. Quill et al.[69] suggested that voluntary cessation of 'eating and drinking are clinical options that may be acceptable to a patient and physician and do not require fundamental changes in the law'.

ALTERNATIVE HYDRATION TECHNIQUES

There is universal agreement that the best and most convenient route to correct fluid deficits are increasing or improving oral intake. However where this is impossible or inadequate, there are some circumstances where parenteral hydration may be of benefit. It is often misunderstood that we are not necessarily all seeing patients in the same trajectory of illness. Clinical circumstances evolve,[70] and a physically independent and cognitively intact patient at an early stage of a palliative illness is likely to be viewed very differently to the same patient a number of months later who is now cognitively impaired and physically dependent. However, if a decision is made to use parenteral hydration, there are considerations with regard to the type of fluid, volume and route of administration. There is no doubt that intravenous hydration is the route of choice in acute care institutions. There are obvious disadvantages such as difficulty finding venous access, pain, infection, limitations to mobility, and displaced lines, particularly with confused patients. Nevertheless it should be noted that a report from an Italian palliative care program stated that 82 percent of palliative care patients will have an intravenous line and receive a range of 1–1.5 L of fluid per day.[71] In addition they stated that although hypodermoclysis has been suggested as an alternative, experience suggests that it is not less stressful for palliative care patients and that the intravenous route is preferred.

Nasogastric tubes and gastrostomy

Nasogastric tubes are generally uncomfortable for patients and prolonged used, particularly in palliative care populations should be avoided where possible.[72,73] Percutaneous gastrostomies are commonly used with head and neck or esophageal cancer patients with increasing dysphagia who may benefit from nutrition as well as hydration.[74] As patients deteriorate there is a need to review the goals of care with regard to enteral nutrition. However difficulty with discontinuing management and ease of access can result in ongoing enteral nutrition and hydration in circumstances where this might not otherwise have been instituted.

Hypodermoclysis

The safety of hypodermoclysis has been well documented and reported in noncancer patients.[75*,76*] There have also been studies in palliative care patients demonstrating the ease of administration and minimal toxicity.[48*,77*,78*]

The procedure is simple and associated with minimal pain. A butterfly needle is inserted subcutaneously and attached to a fluid line which can run via gravity or an infusion pump. It requires minimal training for insertion and surveillance, and family caregivers can be trained to supervise this management in the home. Our recent study has suggested increasing acceptance of hypodermoclysis in the acute care setting.[18] It is generally recommended that solutions with some electrolytes are used, as nonelectrolytes solutions have been reported to draw fluid into the interstitial space.[11*,12*,79*] Initial recommendation suggested rates of infusion limited to a maximum of 100–120 mL/h, however, patients can tolerate boluses up to 500 mL/h.[80*]

Traditionally the use of hypodermoclysis was assisted by adding hyaluronidase to promote absorption in a dose ranging from 150 units/L to 750 units/L. Initially smaller volumes of hyaluronidase were demonstrated to be just as effective.[80] However a shortage of hyaluronidase led to clinical experience and anecdotal reports suggesting good absorption of hypodermoclysis without hyaluronidase. This resulted in a report of 24 consecutive patients receiving hypodermoclysis without hyaluronidase.[81*] Hydration was maintained for a mean 12 ± 9 days, with an infusion varying in range between 20 mL/h and 300 mL/h. Three patients were demonstrated to tolerate twice daily boluses of 500 mL over 1 hour. The average infusion site duration was 3.3 ± 3.6 days. These results and the increasing difficulty obtaining hyaluronidase has resulted in the ongoing clinical observation that most patients tolerate hypodermoclysis without requiring the addition of hyaluronidase.

Proctoclysis

As noted intravenous hydration can be uncomfortable, expensive and difficult to maintain in the home, while even hypodermoclysis can be expensive and too complicated in some settings. The potential advantage of the rectal administration of fluid, particularly in resource limited developing countries prompted a trial of rectal hydration in terminally ill cancer patients.[82*] Proctoclysis was offered to 17 adult patients with a fluid deficit where resources were inadequate for the use of hypodermoclysis. Tap water was used and the rectal infusion was increased from 100 mL to a maximum of 400 mL/h, unless fluid leakage occurred before the maximum volume was achieved. The mean daily volume, hourly rate, and duration was reported as 1035 ± 150 mL/day, 224 ± 58 mL/h, and 14 ± 8 days, respectively. Rectal hydration was noted to be well tolerated with minimal side effects in the majority of patients. A follow-up report[83*] included

78 advanced cancer patients receiving rectal hydration. Volumes infused, patient tolerance and side effects were similar to the earlier report, confirming that this is a safe, effective and low cost technique for rehydration in terminally ill palliative care populations.

CONCLUSION

Reconsider the varying circumstances and sociocultural circumstances of the two patients described in the introduction to this chapter. Discussion of management of these two patients, the manner in which information should be presented to them, literature interpretation as reviewed above, and the biases of healthcare providers and the circumstances in which we work will have significant implications on how we consider the issue of fluid deficit and rehydration. We can perhaps achieve consensus that dehydration is a cause of renal failure, and that hypodermoclysis is a safe and effective way of providing rehydration. There may be some agreement that rehydration of palliative care populations may result in better biochemical parameters at the end of life. There is certainly much evidence to recommend that if terminally ill patients are not rehydrated, medications such as opioids should be gradually decreased to avoid accumulation and unnecessary side effects. There is likely to be consensus that the major clinical issue is to consider whether rehydration will cause benefit or harm to palliative care patients unable to sustain adequate oral intake.

The need to consider individual circumstances and predictions of life expectancy in evaluating the potential benefits of rehydration is a recurring theme.[2,11] Although starting from different perspectives, there is some consensus[10,38,61] that:

- Available data are inadequate for final conclusions on this issue.
- Careful individual assessment of the relevance of fluid deficit to each clinical situation is essential.
- Further carefully designed research trials are required.

Key learning points

- Hydration in palliative care is a controversial topic with divergent opinions.
- Fluid deficits can cause confusion and renal failure.
- Hydration research is inconclusive in guiding clinical care.
- Hypodermoclysis is an excellent alternative for rehydration in palliative care populations.
- Diverse clinical and sociocultural circumstances need to be considered.

- Evidence recommends that if terminally ill patients are not rehydrated, medications should be decreased to avoid accumulation and side effects.
- Rehydration may be helpful in some individual situations.

Fever, sweats, and hot flashes

SHALINI DALAL, DONNA S ZHUKOVSKY

INTRODUCTION

Fever, sweats, and hot flashes are commonly encountered in the terminally ill and in patients with cancer, and sometimes may be associated with considerable morbidity and mortality. Although infection remains the most common etiology of fever in patients, irrespective of whether they are receiving chemotherapy or not, fever is commonly seen in patients in the absence of infection as well. Fever is also one of the most common symptoms experienced by elderly people at the end of life.[1,2] Similarly, hot flashes are reported by the majority of menopausal women, and in some women can be a major source of distress.[3,4] Less well recognized is the impact of hot flashes on individuals with cancer, particularly women with a history of breast cancer and men with prostate cancer. In women with a history of breast cancer, approximately two-thirds experience hot flashes.[5,6] Optimal management of fevers, chills, sweats, and hot flashes is therefore of vital consideration in symptom management. As detailed in this chapter, it is contingent on meticulous patient assessment, on ascertaining the likely etiology, if possible, and on implementation of appropriate treatment interventions befitting patient-determined goals of care.

FEVERS

Fever, as defined in *Stedman's Medical Dictionary* is a 'complex physiologic response to disease mediated by pyrogenic cytokines and characterized by a rise in core temperature, generation of acute phase reactants, and activation of immune systems'.[7] More commonly, fever is defined as the elevation of core body temperature above normal. Normal average adult core body temperature is 37°C (98.6°F) and displays a circadian rhythm with body temperatures being the lowest in the predawn hours, at 36.1°C (97°F) or lower, and rising to 37.4°C (99.3°F) or higher in the afternoon. In oncology practice, a single reading of temperature of more than 38.3°C (101°F) or three readings (each taken at least an hour apart) of temperatures more than 38°C (100.4°F) is considered significant.

Pathophysiology of fever

Much like other fundamental aspects of human biology, core body temperature is closely regulated by intricate control mechanisms, involving a complex interplay of autonomic, endocrine, and behavioral responses. Integral to this process is the hypothalamus which functions much like a thermostat, balancing heat production with heat loss. Fever is considered a hallmark of immune system activation, resulting in a regulated rise in body temperature. The regulation of this phenomenon is accomplished by the actions of two types of endogenous immunoregulatory proteins called cytokines, some functioning as pyrogens and others as antipyretics. This is described below and illustrated in Figure 77.1.

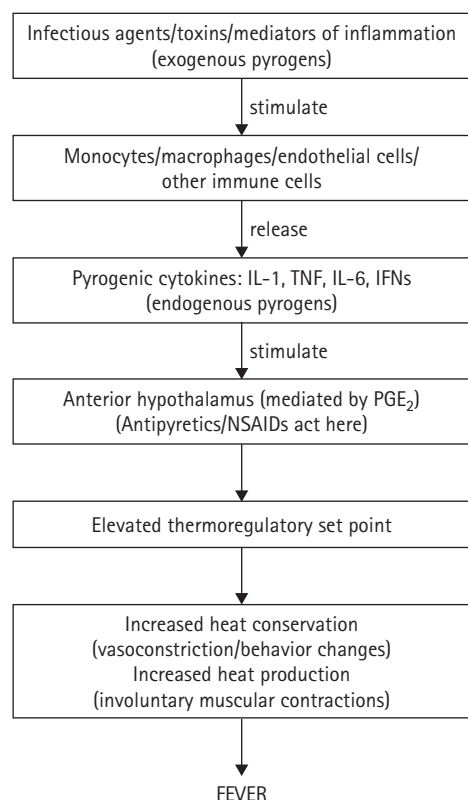
A number of exogenous substances, often referred to as exogenous pyrogens, have been found to be capable of evoking fever in animal models.[8] Of these, lipopolysaccharide (LPS), a cell wall product derived from Gram-negative bacteria, has been the most extensively studied. Exogenous pyrogens induce the production of proinflammatory cytokines, such as interleukin (IL)-1β and IL-6, interferon α (INFα) and tumor necrosis factor (TNF), which act as humoral mediators influencing brain structures involved in resetting the hypothalamic set point.[9] Cytokines are thought to exert their effect on the brain via direct and indirect mechanisms.[10–12]


Figure 77.1 *Pathophysiology of fever. IL, interleukin; TNF, tumor necrosis factor; IFN, interferon; PGE, prostaglandin E; NSAID, nonsteroidal anti-inflammatory drug.*

Peripherally produced cytokines reach the central nervous system (CNS) directly by crossing at leaky areas in the blood–brain barrier via circumventricular vascular organs, which are networks of enlarged capillaries surrounding the hypothalamic regulatory centers.[13,14] In disease states such as bacterial infections, the blood–brain barrier can be compromised further, leading to an influx of cytokines from the periphery and which account for several of the neurological manifestations associated with sickness behavior, including fever.[15,16] Cytokines are also produced locally within the CNS,[11] and may account for the hyperpyrexia of CNS hemorrhage. Among the cytokines measurable in the blood plasma during LPS-induced fever, circulating levels of IL-6 have shown the best correlation with fever.[17,18]

Although not fully understood, it is proposed that cytokines stimulate the central production of the inducible enzyme cyclooxygenase (COX)-2, and subsequently stimulate the production of prostaglandins of the E series.[19,20] These prostaglandins activate thermoregulatory neurons of the anterior hypothalamic area to elevate body temperature.[21] Peripherally produced cytokines can also communicate with the brain indirectly in several ways, including the stimulation of terminal fibers of the autonomic nervous system.[22,23] Norepinephrine is the principal neurotransmitter, although several others such as acetylcholine, endorphins, enkephalins, substance P, somatostatin and vasoactive intestinal polypeptide (VIP) have also been implicated.[24]

Etiology of fever (Box 77.1)

INFECTIONS

Nearly two-thirds of fever in patients with prolonged neutropenia may be attributed to infection,[25] a major cause of morbidity in patients with cancer. Fever in a cancer patient should be considered indicative of infection until proved otherwise, with appropriate assessments being instituted in a timely fashion. Febrile neutropenic patients (granulocyte count <500) represent an absolute emergency. In patients with advanced Alzheimer disease, physical consequences of the progression of dementia predispose them to infection and fever, especially to aspiration pneumonia and urinary tract infections.[26–29]

PARANEOPLASTIC FEVERS

Fever may be a common presentation for some malignancies and their progression may parallel the occurrence of fevers. Although Hodgkin disease has classically been associated with Pel–Epstein fevers (recurring periods of fever lasting for 3–10 days at a time), several other malignancies are also associated with paraneoplastic fevers and include acute leukemias, lymphomas, renal cell carcinoma, bone sarcomas, adrenal carcinomas, and pheochromocytomas. Solid tumors such as breast, lung, and colon cancer are less often associated with paraneoplastic fevers. However, the presence of liver metastasis from these tumors may result in fever. In addition, any solid tumor causing obstruction can result in fever.

Malignancy is often found during the work-up of patients presenting with fever of unknown origin. While earlier reports found an incidence of 20 percent, a more recent study reported malignancy as the cause of fever in 15 percent of patients.[30] In patients with cancer presenting with fever of unknown origin, paraneoplastic was found to be the most common etiology.[31] Although the exact mechanism of

Box 77.1 Etiology of fever in cancer patients

- Infections
- Tumor (paraneoplastic fever)
- Drug-associated (e.g. cytotoxic agents, antibiotics, IFN)
- Blood transfusion reaction
- Thrombosis
- CNS metastasis
- Radiation-induced (e.g. radiation pneumonitis)

tumor-associated fever is unclear, it is thought to involve inflammatory cytokines such as TNFα, IL-1, and IL-6, which are produced either by host macrophages in response to the tumor or by the tumor itself.[32,33]

TRANSFUSION–ASSOCIATED FEVER

Febrile and allergic nonhemolytic transfusion reactions (NHTRs) are the most common adverse effects of blood transfusion.[34,35] These reactions are generally not life threatening, but they are expensive in their management, evaluation, and associated blood product wastage. The true incidence of febrile NHTRs (FNHTRs) is not well established in patients with cancer. In a large retrospective study, the incidence of side effects following transfusion of 100 000 units of packed red blood cells to more than 25 000 cancer patients over a 4-year period was found to be at 0.3 percent (of these, 51.3 percent were FNHTRs, 36.7 percent were allergic urticarial reactions, and 17 percent were hemolytic reactions).[36] This is comparable to other studies where the incidence has ranged from 0.2 percent to 0.7 percent.[37,38]

The occurrence of fever is usually caused by the presence of antibodies to antigens on the donor's white blood cells and its prevention by using leukodepleted blood components was demonstrated more than two decades ago.[39–41] Some studies have shown a correlation with storage time of platelets and the release of cytokines, as another reason for the occurrence of FNHTRs.[42–44]

Infection may also be a source of fever in patients receiving blood transfusions.[45–47] The prevalence of bacteria is estimated to be about 0.04–2 percent, depending on the type of components, the number and age of the evaluated components, and the detection methods used.[48–51] The last of these studies estimated that 1 in each 1000/2000 units of platelet concentrates (obtained from whole blood or apheresis) is bacterially contaminated. The incidence of bacterial contamination in red cell concentrates is much lower and almost zero for fresh frozen plasma and cryoprecipitate.

DRUG FEVER

Drug-associated fever is usually a diagnosis of exclusion, except for some drugs such as biological response modifiers, amphotericin B, and bleomycin, where the occurrence of fever may be predictable. Other drugs commonly implicated as a cause of fever include antibiotics, cardiovascular drugs, anticonvulsants, cytotoxics, and growth factors. In one retrospective study of 148 episodes of drug fever, antimicrobials were found to be the most common offending agent (31 percent).[52] Cytotoxic agents accounted for 11 episodes (7.4 percent).

In a retrospective chart review of 50 patients who had received at least 100 mg of amphotericin B for at least 3 days, the incidence of fever was 34 percent and chills was 56 percent, with rates of 2.6 and 3.5 mean episodes per patient per treatment course, respectively.[53] Interferon therapy is associated with acute 'flulike syndrome consisting of fever, chills, fatigue, myalgias, arthralgia, and headache, with some variation according to type of IFN, route of administration, schedule, dose, and age of patient.[54] The administration of growth factors is also associated with fever, being more common following granulocyte macrophage colony-stimulating factor (GM-CSF) administration than granulocyte colony-stimulating factor (G-CSF) administration. Bleomycin-associated fever occurs in 20–50 percent of patients and is more common when it is administered intravenously. Fever is also associated with other cytotoxic agents such as cisplatin, streptozocin, 5-fluorouracil, and therapy with monoclonal antibodies.[55–58]

Evaluation of fever

Assessment of fever requires careful history taking, medication review, and a thorough physical examination to include all major body systems. Patients should undergo meticulous evaluation of the skin, and all body orifices including mouth, ears, nose, throat, urethra, vagina and rectum, venipuncture sites, biopsy site, and skin folds (i.e. breast, axilla, abdomen, groin). In nearly two-thirds of neutropenic patients the initial evaluation may not identify a focus of infection.[32] This may relate in part to the high frequency of empirical treatment with broad-spectrum antibiotics, which may make it harder to determine the site of infection. Careful physical examinations should be repeated at least daily in patients with neutropenia, even after the initiation of empirical antibiotics. It must be remembered that immunocompromised patients may be vulnerable to more than one infection and that different organisms may emerge during a single febrile episode.

Interventions for fever

GOALS OF CARE

The presence of fever may be associated with potential metabolic consequences including dehydration and increased oxygen consumption and metabolic rate,[59,60] which may be especially pronounced in debilitated terminally ill patients. If prolonged, fevers may be associated with increased nutritional demands and debilitating fatigue. Although fever may be beneficial for enhancing host defense,[61,62] other factors such as the patient's comfort and physiological responses also deserve consideration. Suppression of fever may help alleviate uncomfortable, constitutional symptoms of fatigue, myalgias, diaphoresis, and chills. In addition to constitutional symptoms, focal findings related to the etiology of fever may also contribute to symptom burden. For example, abscess formation is often associated with pain, while uncomfortable dyspnea and cough can be related to pneumonia. The specific interventions used for fever management are determined by the

underlying etiology, together with patient-determined goals of care. Patients with advanced cancer may opt not to treat the underlying etiology of fever and seek only nonspecific palliative measures. For example, individuals seeking comfort-oriented care exclusively may decline parenteral antibiotic treatment of pneumonia to avoid hospitalization and remain at home. For others, treating the underlying etiology of fever with more aggressive interventions, such as surgical drainage of a painful abscess, will offer symptom palliation and potentially contribute to life prolongation. Aggressive treatment of infection does not improve survival rates among persons with severe dementia and has been associated with accelerated progression of the severity of dementia.[63] Antibiotics and other aggressive measures are often associated with numerous deleterious outcomes, including renal failure and ototoxicity, allergic or drug reactions, rash, diarrhea, blood dyscrasias, antibiotic resistance, use of intravenous lines and mechanical restraints, prolonged time to death, and increased costs.[64,65]

NONSPECIFIC INTERVENTIONS

During febrile episodes, increasing fluid intake, removing excess clothing and linens, tepid water bathing or sponging, and use of antipyretics may offer relief. In the very sick, administration of fluids intravenously or subcutaneously may be warranted. Other comfort measures include application of lubricant to dried lips and keeping mucous membranes moist with ice chips. Convective cooling via increasing air circulation by fans or using an airflow blanket may be effective to reduce temperatures and improve patient comfort.[66*] Additionally, ensuring clothes and bed linens are dry should be done and changed as needed.

Antipyretic agents such as acetaminophen (paracetamol), aspirin or nonsteroidal anti-inflammatory drugs (NSAIDS) act by lowering the elevated thermal set point by inhibition of enzyme cyclooxygenase. Although these agents are commonly administered to hospitalized patients to enhance patient comfort,[67] no studies have been done in the cancer population with fever, and carefully controlled efficacy studies have not quantified the degree to which the antipyretics therapy enhances the comfort of febrile patients in other populations. Although theoretically patients with pulmonary and cardiovascular disorders may benefit from antipyretic therapy to minimize the impact of increased metabolic demands, the risk versus benefit of this approach has not been determined. Similarly, antipyretic therapy has not been demonstrated to prevent febrile seizures in children.[68] Several studies have confirmed that increasing the dose of acetaminophen from moderate dosage (10 mg/kg every 4 hours, maximum five doses per day) to relatively higher dosage (15–20 mg/kg every 4 hours, maximum five doses per day) in children failed to reduce the rate of recurrence of febrile seizures.[69]

Fever control may be enhanced by combining physical methods with antipyretics. In children, a randomized placebo-controlled trial of sponging with ice water, isopropyl alcohol or tepid water (with or without acetaminophen) demonstrated that all combinations enhanced fever control, but comfort was greatest in children receiving placebo or sponging, followed by those who received acetaminophen combined with tepid water sponging.[70] Discomfort was found to be greatest when sponging with ice water or isopropyl alcohol with or without concomitant administration. Like acetaminophen, aspirin may be effective in reducing fever, but should be used with caution in patients with or at risk of thrombocytopenia due to its antiplatelet effects. In children, aspirin use is contraindicated due to the risk of Reye syndrome with fever related to certain viral etiologies, including varicella and influenza.[71] Nonsteroidal anti-inflammatory drugs should also be used cautiously in the cancer population, as they inhibit platelet function and may also cause gastrointestinal hemorrhage.

PRIMARY INTERVENTIONS DIRECTED AT THE ETIOLOGY OF FEVER

Infections

Patients should be instructed to seek medical help if a fever develops when the neutrophil count is low or declining. In febrile neutropenic patients broad-spectrum antibiotics should be initiated immediately even before culture results are available,[72] as mortality rate is 70 percent for patients not receiving antibiotics within 48 hours.[73] Initial antibiotic use is guided by knowledge of the treating institution's antimicrobial spectrum and antibiotic resistance pattern, as well as the suspected cause. Although there is general consensus that empirical therapy is appropriate, there is no consensus as to which antibiotics or combinations of antibiotics should be used. The Infectious Diseases Society of America (IDSA) Fever and Neutropenia Guidelines Panel recommends empirical antibiotics based on the patient's clinical condition and risk for complications, and determination of the need of vancomycin in the initial regimen.[74] These four protocols are depicted in Table 77.1.

Treatment regimens are further modified by the duration of fever and individual patient risk factors such as the presence of central lines or other artificial devices, history of steroid use, and history of injection drug use. After a specific pathogen is isolated, antibiotic therapy is then changed to provide optimal therapeutic response. The single most important determinant of successful discontinuation of antibiotics is the neutrophil count. If infection is not identified after 3 days of treatment, if the neutrophil count is $\geqslant$500 cells/mm^3 for 2 consecutive days, and if the patient is afebrile for $\geqslant$48 hours, antibiotic therapy may be discontinued. For neutropenic hosts with persistent or recurrent fevers after 1 week of broad-spectrum antibiotic therapy, the addition of an antifungal agent is recommended, as continued granulocytopenia is usually associated with the development of nonbacterial opportunistic infections, particularly candidiasis and aspergillosis.

Table 77.1 *Empiric antibiotic regimens for unexplained neutropenic fever in the cancer population[35]*

Regimen	Route		Antibiotic selection	Comments
1	Oral		Ciprofloxacin *plus* amoxicillin-clavulanate	For use in select *adult* patients: In remission At low risk for serious life-threatening complications Not recommended for patients with comorbidities May be used on an outpatient basis if ready access to care, no signs of focal infection, and no signs or symptoms suggestive of systemic infection other than fever
2	Intravenous	Mono-drug (without vancomycin)	Choose one: cefepime, ceftazidime, imipenem or meropenem	Mono-drug as effective as multiple drug combinations for uncomplicated neutropenic patients Monitor closely for nonresponse, emergence of secondary infection and drug resistance
3	Intravenous	Two-drug regimen (without vancomycin)	Aminoglycoside *plus* antipseudomonal penicillin or ceftazidime or carbapenem	Advantages: Potential synergistic effects against some Gram-negative bacilli Minimal emergence of drug-resistant strains during treatment
4	Intravenous	One or two drug regimen *with* vancomycin	Vancomycin *plus* antibiotics from regimens 2 or 3 above	Restrict to: Institutions with high prevalence of infections with penicillin-resistant Gram-positive bacteria Suspected catheter-related cellulitis or bacteremia Gram-positive bacteremia Evidence of septic shock

Aciclovir is the drug of choice in the treatment of herpes simplex or varicella zoster viral infection. Ganciclovir has activity against cytomegalovirus. Both agents can be used prophylactically in the management of patients at high risk for these infections. Foscarnet is useful in the treatment of cytomegalovirus and aciclovir-resistant herpes simplex virus.

Various investigators have developed models predicting risk groups of febrile neutropenia, with implications for management strategies. Therapeutic options under evaluation include early hospital discharge, home intravenous antibiotic therapy and oral antibiotic regimens. Due to rapid changes in the field, the reader is directed to specialized sources for specific management recommendations of febrile neutropenia.

Paraneoplastic fever

The best management for paraneoplastic fevers remains in the treatment of the underlying neoplasm with definitive antineoplastic therapy. If not possible, NSAIDs have been considered as the mainstay of treatment, with naproxen

being the most extensively studied. However, indometacin and diclofenac have also been found to be effective.[75**] Several studies suggesting that neoplastic fevers are more responsive to NSAIDs than are infectious fevers, has led to advocacy of the 'naproxen test' to differentiate between neoplastic and non-neoplastic fevers.[76,77] However, this approach has not been validated.[78] Thalidomide, an immunomodulatory agent, has been shown to have modulatory and/or suppressive effects on several cytokines such as TNFα, IL-1, and IL-6,[79,80] all involved in paraneoplastic fever and which, theoretically, may have a role in treatment of cancer patients with fever and sweats.[81] Despite reports of its antipyretic and antidiaphoretic activity,[82,83] this agent has not been formally tested in clinical studies with cancer patients for fever or sweat control.

Transfusion–associated fever

Many institutions have moved toward leukoreduced transfusions in an effort to decrease incidence of FNHTRs and several countries have even restricted the manufacture and

transfusion of blood products to prestorage leukodepleted blood components only. A retrospective analysis conducted at Johns Hopkins Hospital examined the frequency of transfusion reactions associated with transfusion of red blood cells (RBCs), between July 1994 and December 2001.[84] The study directly compared two time periods before and after the initiative towards leukoreduction. In the initial period (July to December 1994) before the initiative to move toward leukoreduction, 96 percent of RBC inventory was non-leukoreduced. In the study period after leukoreduction (July to December 2001) 99.5 percent of RBC inventory was leukoreduced. When comparing these two time periods, the incidence of FNHTRs decreased from 0.37 percent to 0.19 percent ($P = 0.0008$). The trend over the entire 7.5-year study period confirmed the decrease in FNHTRs as the percentage of leukoreduced RBCs increased. The incidence of allergic NHTRs remained unchanged. The decreased incidence of FNHTRs with leukoreduction have been found in other studies as well.[85–88] Common clinical practice prior to blood product transfusions include premedication with acetaminophen, diphenhydramine with or without steroids. The use of erythropoietin for cancer-related anemia may decrease the need of blood transfusions and may be used for cancer-related anemia. The risks versus benefits, and costs, of such prophylactic treatments to avoid or delay transfusion need further investigation.

Drug fever

Drug-associated fever responds to cessation of the offending agent, when possible. Fever and related symptoms with biological response modifier administration is type, route, dose, and schedule dependent. These factors may sometimes be altered for fever control without sacrificing efficacy. Liposomal amphotericin B is as effective as conventional amphotericin B for empirical antifungal therapy in patients with fever and neutropenia, but is associated with decreased toxicity, including occurrence of fever and chills.[89] Fever may also be attenuated by the use of acetaminophen, NSAIDs, and steroid premedication. The same may be true for fever associated with some cytotoxic agents and antimicrobials (i.e. amphotericin). It is common clinical practice to administer meperidine to attenuate severe chills associated with a febrile reaction, although empirical data confirming its efficacy are not available.

Fever versus hyperthermia

Although in the vast majority of patients an elevated body temperature usually represents a fever, there are instances where elevated temperatures could be secondary to hyperthermia. These include heat stroke syndromes, certain metabolic diseases (hyperthyroidism), and drugs that interfere with thermoregulation. With fever, thermoregulatory mechanisms remain intact, but the hypothalamic thermal set point is raised by exposure to endogenous pyrogens,[90] leading to behavioral and physiological responses to elevate body temperature. In contradistinction to fever, during hyperthermia, the setting of the thermoregulatory center remains unchanged at normothermic levels, while body temperature increases in an uncontrolled fashion and overrides the ability to lose heat. Hyperthermia thus results from overwhelming of the peripheral heat-dissipating mechanisms by disease, drugs or from excessive heat, be it external or internal.[91]

Atropine may increase endogenous heat production by interfering with thermoregulation, in that it blocks sweating and vasodilation, thereby raising core temperature. Hyperthermia also occurs with neuroleptic malignant syndrome (NMS), an idiosyncratic reaction to drugs that block the dopamine receptor. Haloperidol, an antipsychotic agent, is the most common offender.[92,93] Atypical antipsychotic medications, including clozapine, risperidone, olanzapine, and quetiapine have also been associated with NMS.[94,95] There are also case reports of other medications causing NMS, including venlafaxine, promethazine and metoclopramide.[96,97] Neuroleptic malignant syndrome typically occurs within several days of the initiation of treatment and dosages and serum concentration of these medications are usually within the therapeutic range. The probability of developing NMS is directly related to the antidopaminergic potency of the neuroleptic agent. In addition, specific polymorphisms of the dopamine D_2 receptor may predispose some patients to NMS.[98]

It is important to make the distinction between fever and hyperthermia since management approaches to these distinct syndromes differ. There is no rapid way to differentiate elevated core temperature due to fever from hyperthermia and a diagnosis of hyperthermia is often made because of a preceding history of heat exposure or use of certain drugs that interfere with normal thermoregulation. On physical examination, the skin is hot but dry in heat stroke syndromes and in patients taking drugs that block sweating.

Antipyretic agents act by lowering the elevated thermal set point and are used in the treatment of fever, but are ineffective in hyperthermia, where the thermal set point is normal. In hyperthermia, drugs that interfere with vasoconstriction such as phenothiazines and those that block muscle contractions or shivering are useful. However, these are not true antipyretics as they can reduce body temperature independently of hypothalamic control. Shivering may be suppressed with intravenous benzodiazepines such as diazepam or lorazepam. Chlorpromazine intravenously (25–50 mg) may also be used for this purpose if NMS is not suspected.

In patients diagnosed with hyperthermia, physical cooling should be started immediately with techniques such as removing bedclothes, sponging the patient with tepid water and use of bed fans. More rapid reductions in body temperature can be achieved by sponging the patient with alcohol or by using hypothermic mattresses or ice packs.

Immersion in ice water is the most effective means of physical cooling, but it should be reserved for true hyperthermic emergencies, such as heat stroke. In true emergencies, treatment may also include the intravenous or intraperitoneal administration of cool fluid, gastric lavage or enemas with ice water, and even extracorporeal circulation. No matter what technique is used, the body temperature must always be monitored closely to avoid hypothermia.

SWEATS

In patients with advanced disease or those receiving palliative care, the prevalence of sweating ranges from 14 percent to 28 percent, is frequently nocturnal and is moderate to severe in intensity.[99–101] Although night sweats have been defined as drenching sweats that require the patient to change bedclothes, this definition may not describe the majority of patients who complain of the symptom. Clinically, hot flashes are often seen in association with sweats and by far this is the most common cause of sweats encountered in clinical medicine, experienced by the majority of perimenopausal and menopausal women and hence this topic will be covered in detail. In the literature, night sweats has also been associated with a variety of medical problems including malignancies (e.g. lymphomas), some infections, tuberculosis, autoimmune diseases, and drugs. Common malignancies associated with night sweats include lymphomas, leukemia, renal cell carcinoma, and Castleman disease. The classic presentation of tuberculosis includes fever, weight loss and night sweats. AIDs-related infections might also cause night sweats, including *Mycobacterium avium* complex (MAC) infection and cytomegalovirus (CMV) syndromes. The differential diagnosis for night sweats is broad and Box 77.2 lists some of these conditions.

Box 77.2 Etiology of night sweats

Malignancy

- Lymphoma
- Leukemia
- Renal cell carcinoma
- Castleman disease
- Other neoplasms

Infections

- Human immunodeficiency virus
- Tuberculosis

- *Mycobacterium avium* complex
- Infectious mononucleosis
- Fungal infections
- Lung abscess
- Endocarditis

Others

- Obstructive sleep apnea
- Gastroesophageal reflux disease
- Chronic fatigue syndrome
- Granulomatous disease
- Diabetes insipidus
- Anxiety
- Rheumatological diseases

Endocrine

- Perimenopausal and postmenopausal women
- Hyperthyroidism
- Diabetes mellitus (nocturnal hypoglycemia)
- Endocrine tumors (pheochromocytoma, carcinoid tumor)
- Orchiectomy

Drugs

- Antipyretics (salicylates, acetaminophen)
- Selective estrogen receptor modulator drugs: tamoxifen and raloxifene
- Leuprolide
- Niacin
- Selective serotonin receptor inhibitors
- Antihypertensives
- Phenothiazines
- Drugs of abuse: alcohol, heroin

Patients presenting with night sweats warrant a detailed evaluation including history and physical examination aimed at revealing associated symptoms to help narrow the broad differential diagnosis and guide further work-up. The prevalence of sweats and their impact on quality of life in the cancer population is not well established and requires further definition.

HOT FLASHES

Hot flashes, experienced by three-quarters of menopausal women, are described as a sudden onset of an uncomfortable sensation of intense heat, accompanied by skin flushing, warmth and sweating, usually of the chest and face.[4] Hot flashes typically last for 2–4 minutes and are often accompanied by palpitations and anxiety, may be triggered by emotional stress, anxiety, alcohol, and certain foods.[102] Factors associated with a greater risk of hot flashes are listed in Box 77.3.[103–106] Approximately two-thirds of women with history of breast cancer experience hot flashes.[5] In postmenopausal women with a history of breast cancer, predictors of hot flash severity include higher body mass index, a high school education or less, younger age at diagnosis, and tamoxifen use.[107,108] For patients starting tamoxifen, hot flashes typically increase in the first 2–3 months, followed by a plateau and then gradual dissipation.[109]

In men treated with androgen ablation for locally advanced or metastatic prostate cancer, 50–88 percent experience hot flashes.[110,111] Patients with other cancers are also affected with hot flashes, however data on this are limited.

Box 77.3 Factors associated with hot flashes

Abrupt menopause

- Chemotherapy
- Drugs
- Radiation
- Surgery

Cancer type

- Breast
- Prostate

Early menopause

Ethnicity

- African women
- Western women

Lack of exercise

High body mass index

Low education

Low estrogen levels

Low socioeconomic status

Smokers

The rapid menopause associated with cancer treatments does not allow for a gradual adjustment of falling estrogen levels and this may explain why hot flushes resulting from cancer treatment tend to be more profound.

Pathophysiology

The prevailing hypothesis relates the development of hot flashes to lowering of estrogen levels leading to complex neuroendocrine mechanisms, including alterations in the level of hypothalamic neurotransmitters, which resets the thermostat to a lower level with a narrower range, as compared with those who do not experience hot flashes.[112,113] A small rise in core body temperature has been found to occur 15 minutes prior to hot flashes in 60 percent of hot flash episodes.[114] This subtle elevation in core body temperature stimulates mechanisms of heat dissipation, resulting in cutaneous vasodilation and sweating, the two central components of the hot flash syndrome.

Two most recognized neurotransmitters involved in hypothalamic thermoregulatory processes are norepinephrine and serotonin. Catecholestrogens (estrogenic metabolites) abundant in the hypothalamus stimulate the production of β-endorphins. Both catecholestrogens and endorphins inhibit the production of hypothalamic norepinephrine. Loss of this negative feedback in low estrogenic states results in rise of norepinephrine levels and an upregulation of certain hypothalamic serotonin receptors responsible for resetting of the thermostat.[115] Norepinephrine is believed to be responsible for the rise in core temperature prior to onset of hot flashes.[114] In men, it is uncertain if low testosterone levels or decline in estrogen levels or both, are responsible for development of the hot flash syndrome.

Assessment and treatment of hot flashes

Hot flashes should be routinely assessed as a component of systematic symptom surveys and if present, a careful assessment of hot flash frequency, intensity, duration, potential triggers, and impact on quality of life is advised in order to construct an individualized treatment plan. Patient self-report diaries with hot flash frequency, intensity, and associated distress can be helpful to clinicians to formulate treatment recommendations.[116] Hot flash score is determined by multiplying the daily frequency of hot flashes by their average severity. Box 77.4 lists the possible options for management of hot flashes.

HORMONE REPLACEMENT THERAPY

Estrogen
Estrogen replacement is effective for treatment of hot flashes in 80–90 percent of patients, regardless of underlying

---

etiology.[117**,118,119*,120**] However, some women have absolute or relative contraindications to hormone replacement therapy (HRT), and others are reluctant to take hormones due to perceived risks and side effects. The Women's Health Initiative Study evaluated the risks and benefits of estrogen plus progestin therapy in healthy postmenopausal women.[121**] The estrogen plus progestin arm was stopped prematurely in women with an intact uterus at a mean follow-up of 5.2 years ($\pm$1.3) due to detection of a 1.26 times increased breast cancer risk (95 percent CI 1.00 to 1.59). Observed benefits of HRT on hip fractures and colon cancer risk were far outweighed by increased risks of venous thromboembolic disease, breast cancer, stroke, and coronary artery disease. Supporting an increased risk of breast cancer with combined HRT is another recent population-based, case–control study of 975 postmenopausal women diagnosed with breast cancer.[122] In this cohort, HRT use was associated with an increased risk of breast cancer, including lobular, ductal and estrogen and progesterone receptor positive tumors.

Progestational agents

Progestational agents have comparable efficacy to estrogens for hot flash reduction. Agents studied include megestrol acetate and transdermal progesterone, and the long-acting intramuscular preparation, depo-medroxyprogesterone acetate (DMPA).[123**,124**,125*]

Despite benefit of amelioration of hot flashes, there is ongoing debate about safety of progesterone in patients with breast, uterine, or prostate cancer. In men with prostate cancer, several investigators have reported a decline in prostate-specific antigen levels after withdrawal of megestrol acetate, raising concerns that its use may be harmful in this population.[126–128] Risk associated with progestin use in women with a history of breast cancer is unknown at this time, as is its effect on outcome of tamoxifen treatment. Some data have suggested that progestational agents may increase epithelial cell proliferation, an undesirable effect in breast cancer.[129,130] There is also some evidence of antitumor activity in breast cancer.[131]

Tibolone

Tibolone, a synthetic steroid compound with combined estrogenic, progestogenic, and androgenic properties, has been reported to reduce hot flashes.[132*,133] A recent study of postmenopausal women receiving tamoxifen after surgery for breast cancer found a significant reduction in the severity of hot flashes with tibolone compared with placebo (0.4 vs. 0.2, respectively, $P = 0.031$) but no change in the daily number of hot flashes with either tibolone or placebo ($P = 0.219$).[134**] Tibolone is not available in the USA.

NONHORMONAL AGENTS

Nonhormonal agents are gaining popularity as therapy for hot flash reduction due to the heightened concerns about the risks of using HRT. These include pharmacotherapies, and complementary and alternative medicine approaches.

Antidepressants

Several large placebo-controlled, randomized trials have shown the beneficial effects of antidepressants from the selective serotonin reuptake inhibitors (SSRIs) and selective serotonin and norepinephrine reuptake inhibitors (SNRIs) class in hot flash management. In the Mayo Clinic study, breast cancer survivors and menopausal women experiencing hot flashes were assigned to receive one of three different dose levels of venlafaxine (37.5 mg, 75 mg, and 150 mg daily), or placebo for 4 weeks.[135**] A dose-related diminution in average hot flashes scores from baseline was noted (27 percent in the placebo subjects vs. 37 percent, 61 percent, and 61 percent for the three venlafaxine groups, respectively). Similar beneficial results have been found in studies with paroxetine and fluoxetine.[136**,137**] Preliminary studies with other newer antidepressants, including citalopram and mirtazapine have also shown good results in standard starting doses.[138*,139*]

Of note, many of the SSRIs can inhibit the cytochrome P450 enzyme system involved in the hepatic metabolism of tamoxifen, a drug commonly used in the treatment of breast cancer. In a prospective study, co-administration of paroxetine with tamoxifen was shown to result in decreased concentrations of 4-hydroxy-*N*-desmethyl-tamoxifen, an

active tamoxifen metabolite (also known as endoxifen).[140] Women with the wild-type CYP2D6 genotype demonstrated greater decreases in endoxifen levels than those with a variant genotype ($P = 0.03$). Given the widespread use of SSRIs for the treatment of mood disorders and hot flashes, the interactions of SSRIs with tamoxifen merit further study.

OTHER NONHORMONAL AGENTS

Several other agents have been found to be useful in hot flash management. In a placebo-controlled, randomized study of 59 postmenopausal women, gabapentin was more effective than placebo in reducing hot flash frequency (45 percent vs. 29 percent, respectively) and hot flash composite score (54 percent vs. 31 percent, respectively).[141**] Clonidine, a central acting α_2-adrenergic receptor agonist has been shown to have modest benefits in hot flash reduction in several studies in healthy postmenopausal women, breast cancer survivors on tamoxifen, and men with prostate cancer, but with significant dose-related side effects.[142**,143**] The North Central Cancer Treatment Group (NCCTG), in a randomized, placebo-controlled crossover trial of vitamin E in women with a history of breast cancer, found a minor decrease with treatment, with a mean reduction of 1 flash/day, without adverse effects.[144**] This reduction is unlikely to be of meaningful clinical benefit. Bellergal, a combination of belladonna and phenobarbital was widely used in the past for hot flash management. Although several reports favor its use over placebo,[145] this therapy cannot be recommended in view of the risk of phenobarbital dependence and dose dependent anticholinergic side effects of belladonna, including dry mouth, constipation, blurry vision, and dizziness.

COMPLEMENTARY AND ALTERNATIVE MEDICINE APPROACHES

Eighty percent of women in the 45–60 age group have reported the use of nonprescription therapies for management of menopausal symptoms.[146] Often perceived to be safer than hormone replacement therapy, CAM may provide users with a sense of personal control over their healthcare.

Soy phytoestrogens are weak estrogens found in plant foods and while dietary supplementation with natural soy products appears to be a benign intervention, long-term effects are not known. Two randomized, placebo-controlled studies show no clinical benefit of soy over placebo for hot flash management.[147**,148**] Breast cancer risk in the general population and risk of recurrence in breast cancer survivors has not yet been clarified, nor has its effect on hormonally mediated antitumor therapies, such as tamoxifen and the aromatase inhibitors. Black cohosh (*Cimicifuga racemosa*) is approved in Germany for the treatment of hot flashes. The anecdotal clinical and observational experience suggests black cohosh may produce 25–30 percent more efficacy than placebo for menopausal symptoms, including hot flashes.[149] In a randomized, double-blind, placebo-controlled study on breast cancer survivors in the USA, however, efficacy of black cohosh was not significantly different from placebo.[150**] The

high prevalence of tamoxifen use in study participants may have confounded study results. Red clover, which contains isoflavones (phytoestrogens), and dong quai have not been found to be beneficial in the management of hot flashes.

Acupuncture has been suggested as a remedy for hot flashes. In a randomized controlled study Wyon *et al.* compared the efficacy of electro-acupuncture with oral estradiol treatment and superficial needle insertion on hot flash reduction in 45 postmenopausal women.[151**] They found that electro-acupuncture decreased the number of hot flashes significantly over time, but not to the same extent as the estrogen treatment. No significant difference in effect was found between electro-acupuncture and the superficial needle insertion. In a small pilot study of prostate cancer patients who underwent castration therapy, a substantial decrease (70 percent reduction) in hot flash symptoms was noted at 10 weeks, with a sustained reduction of 50 percent at 3 months.[152*] Further studies are warranted to determine efficacy and potential mechanisms of action of acupuncture as a modality of therapy for treatment of hot flashes.

Behavioral methods may play a role in hot flash management. Studied methods include relaxation response training[153**] and paced respirations.[154**] These may be used as primary alternatives for patients who do not want to take medications, or as an adjunct for individuals who achieve suboptimal relief with other interventions. The beneficial effects may be related to the decreased adrenergic tone mediated by relaxation techniques. Exercise would similarly be beneficial.

Key learning points

- Fever, chills, and hot flashes are frequently encountered in palliative care patients.

- Fever in patients with cancer should be considered indicative of infection unless proved otherwise. Neutropenic fever is a medical emergency.

- Fever may be associated with potential metabolic consequences including dehydration and fatigue, which may be especially pronounced in debilitated terminally ill patients.

- Paraneoplastic and drug fevers should be considered in the differential diagnosis of fever.

- Cytokines are implicated in the etiology of fever secondary to infections and paraneoplastic fevers.

- Both fever and hyperthermia result in elevation of core body temperatures but differ physiologically and in their management. Many palliative care patients are on drugs which have the potential to cause hyperthermia.

- Patients should be assessed for night sweats and hot flashes. The latter is widely prevalent in some cancers (breast, prostate) and postmenopausal women and may be associated with significant distress.

- Many nonhormonal therapies are available for consideration for hot flash management.

Pruritus

VICTORIA LIDSTONE, ANDREW THORNS

INTRODUCTION

Pruritus is defined as 'an unpleasant sensation that provokes the desire to scratch'. It has a prevalence of 27 percent in common tumor sites,[1] and in cholestasis up to 80 percent of patients may complain of itch.[2] In severe cases it can cause undue distress and can be difficult to treat. This chapter will summarize the pathogenesis of pruritus as far as it is known and the causes and effects of pruritus, and will discuss possible treatment options.

PATHOGENESIS OF PRURITUS

The pathogenesis of itch is complex and has not been fully elucidated. Both central and peripheral mechanisms are involved and a number of mediators are being studied to generate future treatment options. Twycross has suggested a clinical classification based on the understandings of the origins of itch[3] (Box 78.1).

Box 78.1 Classification of pruritus based on origin

- Pruritoceptive itch – originating from the skin and transmitted by C fibers, e.g. scabies, urticaria

- Neuropathic itch – originating from disease located along the afferent pathway, e.g. herpes zoster, multiple sclerosis and brain tumors

- Neurogenic itch – originating centrally without any evidence of neural pathology, e.g. itch caused by cholestasis which is due to the action of opioid neuropeptides on μ-opioid receptors

- Psychogenic itch – as in the delusional state of parasitophobia

---

NEURAL PATHWAYS

The neurons responsible for the sensation of itch are a subset of the large population of polymodal C-nociceptors. They are situated close to the dermal–epidermal junction and comprise about 20 percent of the C fiber population in the skin.

The sensation of itch is closely linked to that of pain and for many years it was thought that both were transmitted identically. Both are unpleasant sensory experiences, however, pain sensation results in a reflex withdrawal whereas itch results in a scratch reflex. It is also now known that although the C fibers that are associated with itch are anatomically identical to those that mediate pain, there are some important functional differences. The C fibers responsible for itch are insensitive to mechanical stimuli and are more sensitive to histamine than those responsible for the sensation of pain.[4] Conduction along itch fibers is 50 percent slower than for those fibers transmitting pain and the receptor field is three times larger and more superficial than that associated with pain.[5]

The neural impulse passes via the C fibers to the ipsilateral dorsal root ganglia, and from here to the opposite anterolateral spinothalamic tract, on to the posterolateral

ventral thalamic nucleus and through the internal capsule to the somatosensory cortex of the post central gyrus. There is substantial coactivation of the motor areas of the brain which supports the clinical observation that itch is linked to scratching. There does not appear to be a distinct 'itch center'.[6]

The sensation of itch can originate at several points on the neural pathway. Activation of the C fibers in the skin/mucous membranes will trigger itch, and this type of pruritus is mediated by histamine and therefore generally responsive to treatment with H_1 antihistamines, although in the chronic setting this response diminishes, presumably secondary to desensitization at a central level. In addition to pruritogenic stimuli to the skin, itch can originate at any point along the afferent pathway. This may occur with neural damage locally (e.g. postherpetic neuralgia) or centrally (e.g. a space-occupying lesion).[7,8] This neuropathic itch is not usually H_1 antihistamine responsive. In addition pruritus may also be caused by accumulation of toxins (endogenous or exogenous) in the spinal cord or brain; again this type of pruritus is histamine independent. The sensation of itch can be magnified by psychological factors such as stress or anxiety, and conversely, reduced by training and distraction. It appears that the central inhibitory circuits can be altered so affecting the threshold for detecting pruritogenic stimuli.

Central and peripheral mediators

There are many substances known to be involved in the mediation of itch. Histamine is perhaps the best known of these; it is released from mast cells in response to pruritogenic stimuli and acts on the H_1 receptors of the C fibers in the skin causing the characteristic wheal and flare reaction specific to histamine-mediated pruritus. Prostaglandins E_2 and H_2 potentiate pruritus via other mediators including histamine,[9] and, in the case of prostaglandin E_2, also directly.[10] Substance P is synthesized in the cell bodies of C fibers and can directly induce itch as well as modulate the sensation. The release of substance P can be stimulated by tryptase from activated mast cells and neutrophils and this may increase itch. Other neuropeptides, vasoactive intestinal polypeptide (VIP) and calcitonin gene-related protein (CGRP) are found in the free nerve endings and have been implicated in the mediation of itch. An intradermal injection of acetylcholine causes itch in atopic subjects, but pain in nonatopic subjects,[11] which may explain why some atopic subjects experience itch when sweating.

Opioids are thought to mediate itch at several points in the pathway. Peripherally, opioids cause mast cell degranulation and histamine release, but it is at a spinal level that role of opioids appear most interesting. They modulate secondary transmission of the itch sensation by stimulating inhibitory signals to afferent neurons. Centrally opioids have been shown to trigger itch in the laboratory setting by direct action on the floor of the fourth ventricle.

Serotonin induces itch by two mechanisms: indirectly by release of histamine from dermal mast cells, and centrally via a mechanism which may involve opioid neurotransmitters. Both opioid and serotonin receptors appear to alter the central inhibitory circuits and so adjust the itch threshold.

SCRATCH

Scratch is the natural response to itch. In evolutional terms it is likely to have originated when most pruritogens were parasites or insects and served to remove the superficial layers of skin which harbor these.[12] Itch is linked to the motor response of scratching via a spinal reflex and can be inhibited by cortical centers. Scratching stimulates A fibers adjacent to those conducting itch and the A fibers in turn synapse with inhibitory interneurons subsequently causing inhibition of C fibers and a reduced sensation of itch. Scratching provides relief for several minutes; it has been postulated that this occurs due to temporary disruption of the circuits in the relay synapses of the spinal cord which otherwise reinforce the itch sensation.

COMPLICATIONS OF PRURITUS

The commonest complication is excoriation, which can result in secondary infection. The effects of lack of sleep, social unacceptability, and interference with daily functioning should not be overlooked. One study found depressive symptoms in one third of patients with generalized pruritus.[13] The power of suggestion can result in itch and learned behavior can quickly develop. The resultant itch–scratch cycle can be hard to break.

ASSESSMENT OF THE PRURITIC PATIENT

Routine assessment involves careful history and examination, particularly noting whether the itch is generalized or localized, and with careful attention to drug history, exacerbating factors, and previous medical history. Examination should involve detailed description of the site and nature of any skin lesions and ideally photographic records. General first-line investigations may include full blood picture, erythrocyte sedimentation rate (ESR), and renal and liver profiles if clinically indicated. Biopsy of any suspicious lesions should be discussed with a dermatologist or dermooncologist prior to proceeding.

MEASURING ITCH

The subjective nature of this symptom makes it notoriously difficult to quantify, although a number of researchers have designed tools for this purpose but none have been very

successful.[14] More recently two validated questionnaires have been developed that attempt to assess the qualitative, temporal, and spatial characteristics of itch, based on the long and short forms of the McGill Pain Questionnaire which show more promise.[6] Also monitoring systems have been developed that provide quantitative data independent of hand/arm movement and these provide the most reliable assessment method to date.[15]

CAUSES OF PRURITUS IN ADVANCED DISEASE

Table 78.1 summarizes the causes of pruritus that may be relevant in patients with advanced disease. These can be divided into general causes of pruritus and those specifically related to disease (e.g. malignancy, human immunodeficiency virus [HIV]) and in either case pruritus may be localized or generalized.

Senile itch is experienced by 50–70 percent of those over the age of 70 years. The majority have xerosis and skin atrophy, in others the cause is unknown. It is best treated with general measures (see below) and the application of emollient cream. Pruritus can be iatrogenic and the following drugs are commonly culprits: opioids, aspirin, etretinate, amfetamines, and drugs that can cause cholestasis such as erythromycin, hormonal treatment, and phenothiazines.

Iron deficiency with or without anemia can cause pruritus[16] and responds to iron replacement. Pruritus occurs in up to 11 percent of patients with thyrotoxicosis, particularly long-term untreated Graves disease, and less commonly in hypothyroidism. The link between diabetes mellitus and pruritus is controversial.

Other common causes of pruritus are discussed in the management section.

MANAGEMENT OF PRURITUS

Removal of causative agents (e.g. drugs) and appropriate investigation and treatment of underlying disease are essential first-line measures in the treatment of pruritus. Management can be divided into general and pharmaceutical measures suitable for all causes, and pharmacological measures which are more cause specific. When considering any interventions for pruritus a strong placebo response is common.

Evidence for the use of different systemic agents in the treatment of pruritus is limited, and largely pertains to the treatment of opioid-induced pruritus, particularly following neuro-axial administration. This topic is outside the scope of this chapter but is covered well in a recently published systematic review.[17] In the context of treating pruritic patients with advanced disease there are few useful trials and the use of many agents remains historical or originates from case reports. This is not to say these agents are not helpful, just that the evidence either confirming or refuting their use is, thus far, unavailable.

Some of the main groups of drugs used to systemically treat pruritus and the evidence for their efficacy are summarized in Table 78.2, and discussed in more detail below.

Table 78.1   *Causes of pruritus*

Localized	Generalized
Dry skin (xerosis)	Primary skin diseases
Infestation, e.g. scabies	Metabolic disorders: hypothyroidism and hyperthyroidism, carcinoid
Insect bites	syndrome, diabetes mellitus and insipidus
Candida	Renal disorders: renal failure with uremia
Eczema	Liver disorders: cholestasis
Contact dermatitis	Infection: HIV, syphilis
Bullous pemphigoid	Hematological disorders: polycythemia vera, iron deficiency anemia
Dermatitis herpetiformis	Neurological disorders: cerebrovascular accident multiple sclerosis,
Urticaria	brain abscess/tumors
	Drug-induced (see text)
	Senile pruritus
	Aquagenic
	Psychogenic
Cancer-specific pruritus	
Melanomatosis	Chronic lymphocytic leukemia
Mycosis fungoides	Hodgkin and non-Hodgkin lymphoma
Carcinoma *in situ*: vulval, anal	Mycosis fungoides
Paraneoplastic syndrome: prostatic, rectal/	Cutaneous T cell lymphoma
colonic, cervical carcinomas; glioblastoma	Multiple myeloma
Metastatic infiltration of skin	Paraneoplastic syndrome: breast, colonic, lung, stomach carcinomas and others

Table 78.2 *Evidence for the systemic treatment of pruritus*

Cause	H$_1$ receptor antagonists	H$_2$ receptor antagonists	5–HT$_3$ receptor antagonists	Opioid receptor antagonists	NSAIDs	SSRIs	17–α alkyl androgen	Cholestyramine	Thalidomide	UVB	Psoralen + UVA	Capsaicin cream (localized)
Solid tumor		+			+							
Hematologic malignancy		+			+ CT			+				
Skin malignancy		+			+							
Paraneoplastic			+			+ RCT			+			
Opioid-induced			+ RCT	+								
Uremia	–	–	+ RCT – RCT	+ RXT – RCT				+	+ RXDB	+ RCT		+
Cholestasis			+ RPCDBX	+ DBPC 4 × CT			+	+			+	
Atopy	+										+	
Notalgia paresthetica												+ [18]
HIV										+	+	
Polycythemia											+	
Central lesions/ multiple sclerosis				+								

+, evidence supporting use; –, evidence against use.
More robust evidence is detailed as: CT, controlled trial; RCT, randomized controlled trial; RXT, randomized crossover trial; DBPC, double blind, placebo controlled trial; RPCDBX, randomized, placebo controlled, double blind, crossover trial; RXDB, randomized crossover, double blind trial.
SSRIs, selective serotonin reuptake inhibitors; NSAIDs, non-steroidal anti-inflammatory drugs.

General management techniques

These measures are widely accepted as essential although the evidence for their efficacy is largely anecdotal. Exacerbating factors such as heat, dehydration, anxiety and boredom should be avoided. Particular attention should be paid to measures that keep the skin well hydrated and avoid sweating. Patients should wear light clothes, use fans to maintain a passage of air, take tepid baths or shower avoiding hot water, and use emulsifying ointment or aqueous cream instead of soap. Skin hydration should be maintained with regular use of emollients. Alcohol and spicy foods may worsen itch.

Patients should be advised to gently rub the skin rather than scratching it, and to keep nails short and wear cotton gloves at night to limit the damage to the skin. Sweating may exacerbate itch; the general measures described above may help reduce sweating, otherwise an antimuscarinic agent may be required.

Exposure to ultraviolet (UV) B light may help in both cholestatic, uremic and acquired immune deficiency syndrome (AIDS)-related pruritus. Although the nontoxic nature of this treatment makes it an attractive alternative, it may not be a suitable treatment for a very sick patient. The antipruritic effect is thought to be due to a reduction in the vitamin A content of the skin, inhibition of the release of histamine, and inhibition of dermal mast cell proliferation.[19,20]

Sedatives such as benzodiazepines do not relieve itch but may help improve associated anxiety and insomnia.[21] Behavioral treatments and hypnotherapy may help ease associated psychological issues and break the cycle of itching and scratching.[22] Transcutaneous electronic nerve stimulation (TENS) and acupuncture have been successful in case reports.[23,24]

Topical agents

Topical agents generally provide some relief but may be inconvenient to apply in generalized pruritus, and are probably best reserved for localized symptoms. A number of topical agents have been suggested such as: zinc oxide, calamine, glycerin, and salicylates but their mechanisms are not understood and their effectiveness is unproved. One double blind, controlled trial of crotamiton (Eurax®) showed it to be ineffective.[25] Polidocanol bath oil has been shown to reduce itch in uremia,[26] and 3 percent polidocanol/5 percent urea cream has been shown to reduce itch in psoriasis.[27]

Corticosteroid creams may help localized areas of inflamed skin. Local anesthetic creams can be helpful but may cause skin sensitization. Lidocaine is the least likely to have this effect but systemic absorption prevents its use over large areas or for prolonged periods. Topical counterirritants such as menthol 0.25–2 percent or camphor 1–3 percent may be useful.

Capsaicin 0.025 percent may be useful; it acts by depleting substance P in C fibers on repeated application, reducing pain and itch. It needs to be applied four times a day and has been shown to be helpful in uremic pruritus.[28] Application can cause an initial burning sensation which prohibits widespread application and decreases compliance; for these reasons it is best reserved for localized pruritus.

Strontium nitrate cream is an effective antipruritic, which may act by selectively blocking C-fiber transmission.[29] Doxepin, a tricyclic antidepressant with potent antihistaminic action now produced in a topical form, has been shown to be effective in atopic dermatitis and chronic urticaria. The topical form has been shown to be less effective than the systemic form;[30] its place in other causes of pruritus has not been established.

Systemic agents

Antihistamines are active at either the H_1 or H_2 receptor. H_1 receptor antagonists are often used as the first choice for any form of generalized pruritus, however there is little evidence for their use other than in urticaria or allergy. The more sedative agents such as chlorphenamine are believed to be more effective either because of a more potent central action or because the sedation itself helps to improve the insomnia caused by the itch. H_2 antihistamines such as cimetidine have been shown to be beneficial in the pruritus associated with lymphoproliferative disorders (see below). Doxepin, which acts at H_1 and H_2 receptors is effective in atopic dermatitis as discussed above.

The 5-hydroxytryptamine 3 ($5-HT_3$) receptor antagonists have shown promising results in the treatment of opioid-induced pruritus, particularly when the opioids are delivered by the neuro-axial route; early results in cholestatic and uremic pruritus showed some benefit too[31,32] but more recent randomized trials have shown minimal or no benefit.[33**,34**,35**]

The serotonin selective reuptake inhibitor (SSRI) paroxetine is helpful in paraneoplastic pruritus but the effect may only be temporary, lasting about 6 weeks,[36] and may also be associated with initial nausea and vomiting. Mirtazapine is a norepinephrine and specific serotonin antidepressant and its actions include blocking H_1, $5-HT_2$ and $5-HT_3$ receptors. It has been shown to be a helpful antipruritic agent in cholestasis, uremia, and lymphoma.[37]

Specific management strategies

CANCER–SPECIFIC PRURITUS

Pruritus is associated with hematological malignancies such as Hodgkin lymphoma and polycythemia rubra vera. Pruritus occurs in about 50 percent of patients with polycythemia and is commonly aquagenic pruritus; in almost 100 percent of patients with cutaneous T cell lymphoma; and in 30 percent of patients with Hodgkin disease and is more common in the nodular sclerosing subtype with mediastinal mass.[38] Its presence may precede overt disease

by up to 5 years.[39] In pruritus secondary to polycythemia vera the use of disease-modifying therapy often reduces pruritus and should be considered first,[40] aspirin, paroxetine, and cimetidine have been shown to be helpful.[41**,42,43]

In Hodgkin disease cimetidine[44] and topical 5 percent sodium cromoglycate[45] have been reported as helpful. Corticosteroids have been used historically and are felt to be effective but evidence is lacking. Although cimetidine is an H_2 receptor antagonist, its action is not thought to be a direct antihistaminic effect as it has little effect on itching caused by histamine, but is thought to be related to its inhibitory action on CYP2D6 liver enzymes which are involved in the synthesis of endogenous opioids and possibly other pruritogens.[46] See Figure 78.1 for a suggested approach to treatment.

Mycosis fungoides often presents in the early stages with pruritic dermatitis that may precede cutaneous lesions by up to 10 years.[48] Tumor-modifying treatments are effective in reducing pruritus and mycosis fungoides cells are very radiosensitive. Ciclosporin is also effective but long-term effects of treatment are currently unevaluated.[49]

Tumors of the anus and vulva can present with local itch. Pruritus can also present as part of a paraneoplastic syndrome in association with some solid tumors including lung, colon, breast, stomach, and prostate. In these cases it is usually generalized rather than localized with a few notable exceptions:

gliomas and carcinomas of the cervix, rectum, sigmoid colon, and prostate, which may manifest with pruritus of the face, nostrils, vulvae, anus, and scrotum, respectively. It may be the presenting symptom in these diseases, and, as for Hodgkin disease may appear some years before the tumor is identifiable. However research has shown that patients with generalized pruritus followed-up for 6 years did not have a higher overall incidence of malignancy and that follow-up screening was therefore not warranted in this group of patients.[50]

Paroxetine, an SSRI antidepressant has been shown to relieve itch in a case series of advanced cancer patients with paraneoplastic itch and in a randomized controlled trial for severe nondermatological pruritus, probably due to down regulation of 5-HT_3 receptors, but side effects (nausea, vomiting and sedation) may limit its use.[36**,51**] See Figure 78.2 for a suggested approach to management.

OPIOID–INDUCED PRURITUS

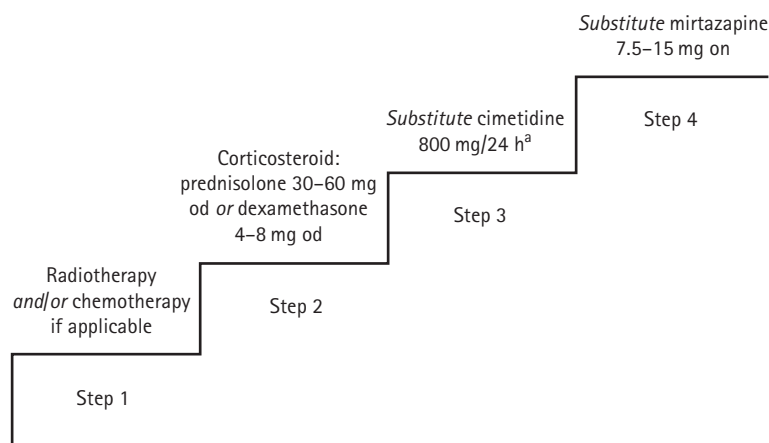
Opioids provide good pain control for the majority of patients, and are used frequently in advanced disease in accordance with the World Health Organization (WHO) analgesic ladder guidelines. Itch is a well-recognized side effect of opioids although the exact etiology is currently unknown. Pruritus occurs in about 1 percent of patients on opioids delivered subcutaneously, orally or intravenously, and up to 90 percent of


Figure 78.1 *Treatment of pruritus in Hodgkin lymphoma. [a]Alternative H_2 receptor antagonists probably equally effective. od, once daily; on, every night . Redrawn with permission from Twycross and Zylicz.* Prog Palliat Care *2002; 10: 285–9[47] with permission.*

patients receiving neuro-axial opioids. Experience suggests that pruritus tends to be generalized in patients on nonspinal opioids, although in children it is more common in the facial area, particularly the nose. In neuro-axial delivery, the pruritus spreads upwards from the level of injection, is commonly maximal in the face, and may be limited to the nose.[52] Postulated mechanisms include a direct central effect,[53] and related histamine release[54] and more recently serotonin release.[55] There is some evidence that itch is more common with the naturally occurring opioids and is also related to the route of administration, being commoner with neuro-axial opioids than oral opioids. Previous researchers have reported itch with epidural morphine,[56] intravenous and oral morphine,[57] and epidural fentanyl,[58] and oral oxycodone.[59]

In the treatment of opioid-induced pruritus opioid antagonists are useful in reducing pruritus but may reverse the analgesic effects,[60] making them an unhelpful choice of treatment for most patients with advanced disease. One study suggests that using an agonist-antagonist drug such as nalbuphine can reduce pruritus without compromising its analgesic effect.[61] One disadvantage of opioid antagonists is that they are generally expensive. Opioid rotation, in particular changing to hydromorphone, may be a more practical solution and may be effective.[57]

Ondansetron has been shown to be useful in opioid-induced itch[62] at traditional antiemetic doses, although most studies pertain to its success in treating the pruritus associated with neuro-axial opioids.

CHOLESTASIS

Cholestasis may occur in the general population as a result of gallstones, drugs or intrahepatic disease, as well as obstruction from primary or secondary tumors involving the biliary tree. Pruritus is a common sequela of cholestasis, starting on the palmar and planter surfaces and becoming more generalized. Accumulation of bile salts have long been suspected as an etiological factor and although they may have a role to play the evidence for a central mechanism related to increased opioidergic tone and activation of itch centers

in the brain is gathering pace.[3] Treatment of cholestatic pruritus with the opioid antagonists naltrexone, naloxone, and nalmefene follow this body of evidence and are successful.[63**,64*,65*] It is interesting to note that opioid withdrawal effects were noted even in opioid-naïve patients with cholestatic pruritus; this may be an effect of high levels of endogenous opioids. Pain may also be a complication of using opioid antagonists for symptom control.[66] It has been suggested that these side effects may be avoided by titrating an infusion of naloxone to establish an effective dose before switching to an oral form.[67]

Treatment of cholestatic pruritus with 5-HT$_3$ antagonists was supported by early evidence but recent robust trials have found little or no benefit.[31,33**,34**] These drugs are used at traditional antiemetic doses and are relatively expensive, and constipation can be a troublesome side effect.

The most effective method of relieving pruritus secondary to cholestasis is to relieve the obstruction. This may be possible by treating the underlying disease with surgery or chemotherapy or high-dose dexamethasone but where this is not possible the treatment of choice is a biliary stent (Fig. 78.3), even in the terminally ill. Cholestyramine binds bile salts in the gut and has traditionally been used for the treatment of cholestatic pruritus, although evidence for benefit is limited to one small, open label study completed nearly 40 years ago.[68] As a result of this mechanism of action it is ineffective in complete biliary obstruction. Its use is limited because it is unpalatable and relatively large quantities must be consumed for effect, although helped by mixing with fruit juice. Charcoal has been used along the same therapeutic line, with similar success and similar consumer acceptability problems. Rifampicin is a hepatic enzyme inducer and also inhibits reuptake of bile acids by hepatocytes. It is thought to interrupt the enterohepatic circulation of bile acids and therefore reduce the impact of bile acids on the metabolic processes of the liver, and has been shown to reduce pruritus in cholestasis.[69**] However the presence of severe idiosyncratic side effects in one study may limit its use.[70]

The 17-α alkyl androgens have also been used historically with some effect.[71] The action is not fully understood, but the

17-α alkyl androgens are directly toxic to hepatocytes and may limit the capacity of the liver's enkephalin production.[72] Care should be taken when considering long-term use of 17-α alkyl androgens in patients with years to live as they have the potential to cause masculinization in women and also, occasionally serious liver impairment. Other experimental options have been explored including: propofol, S-adenosyl-methionine (SAMe), anti-oxidants, tetrahydrocannabinol, macrolide antibiotics, plasmapheresis and albumin dialysis.[73]

CHRONIC RENAL FAILURE

Renal failure may occur as a primary disorder or secondary to a cancer either as a result of direct tumor infiltration of the kidney or ureteric obstruction caused by tumor mass, metastases, or lymph nodes. It is chronic renal failure that is likely to be associated with pruritus. Pruritus may be generalized or be limited to the back and the forearm at the site of the arteriovenous shunt.[74] The pathogenesis of pruritus in this setting has not been fully defined but is thought to be multifactorial. The skin of these patients is atrophic and dry,[75] cytokine production in the skin may contribute, and interleukin-1 may cause release of pruritogens. Mast cells are more numerous in patients with pruritic uremia[76] and although plasma histamine levels have been shown to be much increased in this group of patients, antihistamines *per se* are ineffectual in improving the pruritus.[77]

Pruritus is more common in uremic patients receiving dialysis than those who are not, and a recent study supports the idea that the itch is caused by accumulation of pruritogenic metabolites rather than hypersensitivity to dialysis equipment.[78] Pruritus is reduced by the use of more permeable membranes in hemodialysis, suggesting that this facilitates clearing of pruritogens.

Pruritus is local in 70 percent of patients and for these patients capsaicin cream can be effective and practical.[28] The efficacy of opioid antagonists is under dispute: opioid antagonists have been found to be effective by some researchers,[79**] and not by others.[32**] Ondansetron has been used to treat uremic pruritus but the evidence for success is conflicting.[35**,80] There is some good evidence of thalidomide having an antipruritic effect in uremia.[81**] Postulated mechanisms for its antipruritic effect include: reduction of tumor necrosis factor synthesis by monocytes; anti-inflammatory action; and interference with cytokine production. It has also been shown to be effective in the pruritus of various primary skin conditions, senile pruritus, and primary biliary cirrhosis.[82] UVB phototherapy may also be effective.[20]

Homeopathic treatments have also been shown to be effective: in one controlled trial patients reported a 49 percent reduction in pruritus score.[83] An approach to management is suggested in Figure 78.4.

HIV/AIDS

There are many causes of pruritus in HIV-positive patients,[84] and itch can be the first symptom of disease even in the absence of apparent skin lesions. Pruritus in HIV may be related to cytokine-induced prostaglandin 2 synthesis, and increased plasma cytokine levels are not uncommon in patients with HIV.[85,86] Localized pruritus may occur with peripheral neuropathy.[6] Exposure to UVB light has been shown to be effective.[87] Treatment should relate to the specific cause, but in the absence of an obvious cause indometacin 25 mg three times daily may be helpful.[58]

CENTRAL LESIONS AND MULTIPLE SCLEROSIS

Historically pruritus in this group of patients has been treated effectively with anti-epileptic drugs such as carbamazepine. Gabapentin may be a better tolerated choice and does not interfere with other medication by inducing liver enzymes.[88] NSAIDS such as ibuprofen may also be helpful.[89]

SUMMARY

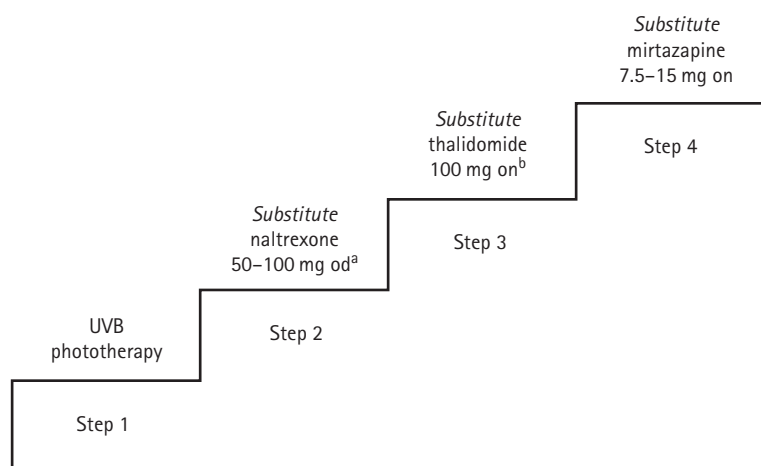
Pruritus can be a troublesome symptom in patients with advanced disease and may have a substantial effect on


Figure 78.4 *Treatment of uremic pruritus. ªBenefit disputed; contraindicated in patients needing opioids for pain relief. ᵇUndesirable effects include peripheral neuropathy and congenital malformations (shortened or absent limbs). od, once daily; on, every night. quality of life despite the apparent trivial nature of the symptom relative to a life-limiting diagnosis. Careful history and examination may reveal an easily reversible cause; where this is not the case intervention may be helpful. First and foremost, management should include patient education and life-style changes to recognize and avoid triggering factors, and to include important general measures for maximal skin hydration in daily routine. Alongside these measures investigation and treatment of the underlying cause, where possible, is helpful. Topical or systemic medication should be used appropriate to the cause when required. The relatively limited etiological understanding of pruritus has hindered logical management but there is now a more compre- hensive body of evidence slowly but surely being created. Development of further useful interventions depends on continued investigation of the complex mechanisms by which pruritus is created, and more detailed evaluation of currently available interventions.

<div style="background:#e0e0e0; padding:1em;">

Key learning points

- Pruritus may be directly related to advanced disease (e.g. cancer, multiple sclerosis), indirectly related (e.g. cholestasis, uremia), or associated with the treatment of advanced disease.

- Pruritus may significantly impact on sleep, social acceptance, and daily functioning; and has been shown to be associated with depression.

- Initial management should include patient education and lifestyle changes to encourage identification and avoidance of triggering factors.

- The use of emollients to keep the skin continually hydrated cannot be overemphasized and must continue on a long-term basis. In addition large numbers of other topical agents are available and there is a reasonable evidence base supporting their use.

- Diagnosis of the underlying cause of pruritus is important and treatment of underlying disease will in many cases resolve the pruritus.

- If topical measures and lifestyle changes are not adequate, systemic treatment may be necessary and this chapter provides some evidence-based suggestions for first, second, and third line treatments based on etiology.

- The historical use of histamine antagonists in the treatment of all pruritus has now been modified by the growing evidence base in this area, and these drugs are now only recommended for use in the treatment of urticaria, allergy, and lymphoproliferative pruritus.

Infections

PAULA S PROVINCE, RUDOLPH M NAVARI

INTRODUCTION

Patients receiving palliative care are at high risk for infections as a result of their underlying disease, poor nutritional state, and/or a direct suppression of the hematological system due to chemotherapy or radiation treatments, viral infection, or corticosteroids.[1*] An infectious complication may occur due to an alteration in the phagocytic, cellular, or humoral immunity, an alteration or breach of skin or mucosal defense barriers, indwelling catheters, or a splenectomy. A high index of suspicion, an awareness of the possibility of unusual infectious agents, consideration of the empirical institution of antimicrobials, and constant surveillance of the hematological status of the patients are necessary to provide optimal management of infections in this patient population.

In addition to the high risk of infections, patients in palliative care also experience a high incidence and a wide variety of infections.[1*,2***] Several retrospective studies have shown that a large number of patients receiving hospice or palliative care are treated with antibiotics for suspected or documented infections.[3*,4*,5*,6*] The benefits and burdens of the use of antimicrobials in this patient population are topics of much discussion.[3*,4*,6*,7***] Two prospective studies have suggested that symptom control may be the main objective in the decision to use antimicrobials to treat clinically suspected or documented infections in patients receiving palliative or hospice care.[9*,10*] The use of symptom control as the main determinant of whether to use antimicrobials in any given clinical situation is markedly affected, however, by the uncertainty of predicting which patients will achieve symptom relief and which patients will experience only the additional burdens of treatment. Determining whether fever is due to infection, tumor, or other causes, and deciding which symptoms from suspected infections might respond to various antimicrobial interventions can be difficult clinical judgments, particularly in a patient population which has multiple active medical problems and where the goal of treatment is symptom control. These are crucial issues in patients receiving palliative care in that studies have shown that incurably ill patients often receive nonpalliative interventions at the end of life.[8*]

This chapter will discuss the incidence and the type of infections seen in various palliative care clinical settings (Table 79.1) and the judicious use of antimicrobials, and will also suggest the use of symptom control as a major criterion for treatment. The chapter concludes by suggesting guidelines for the approach to infections in palliative care.

INCIDENCE AND TYPE OF INFECTIONS

Patients who are receiving palliative care or hospice care have a high frequency of infections due to the underlying disease, the use of indwelling urinary catheters and vascular access devices, as well as the generally poor functional status of the patients, characterized by impaired cognition and immobility. There have been a number of reports on the use of antimicrobials in patients receiving hospice and palliative care.[1*,3*,4*,6*,9*,10*]

Vitetta et al.[3*] performed a retrospective chart review on the prevalence of infections in 102 patients (92 percent with terminal malignant illness) who died after admission to a tertiary care inpatient palliative care unit. Thirty-seven patients were diagnosed with 42 infections. The urinary tract, respiratory tract, blood, skin and subcutaneous tissues, and eyes were the most common sites of infection. Escherichia coli was the most common organism. Of the 37 patients, 35 were treated with antibiotics and symptom improvement was noted in half

Table 79.1 *Summary of studies of infections in patients receiving palliative care*

Study (type)	Location of care (No. of patients)	Percentage of patients with infection (n/N)	Measurement of symptom control	Conclusions
Ahronheim et al.[8] (retrospective)	Teaching hospital (84)	83 (70/84) received antibiotics	Not done	Nonpalliative interventions are frequently used at the end of life. Cancer patients receive more diagnostic tests and dementia patients receive more enteral tube feeding. Many patients received systemic antibiotics (88%)
Chen et al.[5] (retrospective)	Hospice and palliative care unit (535)	68.8 (93/135) febrile 84.9 (79/93) treated with antibiotics	Significantly greater proportion of clinical improvement when patients were treated with antibiotics 3 days post-initial fever (54.4%)	Based on mean survival rate, appropriate antibiotic use may diminish fever, ultimately decreasing fever related discomfort. Reasons to withhold antibiotics include poor Karnofsky Performance Status, or poor prognosis at time of fever. From study, it is known that antibiotics may reduce fever but it is not known if antibiotics increase the quality of life
Clayton et al.[10] (prospective)	Palliative care unit (913)	4.49 (41/913) received antibiotics	43 courses of parenteral antibiotics given. In 62% (27/43), parenteral antibiotics were considered helpful. Of 'helpful' outcomes, 22 patients had documented symptomatic benefit and 5 had no documented response, but clinical signs showed improvement	In specific circumstances, particularly in urinary tract infections, there appeared to be a beneficial role for the use of parenteral antibiotics, even in the terminal phase
Fabiszewski et al.[11] (prospective)	Hospital intermediate care unit (104)	72.1 (75/104) developed fever; 172 fever episodes in 75 patients	In the antibiotic group, 64 episodes of fever were treated with antibiotics and 28 without use of antibiotics. The palliative group had 1 instance of antibiotics use	Use of antibiotics to treat fevers in Alzheimer patients is complicated by several factors (increased susceptibility to infection, poor communication, and normal fever accompaniment to disease). The use of antibiotics did not influence the outcome of patients with advanced dementia, but treatment of patients in less advanced stages may be beneficial
Homsi et al.[1] (retrospective)	Acute care palliative medicine unit (393)	29.3 (115/393)	Not done	Infections are an underrecognized but common complication in non-neutropenic palliative care patients with advanced solid tumors. Infections are associated with significant mortality, increased morbidity, and are frequently responsible for hospital admission.

Nagy-Agren and Haley[7] (evaluation of mainly retrospective studies)	Palliative care units, hospice, teaching hospitals, hem/onc units, home; 8 reports and 957 patients	Overall, rate of infection among studies was 41.6%	Considered by one study	Decision on whether or not to use antibiotics in the palliative care setting is very individualized and can be influenced by factors such as potential adverse side-effects, the need for laboratory monitoring, and the comfort and convenience of the patient. Studies show that increased education of the public and health professionals is necessary to develop more universal guidelines concerning this issue
Oneschuk et al.[6] (retrospective)	Acute care hospital, Tertiary palliative care unit, and hospice settings (150)	44 (66/150) of patients given antibiotics	Not done	There was a great deal of variability in the numbers and types of antibiotics prescribed in the different locations of care. Results also indicate the need for further investigation into this area because of the high number of patients receiving antibiotics at the time of death
Pereira et al.[4] (retrospective)	Acute palliative care unit (100)	55 (55/100); 74 total infections	Not done	The study found a high frequency of symptomatic infections in patients with advanced cancer, most often caused by respiratory and urinary tract infections. The goal of antibiotic therapy in a palliative setting should be one of symptom control rather than decreasing mortality/morbidity. Patient discomfort level should be avoided or at least minimized
Vitetta et al.[3] (retrospective)	Hospice (102)	36.3 (37/102); overall rate of infection was 41.6%	36 patients were evaluated for symptom control. Appropriate infection management resulted in enhanced palliative symptom control in 8/17 patients with urinary tract infections, 3/9 patients with respiratory tract infections, 1/5 patients with skin infections, and 1/5 patients with bacteremia	Multiple factors contribute to terminally ill patients' heightened risk of infections, especially urinary tract and respiratory infections. Results are suggestive, however, that appropriate management of such infections via antibiotic treatment will enhance palliative symptom control
White et al.[9] (prospective)	Outpatient hospice and palliative care program (255)	45.9 (117/255)	A positive symptom response was seen in 25/30 patients with urinary tract infections, 10/26 of patients with lower respiratory infections, 4/9 patients with skin infections, 4/9 patients with oral infections, and 0/3 patients with bacteremia	This study showed that symptom control may be the main indication for the use of antimicrobials in patients receiving hospice or palliative care. Antimicrobials were most effective in treating urinary tract infections. Patient survival was not affected by the use of antimicrobials

of the patients treated; 2 of 37 patients were not treated with antibiotics due to survival limited to the day of admission. Pereira et al.[4*] reported a retrospective chart review of the prevalence of infections in 100 consecutive admissions to a tertiary care palliative care unit. There were 74 infections in 55 patients. The urinary tract, respiratory tract, skin and subcutaneous tissue, blood, and mouth were the most common infection sites. E. coli, Staphylococcus aureus, and Enterococcus were the most common organisms. Twenty-one of the 74 infections were not treated, and the reasons for not using antimicrobials were documented in 10 patients: very poor general condition (n = 5), not able to take oral antimicrobials and refusal of parenteral antimicrobials (n = 3), and family refusal in (n = 2). The retrospective nature of the study did not allow for an adequate analysis of the symptom response to antibiotic therapy. Homsi et al.[1*] reported a retrospective analysis of 393 patients with advanced cancer who were admitted to an acute care palliative medicine unit over an 8-month period. A total of 115 patients had at least one positive bacteriological culture and 100 patients were evaluable. Of these, 66 patients had a urinary tract infection, 31 patients had bacteremia, and 21 patients had pneumonia. E. coli, Staphylococcus spp., Enterococcus, and Klebsiella pneumoniae were cited as the most common organisms. Symptom response was not reported in this study.

Oneschuk et al.[6*] retrospectively examined the frequency and types of antibiotics prescribed in the last week of life in three palliative care settings: acute care hospital, tertiary palliative care unit, and hospice inpatient unit. Of 50 patients in each setting, 29 (58 percent) in the acute care hospital, 26 (52 percent) in the palliative care unit, and 11 (22 percent) in the inpatient hospice unit received antibiotics in the last week of life. The types of infection, the specific organisms, and symptom response were not reported. Clayton et al.[10*] prospectively studied all patients receiving parenteral antibiotics in a palliative care unit. Of 913 consecutive admissions over a 13-month period, 41 patients received 43 courses of parenteral antibiotics. The most common sites of infection were urinary tract infections (37 percent), lower respiratory tract infection (26 percent), soft tissue/skin infections (16 percent). The predominant organisms were not reported, and the use of antibiotics was considered 'helpful' in 27 of the 43 antibiotics courses (62 percent).

White et al.[9*] studied 255 patients with advanced cancer at the time they entered a community-based outpatient hospice and palliative care program and prospectively documented the use and effectiveness of the antimicrobials employed during the palliative care period. The 117 patients had a total of 129 infections with the most common sites being urinary tract, respiratory tract, mouth/pharynx, and skin/subcutaneous tissues. The most common organisms in this patient population were E. coli, S. aureus, Enterococcus spp., and K. pneumoniae. The use of antimicrobials controlled symptoms in the majority of the urinary tract infections, but were less effective in controlling symptoms of the other sites of infection. Survival was not affected by the patients' choice of whether to use antimicrobials, the prevalence of infections, or the actual use of antimicrobials.

These studies, carried out in a wide variety of palliative care settings, have suggested that 30–55 percent of patients receiving palliative care have at least one or more infections which are considered for antimicrobial treatment. The most common clinical conditions are urinary tract infections, upper and lower respiratory tract infections, skin and subcutaneous tissues infections, and a fewer number of patients with bacteremia. The most common organisms are E. coli, Staphylococcus spp., Enterococcus, and K. pneumoniae. Most patients are treated with antimicrobials when an infection is suspected, with varying responses.

EVALUATION OF FEVER

In patients with advanced cancer, fever is common and it may or may not have an infectious etiology. It must be noted that fever may be the only manifestation of an infection in an immunocompromised patient, and there is no pattern of fever that can be used to definitively rule out an infectious etiology. Fever may also be modified by the use of specific medications such as corticosteroids or nonsteroidal anti-inflammatory agents.

Fever in patients with advanced or terminal cancer must be evaluated in terms of the underlying disease, the specific risk for a local or systemic infection, the urgency for empirical antimicrobial therapy, the presence or absence of neutropenia, and any signs or symptoms which may suggest a site of infection. Attention should be directed to the most common sites of infection such as the oral cavity, lungs, perirectal area, urinary tract, skin, and soft tissues. In most patients with fever and neutropenia the initial evaluation does not identify a site of infection.

Depending on the status of the patient at the time of the fever, an initial evaluation may include, in addition to the history and physical examination, a hematological profile, cultures of nose and throat, urine, blood, stool, and cerebrospinal fluid, and radiological evaluation of the chest and sinuses. Whether or not antimicrobials are begun at the time of the initial fever, patients should be carefully reevaluated at least every 24 hours. It must be remembered that in patients with profound and prolonged neutropenia, multiple sites of infection and multiple organisms may be present.

The approach to fever in patients receiving palliative care should be similar to that outlined above, with symptom control, accomplished through a minimum of interventions, as the primary goal. Chen et al.[5*] retrospectively studied 535 admissions to a hospice and palliative care unit and identified 93 fever episodes, of which 79 episodes were treated with antibiotics. Although the use of antibiotics appeared to decrease fever-related discomfort, it was not clear that quality of life was improved.

TREATMENT WITH ANTIMICROBIALS

Studies suggest that antimicrobials are initiated in the overwhelming majority (70–90 percent) of patients receiving palliative care when they have fever or a suspected or documented infection.[1*,5*] The response rate to antibiotics appears to be varied with symptom improvement in the majority of urinary tract infections, but symptom improvement in less than half of the patients with infections of other organ systems.[9*]

The decision making process in the use of antimicrobials in patients receiving palliative care is highly complex. In most situations, the approach should be individualized for each patient based on the desires of the patient, the control of symptoms, and quality of life issues. Issues to be considered include the potential benefit of the use of antimicrobials compared to the potential toxicities that may result from the extent of the investigation of a suspected infection, the number of diagnostic tests to be employed, and the means to be employed to treat a suspected or documented infection. It may be appropriate to treat a fever with an antipyretic alone in a patient whose death is imminent rather than proceed with an extensive laboratory workup and the initiation of antimicrobials. Alternatively, the pain resulting from a symptomatic, localized skin or soft tissue infection may be treated more successfully with both antibiotics and pain medications. For patients receiving hospice care at home or in an institution such as a hospital palliative care unit or a chronic care facility, consideration should be given to initiating oral or parenteral antibiotics based on only clinical indications without the use of laboratory or imaging criteria. Mobilization of the patients for diagnostic interventions may be associated with significant discomfort.

Table 79.2 suggests an approach to the management of common infections in patients receiving palliative care.

Patients with uncomplicated cystitis can be effectively and inexpensively treated with a 3-day course of oral trimethoprim-sulfamethoxazole or a fluoroquinolone. Acute uncomplicated pyelonephritis can often be managed with a 7-day course of an oral fluoroquinolone.[12] For community-acquired bacterial pneumonia, an oral macrolide (erythromycin, azithromycin, or clarithromycin), doxycycline, or a fluoroquinolone with good anti-pneumococcal activity (levofloxacin, gatifloxacin, or moxifloxacin) is recommended.[12,13] For patients who require parenteral antibiotics, cefotaxime or ceftriaxone may be reasonable first choices. An antipneumococcal fluoroquinolone may be added to cover *Legionella*, *Mycoplasma*, and *Chlamydia*. These agents would not require monitoring of blood levels.[12,13]

Issues that patients, families, and physicians consider when making decisions concerning the use of a respirator, cardiac resuscitation, dialysis, etc. should, in general, also apply to the use of antimicrobials. Antimicrobial use in patients receiving palliative care may be a part of symptomatic care, may or may not result in prolongation of life, and/or may be associated with symptom producing interventions such as laboratory testing, venous access, and direct antimicrobial toxicities. The goal of antimicrobial therapy in palliative care is symptom control, in contrast to the goal of decreased morbidity and mortality in acute medical or surgical situations.

SYMPTOM CONTROL

There has been much discussion in the literature about the use of symptom control as criterion for use of antimicrobials in patients receiving palliative care. However, there have been only a few studies which have evaluated the effects of antimicrobials on the symptoms associated with infections

Table 79.2 *Management of common infections in patients receiving palliative care*

Infection	Signs/symptoms	Antimicrobial(s)	Diagnostic[a]
Urinary tract	Dysuria, fever, frequency, pain	Oral trimethoprim-sulfamethoxazole or fluoroquinolone	Urine analysis, culture and sensitivity
Oral/upper respiratory	Fever, mucositis, odynophagia, pain	Fluconazole, nystatin	Mouth swab for culture and sensitivity, endoscopy
Lower respiratory	Cough, dyspnea, fever, sputum production	Oral macrolides (erythromycin, azithromycin, clarithromycin), doxycycline, fluorquinolone (levofloxacin, gatifloxacin, moxifloxacin), or parenterals (cefotaxime, ceftriaxone)	Sputum culture and sensitivity, chest X-ray, bronchoscopy
Skin/subcutaneous	Fever, pain, skin rash/discoloration	Cephalexin	Skin culture and sensitivity, blood cultures
Bacteremia	Fever, disorientation, dyspnea, hypotension, tachycardia	Cefotaxime or ceftriaxone	Blood cultures

[a] The decision to use any diagnostic intervention should be evaluated in terms of potential benefit to the patient in symptom control versus the potential toxicities of the diagnostic interventions.

in patients with advanced cancer. Bruera[14] reported a marked improvement in pain with the use of antimicrobials for seven patients with infected, ulcerated head and neck neoplasms. Green et al.[15] described improved symptom control with the use of antibiotics in two patients with advanced cancer. One patient had severe respiratory distress from pneumonia and one patient had sepsis-induced delirium.

In a retrospective study of 102 patients admitted to a tertiary care palliative care unit, Vitetta et al.[3*] reported on antibiotic-induced symptom control in 36 patients. Antibiotic-associated positive symptom response was seen in 8 of 17 patients with urinary tract infections, 3 of 9 patients with respiratory tract infections, 1 of 5 patients with subcutaneous skin infections, and 1 of 5 patients with bacteremia. Clayton et al.[10*] reported that the use of parenteral antibiotics was 'helpful' (overall condition improved or symptoms and/or signs of infection improved) in 27 of 43 infections in 41 patients in an inpatient palliative care unit. Antibiotic response was seen in 14 of 16 patients with urinary tract infections, 6 of 11 patients with lower respiratory tract infections, 2 of 2 patients with purulent terminal respiratory secretions, 5 of 7 patients with soft tissue/wound infections, and none of 7 patients with other suspected infections. The types of infections and the response rates followed a similar pattern to that found in Vitetta et al.'s[3*] study, with a somewhat higher response rate possibly due to the use of parenteral rather than oral antibiotics. In a prospective study by White et al.[9*] of antibiotic choices by patients with advanced cancer receiving outpatient hospice care, antibiotic associated positive symptom response was seen in 25 of 30 patients with urinary tract infections, 10 of 26 patients with respiratory tract infections, 4 of 9 patients with mouth/pharyngeal infections, 4 of 9 patients with subcutaneous skin infections, and none of 3 patients with bacteremia.

The types of infections and the responses recorded appear similar in the above studies, despite major differences in the types of palliative care settings. In these studies, it appeared that the majority of the organisms cultured were sensitive to the antimicrobials used, suggesting that the lack of symptom response in some patients may have been due to comorbid condition such as an immunocompromised state, malnutrition, the failure of host barriers, decreased level of consciousness or immobility, or the presence of a neoplasm in the symptomatic organ. Regardless of the reason for the lack of symptom response, it is essential that treating clinicians be aware of the limitations of the use of antimicrobials in palliative care.

PATIENT SURVIVAL

Although symptomatic care, and not survival, is the main issue in palliative and hospice care, survival may be an issue for some patients, families, and healthcare professionals. Survival was not affected by the patients' choice of whether to use antimicrobials, the prevalence of infections, or the actual use of antimicrobials in the recent study by White et al.[9*] Also, antimicrobial use did not affect survival in patients severely affected with Alzheimer disease who were treated for fever.[11*] Vitetta et al.[3*] and Chen et al.,[5*] however, showed that terminally ill hospice patients with documented infections treated with antibiotics had a longer median survival. The proposed explanation for the increased survival was that the probability of infection increases with the duration of survival rather than an increased survival due to the use of antimicrobials.

The effect of the use of antimicrobials on survival is important information for patients entering hospice care. This information might strongly influence their choice of whether to receive antimicrobials.

GUIDELINES FOR ANTIBIOTIC USE

Based on the data generated in the current and previous studies, we suggest the following guidelines in patients with advanced cancer receiving hospice care:

- On entry into hospice care, discussions should be held with the patient and family on their wishes in the treatment of infections, just as is done with cardiopulmonary resuscitation, use of a respirator, blood transfusions, etc.
- Strong consideration should be given to symptom control as the major indication for the use of antimicrobials for the treatment of infections. In a previous study,[9*] the majority of patients chose either no antimicrobials or symptomatic use only.
- One recent prospective study[9*] and two other studies in the literature[10*,3*] suggest that antimicrobial treatment of urinary tract infections improve symptoms in a large majority of patients, but antimicrobial treatment of respiratory tract infections, mucositis, and skin infections is much less successful in symptom control. Sepsis/bacteremia is very poorly controlled by antimicrobials in this patient population
- Overall survival appears to be unaffected by antimicrobial use.
- Patients and families should be informed of the effects of antimicrobials on symptom control of various infections and on survival.
- Each patient's specific situation and condition must be evaluated in the decision to employ antimicrobials for a suspected or documented infection.

Key learning points

- Patients in palliative care settings experience a high incidence of infections.
- The most common sites of infection in patients receiving palliative care are the urinary tract, respiratory tract, skin

and subcutaneous tissues, mouth and blood. The most common pathogens are *E. coli*, *Staphylococcus* spp., *Enterococcus*, and *K. pneumoniae*.

● Although the use of antimicrobials improves symptoms in the majority of patients with urinary tract infections, symptom control is less successful with antimicrobial use in infections of the respiratory tract, mouth/pharynx, skin/subcutaneous tissue, or blood.

● Physicians should be aware of the limitations of the use of antimicrobials in patients receiving palliative care

● Strong consideration should be given to the use of symptom control as the major indication for the use of antimicrobials for the treatment of infections.

● Antimicrobial use has not been shown to affect patients' survival and this information is very valuable to physicians, patients, and caregivers when making decisions about the use of antimicrobials.

● Each patient's specific situation and condition in the palliative care setting must be evaluated in the decision to employ antimicrobials for a suspected or documented infection.

Pressure ulcers/wounds

KATHRYN G FROILAND

INTRODUCTION

Skin is an essential organ for physical protection from environmental trauma and for emotional wellbeing. It functions as a protective barrier providing immunity, thermo-regulation, sensation, and synthesis of vitamin D. It performs individual identification and communication roles. Impairment of any of these functions can result in loss of integrity of the skin, which can lead to life-threatening consequences. Age, nutritional status, hydration status, prior sun exposure, current medications, and even the soap used for bathing, can affect normal skin function and its ability to heal as breakdown occurs.

Skin breakdown in a patient with cancer can be especially difficult to prevent and treat effectively. Prevention of skin breakdown is essential at all phases of cancer management. The challenges include: immunosuppression, infection, edema, prior irradiation of tissue, malnutrition, dehydration, neuropathy, incontinence, and several comorbid conditions (e.g. diabetes mellitus, peripheral vascular disease, auto-immune disorders). These challenges can compromise the ability to heal and may actually prevent healing from occurring. Management of all of these factors must be optimized to progressively heal areas of skin breakdown. Healing often reflects progress in gaining control of the primary cancer disease process. As the cancer becomes resistant to treatment, the potential for skin breakdown increases, and wounds become more difficult to heal.

PATHOPHYSIOLOGY

Pressure ulcers are localized areas of tissue necrosis that develop when soft tissue is compressed between a bony prominence and an external surface for a prolonged period of time.[1***] The coccyx, sacrum, and heel are most vulnerable, as less soft tissue is present between the bone and skin in these areas than in other areas of the body. Sixty percent of these ulcers develop in the area of the pelvis.[2*] However, they may develop in conjunction with any improperly fitting assistive device. The risk of pressure ulcer formation increases for those who experience atrophy of subcutaneous and muscle tissue layers. Pressure ulcers can be classified in stages that identify tissue layers.

Stage 1: An observable, pressure-related alteration of intact skin whose indicators, compared with the adjacent or opposite area on the body, may include changes in one or more of the following: skin temperature (warmth or coolness), tissue consistency (firm or boggy feeling), and sensation (pain, itching). The ulcer appears as a defined area of persistent redness in lightly pigmented skin, whereas in darker skin tones the ulcer may appear with persistent red, blue, or purple hues. It appears as nonblanchable erythema of intact skin.
Stage 2: Partial-thickness skin loss involving epidermis, dermis, or both. The ulcer is superficial and presents clinically as an abrasion, blister, or shallow crater.
Stage 3: Full-thickness skin loss involving damage or necrosis of subcutaneous tissue, which may extend down to, but not through, underlying fascia. The ulcer presents clinically as a deep crater with or without undermining of adjacent tissue.
Stage 4: Full-thickness skin loss with extensive destruction, tissue necrosis, or damage to muscle, bone, or supporting structures (e.g. tendon, joint capsule). These lesions appear as deep craters; undermining and sinus tracts are common. NB: If the wound involves necrotic tissue, staging cannot be confirmed until the wound base is visible.[1***]

Patients with cancer are at greater risk of pressure ulcer development because they often are older than the

population average and have concurrent chronic illnesses. Poorly controlled pain and fatigue may contribute to self-limited mobility during the course of the disease and its treatment. Poor nutritional status is a common finding for patients with cancer, which further impairs their ability to maintain skin integrity and their wounds to heal. The situation may be further complicated if the wound is infected or the patient is incontinent.

Friction and shear are extrinsic forces that may exacerbate the effects of pressure on the skin. Friction causes damage to the epidermal and upper dermal layers of the skin caused when two surfaces rub against each other. This may occur when a patient is dragged rather than lifted. Moisture from perspiration or incontinence adds to the force of friction. Shearing force results when friction acts synergistically with gravity. Separation of the skin from underlying structures results when gravity pulls the body downward while resistance from the surface holds the skin in place. Deeper fascia level tissue and blood vessels are primarily affected by shear.[3**]

Although a pressure ulcer can occur at any time during the cancer care continuum, a Kennedy terminal ulcer may develop as a person is dying. These ulcers begin as stage 2 blisters, and progress rapidly to stages 3–4 pressure ulcers. They usually occur on the sacral area, are large, superficial, and then change in color from red, to yellow, and finally become black. They have been observed most often in older patients rather than in children. The ulcer tends to progress quickly and appears to be a hallmark sign of impending death within 8–24 hours, although some patients have lived up to 2 weeks following the development of the ulceration. Causation may be due to a decline in peripheral perfusion during the dying process. The skin is the largest organ of the body. As the only organ visible to the outside observer, it may reflect the gradual shutdown of function of the internal organs. The ultimate result is multisystem organ failure. Skin organ failure in the form of pressure ulceration over bony prominences occurs over a relatively short period of time and coincides with the patient's death.[4*]

ASSESSMENT AND DIAGNOSIS

Wounds do not exist in isolation. The healthcare professional must assess the patient as a whole being to determine the events leading up to the development of a pressure ulcer. This holds true in assessing patients with any type of wound including vascular wounds, diabetic foot ulcers, malignant cutaneous wounds, surgical wounds, burns, or wounds due to trauma. Information on the current status of the underlying cancer disease and its treatment to this point in time is essential. The history of the wound and its management is also necessary for classification and identification of previous unsuccessful treatment strategies. Reasons for delayed healing or progressive deterioration of

the wound may be explained by thorough evaluation of the patient's past history and physical status. Remember to position the patient comfortably and medicate if necessary prior to wound assessment and care. Wound assessment and documentation should include the following aspects:

- degree of tissue layer destruction and color
- anatomical location
- length, width, depth, and tunneling using consistent units of measure
- appearance of the wound bed and surrounding skin
- drainage and bleeding – specifying amount, color, odor
- pain or tenderness of wound and surrounding skin
- temperature of tissue.[5***]

Wound dimensions can be measured by using a sterile cotton-tipped applicator and a wound measuring guide or ruler. The thumb and forefinger are placed at the point on the applicator that corresponds to the wound's length, width, or depth. Measurements are commonly recorded in centimeters. The depth of tunneling can be measured in the same fashion. The direction of tunneling also can be described. The cotton-tipped applicator is again used to assess the wound for tunneling. The wound is compared to the face of a clock, with 12 o'clock pointing toward the head. Beginning at the 12 o'clock position progress in a clockwise direction assessing the wound. Document the direction of the existing tunnel(s) according to their corresponding positions on a clock face.[5***] Accurate measurement of the wound serves to describe and then classify the wound.

Potential for further breakdown of the surrounding skin should be assessed so as to plan preventive measures. Excessive dryness, moisture, or nonviable tissue may result in pruritus, pain, and loss of skin integrity. Assessment of the wound for the presence of foreign objects is advised, as these objects may cause infection or delayed healing.

MANAGEMENT

Prevention

A comprehensive program for prevention of the development of pressure ulcers is advised. Monetary savings in the limited use of wound dressings and treatments, specialized beds, as well as the cost of excess caregiver time, enforces the need for prevention. Any value placed on patient suffering argues for the need for a plan that is comprehensive, but easily implemented.

Risk assessment tools such as the Braden scale or Norton scale for adults, and the Braden Q scale for children, are easy to use and provide basic information useful in developing an individualized plan of care. These scales assess general physical condition, mental status, activity, mobility, incontinence, and nutritional status.[5***]

Following assessment of risk, preventative measure can be implemented. Basic, but essential measures include:

- Inspecting skin at least daily.
- Keeping skin clean and dry:
  - cleanse skin with cleansers or soaps with neutral pH to maintain skin's acid mantle
  - apply barrier ointment to protect skin from stool or urine
  - consider use of absorbent pads or containment devices for the incontinent patient.
- Preventing friction and shear injuries:
  - use lifting pads and turning sheets when transferring patients
  - apply lubricants, thin film dressings, or protectors to heels and elbows.
- Mobilizing patients if tolerable, or performing range-of-motion exercises for bed-bound patients.
- Reducing pressure on tissues:
  - turn and reposition at least every 2 hours
  - shift weight if chair-bound every 15 minutes
  - avoid positioning on trochanters
  - use supports (foam wedges, pillows, heel supports)
  - consider use of special mattresses
  - avoid massaging skin over bony prominences[6***]
  - avoid using foam or rubber rings (i.e. donuts), as they concentrate the intensity of pressure to surrounding tissues
  - avoid using sheepskin as it does not relieve pressure.[3**]
- Monitoring nutritional status:
  - assess current and usual weight
  - assess history of involuntary weight loss or gain
  - assess nutritional intake versus protein, calorie, and fluid needs
  - assess appetite
  - assess dental health
  - assess oral and gastrointestinal history; chewing or swallowing difficulty, and ability to feed him/herself
  - assess drug/nutrient interactions
  - assess for prior medical/surgical interventions affecting intake or absorption of nutrients
  - assess psychosocial factors affecting food intake.[7**]
- Assessing laboratory parameters for nutritional status. Standard measurements of protein status: albumin, transferrin, prealbumin, total lymphocyte count.

By using an assessment tool for screening, at-risk individuals can be identified early. Incorporating these measures will improve outcomes by reducing the incidence of pressure ulcers and the stress that they incur on the individual and their caregivers.

Treatment

Healing wounds caused by pressure or any other source is the ultimate goal of any treatment plan. However, healing may be unattainable if the patient's cancer disease, effects of treatment, or other medical condition cannot be controlled. Healing may be delayed while the patient is immunosuppressed, malnourished, or infected. Maintaining the wound as is and preventing further deterioration are realistic goals for a patient with aggressive end-stage disease. Palliation of the symptoms of pain, odor, itching, and managing exudate and bleeding are appropriate goals in this situation.

Prevention strategies of reducing the effects of friction, shear, and pressure must be evaluated and used to prevent further skin breakdown. The patient may become incontinent of urine and/or stool. Establishing a bowel and bladder program may be feasible if the cause can be manipulated. Gentle pH balanced skin cleansers should be used at each soiling episode. Skin barriers (e.g. creams, ointments, films), may protect and maintain intact skin. Absorbent underpads and diapers should wick moisture away from the skin rather than trapping it against the skin causing maceration. Urinary collection pouches are available for the bed-bound female. Condom catheters can be safely used for males. If urinary or fecal incontinence causes contamination or infection of the pressure ulcer, use of an indwelling device is indicated. Indwelling urinary catheters are accessible and easy to care for. Although various types of rectal catheters have been used with considerable morbidity and difficulty, a promising device has recently become available. This catheter keeps the wound clean while minimizing pressure to vulnerable bowel mucosa. It is easily inserted and can be maintained in the rectum up to 29 days. It has been tested in several acute care settings in patients with various types of wounds. Nosocomial infections have been reduced in these high-risk patients.[8*]

A critical area of need and intervention in a patient with a pressure ulcer is to correct nutritional deficiencies. Protein and calorie malnutrition results in decreased fibroblast proliferation and angiogenesis which impairs collagen synthesis and inhibits wound repair.[7***] General recommendations for calorie and protein requirements for patients with pressure ulcers are 35–49 kcal/kg of body weight per day, and 1.0–1.5 g protein/kg of body weight perday.[1***] Various dietary supplements (e.g. amino acid supplements) have been used, however, none of the available data support their use.[9*] Facilitation of weight gain with oxandrolone, an anabolic steroid, and glutamine has been studied in a small series of patients with weight loss and pressure ulcers.[10*,11*] Involving a dietician, nutritionist, and/or nutritional pharmacist in treatment planning is advisable.

Wound care management should be simplified to be comfortable for the patient and achievable for the caregiver. Management techniques must address the following aspects of care:

- manipulation of the cellular environment
- prevention or treatment of infection
- debridement of nonviable tissue

- promotion of closure of a clean wound
- protection of wound edges from the effects of excess moisture.

Topical wound care is designed to keep the wound moist, clean, warm, and protected from trauma and infection. The choice of an appropriate product(s) depends on:

- amount and character of exudate
- debridement needs
- odor control needs
- compression needs
- frequency of assessment
- ease of use by caregiver
- cost and accessibility.

Warmed saline is the preferred cleansing solution for chronic wound care. It cleans the wound gently without harming viable tissue. It can be applied via soaked gauze or by irrigating by pouring solution, using a spray bottle or piston syringe. Pressures of 34.5–55.2 kPa (5–8 psi) are adequate for cleansing, although 34.5–103.4 kPa (5–15 psi) may be necessary to remove thick exudate. Devices delivering higher pressures should be avoided as they may cause tissue damage and bleeding. Use of commercial wound cleaning products and antiseptic agents is controversial. They require significant dilution to maintain phagocytic function and white blood cell viability. Guidelines can be found online through the National Guidelines Clearinghouse (www.guidelines.gov). Saline remains acceptable as readily available, comforting, inexpensive, and harmless to the wound bed.

Odor is one of the most distressing symptoms for the patient to cope with. This concern should be addressed even when others cannot detect it. Necrotic tissue, infected tissue, or saturated dressings are sources of odor. There exist several methods of debridement to remove necrotic, devitalized tissue. Surgical or sharp debridement is the fastest method. It is invasive, may require anesthesia, and should not be done if vasculature of the cutaneous tumor places the patient at risk for excessive bleeding. Licensure regulations and institutional policies require that a trained wound care professional perform this type of debridement. Mechanical debridement involves physical force to remove debris and necrotic tissue. It cannot discriminate between viable and nonviable tissue. Although commonly used in the past, wet-to-dry dressings are not recommended as they cause pain, bleeding, and tissue damage upon removal. Enzymatic debridement uses enzymes to dissolve necrotic tissue from the wound. Topical gels and solutions are directly applied to the eschar or applied following scoring of the eschar to allow penetration into the tissue. Enzymes are categorized as collagenases, fibrinolytics, and proteolytics. Autolytic debridement is a process that creates a moist environment allowing the wound bed to rid itself of dead tissue by endogenous proteolytic enzymes and phagocytic cells present in the wound and its drainage. Creation of this environment is achieved by application of an occlusive, semiocclusive, or moisture interactive dressing and/or an autolytic debriding gel directly applied to the wound surface. This process is potentially more time consuming; however, it can be effective and less traumatic than surgical, sharp, or mechanical methods. Biological debridement (larvae therapy) has resurfaced as a method useful in digesting necrotic tissue and pathogens. Consideration of this method may be appropriate when surgical debridement is not an option.[12***] It is recommended that dry, stable, black eschar on heels should not be debrided if the heel is nontender, nonfluctuant, nonerythematous, and nonsuppurative.[1***]

Chronic wounds are contaminated with surface aerobic pathogens. Wounds may become infected (greater than 10^5 colony-forming units of bacteria) by bacteria that may/may not be normal flora. Odor is associated with anaerobic infection. If infection is suspected, a quantitative culture can be obtained by tissue biopsy or swab culture technique. Use of topical antibiotics is controversial and not supported by clinical research.[7**] Systemic antibiotics are warranted if the patient has bacteremia, sepsis, advancing cellulitis, or osteomyelitis.[1***]

Adjunctive therapies in wound management have become available in recent years. Several of these therapies are listed below:

- Growth factors
- Electrical stimulation
- Ultrasound
- Electromagnetic therapy
- Noncontact normothermic wound therapy or radiant heat dressing
- Vacuum-assisted wound closure therapy
- Hyperbaric oxygen therapy[7***]

Surgical closure of stage 3 and stage 4 pressure ulcers may be appropriate if the wound does not respond to conservative therapy.

The shape of the wound and volume of exudate must be matched to the dressing chosen for containment. Changing dressings more than twice a day can be burdensome for the caregiver. Alginate, hydrofiber, or foam dressings absorb higher volumes of drainage than hydrocolloids or gauze. Collection of very heavily exudative wound drainage may be accomplished by using a drainable ostomy or wound collection device. These plastic odor-controlling pouches are available in many sizes, have a protective barrier applied to intact surrounding skin, and require changing as infrequently as once a week. Pouches are drained as needed and are less bulky than dressings. Mobility may be facilitated with the use of these products. Charcoal-containing dressings can be used to filter odorous exudate. Silver ion-containing dressings and powders may also be useful in managing odorous and potentially infected wounds. Thousands of wound care products are commercially available. Consultation with a certified wound care specialist is advised for continuity and cost-effective wound care management.

The feasibility of any wound treatment plan must be evaluated. Consideration of the wound's healing potential, accessibility of therapy, cost, and the patient's wishes must be realistically addressed. Management of pain caused by the wound, the removal and application of dressings, and distress caused by seeing the wound must also be acknowledged and resolved. Educating patients and their caregivers in the cause of the wound, its treatment, and in ways to minimize progression must be included in any wound management plan.

Care of a patient with any wound takes time for thorough assessment and ongoing management. Periodic assessment of the wound is necessary, as its characteristics may evolve or the condition and desires of the patient may change. Management goals and treatment plans require review and alteration over time. Patients may present with more than one wound, or more than one type of wound, adding to the complexity of management. Emotional and social issues, pain control, and management of other symptoms of the disease process are challenges that the interdisciplinary palliative care team must address. Of utmost importance, the patients and their families or caregivers need our encouragement, praise, and guidance throughout the course of caring for the wound.

Key learning points

Managing patients with pressure ulcers in the palliative care setting involves:

- Recognizing the multiple functions of the skin.

- Identifying impediments to healing in the patient with cancer.

- Identifying patients at risk for developing pressure ulcers.

- Implementing preventative measures for patients at risk.

- Assessing the wound is just as important as assessing patients and their cancer disease.

- Setting realistic treatment goals based on wound characteristics and the patient's healing potential.

Mouth care

FLAVIO FUSCO

INTRODUCTION

In the palliative care patient, the oral cavity represents the true 'target organ'. The mouth plays a fundamental role in a many aspects of life: nutrition, hydration, phonation, speech articulation processes, relational and communication activities, and emotional, affective and sexual relations.[1] Several studies have shown that oral complications and abnormalities of the oral microflora can be found in significant numbers of terminally ill cancer patients, affecting their quality of life. Sixteen of 99 consecutive patients with advanced cancer, followed in a palliative care program, reported experiencing mouth pain at a mean (SD) intensity of 5.5 ± 2.21 on a 0 (no pain) to 10 (worst possible pain) numerical scale, and 88 patients reported dry mouth at a mean intensity of 6.2 ± 2.21.[2*]

Sweeney and Bagg[3*] studied the prevalence of oral signs and symptoms among a group of 70 terminally ill cancer patients: 68 patients (97 percent) complained of oral dryness during the day and 59 patients (84 percent) complained of oral dryness at night. Oral soreness was reported by 22 patients (31 percent). Forty-six patients (66 percent) had difficulty talking and 36 (51 percent) reported difficulty eating. Oral mucosal abnormalities were detected in 45 patients (65 percent), most commonly erythema (20 percent), coated tongue (20 percent), atrophic glossitis (17 percent), angular cheilitis (11 percent) and pseudomembranous candidiasis (9 percent).

This chapter describes the major and more frequent oral problems experienced by patients with advanced cancer followed in palliative care programs. Aspects of their management will also be discussed.

INFECTIONS

Fungal and viral infections frequently develop in patients with advanced cancer.

Fungal infections

The most common oral infection is oral candidiasis: high levels of *Candida* have been reported among terminally ill patients, with correspondingly high levels of mucosal disease.[4] Debilitated patients, such as those receiving antibiotics, steroids, cytotoxic therapies, are particularly susceptible to oral candidiasis. Other general factors, such as diabetes mellitus, or predisposing local factors (e.g. poor denture hygiene, presence of xerostomia) are also important in the pathogenesis of oral candidiasis.

There are more than 150 species of *Candida* but only 10–15 of them are regarded as important pathogens for humans. *Candida albicans* is one of these candidal species, which is found in the oral cavity and responsible for most oral candidal infections.

The *pseudomembranous form* (thrush) is a classic clinical feature, characterized by creamy white, curdlike patches on the tongue and other oral mucosal surfaces. The patches can be removed by scraping and leave a raw, bleeding, and painful surface. Besides the classic lesion, other manifestations include:

- *Acute atrophic candidiasis* or 'antibiotic-related stomatitis'. This is a nonspecific atrophy of the tongue, associated with burning sensation, dysphagia, and mouth pain.

- *Chronic atrophic candidiasis* (erythematous candidiasis) or 'denture sore mouth'. This is a chronic inflammatory reaction with epithelial thinning under the dental plates.
- *Angular cheilitis.* This is an inflammatory reaction at the corners of the mouth (not due exclusively to *Candida* but to mixed infection with *Staphylococcus aureus* or, less frequently, β-hemolytic streptococci.
- Candida *leukoplakia* (hyperplasic candidiasis). In this the lesions are firm, adherent plaques involving the cheek, lips, and tongue.

The diagnosis can be made by the clinical appearance of the lesion, by scraping (using either a potassium hydroxide smear or a Gram stain to show masses of hyphae, pseudo-hyphae, and yeast forms). Other simple methods are swabs, imprint cultures, or culture of oral rinses.

TREATMENT OF ORAL FUNGAL INFECTIONS

Specific antifungal treatment may be provided either topically and systemically. Nystatin in the form of suspension (100 000 units/mL, 1–5 L), pastilles, or tablets (100 000 units) is a traditional local treatment. Duration of treatment is usually 10–14 days but some patients need to continue the treatment for at least 2 weeks after clinical resolution. Miconazole gel is useful for the management of angular cheilitis; it has weak activity against Gram-positive cocci as well as yeasts.[5] In a randomized, double-blind trial, a 50 g clotrimazole troche was found to be effective and safe in the treatment of oropharyngeal candidiasis.[6**] Ketoconazole is available in a number of oral and topical forms. The slow therapeutic response, variable absorption, and frequent adverse effects (anorexia, nausea, vomiting, liver toxicity) make it a poor choice in patients with advanced cancer. Fluconazole is a triazole with established therapeutic efficacy in candidal infections. It is both an oral and a parenteral fungistatic agent that inhibits ergosterol synthesis in yeasts. Fluconazole 50–100 mg once daily is one of the most effective treatments for oropharyngeal candidiasis; daily doses of 100–200 mg are recommended for esophageal candidiasis. Extensive clinical studies have demonstrated fluconazole's remarkable efficacy, favorable pharmacokinetics, and reassuring safety profile, all of which have contributed to its widespread use.[7,8**] Itraconazole, structurally similar to ketoconazole, has a broader spectrum of action and it is available in parenteral and oral formulations. To achieve the highest plasma concentration, the tablet is given with food and acidic drinks, whereas the solution is taken in the fasted state.

The most common triazole-related adverse effects are dose-related nausea, abdominal discomfort and diarrhea, but these symptoms rarely necessitate stopping therapy.[9] Ketoconazole and itraconazole may seriously interact with some of the substrates of CYP3A4. In a double-blind, randomized, three-phase crossover study, Varhe *et al.*[10**] reported that ketoconazole and itraconazole seriously affect the pharmacokinetics of triazolam and increase the intensity and duration of its effects, with potentially hazardous consequences. Azoles have also been implicated in fatal interactions with antihistamines (polymorphic ventricular tachycardia). Caution should be used when fluconazole and methadone are administrated concurrently.[11**,12]

Several recent studies have showed an emerging high prevalence of non-*C. albicans* yeasts and azole resistance in the oral flora of patients with advanced cancer. Bagg *et al.*[13*] examined the oral mycological flora of 207 patients receiving palliative care. A total of 194 yeasts were isolated, of which 95 (49 percent) were *C. albicans*. There was a high prevalence of *C. glabrata* (47 isolates) of which 34 (72 percent) were resistant to both fluconazole and itraconazole. Other non-*C. albicans* species, such as *C. parapsilosis*, *C. krusei*, and, more recently, *C. dubliniensis* are less susceptible than *C. albicans* to fluconazole.[14]

Viral infections

Herpes simplex virus 1 (HSV-1) is the commonest cause of viral infection of the oral mucosa. Herpes viruses are characterized by their ability to establish and maintain latent infections, which can get reactivated. Several stimuli, such as radiotherapy or chemotherapy, can trigger the reactivation of herpes viruses.

Small vesicles usually appear on the pharyngeal and oral mucosa; these rapidly ulcerate and increase in number, often involving the soft palate, buccal mucosa, tongue, and floor of the mouth. Anorexia, fever, mouth pain, and dysphagia may be present. The disease generally runs its course over 10–14 days.

TREATMENT OF ORAL VIRAL INFECTIONS

Aciclovir triphosphate is available as a topical 5 percent ointment, and as intravenous and oral formulations. In the immunocompromised patient, aciclovir is useful for both treatment and suppression of recurrent mucocutaneous HSV lesions.[15**] Penciclovir, a novel acyclic nucleoside analog, has shown efficacy against HSV types 1 and 2 and seems to have a pharmacological advantage due to a prolonged half-life of its active form in HSV-infected cells.[16,17**]

Al-Waili[18*] carried out an interesting, small, prospective, randomized trial that compared topical application of honey with aciclovir cream in patients with recurrent episodes of labial and genital herpes simplex lesions. For labial herpes, the mean duration of attacks, occurrence of crust, healing time, and pain duration were significantly lower when treated with honey when compared with aciclovir treatment ($P < 0.05$).

XEROSTOMIA

Xerostomia, defined as the subjective feeling of oral dryness, is one of the five most common symptoms affecting

patients with advanced cancer, with a reported prevalence between 30 percent and 97 percent.[1,19,20] Indeed, despite the high prevalence of this distressing symptom – which may contribute to mouth pain and oral infections – there has been relatively little research into this 'orphan topic in supportive care'.[21]

There are many general causes of xerostomia (Box 81.1), but drug therapies are probably the most important, via a number of different mechanisms: the direct effects include interference with the nerve supply to the salivary glands (e.g. antidepressants), or with the productive capacity of salivary glands (e.g. diuretics, opioids). The indirect effects include imbalance with the normal stimuli to the secretion of saliva.[22*]

The effects of xerostomia on patient's symptoms are numerous: the absence of protective effect of saliva on the oral mucosa facilitates exogenous bacterial colonization and infections, and the loss of lubrication makes swallowing and chewing difficult and painful. Another feature of xerostomia is taste alteration with a subsequent loss of appetite. The sensations of burning, soreness, and dryness may have a considerable effect on speech, with subsequent fall in mood state and relational abilities. Saliva also plays an important role in preventing loss of tooth substance by its antimicrobial, buffering, and cleansing activities; thus, dental caries and dental erosions are often seen in terminally ill patients.[3,20]

MANAGEMENT OF XEROSTOMIA

The primary management of xerostomia involves treatment of the underlying cause. Take a detailed treatment history. Discontinuation or substitution of regimens of xerostomic drugs may sometimes be possible. Patients with ill-fitting dentures can be advised to see their dentist: relining of dentures can improve their fit and function and help to lessen oral pain and dryness caused by the lack of support for dentures. Dentate patients should receive preventive or dietary advice, as well as treatment for any caries present.

The secondary management of xerostomia involves the use of salivary substitutes and stimulants. Pilocarpine is a muscarinic agonist, although it does have some effect on the β-adrenergic receptors in the salivary and sweat glands. There have been a number of double-blind, randomized controlled studies that have shown that pilocarpine is an effective treatment for radiation and drug-induced xerostomia. Davies et al.,[23**] in a multicenter, crossover study, compared a mucin-based artificial saliva with oral formulation of pilocarpine hydrochloride in 70 patients with advanced disease and xerostomia. The pilocarpine formulation was found to be more effective than artificial saliva but it was found to be associated with more side effects such as sweating, lacrimation, and dizziness. Extreme caution in the use of pilocarpine is important due to reported side effects of glaucoma, cardiac disturbances, and sweating. For this reason, other studies have explored the possibility of using other saliva stimulants. Davies[24**] carried out a prospective, open, crossover, randomized study comparing a mucin-based artificial saliva with a low-tack, sugar-free chewing gum in the management of xerostomia in 43 patients with advanced cancer. Chewing gum is a saliva stimulant. It produces an increase in salivary flow due to a combination of stimulation of chemo- and mechanoreceptors. In this study, both artificial saliva and chewing gum were effective in the management of xerostomia, but 61 percent of the patients preferred the chewing gum to the artificial saliva. The use of chewing gum may be limited by the presence of jaw and oral discomfort, headaches, and swallowing difficulties.

A variety of saliva substitutes is now commercially available. The substitutes contain different synthetic polymers as thickening agents, e.g. carboxymethylcellulose, polyacrylic acid, and xanthan gum, but conflicting results have been

---

Box 81.1 Main causes of xerostomia in patients with advanced cancer

Related to cancer itself

- Head and neck cancer
- Obstruction/compression/destruction of the salivary glands

Related to dehydration

- Anorexia, poor fluid intake
- Diarrhea, vomiting
- Hemorrhage
- Fever
- Oxygen supply

Related to treatment

- Radiotherapy
- Oral and jaw surgery
- Drug therapy: anticholinergics; antihistamines; antihypertensive/diuretics; opioid analgesics; nonsteroidal anti-inflammatory drugs (NSAIDs); corticosteroids; proton pump inhibitors

Related to concurrent disorders

- Sjögren syndrome
- Diabetes (mellitus and insipidus)
- Sarcoidosis
- Thyroid dysfunctions
- Anxiety/depression states

reported.[1,3,20,25] Recent developments – still in the experimental stage – include bioactive salivary substitutes and mouthwashes containing antimicrobial peptides to protect the oral tissues against microbial colonization and to suppress and cure mucosal and gingival inflammation.[25]

A randomized controlled trial of standard fractionated radiation with or without amifostine (200 mg/m^2) before each fraction of radiation, was conducted in 315 patients with head and neck cancer. Amifostine administration was associated with a reduced incidence of grade $\geqslant 2$ xerostomia over 2 years of follow-up ($P = 0.002$), an increase in the proportion of patients with meaningful (>0.1 g) unstimulated saliva production at 24 months ($P = 0.011$), and reduced mouth dryness scores on a patient benefit questionnaire at 24 months ($P < 0.001$).[26**]

CHEMOTHERAPY/RADIATION–INDUCED STOMATITIS

The oral mucosa is frequently damaged during chemotherapy/radiotherapy in patients with cancer, leading to a high incidence of oral and esophageal mucositis. Patients with mucositis often experience considerable pain and discomfort. The incidence of oral mucositis ranges from 15 percent to 40 percent in patients receiving stomatotoxic chemotherapy or radiotherapy and from 70 percent to 90 percent in bone marrow recipients.

Raber-Durlacher et al.[27*] reported a retrospective analysis of the incidence and the severity of chemotherapy-associated oral mucositis in 150 patients with various solid tumors. Eighty-seven episodes of mucositis occurred in 47 (31 percent) patients. Twenty-six patients each experienced only one episode, whereas 21 patients had up to eight episodes of mucositis. Multivariate analysis identified the administration of paclitaxel, doxorubicin, or etoposide as independent risk factor (adjusted rate ratios 8.06, 7.35, and 6.70, respectively), whereas low body mass was associated with a slightly increased risk (adjusted rate ratio 0.92). Other anticancer drugs, such as alkylating agents, vinca alkaloids, antimetabolites and antitumor antibiotics are especially liable to cause stomatitis, and it is important to carefully consider their use in patients with advanced cancer.[28]

Both chemotherapy and radiotherapy interfere with cellular mitosis and reduce the regenerative properties of the oral mucosa. A poor nutritional status further interferes with mucosal regeneration; oral infections can exacerbate the mucositis and may lead to systemic infections. If the patient develops both severe mucositis and thrombocytopenia, oral bleeding may occur, and this may be difficult to treat. Direct stomatotoxicity is usually seen 5–7 days after the start of chemotherapy or radiotherapy; in non-immunocompromised patients, oral lesions heal within 2–3 weeks. The most common sites include the buccal, labial and soft palate mucosa, as well as the floor of the mouth and the ventral surface of the tongue.[28]

MANAGEMENT OF CHEMOTHERAPY/ RADIATION–INDUCED STOMATITIS

Chlorhexidine, amifostine, hematological growth factors, pentoxifylline, sucralfate, glutamine, and several other agents have been investigated for prevention of oral mucositis. Results have been conflicting, inconclusive, or of limited benefit. Topical anesthetics, mixtures (also called cocktails), and mucosal-coating agents have been used despite the lack of experimental evidence supporting their efficacy. Of the current available topical products, the supporting evidence is strongest for ice chips and benzydamine in the prophylaxis of mucositis.[29*,30***] Promising investigational approaches have recently emerged: the candidate that is most advanced in terms of drug development is recombinant human keratinocyte growth factor (rHuKGF; palifermin), which in phase III clinical trials has been shown to reduce the severity and duration of oral mucositis and improve clinical outcome.[29*]

Biswal et al.[31**] carried out the first prospective, randomized trial to evaluate the effect of pure natural honey in radiation-induced mucositis. Forty patients received topical application of honey along with radiotherapy to the head and neck region or radiotherapy alone. A significant reduction in symptomatic grade 3–4 mucositis (Radiation Therapy Oncology Group [RTOG] grading system) was found in the honey group compared with the control group ($P = 0.0005$). Fifty-five percent of patients treated with topical honey showed no change or a positive gain in body weight compared with 25 percent in the control arm, the majority of whom lost weight. Recent articles have reported successful use of topical opioids, prepared with taste supplements, in treating persistent mucosal pain in palliative care patients.[32,33*]

ALTERED TASTE SENSATIONS

A reduction (hypogeusia), distortion (dysgeusia), or absence (ageusia) of normal taste sensation is common in patients with cancer, and can be the result of the disease itself and/or its treatment (drug therapy, chemotherapy, radiotherapy). Between 25 percent and 50 percent of patients with cancer are reported to experience taste changes. Typically, patients appeared to have difficulty in differentiating sour and bitter tastes, which are affected more than salty and sweet tastes. Women appeared to report greater changes in taste than men.[1,34,35] Zinc deficiency has been linked with abnormalities in taste sensation.

MANAGEMENT OF ALTERED TASTE SENSATIONS

Ripamonti et al.[36**] in a randomized, double-blind, placebo-controlled trial, described the beneficial effects of oral zinc sulfate tablets (45 mg three times a day) in 18 patients with

cancer receiving external radiotherapy to the head and neck region (ERT). One month after ERT was terminated, the patients receiving zinc sulfate had a quicker recovery of taste acuity than those receiving placebo.

Nonpharmacological treatment includes mouth care, dental hygiene improvement, and dietary advice. The urea content in the diet can be reduced by eating white meats and eggs. This masks the bitter taste of food. Food should be eaten cold or at room temperature.

ORAL LESIONS IN PATIENTS WITH HIV/AIDS

Oral candidiasis, hairy leukoplakia, Kaposi sarcoma, necrotizing ulcerative gingivitis, linear gingival erythema, necrotizing ulcerative periodontitis, and oral non-Hodgkin lymphoma are strongly associated with human immunodeficiency virus (HIV) infection and may be present in up to 80 percent of people with acquired immune deficiency syndrome (AIDS).[37] These lesions parallel the decline in number of CD4 cells and an increase in viral load. Cross-sectional studies have shown an association between low CD4 lymphocyte count with the presence of oral Kaposi sarcoma, non-Hodgkin lymphoma, and necrotizing ulcerative peridontitis.[38*]

Highly active antiretroviral therapy (HAART) with protease inhibitors (PIs) has reduced the frequency of occurrence and the severity of many oral lesions such as oral candidiasis and hairy leukoplakia. Interestingly, the prevalence of Kaposi sarcoma has not changed, and HAART may predispose to human papilloma virus infection and potentially increase the risk of later oral squamous cell carcinoma.[39*,40] Regimens based on PIs may also have adverse effects including oral problems such as paresthesia, taste disturbance, and xerostomia, and may interact with a number of drugs used in oral healthcare.[41]

MANAGEMENT OF ORAL LESIONS IN PATIENTS WITH HIV/AIDS

At the end of 2005, the great majority of HIV/AIDS-affected people are in the developing world and do not have affordable access to HAART and/or conventional antifungal therapy (clotrimazole, fluconazole, itraconazole). For this reason some less expensive and more readily available alternatives are been tested. In Malawi, gentian violet was found to be as effective as nystatin for the management of oral candidiasis; topical chlorhexidine, in a pilot study, has also shown promise in the prevention of oral candidiasis in HIV-infected children; the essential oral oil solution of *Melaleuca alternifolia* (tea tree oil) has been successfully used to treat fluconazole-refractory oropharyngeal candidiasis in AIDS patients.[37,42,43] In poor resource-limited settings, thalidomide may be a cheap palliative therapy for mucocutaneous Kaposi sarcoma in children.[37]

OSTEONECROSIS OF THE JAW: AN EMERGING PROBLEM

Osteonecrosis of the jaw has been recently shown to be associated with the use of pamidronate and zoledronic acid, two bisphosphonates that inhibit bone resorption and thus bone renewal by suppressing the recruitment and activity osteoclasts. People at risk include those with multiple myeloma and cancer metastatic to bone who are receiving intravenous bisphosphonates. The risk of developing complication appears to increase with time of use of the medication.[44***,45*]

Bamias et al.[46*] studied the incidence, characteristics, and risk factors for the development of osteonecrosis of the jaw among 252 patients with advanced cancer. The incidence increased with time to exposure from 1.5 percent among patients treated for 4–12 months to 7.7 percent in those treated for 37–48 months. The cumulative hazard was significantly higher with zoledronic acid compared with pamidronate alone or pamidronate and zoledronic acid sequentially ($P < 0.001$). In addition, some authors have reported a few cases of osteonecrosis of the jaw in patients taking oral doses of alendronate for the treatment of osteoporosis or osteopenia.[47*,48]

Comorbid factors may play a role, such as the presence of diabetes mellitus, the degree of immunosuppression, the use of other medications (chemotherapeutic agents, corticosteroids). Other drug-related risk factors include the use of antiangiogenic agents such as thalidomide and bortezomib in patients with multiple myeloma.[49] Local comorbid factors include oral health status, presence of infection, and history of radiation therapy.

A recent internet-based survey evaluated the incidence of bisphosphonate-associated osteonecrosis in 1203 patients receiving intravenous bisphosphonate therapy for the treatment of myeloma or breast cancer. This study showed that 81 percent of the patients with myeloma and 69 percent of the patients with breast cancer who developed osteonecrosis had underlying dental disease, such as infection, or had had a dental extraction, compared with 33 percent of the patients who did not develop osteonecrosis.[45*]

The most common initial complaint is the sudden presence of intraoral discomfort and roughness that may traumatize the oral soft tissues surrounding the area of necrotic bone. The classic clinical features are a growing, painful and unilateral swelling with jaw pain, and difficulty chewing and brushing teeth.[50] The mandible and maxilla, with or without oroantral fistulas, are the main areas affected by osteonecrosis.

MANAGEMENT OF OSTEONECROSIS OF THE JAWS

The treatment in patients receiving oral or intravenous bisphosphonate therapy is principally preventive in nature.[44***] Ruggiero et al.[47*] in a case series of 63 patients, reported that despite several treatment modalities, such as minor

debridement, major surgical sequestrectomies, partial or complete maxillectomies and hyperbaric oxygen therapies, no healing occurred in any of the patients treated. For this reason, preventive measures prior to the initiation of intravenous bisphosphonate therapy are of paramount importance, with the dentist and oncologist working collaboratively. Box 81.2 summarizes the potential preventive measures in osteonecrosis of the jaw. There is no scientific evidence to support discontinuation of bisphosphonate therapy to promote healing of necrotic osseous tissues in the oral cavity.[44***]

Box 81.2 Bisphosphonate–associated osteonecrosis of the jaw: preventive measures

- Clinical dental examination: comprehensive extraoral and intraoral examination; full-mouth radiographic series plus panoramic radiograph; evaluation of third molars

- Removal of abscessed and nonrestorable teeth

- Restoration of periodontal health status (pocket elimination, plaque reduction)

- Caries control, elimination of defective restorations

- Oral hygiene and self-care education

- Functional rehabilitation of salvageable dentition (endodontic therapy)

- Properly fitting dentures

- Scheduled periodic follow-up visits

Systemic antibiotic therapy to control secondary infection and pain may be beneficial and should be administered whenever active infection is present. Antibiotics that have been found useful for osteonecrosis include penicillin or amoxicillin, and in presence of penicillin-related allergy, clindamycin or erythromycin ethylsuccinate. A 0.12 percent chlorhexidine antiseptic mouthwash, or minocycline hydrochloride, can be useful for periodontal pockets.[51*,52*]

Key learning points

- Oral lesions are frequently experienced by patients with advanced cancer.

- The most common problems are xerostomia, fungal infections, treatment-related mucositis, and taste disturbances.

- Azole resistance may become a clinical problem in the treatment of oral fungal infections.

- Improving dental and oral hygiene, good fluid intake, ice chips and dietary advice are the mainstay of nonpharmacological prophylaxis and treatment of xerostomia, mucositis, and taste alterations in palliative care patients.

- Honey may be a cheaper and worldwide-available choice for treating herpes simplex lesions and radiation-induced mucositis.

- In poor resourced-limited settings, mouth care for people with AIDS is a basic clinical strategy.

- Bisphosphonate-related osteonecrosis of the jaw is an emerging and challenging problem in palliative care: prevention of the osteonecrosis is the best approach to management of this complication.

Fistulas

FABIO FULFARO, CARLA RIPAMONTI

INTRODUCTION

A fistula is an abnormal communication between two digestive organs (internal fistula) or between the skin and a hollow organ (external fistula).[1] Fistulas may be classified according to the amount of the output: low output (<200 mL/24-h period), moderate output (200–500 mL/day), and high output (>500 mL/day).[2] Fistulas may be single or multiple.[3] The most frequent causes of fistulas in oncological patients are given in Box 82.1.[4–16]

Box 82.1 Causes of fistulas in patients with cancer

Causes related to treatments

- Surgery
- Radiotherapy
- Chemotherapy
- Photodynamics
- Endoscopy
- Invasive diagnostic procedures

Causes related to cancer

- Tumoral local progression
- Locoregional relapse of the disease

Mixed causes (related to treatments and to cancer)

The development of a fistula produces various complications (Box 82.2). Sepsis is the most frequent cause of death in patients with fistulas.[17] Nutritional status as well as a condition of impaired tissue vascularity may be predisposing factors.[18,19]

Box 82.2 Frequent complications of fistulas

- Infection → sepsis
- Hydro-electrolytic losses: electrolyte imbalance, dehydration
- Malnutrition
- Skin lesions
- Hemorrhages
- Delay in oncological treatments
- Psychosocial problems

GENERAL PRINCIPLES OF TREATMENT

Prior to planning a treatment, it is important to define the objectives to be achieved. In patients with advanced cancer, treatment will be conservative, whereas for a patient with a longer survival expectancy, more invasive treatment may be performed. Box 82.3 shows the possible conservative[20–22] and nonconservative treatments.[19,23,24]

Box 82.3 General management of fistulas

Conservative treatment

- Skin care and local disinfection

- Pouching of secretions (particularly gastric and pancreatic)

- Control of odor, delicate fistula areas, use of antibiotics against anaerobic bacteria (metronidazole)

- Control of local itching and pain

- Control of infections (specific antibiotic treatment, care in the use of corticosteroids, radiotherapy, and chemotherapy)

- Control of nutrition and electrolytes (particularly in high-output fistulas) and eventual total parenteral nutrition (TPN) and antisecretory treatments (scopolamine, octreotide)

- Treatment of site-related symptoms (antiemetic, antispastic, antihemorrhagic, antisecretory, use of vasopressin for urinary incontinence, use of urinary catheters)

- Control of psychological conditions (distortion of body image, isolation, social discomfort).

Nonconservative treatment

- Surgical resection of fistula

- Surgical repair with corrective procedures or with myocutaneous flaps

- Colonic and/or urinary diversion

- Endoscopic treatments with metallic stents

GASTROINTESTINAL FISTULAS

Gastrointestinal fistulas may be classified as external (enterocutaneous fistulas) and internal (communication between hollow organs), or according to the anatomical site of onset: esophageal, gastric and duodenal, pancreatic, enteric and colonic.[18]

Esophageal fistulas

Esophageal fistulas may be classified as esophagorespiratory (particularly esophagotracheal) and esophagocardiovascular. As far as the former are concerned, most of them are due to esophageal carcinoma (75 percent) and lung cancer (16 percent).[25,26] Some rare cases due to Hodgkin disease are cited in the literature.[27] Symptoms may be dysphagia,

coughing, aspiration, suffocation, and fever. When the patient's clinical condition allows it, surgery may be performed[28] with an eventual gastrostomy and/or jejunostomy, the use of metallic stents[29,31] and/or palliative radiotherapy. Chemotherapy is indicated particularly in the presence of lymphomas. From a prognostic point of view, patients with esophagorespiratory fistulas are at high risk of developing lung abscesses, empyema, and pneumonia ab ingestis.[28]

Esophagocardiovascular fistulas are rare in patients with cancer and also include the aortoesophageal fistula, which is mainly caused by the rupture of a thoracic aneurysm into the esophagus, and the esophagocardiac fistula.[4,28]

Gastric and duodenal fistulas

More than 90 percent of gastric and duodenal fistulas are a consequence of surgery in those areas.[32] Postoperative fistulas are frequently due to an 'anastomotic leak' and abscess formation. Cancers of the transverse colon, stomach, and duodenum are more prone to fistulization. Other rare causes are lymphomas and the placing of pumps for chemotherapy infusion in the gastroduodenal artery.[10] Whereas external fistulas are easily diagnosed, internal fistulas that can cause diarrhea and nutritional deficit are less detectable.

Most postoperative gastrointestinal fistulas heal spontaneously within 4–5 weeks. Factors associated with poor healing or delayed healing include multiple fistulous tracts, malnutrition, acute infection or sepsis, decreased level of serum transferrin (unfavorable $<200\,\mathrm{mg/dL}$),[33,34] cancer progression, and previous radiotherapy in the involved areas.[17] Treatment of gastric and duodenal fistulas may be medical, endoscopic, and/or surgical. Nutritional support[35*] and treatment of infection[36*] are essential in the management of postoperative fistulas.

With regard to endoscopic treatment, some authorities have reported obliteration of the fistula tract with adhesive fibrin tissue.[37*] For patients with persistent fistulas and a good performance status, three different surgical approaches have been described: exclusion, resection, and 'closure of the leak'.[32] Exclusion of a fistula is not the treatment of choice and is reserved for very ill patients. The procedure involves resection of the diseased segment and exteriorization of the proximal and distal segments. In this way an uncontrolled anastomotic leak is converted into a controlled external fistula. The procedure of choice is the resection of the anastomotic leak with the formation of a new anastomosis. Major contraindications to this procedure are ischemia or tension on the anastomosis. If the anastomotic leak cannot be resected then closure of the leak with a serosal patch or Roux-en-Y anastomosis is the preferred surgical alternative.[32]

Pancreatic fistulas

Pancreatic fistulas are more frequently external and are usually complications of upper abdominal invasive procedures

on the pancreas or surrounding area[38] and occur in 6 percent to 25 percent of pancreaticoduodenectomies.[39] Fistulas are more frequent during the first postoperative week and associated with high levels of serum amylase. Internal fistulas, which most commonly involve the peritoneum, are rare. They are usually diagnosed by radiological examination (fistulography, computed tomography [CT] scan), ultrasonography and/or by endoscopic retrograde cholangiopancreatography (ERCP).[40]

Postoperative external fistulas heal spontaneously in 80 percent of cases with conservative treatment incorporating skin care, drainage and collection of pancreatic secretion, control of infection and parenteral nutrition (to reduce pancreatic secretion).[40] Octreotide, in doses of 50–200 μg three times daily, have been used in conservative treatment to reduce gastrointestinal secretion.[41,42] Many authors have suggested the use of subcutaneous injection of octreotide at doses of 50–200 μg three times daily according to output.[43] Recently, Barnett et al.[44] have expressed some concern about the use of octreotide in the treatment of pancreatic fistula.

Surgical approaches are reserved for situations of failure of conservative management in patients with good performance status and favorable tumor anatomy.[40] Placement of an endoscopic stent has proved effective in certain studies but a longer follow-up is necessary to evaluate possible long-term complications.[40*] Another surgical approach involves creating a subcutaneous fistulojejunostomy.[45*]

Small bowel and colonic fistulas

Intestinal fistulas are classified as internal, external, or mixed; the most common are external (enterocutaneous).[46] Most of them are a consequence of postoperative complications following surgery on gastrointestinal cancers with diastasis of the anastomotic wound and damage to the bowel and its vascularization.

The severity of the consequences of an enterocutaneous fistula depends on the site and the amount of secretion, for example, large volumes of secretion and small bowel fistulas may be associated with severe fluid and electrolyte abnormalities and malabsorption. In a series of 25 cancer patients with enterocutaneous fistulas, the most frequent site was the jejunum-ileum, and mortality was correlated to previous radiotherapy, the site, fistula output, and the presence of hypoalbuminemia. In 63 percent of patients, the presence of a fistula resulted in suspension of any ongoing anticancer treatment.[46] A rare presentation of an enterocutaneous fistula may be subcutaneous emphysema.[47]

Enterocutaneous fistulas may heal spontaneously with adequate supportive therapy including TPN, prevention, and treatment of infective complications (in 70 percent of these cases). Limited data support the use of octreotide to reduce secretion volume.[48,49**] The use of TPN allows an adequate fluid intake, normalization of electrolytes as well as catabolic blockage. Factors which negatively influence spontaneous

closure of the fistula include the presence of cancer together with sepsis, malnutrition, distal obstruction to the fistula, and the epithelialization of the fistulous tract.[50] Surgery is indicated whenever conservative treatment has not been effective and when the patient's condition allows it.[50*] Recently, a case of enterobiliary fistula following radiofrequency on the liver was reported.[51]

Colonic fistulas, although considered uncommon, can also be classified as external, internal (colocutaneous), and mixed.[52] Among the internal fistulas, the most common are colovesical, followed by colovaginal and coloenteric. The most evident sign of colocutaneous fistulas is the passage of air and feces through an incision in the abdominal wall following surgery. Other signs and symptoms are sepsis, fever, tachycardia, leukocytosis, and pain due to abscess with local peritonitis. Patients with an internal fistula complain of a variety of symptoms depending on the viscera involved. Patients with colovesical fistulas frequently have cystitis, high fever, shivering and sweating and, if the fistulous tract is wide, pneumaturia and fecaluria. Patients with colovaginal fistulas suffer from increased vaginal secretion, sometimes associated with the passage of feces. Patients with coloenteric fistulas suffer from abdominal pain and severe diarrhea.[53]

An internal colovesical fistula is diagnosed by means of cystoscopy, a colovaginal fistula is diagnosed by means of a fistulogram and/or a vaginogram, and a coloenteric fistula is diagnosed by means of an abdominal CT scan with contrast. Colocutaneous fistulas may be conservatively treated even if the rate of healing is lower than of enteric fistulas, particularly in the presence of a malignancy or a distal occlusion. Some patients may require a surgical bowel diversion. In the presence of a malignancy, a partial cystectomy together with the removal of the sigmoid colon is indicated for colovesical fistulas. Radiotherapy-induced fistulas may be complex and often involve more than one organ, for example, either the colon or the rectum with the bladder, the vagina, the small bowel and the skin. These fistulas are more difficult to treat because of the low rate of spontaneous healing and the high rate of relapse.[54*] It is possible to treat coloenteric fistulas with stents.[53*]

HEAD AND NECK FISTULAS

As regards patients with head and neck cancer, the most frequent fistulas are pharyngocutaneous; these are the most common complications resulting from total laryngectomy. It has been observed that 12–16 percent of the patients undergoing laryngectomy develop fistulas 11–14 days after surgery.[55–57] Although spontaneous closure of the fistula occurs in two-thirds of the cases, about 20 percent of patients have to undergo surgery with direct suture of pharyngeal mucosa or reparative surgery by means of a deltopectoral flap or a pectoralis major myocutaneous flap.[58,59]

Negative prognostic factors that give rise to fistulas are: hemoglobin levels lower than 12.5 g/dL, concomitant heart

pathology, extension of surgery, the surgeon's experience, tumor size, and the use of catgut.[55,60,61] Previous radiotherapy to the head and neck increases the risk of developing fistulas by 10–12 percent and the healing rate is lower.[62,63] In some groups of patients treated with radiotherapy, the percentage of fistulization increases up to 30 percent after total laryngectomy with prolonged hospitalization.[64]

Some authors have suggested using growth factors with the aim of preventing infection and sepsis.[65*] The concomitant use of oxygen therapy and radiotherapy favors neovascularization and prevents fistulas from occurring.

Another relatively frequent group of fistulas are the esophagotracheal fistulas (see Esophageal fistulas above). Rarer fistulas are the tracheocutaneous, which are often related to long-term tracheostomy, salivary fistulas,[66] oroantral fistulas,[67] and chylous fistulas.[68]

BRONCHOPLEURAL FISTULAS

Bronchopleural fistulas are often related to pneumonectomy for the treatment of lung cancer.[69,70] The incidence is about 8–10 percent.[71] Significant risk factors involved in the development of fistulas are: preoperative infection, diagnostic pneumonectomy and the presence of subcarinal metastatic lymph nodes, preoperative radiotherapy, and diabetes.

From a pathophysiological view, it is difficult to preserve bronchial arteries in the dissection of the metastatic subcarinal lymph nodes which adhere to the bronchial tree. Ligation of the bronchial arteries or the protrusion of the bronchial stump into the pleura reduces the blood flow to very low levels, thus favoring fistula development.[71] The most common signs and symptoms are: air in the pleural cavity, dyspnea, anterior chest pain.[72] The diagnosis is usually made by a bronchoscopy, even though scintigraphic techniques using xenon-133 and technetium-99m have given good results.[73] Surgery is the first choice of treatment whenever possible.[74*] In the case of fistulas smaller than 3 mm, however, successful results with reparative endoscopy have been reported.[74,75] A thorough follow-up in the first 3 months after pneumonectomy is indicated as a preventive measure.[74]

GENITOURINARY FISTULAS

The incidence of fistulas in the genitourinary tract is about 2 percent in patients with cancer. The most frequent causes are: surgery (hysterectomy, prostatectomy, rectal resections, pelvic evisceration,[76,77]), radiotherapy on the pelvic organs[78] and locoregional relapses. Signs and symptoms are characteristically urinary incontinence, pain and itching at the fistula site, pneumaturia, sometimes fecaluria, GI disorders, hemorrhage, and are often present with psychological distress.[79] For diagnostic reasons, the following are often

used: CT, nuclear magnetic resonance (NMR), cystoscopy, charcoaluria, and barium enema.[80–82]

As far as the anatomical site is concerned, the most frequent fistulas in this group of patients are: rectovaginal, enterovescical, vescicovaginal, ureterovaginal, urethrocutaneous, rectoureteral. The rarer ones are the vescicocutaneous and the vescicouterine.[83,84] The rectovaginal and enterovesical fistulas are often the consequence of radiotherapy on the pelvis, with necrosis of the vaginal and rectal walls or hysterectomies.[82,85,86]

Carcinomas of the rectum, uterine cervix, and vagina are those most at risk of fistulization due to the site of disease.[87] When the fistula is in the lower part of the rectum, fecal incontinence due to involvement of anal sphincter may be present. Surgical treatment consists of a colon or urinary ostomy.[88*] Profuse hemorrhages can be controlled by embolization.[89]

Vescicovaginal fistulas are often the outcome of hysterectomies[90] and the two orifices are 1 cm above the trigone for the bladder and in the anterior wall for the vagina. These fistulas heal with the use of a catheter from 12 to 20 days with closed drainage to prevent infection.[91]

Ureterovaginal fistulas are often the result of radical hysterectomy via laparotomy. The risk of renal damage should always be taken into consideration and the areas most at risk of fistulization are the common iliac artery, uterine artery, and sacrouterine ligament. The treatment of the fistulas in these areas involves the use of the ureteral catheter of Finney, when possible, or eventually an ureteroneocystostomy may be indicated.[92]

Urethrocutaneous fistulas more frequently involve the prostatic urethra than the bulbar urethra. These fistulas are the result of a perineal prostatectomy and there is often a concomitant prostatic abscess. The cutaneous orifice is usually central and in a pre-anal area. The urethral orifice is located above the urogenital diaphragm and may reach the bladder.[93] Urethrorectal fistulas are often associated with carcinoma of the rectum, prostate and bladder with concomitant abscess. The rectal orifice is suprasphinteric, concealed behind a mucosal fold or in the Morgagni cyst. The urethral orifice is situated in the prostatic urethra.[93]

Vescicocutaneous fistulas are rarer and are usually related to lesions of the bladder fundus on the laparotomy wound. The cutaneous orifice is suprapubic. Treatment aimed at achieving continence is important in these fistulas.[94,95*]

CONCLUSIONS

In patients with cancer fistulas are complications that need consideration due to delays that can be caused in the treatment of cancer as well as in the worsening of patients' clinical and psychological status. Prior to planning conservative treatment rather than an invasive one, it is mandatory to assess patients' chances of survival as well as their quality of

life. Considerable effort should be made by caregivers to manage all the different symptoms related to this complication in patients with cancer.

<div style="border:1px solid #000; background:#cccccc; padding:10px;">

Key learning points

- A fistula is an abnormal communication between two digestive organs (internal fistula) or between the skin and a hollow organ (external fistula).

- In oncological patients, the most frequent causes of fistulas are related to cancer and/or treatments.

- The development of a fistula produces various complications: infections, electrolyte imbalance, dehydration, malnutrition, cutaneous lesions, bleeding, delay in oncological treatments, and psychosocial problems.

- In patients with advanced cancer, treatment will be conservative, whereas for a patient with a longer survival expectancy a more invasive treatment may be undertaken.

- Conservative treatment includes: skin care and local disinfection, control of local itching and pain, control of nutrition and electrolytes, control of infections, pouching of secretions, control of psychosocial distress. Nonconservative treatments are: surgical resection of fistula, surgical repair with corrective procedures or with myocutaneous flaps, colonic and/or urinary diversion, and endoscopic treatments with metallic stents.

Lymphedema

YING GUO, BENEDICT KONZEN

INCIDENCE AND CLASSIFICATION OF LYMPHEDEMA

Lymphedema is a chronic, progressive, incurable condition, affecting at least 3 million Americans, and 140–250 million patients worldwide. Filariasis, a parasitic infestation is the most common cause. Lymphedema is an accumulation of lymphatic fluid in the interstitial tissue that causes swelling, most often in the upper or lower extremity(ies), and occasionally in face, neck, trunk, and external genitalia. Lymphedema negatively affects the activities of daily living, vocational, domestic, psychosocial, sexual lives, and quality of life of patients.[1*,2,3*,4*,5*] In addition, it puts patients at increased risk for life-threatening infections and malignancies.[6] Lymphedema is classified as primary and secondary lymphedema.

Primary lymphedema

Primary lymphedema is caused by a congenital abnormality or dysfunction in the lymphatic system and can be further classified according to age of onset. Primary lymphedema is rare, affecting 1.15 per 100 000 younger than 20 years of age.[7] The congenital form is detected at birth or in the first year of life and may either be sporadic or familial. The onset of lymphedema praecox is between the ages of 1 and 35 years. The onset of lymphedema tarda occurs after 35 years of age.

Alternatively, primary lymphedema can be classified according to the abnormality found in the lymphatics. Thus, it may be aplastic, hypoplastic, or hyperplastic. These terms suggest an abnormality in the development of the lymphatic system. Whereas this is true for congenital lymphedema, cases of later-onset primary lymphedema might be due to an acquired abnormality.

Secondary lymphedema

Secondary lymphedema is edema that occurs due to a reduction in lymph flow by an acquired cause. The causes of secondary lymphedema include trauma, recurrent infection, and malignancy and its treatment (surgery, radiation). In the developed world, the most common cause of secondary lymphedema is malignancy (including that resulting from cancer treatment). Lymphedema is common in the developing world secondary to infection with the parasitic nematode *Wucheria bancrofti* (otherwise known as filariasis), making this the most common cause of lymphedema worldwide.[8] Cancer-related lymphedema usually occurs at proximal limb segments (i.e. lymph nodes) due to infection, ligation, malignancy, scar tissue, and radiation therapy.[9] The pelvic and inguinal nodes in the lower extremities and the axillary nodes of the upper extremities are the primary sites of obstruction.

This chapter will be emphasizing on secondary lymphedema related to cancer and its treatment, which is frequently overlooked. The reported incidence of lymphedema secondary to postmastectomy radiotherapy ranges from 2.4 percent to 54 percent.[10*,11*,12–17] The incidence of lower limb lymphedema secondary to gynecological cancer has been reported to be 18 percent.[18*] Lymphedema is uncommon from cancer of the abdominal and pelvic urological organs and its treatment, because of the rich anastomotic networks and bilateral lymphatic drainage from the midline organs. In patients with penile carcinomas, lymph node metastasis is reported in up to 35 percent[19] and following treatment by groin node dissection, lymphedema developed in 50–100 percent of patients.[19,20] The incidence and prevalence of lymphedema in other urological cancers remains largely unknown.[21]

In the pre–prostatic-specific antigen era, chronic lymphedema was reported as a complication of bilateral pelvic

lymphadenectomy for prostate cancer in 15 of 82 patients (18 percent), 10 of whom had additional radiotherapy.[22] Greskovich *et al.* reported transient lymphedema in 2 of 65 patients who underwent staging lymphadenectomy prior to radiotherapy.[23]

PATHOPHYSIOLOGY

Lymphedema occurs when lymphatic fluid load exceeds the lymphatic transport capacity and an abnormal amount of protein-rich fluid collects in the tissues of the affected area. In most cases, the transport capacity is impaired, but in patients with venous insufficiency, the lymphatic load is increased. The lymphatic drainage system is separate from the general circulatory system and is the conduit for returning tissue fluids to the circulation.[24] The superficial lymphatic system begins with initial lymphatics, which are formed from one-layer endothelial cells, overlapping each other but not forming a continuous connection. Each of the cells is attached to the surrounding tissue by anchoring filaments. When there is a change in tissue pressure, caused by arterial pulsation, muscle contraction, or respiration, or when the skin is lightly stretched, the anchoring filaments pull on the cells of the initial lymphatics. Because of this, the gap between the cells opens, and fluid drains into the vessels.[25] Initial lymphatics combine to form larger vessels called precollectors and collectors, which in turn lead to the lymph nodes in the axillary and inguinal regions. The collector vessels of the lymphatic system contain smooth muscle and valves to regulate flow.[25] The regional lymph nodes drain fluid from the ipsilateral limb and torso quadrant. Deep lymph nodes for visceral drainage are located along major arteries. Major somatic drainage areas are connected via subcutaneous collateral channels, both anteriorly and posteriorly. Lymph drains from the lower limbs into the lumbar lymphatic trunk, which joins the intestinal lymphatic trunk and cisterna chyli to form the thoracic duct. Lymph returns to the blood circulation at the venous angles, which are formed by the junctures of the internal jugular and subclavian veins. Most of the lymph in the body drains via the thoracic duct, which enters the circulation at the left venous angle. Only the right upper torso, arm, face, and neck drain into circulation on the right side via the right lymphatic duct, which empties into the right subclavian vein.[24] An important function of the lymphatic system is the prevention of infection. The lymphatic system is responsible for picking up excess interstitial water and protein as well as other cells, including bacteria, which can enter the tissue through small cuts or breaks in the skin. Bacteria and other antigens are transported by the lymphatic system from the interstitium to lymphocytes in the lymph nodes, where an immune response may be initiated. Physiologically, most of the interstitial fluid generated daily (18 L) arises from the blood capillaries; 14–16 L subsequently returns directly to the venous circulation. The remaining 10–20 percent, approximately 2 L/day, passes through the lymphatic transport.

Histologically, the reparative process in the traumatized lymphatic vessels after mastectomy demonstrates fibrosis and an accompanying reduction in vessel diameter. With the subsequent ligation or interruption in lymph channels and lymphadenectomy, the body attempts a regenerative process with the formation of collateral circulation. Radiation treatment may lead to fibrosis. Non-irradiated lymph nodes develop compensatory dilated sinuses to handle lymph volume. This may be associated anatomically with lymph node hyperplasia. If the lymphatic system fails locally, protein subsequently accumulates in the interstitium. If no intervention occurs at this point, fibrosclerosis will follow along with inflammation, scarring, and loss of regional lymphatic integrity.[26]

The frequency with which lymphedema occurs after cancer therapy depends on multiple factors (Box 83.1).

Box 83.1 Factors affecting development of cancer–related lymphedema

Extent of lymphatic system damage

- Recurrence of tumor

- Lymph node dissection

- Radiation

Inherent compensatory ability of the lymphatic system

- Age

- Obesity

- Infection

- Heart failure

- Venous insufficiency

- Other factors that affect lymph load

Extent of lymphatic system damage

In a study by Kiel and Rademacher in 1996, in the absence of lymph node dissection, the incidence of edema after breast cancer treatment was 21 percent; with 11–15 nodes removed, edema was present in 27 percent; with more than 15 lymph nodes removed it was 44 percent.[27] Lymphatics have excellent regenerative capabilities. Even after radical lymph node excision for malignancy, lymphedema does not always happen. When it does occur, it is often a late complication. The reasons for this late development are uncertain, but gradual failure of distal lymphatics, which have to 'pump' lymph at a greater pressure through damaged proximal ducts, has been postulated.

The transected lymphatics will regenerate after node clearance procedures. If combined with radiotherapy, however, the risk of lymphedema is higher, as fibrous scarring reduces regrowth of ducts. In approximately 10 percent of patients with cancer, the onset of lymphedema heralds local recurrence of tumor or is the result of metastases.[26]

Inherent compensatory ability of the lymphatic system

A patient's weight and age may affect the development of lymphedema. When compared with their younger counterparts, breast cancer patients older than 55 were shown to have an increased lymphedema risk (14 percent vs. 22 percent, respectively).[27,28] Comorbidities, such as heart failure, renal insufficiency, and venous insufficiency may contribute to the onset and progression of lymphedema. Recurrent cellulitis can further compromise the fluid return. Any situation that causes an increase in lymphatic load can predispose patients to development or worsening of lymphedema. The onset of lymphedema may be provoked in a variety of common situations that occur on a daily basis: muscle fatigue resulting from overuse; vasodilatation following exposure heat; local trauma; vigorous massage; constriction or a 'tourniquet effect', which causes swelling distal to that point; or sustained dependency of the limb. Other situations that may increase lymphatic load include airplane flights and higher altitudes; these situations involve decreased atmospheric pressure and may result in increased filtration into the tissue from the blood capillaries.

COMMON COMPLICATIONS

Lymph fluid reflux

Overdistended lymph vessels cause valvular insufficiency and retrograde flow, and patients present with blister like formation on the surface of the skin, called lymphatic cysts. Lymphatic cysts are usually found in axillary, cubital, genital, and popliteal areas, and easily break open and lead to infection or fistulas. Treatment should include prevention of infection.

Musculoskeletal complications

Lymphedema can lead to musculoskeletal pain, nerve compression, and decreased range of motion. Swelling and pain can interfere with mobility and influence the affected patient's perception of themselves.[1*]

Infection

Bacterial and fungal infections are common in stage 2 and 3 (see below) lymphedema. Clinical signs and symptoms of cellulitis (erysipelas) are fever, erythema, warmth, and tenderness. Patients should be treated with either oral or intravenous antibiotics. In general, an antibiotic needs to cover the normal skin flora (i.e. Gram-positive cocci) and have good skin penetration. Intravenous antibiotics are considered when there is more significant local or systemic infection. Some patients develop chronic infections that may necessitate ongoing antibiotic therapy. Fungal infections cause skin itching, crusting, maceration between the toes, and typical fungal nail changes. Systemic or local antifungal treatment can be used. Recurrence of infection/inflammation indicates reduced local immunity.[29] It is reasonable to emphasize the importance of lymphedema limb care.[30] Decongestive lymphatic therapy is contraindicated until the infection subsides.

Hyperkeratosis

Hyperkeratosis presents as thickening of skin and wartlike papillomas. Care must be taken to avoid skin breakdown and infection.

Malignancies

Lymphangiosarcoma is a rare late complication of lymphedema,[31] also described as Stewart–Treves syndrome[32] and Milroy disease.[33] In patients with longstanding lymphedema and cellulitis that does not respond to systemic antibiotics, physicians should consider a skin biopsy. Treatment is primarily radiotherapy, with surgery reserved for patients with discrete, nonmetastatic disease.

DIAGNOSIS

History and physical examination (Box 83.2)

The history should include full medical history, all anticancer therapies, past surgeries, postoperative complications, radiation treatment, the time interval from radiation or surgery to the onset of symptoms, and intervening variables in the presence or severity of symptoms. History of trauma or infection should be determined, and information concerning current medications elicited, which may be important. Quality and behavior of edema (fluctuation with position, progression over time) and associated symptoms should be assessed. Edema is not detectable clinically until the interstitial volume exceeds 30 percent above normal. Post-mastectomy and radiation lymphedema initially presents as mild edema in the hand or forearm, often in the dorsal epicondylar region (Fig. 83.1). Other complaints related to lymphedema are heaviness or fullness related to the weight of the limb, skin feeling tight, decreased flexibility in the hand, wrist or ankle, difficulty fitting into clothing in one specific area, or ring/wristwatch/bracelet tightness.

Box 83.2 Clinical features of lymphedema

History

- Medical history (anticancer therapies, past operations, postoperative complications, radiation treatment)

- Edema (onset, fluctuation, progression)

- Associated symptoms

- Infection and trauma

- Function

- Social history

- Psychological impact

Physical examination

- Edema: skin texture, color, infection, scar; volume

- Neurological examination

- Range of motion

Associated clinical features of lower limb lymphedema include tightness of or inability to wear shoes, itching of the legs or toes, burning sensation in the legs, sleep disturbances and loss of hair. Ambulation is affected because of the limb size and weight, causing an inability to wear clothing. Impact on activities of daily living, hobbies, work, and psychological status of the patient needs to be assessed as well.

On examination, the affected limb will be swollen with enhanced skin creases, hyperkeratosis, and papillomatosis. Lymphedema is traditionally described as non-pitting, but in early cases pitting may be present. The Stemmer sign – inability to pinch the skin at the base of the second toe due to the thickened skin folds – is a useful clinical sign.[34] Cutaneous fungal or bacterial infections are not unusual in patients with lymphatic obstruction. Skin folds should be frequently inspected for ulcers and infections. A neurological examination should be conducted for possible nerve entrapment and plexus involvement, and range of motion of different joints also needs to be assessed. In established cases of lymphedema, the clinical features are diagnostic and diagnostic investigations are not required.

Skin condition and measurement of volume

The initial assessment of lymphedema and follow-up of the response to treatment should include the measurement of volume and assessment of skin condition.[35] The most commonly used assessment tool involves measuring the contralateral limb circumference at several points along the limb. However, when the disease affects both sides, this type of

Figure 83.1   *(a,b) Right upper extremity lymphedema.*

comparison may not be accurate.[36*] Multiple transverse tapes, placed at 4 cm intervals in a device, can be used to measure the circumference accurately; this is a simple and convenient method.[37] Volume can be calculated from surface measurements.[38] Truncal swelling can be measured with skinfold calipers.

Water displacement volumetry, although no longer commonly used, measures limb volume[35] and is more accurate than the calculation of leg volume from circumferential measurements with a tape measure.[35] The opto-electronic Perometer, a device designed for the measurement of limb volume, has been validated as a reliable and convenient tool for the measurement of limb volume[39] (Fig. 83.2). Bioelectrical impedance has been used successfully for the evaluation of swelling in patients with postmastectomy lymphedema[40] and lower extremity lymphedema.[41*]

Skin condition can be measured by recording deformation of tissue by a mass (tonometry) and the step compression method. In lymphedema, the tissue tonicity (degree of tissue resistance to mechanical compression) is either higher or lower compared with the nonedematous leg.[35]
Figure 83.2 *Measurement of limb volume with the Perometer.*

Measurement of tissue tonometry is more useful in assessing the response to treatment than in the initial assessment of disease.

Imaging studies

Lymphangioscintigraphy (LAS) permits high-resolution imaging of peripheral lymphatic vessels and provides insight into lymph flow dynamics. It is indispensable for patients with known or suspected lymphatic circulatory disorders in confirming the diagnosis and delineating the pathogenesis and evolution of lymphedema. In addition, LAS helps evaluate lymphatic truncal anatomy and radiotracer transport. It is also useful in preoperative evaluation, especially for microvascular anastomoses. The procedure involves intradermal injection of a radioactive tracer and does not adversely affect the lymphatic vascular endothelium. Using a combination of mobile scanners integrated with computer imaging, lymphatic vessels and nodes are visualized, and the speed of lymph node uptake and the rate of lymph transport can be measured.[42] Patients with a provisional diagnosis of peripheral lymphatic dysfunction or idiopathic edema should undergo diagnostic LAS to verify diagnostic accuracy, pinpoint the specific abnormality, and help guide subsequent therapy.[43] Conventional oil-contrast lymphography is no longer commonly used, because it is associated with complications such as allergic and inflammatory reactions, pulmonary embolism and damage to the endothelial lining of the lymphatic vessel.

Magnetic resonance imaging and computed tomography complements LAS in monitoring the progression of cancer. Ultrasonography has proved useful in the setting of filariasis and differential diagnosis of venous obstruction.

Dual X-ray absorptiometry or bi-photonic absorptiometry is useful in assessing the chemical component of limb swelling (percentage of fat, water, and lean mass).[44]

DIFFERENTIAL DIAGNOSIS

Lipedema

The clinical features of lipedema (also known as lipomatosis of the leg) include early age of onset, female exclusivity, and positive family history in some patients.[45,46] The clinical signs include elastic symmetrical enlargement of both legs with sparing of the feet.

Deep vein thrombosis and chronic venous disease

Deep vein thrombosis (DVT) results in obstruction to venous flow. The clinical picture is thus one of a swollen, warm, and tender extremity. The resulting edema is pitting in nature and is usually much softer than in established lymphedema. Often, there are underlying risk factors, such as recent surgery or immobility, malignancy, a preceding long flight, or thrombophilia. The diagnosis is confirmed with duplex scanning or venography, and treatment is with anticoagulation. Chronic venous stasis results in hyperpigmentation, and varicose veins, and in severe cases, venous ulceration may be more difficult to differentiate from lymphedema. Untreated venous insufficiency can progress to a combined venous/lymphatic disorder which is treated in the same way as lymphedema.

Heart failure or renal failure

These conditions need appropriate medical management.[47]

STAGING OF LYMPHEDEMA

Generally, lymphedema is staged using a three-stage scale. However, an increasing number of workers are recognizing stage 0. In this stage, swelling is not evident, despite alteration in lymph transport. In stage 1, there is early accumulation of a high-protein–laden fluid (vs. venous edema) that subsides with limb elevation. Pitting of the extremity may be present. In stage 2, limb elevation alone rarely reduces tissue swelling and pitting is present. In late stage 2, fibrosis is present and there may or may not be pitting of the extremity. Stage 3 is characterized by lymphostatic elephantiasis. Pitting is absent and the trophic skin is characteristically acanthotic with warty overgrowth (Table 83.1).[34] The severity of unilateral lymphedema in each stage can be further assessed by the grading system given in Table 83.2.

Table 83.1   *Staging of lymphedema*

Stage	Edema	Elevation helps	Pitting	Fibrosis	Acanthosis
0	−	+	−	−	−
1	+	+	±	−	−
2 (early)	+	±	+	−	−
2 (late)	+	−	±	+	−
3	+	−	−	+	+

+, present; −, absent.

Table 83.2   *Grading of lymphedema based on severity*

Severity of lymphedema	Volume increase (%)
Minimal	<20
Moderate	20–40
Severe	>40

TREATMENT

As with most chronic problems, the responsibility for managing lymphedema lies with the patient. Education about the etiology of lymphedema and principles of management is the first and most important part of patient care. Management of this condition by decongesting the reduced lymphatic pathways to reduce the size of the limb and preventing infection, encouraging the development of collateral drainage routes, and stimulating the function of remaining patent routes, will result in longlasting lymphedema control. In 1995, the International Society of Lymphology Executive Committee developed a consensus document that offered an integrated view of the management of lymphedema.[48] However, controversy still exists about the efficacy and application of treatment approaches in different situations.

The most commonly used method is called decongestive lymphatic therapy (DLT) (or combined physical therapy [CPT], or complete/complex decongestive therapy [CDT], or complex decongestive physiotherapy [CDP]) and involves a two-phase treatment program.[49] In the first phase, intensive every other day physical therapy visits are recommended for a course of 4–6 weeks, although daily treatment is more effective; these treatments usually include:

- manual lymph drainage (MLD) and teaching the patient about MLD
- multilayer bandaging
- care of the skin
- exercises to promote lymph drainage.

The goals of this phase are to reduce the size of the limb, and improve the texture and the health of the skin. Ko *et al.* used CDP in 299 patients with both upper and lower extremity lymphedema for 15.9 days.[50*] Lymphedema reduction averaged 59.1 percent after upper extremity CDP and 67.7 percent after lower extremity treatment. When followed up at 9 months, improvement was maintained in 86 percent of patients. At least 90 percent of the initial reduction was maintained. Incidence of infection also decreased by approximately 50 percent.[50*] Outcomes of different studies vary because of the skills of the treating therapists, patient compliance, exercise protocols, duration of DLT, number of treatments per week, etc.

In lymphedema that is the result of tumor-obstructing lymphatics DLT may be used palliatively. This treatment is usually conducted in conjunction with chemoradiation. In the past, controversy existed as to whether massage and mechanical compression would promote metastasis. In practice, disease is already present and the goal simply is palliation of morbid swelling.[42,50*,51,52]

In the second phase of treatment the patients are usually recommended to:

- wear strong compression hosiery to maintain the reduction in swelling
- carry out regular daily exercise
- perform regular MLD, where possible.

The goal of the second phase is to preserve and optimize the improvements made in the first phase. The role of weight control and regular exercises in the management of lymphedema is thought to be important.

Relative contraindications to DLT include significant congestive heart failure, acute deep vein thrombosis, acute or untreated infection or inflammation of the affected limb, and active malignancy.

Skin care

Skin care should include routine skin inspection (for ingrown toenails, cuticle integrity, abrasions, bruising, ulcerations, impaired circulation); use of skin emollients; avoidance of extremes in heat and cold including sun exposure. In the clinician's office or hospital setting, blood pressure measurements, venipuncture or injections should not be undertaken on the affected side. The patient is counseled on limiting excessive exercise and avoiding trauma to the affected region from clothing (brassiere, purse straps).

In the early pitting stage, many patients benefit from elevating the limb during the night, at or above relative to the heart level.

Manual lymphatic drainage

This is a therapeutic technique used to increase lymph flow. It consists of movement of the therapist's hands over the patient's skin and subcutaneous tissue. The pressure applied is very gentle, and the movements are slow to correspond with the slow lymphatic pulsations. The massage sequence begins at the center of the body and moves to the periphery, and from unaffected side to affected side. The rationale for this is that the lymph nodes must be emptied before they can receive more lymph from the periphery. Each maneuver is performed in a distal to proximal direction. Patients and also family members or friends can be trained in this gentle form of self-massage. Andersen *et al.* conclude from their study that MLD provided no extra benefit.[53**]

The use of massage (classic massage or effleurage) is not recommended, since it may be excessively vigorous and cause damage to the lymphatic vessels.

Exercise

When combining with nonelastic compression bandage, it has been hypothesized that the contraction of muscle against the elastic bandage provides increased subcutaneous tissue pressure and thus encourages movement of interstitial fluid into the lymphatic system.[54]

Compression bandages and garments

Wrapping the limb with low-stretch bandages in conjunction with padding and foam provides the ideal type of compression in patients with lymphedema. It allows a low resting pressure and a high working pressure during muscle contraction to facilitate lymphatic flow. The bandage accommodates the change of volume over time and provides 'custom-made' compression. The disadvantages of this technique are:

- it is difficult to apply
- it requires training
- it is cumbersome.

One study showed that compression bandaging prior to use of compression garments is more effective than compression garments alone.[55**] Once the extremity reaches its smallest achievable size, a customized low-stretch elastic compression garment can be fitted and used during normal activities. Compression garments provide gradient pressure ranging from 20 mm Hg to 60 mm Hg. Replacements are needed every 6 months. Proper fitting is necessary to avoid a tourniquet effect.[56,57*] Hornsby investigated the use of

hosiery on its own compared with control. Although this was a small study the results suggest that wearing a compression sleeve is beneficial and that the high dropout rate in the control group may have reflected the subjects' lack of progress.[58]

Contraindications include concurrent presence of arterial disease, allergy, ulceration or a painful post-phlebitic syndrome.

Pneumatic compression

Controversy exists regarding the use of pneumatic compression pumps. Some schools of thought that support the utilization of pumps generally suggest using relatively low pressures (40 mm Hg maximum distal pressure) as part of a comprehensive program.[59,60] Pressures greater than 50–60 mm Hg may cause injury to lymphatic vessels.[61] The extremity is placed into a long inflatable sleeve that is connected to a pump that inflates the sleeve to a predetermined pressure. External compression therapy is applied with a sequential gradient 'pump'. In between pump use, the extremity should be wrapped with elastic compression bandage or have temporary compression garments applied to reduce recurrence of lymph in the extremity. It may take months to obtain a demonstrable reduction in the size of the extremity.[62*]

Surgery

Controversy exists regarding surgical intervention in the treatment of lymphedema. Patients with severe lymphedema and minimal improvement with compression therapy may benefit from a lymph-reducing surgical procedure. The patient needs to be informed fully about the intended procedure: the risks; the possible impairment; and disability. Complications such as shunt failure, hypertrophic scarring, sensory loss, aggravation of edema distal to the resection, and gross deformity of the limb, have been reported in surgically treated patients.[63*]

Two types of procedure are available: excisional procedures (or debulking procedures) with or without skin grafting and drainage procedures (or microsurgical procedures). Excisional therapy involves removing a large section of skin and subcutaneous tissue down to the muscle fascia and reapproximating the wound edges. Problems associated with this procedure are in relation to wound healing. In addition, this method does not treat the underlying problem of lymphatic outflow obstruction. Excisional therapy with skin grafting involves completely degloving the overlying tissue on the affected extremity and split-thickness grafting directly onto the muscular bed. By removing all overlying lymphatic tissue within the dermal and subcutaneous space down to the muscle bed, lymphedema in the area of grafting is no longer a concern. The result is one of marked reduction in the size of the extremity, but any tissue distal

to this is left with more exaggerated lymphedema than in the preoperative state. Skin grafting has a 5–10 percent incidence of failure. Frequent complications are protracted lymph leakage and poor healing.

A drainage procedure for lymphatic obstruction may be considered in patients with lymphatic obstruction at the level of the upper leg or more proximal extremity and for those who have short-segment obliteration of lymphatic channels.[64*] The procedure is contraindicated in patients with distal or obliterative disease and those with combined proximal and distal obliterative disease. The drainage procedure currently favored for the treatment of limited lymphatic obstruction is a surgical lymphovenous microvascular anastamosis.[65] Patients still need to wear compression garments for life. Liposuction combined with constant use of compression garment has been reported.[66*]

Drug therapy

Coumarin (5,6-benzo-α-pyrone, or 1,2-benzopyrone) and related drugs have been reported to reduce lymphedema, possibly through stimulation of proteolysis by tissue macrophages. In addition to findings that it decreases the pain and discomfort caused by lymphedema, coumarin has been reported to reduce the incidence of cellulitis or lymphangitis and to soften slowly the brawny edema that is often found in conjunction with lymphedema. In 1993, Casley-Smith et al. reported the results of a double-blind, crossover trial of coumarin in 31 women with postmastectomy lymphedema and 21 men and women with lymphedema of the leg of various causes.[67**] Coumarin was reported to be more effective than placebo in reducing the volume of edema fluid in the arm, in reducing skin temperature, and in increasing the softness of the limb tissue. In 1999, Loprinzi et al. studied 140 women with chronic lymphedema of the ipsilateral arm after treatment for breast cancer. The volumes of the arms at 6 and 12 months were virtually identical, regardless of whether coumarin or placebo was given first, and no significant differences in symptoms were found between the two treatment groups. Coumarin was well tolerated, except that it resulted in serological evidence of liver toxicity in 6 percent of the women.[68**] It appears that at present there is no drug that will reduce chronic lymphedema and allow the reduction to be maintained.[68**,69***]

Psychosocial support

For a patient with lymphedema, physical and emotional challenges are profound. In a study by Tobin et al., patients with arm edema experienced greater functional impairment, and increased difficulty adjusting to their illness, home life, and personal/familial relationships.[1*] The openly exposed lymphedematous limb is a constant reminder to the patient and the community at large of the occurrence of a cancer and that the patient is physically different from the norm. As a result, the patient may lose interest in dressing up or general appearance. This loss of self-esteem may also contribute to difficulties with interpersonal relationships, social activities, and intimacy.[70] Efforts may be made to strengthen patients' coping skills, eventually in a multidisciplinary approach by palliative and rehabilitation professionals.

Key learning points

Lymphedema occurs when lymphatic fluid exceeds the lymphatic transport capacity.
    Lymphedema is classified as:

- primary

- secondary: filariasis, cancer and its treatment, other causes.

Stages of lymphedema are: 0, 1, 2, and 3.
It is graded as: mild, moderate, severe.
Diagnosis of lymphedema is based on:

- History: medical and surgical history, edema and associated symptoms, function, psychosocial effect.

- Physical examination:

    – Volume measurement (circumference, water displacement volumetry, optoelectronic Perometer, bioelectrical impedance, skinfold calipers)

    – Assessment of skin condition (texture, color, tonometry)

- Imaging studies: LAS, magnetic resonance imaging and computed tomography, ultrasonography (differential diagnosis of deep venous thrombosis), dual X-ray absorptiometry or bi-photonic absorptiometry

Treatment:

- Goal: development of collateral drainage routes, stimulating the function of remaining patent routes, decrease volume and improve skin condition, prevent complications.

- Methods: skin care, MLD, exercise, compression bandaging/compression garment, pneumatic compression, surgery and drug therapy, psychosocial support.

PART 14

Emergencies in palliative medicine

This page intentionally left blank

Hypercalcemia

D SCOTT ERNST, GARY WOLCH

INTRODUCTION

Hypercalcemia is a common metabolic complication of malignant disease and is most frequently associated with the prevalent cancers of the breast and lung.[1] Because of the ensuing complications, it is responsible for a significant number of hospitalizations.[2*] Signs and symptoms of hypercalcemia may be subtle and can easily be missed unless the index of suspicion is sufficiently raised.[3] Control of distressing symptoms in patients with advanced cancer is often made more difficult by hypercalcemia symptomatology, which often exacerbates existing palliative issues. Furthermore, hypercalcemia is a readily treatable condition and the management can significantly improve patients' overall palliation.[4,5] Recent developments in the therapeutic armamentarium have simplified management, often allowing for outpatient treatment.[6*]

EPIDEMIOLOGY

Hypercalcemia of malignancy (HCM) was first recognized over 80 years ago by Zondec and has become increasingly recognized with the advent of routine serum calcium measurement.[7*] Still the most common cause of hypercalcemia remains hyperparathyroidism. Primary hyperparathyroidism (PHPTH) is found in approximately 250 new cases per million persons per year compared with 150 new cases per million per year of HCM.[8*,9] The incidence of HCM varies between 0.6 percent and 5 percent of all patients with cancer.[10] It occurs preferentially in certain types of malignancy, with over 50 percent of cases associated with carcinoma of either the lung or breast.[1,11*] The incidence of HCM varies widely and depends on the primary site, histological subtype, and the presence or absence of bone metastases. For instance, HCM occurs in approximately 7 percent of squamous carcinomas of the lung and is rare in primary small cell carcinoma of the lung.[12] It occurs in 15–20 percent of patients with untreated multiple myeloma, whereas more common cancers, such as carcinoma of the colon, uterus and cervix, are rarely associated with hypercalcemia.[3] Patients who have advanced carcinoma of the prostate and who often have widespread metastatic bone disease, rarely develop HCM. Other tumor types which are well known to be associated with HCM include renal cell carcinoma, carcinomas of the head and neck, ovarian cancer and non-Hodgkin lymphomas.[13]

PATHOGENESIS

Hypercalcemia of any etiology can theoretically result from one of or a combination of three different mechanisms:

- enhanced calcium absorption from the gastrointestinal tract
- impaired calcium excretion from the kidney
- accelerated calcium resorption from bone.[14]

In HCM, calcium absorption is generally impaired and dietary factors have little influence on serum levels.[15*]

Two broad categories of HCM have been recognized.[16] In patients with extensive lytic bone metastases, tumor cells have been found to release a variety of cytokines which act locally to induce osteolysis and release calcium into the systemic circulation. Hypercalcemia may also develop in the absence of bone metastasis and results from the secretion of

a hormone produced by the tumor which acts to promote calcium reabsorption in the kidney and to enhance bone resorption, so called humoral hypercalcemia of malignancy. The predominant humoral factor is now thought to be parathyroid hormone-related protein (PTHrP). There may be considerable overlap between these two mechanisms which may explain variable responses to therapy.[17]

Osteolysis

In those patients with bone metastasis, the interaction between the tumor and the resident cells within bone can result in the development of hypercalcemia. Osteoclasts have become recognized as the predominate mediators of osteolysis.[18,19] Tumor cells also release a variety of factors, such as interleukin (IL)-1, IL-6, tumor necrosis factor α and macrophage inflammatory protein-1α, which stimulate the osteoclast to resorb bone.[20] The bone matrix itself is a rich source of growth factors such as transforming growth factor β (TGFβ), insulinlike growth factors (IGFs), and platelet-derived growth factors (PDGFs).[21] These cytokines can in turn stimulate local tumor growth and the release of additional factors from the tumor cells to further incite osteoclast activation.[18,22] In multiple myeloma, extensive osteoclast-mediated bone resorption typically occurs. A wide spectrum of cytokines, osteoclast-activating factors (OAFs), have been implicated in the pathogenesis of the lytic bone disease and of hypercalcemia.[18,23,24,25]

PTH–related protein

In many cases of HCM, the biochemical changes are suggestive of overstimulation by parathyroid hormone (PTH).[26,27*] Not only is calcium resorption from bone increased, but renal tubular reabsorption of calcium is also enhanced. Phosphaturia with consequent hypophosphatemia develops and nephrogenous cyclic AMP levels are increased. PTHrP is a 16 kDa peptide with 61 percent sequence homology with PTH,[28*,29*] and it has four times the bioactivity of PTH and competitively binds with the PTH receptor.[30] PTHrP gene expression is present in several normal tissues including skin, breast, liver and brain.[31] The physiological role of PTHrP is not well established, but it likely acts as a paracrine factor which regulates extracellular calcium homeostasis.[16]

PTHrP appears to be the central mediator of HCM.[32*] PTHrP levels are frequently elevated in patients with humoral hypercalcemia of malignancy and in approximately two-thirds of patients with bone metastasis.[29] It is most often associated with squamous cell carcinomas and rarely found in patients with hematological malignancies such as multiple myeloma and lymphomas.[33] It was found to be elevated in 30–50 percent of breast cancer patients with HCM irrespective of known bone involvement. Furthermore, circulating PTHrP may be generated at specific sites

of bone metastases.[34] Of clinical relevance, patients with HCM mediated by PTHrP tend to be more resistant to therapy.

Renal mechanisms

The kidneys play a central role in regulation of calcium homeostasis.[35] The parathyroid glands are also very sensitive to any fluctuation in calcium levels, and by reducing PTH secretion can retard bone resorption and intestinal absorption of calcium, and can promote renal calciuresis. In HCM, the influx of calcium from osteolysis and/or PTHrP secretion often leads to impairment of the kidney's ability to effectively eliminate the excess calcium. Furthermore, the hypercalcemia-induced nausea and anorexia can reduce fluid intake and diminish intravascular volume. With volume depletion, sodium resorption in the proximal tubule is enhanced and calcium resorption is augmented because of the tight linkage between sodium and calcium transport within the nephron. Consequently, the combined factors of hypercalcemia, volume depletion, and impaired renal excretion of calcium lead to a perpetuating vicious circle which persists until effective therapy is introduced.

DIFFERENTIAL DIAGNOSIS

Although the differential diagnosis of hypercalcemia is extensive, most cases can be accounted for by PHPTH or by HCM.[36] Box 84.1 lists the broad differential diagnosis for hypercalcemia. PHPTH is a common, benign disorder and accounts for the majority of cases among the general population. If symptomatic, treatment with surgery alone is curative.[37***,38*] Although PHPTH is the most common outpatient cause of hypercalcemia, malignancy is the most common inpatient cause. Indeed, benign causes of hypercalcemia are not uncommon in patients.[36] Hutchesson et al. reported a 15 percent rate of concurrent PHPTH and malignancy-related hypercalcemia.[39*] HCM is usually associated with clinical signs suggestive of an underlying malignancy and the biochemical abnormalities usually progress over a short period of time. When a level of clinical uncertainty exists, the two conditions can usually be distinguished by obtaining an immunoradiometric assay for PTH.[40]

CLINICAL PRESENTATION

Symptoms are often not well correlated with serum calcium or bone destruction and are more likely to depend on the rate of onset rather than the absolute serum calcium levels[41] (Table 84.1). The initial symptoms may be very mild and

Box 84.1 Differential diagnosis of hypercalcemia

Primary hyperparathyroidism

- Sporadic

- Familial

Malignancy

- Local osteolysis (e.g. multiple myeloma, breast carcinoma)

- Humoral HCM (e.g. squamous cell carcinomas of the lung, renal cell carcinoma)

- Vitamin D-related (e.g. Hodgkin lymphoma)

Other endocrinopathies

- Thyrotoxicosis

- Adrenal insufficiency

- Pheochromocytoma

- Acromegaly

Medications

- Thiazide diuretics

- Lithium

- Milk-alkali syndrome

- Vitamin D

Other

- Sarcoidosis and granulomatous diseases

- Acute renal failure

- Immobilization

can be difficult to distinguish from those of the underlying disease or from the side effects of cancer therapy. Early recognition is important because, if left untreated, the symptoms can rapidly progress and become severe.[14] The most common symptom is fatigue (75 percent).[42] Other frequent manifestations include: anorexia (64 percent), weight loss (64 percent), bone pain (58 percent) and constipation (58 percent). The mnemonic, 'stones, bones, abdominal moans, and psychic groans' is a simple means of remembering the signs and symptoms of hypercalcemia irrespective of the underlying cause.[36]

The clinical manifestations of the altered renal function include polydipsia and polyuria. Nausea and vomiting may also be present.[35] Nephrolithiasis may develop, particularly if the hypercalcemia occurs over a protracted period of time. Signs of volume contraction, such as postural hypotension, tachycardia, mucosal dryness, and altered skin turgor are commonly seen and should be specifically addressed in the clinical evaluation.

Neurological and cognitive symptoms may be particularly subtle and readily overlooked.[38*] Patients may experience changes in concentration, memory, or mood.[43*] Drowsiness, confusion, and acute delirium may develop and may progress rapidly to coma and death. Slight changes in serum calcium can produce symptoms, particularly in older and debilitated patients.

The laboratory evaluation of HCM should include serum electrolytes, phosphorus, creatinine, albumin, and total serum calcium or serum ionized calcium (where available). Direct measurement of serum ionized calcium is considered the gold standard in the diagnosis of HCM.[44] Total serum calcium results must be interpreted in view of the existence in three forms of calcium in plasma: bound to albumin and other proteins (approximately 40 percent), chelated to serum anions (13 percent), and as free ionized calcium (47 percent).[45,46] Serum (free) ionized calcium is the biologically active component of total calcium, and is responsible for the deleterious effects of HCM. In patients with hypoalbuminemia for various reasons, including malnutrition and chronic illness, measured serum calcium will underestimate actual total calcium.[35] Serum calcium should

Table 84.1 *Classification and symptoms of hypercalcemia*

Severity	Serum calcium level mmol/L (mg/dL)	Associated symptoms
Mild	<3.0 (<12)	Anorexia, mild nausea, constipation, fatigue, subtle mental status alteration, bone pain
Moderate	3.0–3.5 (12–14)	Similar to mild HCM + abdominal pain, nephrolithiasis, nephrocalcinosis, progressive renal dysfunction
Severe	>3.5 (>14)	Similar to moderate HCM + dehydration, severe nausea/vomiting, pancreatitis, marked changes in mental status, coma, cardiac dysrhythmias

HCM, hypercalcemia of malignancy.

be adjusted in accordance with serum albumin using the following formulae:

- In Imperial Units: corrected calcium (mg/dL) = serum calcium + 0.8 mg/dL (4 g/dL − serum albumin)
- In SI Units: corrected calcium (mmol/L) = serum calcium + 0.2 mmol/L (40 g/L − serum albumin)

(Note: serum calcium measurements given in mmol/L can be multiplied by 4 to convert to mg/dL).

TREATMENT OF HYPERCALCEMIA OF MALIGNANCY

The classification of HCM as an 'oncological emergency' arises from the potential complications which may ensue if this condition remains unrecognized or undertreated. In the absence of effective treatment, progressive dehydration and deteriorating renal function may lead to progressive hypercalcemia and possibly coma and/or death.[35] Dysrhythmias and cardiac arrest may occur with rapid escalations of serum calcium.

Treatment of HCM must be recognized as only a temporizing measure, with treatment of the underlying cancer remaining the most definitive method of preventing recurrence. Indeed, since hypercalcemia is often an end-stage manifestation of malignancy, it may be appropriate to withhold treatment depending on patient and family goals.[35]

Hydration and diuretics

Hydration is the cornerstone of the HCM therapy. Fluid therapy is essential to reverse the impending cycle of decreased glomerular filtration, impaired renal calcium excretion, and nephrocalcinosis. Rehydration should begin with isotonic saline solution, and should be pursued aggressively often requiring up to 6 L daily. Mild hypercalcemia in asymptomatic patients may allow for outpatient oral rehydration, although many patients require hospitalization for intravenous hydration along with calcium-lowering agents. Adequate rehydration can be assessed by monitoring urine output along with urine/serum osmolality. Attempts should be made to restore urine output to approximately 2 L/day. Frequent clinical assessments help to avoid the complication of congestive heart failure, as a result of excessive hydration. Electrolytes should be monitored, as patients with HCM may have concurrent hypokalemia and hypomagnesemia, both of which may be exacerbated by volume expansion.[47]

Loop (sulfonylurea) diuretics, such as furosemide and ethacrynic acid, inhibit the Na/K/Cl transporter in the loop of Henle and increase delivery of sodium to the distal nephron, which in turn promotes calcium excretion.[48] Despite their ability to promote calciuresis, loop diuretics should be administered with caution because of the risk of hypokalemia, alkalosis, hypomagnasemia, and recurrent hypovolemia. The effectiveness and favorable side effect profile of newer agents has minimized the role of loop diuretics in the treatment of HCM.

Bisphosphonates

Bisphosphonates are synthetic pyrophosphate analogs characterized by a phosphorus-carbon-phosphorus bond which renders them resistant to enzymatic hydrolysis[49***] (Table 84.2). Bisphosphonates are potent inhibitors of normal and pathological bone resorption. Although their mechanism of action is complex and not fully understood, bisphosphonates exert their hypocalcemic effect principally through inhibition of osteoclast activity.[50***] The agents are avidly taken up within the bone matrix from the circulation and over subsequent months are slowly released into the

Table 84.2 *Bisphosphonates*

Bisphosphonate	Bisphosphonate–R2 side chain	Relative potency	Recommended dose
Non-nitrogen-containing			
Etidronate	$-CH_3$	1	7.5 mg/kg per day by intravenous infusion over 2–4 hours (500 mL diluent) on 3 consecutive days
Clodronate	$-Cl$	10	1500 mg by intravenous or subcutaneous infusion over 4 hours (500 mL diluent)[a]
Nitrogen-containing			
Pamidronate	$-CH_2CH_2NH_2$	100	60–90 mg by intravenous infusion over 2–4 hours (250–500 mL diluent)[a]
Alendronate	$-(CH_2)_3NH_2$	500	5–15 mg by intravenous infusion over 2 hours (250 mL diluent)
Ibandronate	$-CH_2CH_2N(CH_3)$-(pentyl)	5 000	2–6 mg by intravenous infusion over 2 hours (500 mL diluent)[a]
Zoledronic acid	$-CH_2$-imidazole	10 000	4 mg by intravenous infusion over at least 15 min (100 mL diluent)

[a]Smaller volumes and shorter infusion times have been used without significant renal toxicity.

resorptive lacunae.[51***] Once taken up into the osteoclast, the bisphosphonates appear to inhibit protein synthesis and proton production diminishing further bone resorption.[52] Osteoclast apoptosis can be induced *in vivo* and *in vitro* by the bisphosphonates, further retarding bone resorption.[53] The osteoblast may be the initial target of some bisphosphonates. By modulating osteoblastic stimulatory factors, osteoclast function and recruitment are impaired.[50***,54,55] The nature of the side chains stemming from the central carbon determine the potency of the bisphosphonate.[56***] Nitrogen-containing bisphosphonates are more potent inhibitors of bone resorption due to their ability to inhibit the mevalonate biosynthetic pathway within the ostoclasts. The inhibition of this pathway potently decreases osteoclast function and survival.[55]

Intravenous bisphosphonates have become the standard of care for the treatment of HCM unresponsive to hydration alone and can be utilized irrespective of the predominant underlying pathogenic mechanism.[50***,57*] Due to their limited enteral absorption (1–2 percent) and gastrointestinal side effects, oral bisphosphonates are rarely indicated for the management of HCM, although they may be used for maintenance of normocalcemia. The ability of bisphosphonates to reverse HCM has minimized the role of other therapeutic agents such as gallium nitrate, calcitonin, and plicamycin.[50***] The combination of a parenterally administered bisphosphonate and adequate hydration will normalize serum calcium in the majority of patients.[55] Normalization of calcium levels often takes 3–5 days following infusion.

TOXICITY

Although the side effects from bisphosphonates may be similar to those produced by the hypercalcemia, a consistent toxicity profile for bisphosphonate therapy has emerged. The majority of these adverse events occur infrequently and are self-limiting (Box 84.2).[58***]

Box 84.2   Side effects of bisphosphonates

More common

- Fever

Occasional

- Renal toxicity
- Nausea and vomiting

Rare

- Symptomatic hypocalcemia
- Symptomatic hypophosphatemia
- Infusion site reaction

Fever is the most commonly reported adverse event.[56,58***,59**] Fever appears to be more common, with the nitrogen-containing bisphosphonates, occurring in up to 44 percent of patients. Patients may benefit from prophylactic acetaminophen prior to aminobisphosphonate infusion. High systemic bisphosphonate concentrations following rapid intravenous administration may result in the formation of insoluble bisphosphonate– calcium complexes in the kidney and may lead to renal tubule damage, further aggravating renal dysfunction. Although renal complications are rare, cases of acute renal failure have been reported with bisphophonate use.[59**] This risk can be minimized by giving lower doses over a prolonged infusion period. The potential for symptomatic hypocalcemia with bisphosphonate use is small given the intrinsic stimulation of PTH secretion that occurs.[60**] Occasional vision-threatening ocular side effects (uveitis/scleritis) have been reported.[61*]

NON–NITROGEN–CONTAINING BISPHOSPHONATES

Etidronate

Etidronate was one of the earliest bisphosphonate products to be used clinically.[49***] Etidronate (see Table 84.2) administered intravenously over 3 days is the recommended treatment regimen, although a multicenter study has demonstrated the safety and effectiveness of a single 24-hour infusion.[36,62*] The oral formulation of etidronate maintains an indication for the short-term (30–90 days) maintenance of normocalcemia following intravenous infusion. Because of its relative low potency and the observation that it may inhibit normal bone mineralization, etidronate's role in HCM therapy is primarily historical.[63]

Clodronate

The effectiveness of clodronate for the treatment of HCM was first reported in 1980.[56] A double blind, randomized controlled trial published in 1995 demonstrated the superiority of hydration plus clodronate over hydration alone in the treatment of HCM.[64***] In this study, 44 female breast cancer patients with serum ionized calcium >1.6 (normal range 1.09–1.3) were randomized to receive either clodronate (300 mg intravenously in 500 mL normal saline) daily for up to 7 days, or placebo. A significantly larger number of patients achieved normocalcemia in the clodronate group than in the placebo group (17/21 vs. 4/19). The median 'time to normocalcemia' in the clodronate group was 5 days (range 3–7).

To reduce the number of infusion days, O'Rourke *et al.* reported on a cohort of 30 HCM patients with different tumor types, in whom hypercalcemia (>2.63 mmol/L) persisted following 3 days of intravenous hydration.[65*] All were given 1500 mg of clodronate (intravenously in 500 mL of normal saline over 4 hours). Serum calcium normalized in 54 percent of patients by day 3, and 80 percent by day 10. A single 1500 mg infusion of clodronate is as efficient as the 5-day regimen.[50***]

Bisphosphonate use for HCM may be required in settings where symptom palliation is the primary goal. For these terminally ill patients, securing intravenous access may be an obstacle to bisphosphonate therapy. Subcutaneous clodronate infusion has recently been shown to be a safe and reliable alternative for the management of HCM in this population (see Table 84.2 for recommended administration).[66*] Continued experience with this technique has allowed for smaller volumes and shorter durations of infusion without added toxicity.[67*]

NITROGEN–CONTAINING BISPHOSPHONATES

Pamidronate

Pamidronate was the first of the nitrogen-containing bisphosphonates to be available for clinical use. Early studies of pamidronate utilized doses (30–45 mg) at the lower end of the therapeutic range.[68**] Subsequently, a dose–response study found that the majority of patients who failed to achieve normocalcemia with pamidronate had high initial calcium levels (>3.5) and received low-dose pamidronate (30 mg or 45 mg). Higher doses of pamidronate (60–90 mg) were almost universally effective.[69*] Dose adjustments for pamidronate based on initial calcium levels are unnecessary. Pamidronate 90 mg will achieve normocalcemia in over 90 percent of patients and prevent an inadequate response in those with enhanced renal calcium re-absorption.[70***,71]

Pamidronate and clodronate at recommended dosages (see Table 84.2) are equally efficacious, although pamidronate has a longer duration of effect.[58***,64***]

Alendronate

Alendronate has superior antiresorptive potency compared with etidronate and clodronate. In a small randomized controlled trial, intravenous alendronate (10 mg) reversed HCM in a majority of patients.[72*] Intravenous alendronate (7.5 mg) and intravenous clodronate (600 mg) have comparable efficacy in the treatment of HCM. Comparison studies with other nitrogen-containing bisphosphonates are unavailable.

The recommended intravenous alendronate dosage range is 5–15 mg, with a trend toward superior efficacy at the higher doses.[73**] Alendronate may be infused safely over 2 hours.[74**] The availability of intravenous alendronate is limited in many countries, and some national regulatory bodies have not approved its use for HCM.

Ibandronate

In the early 1990s investigators began screening hundreds of new bisphosphonates for their effect on bone resorption in animal models.[75***] Ibandronate emerged as a bisphosphonate with a bone resorption potency 50 and 500 times that of pamidronate and clodronate, respectively.[76*]

As pamidronate had already been widely used for HCM when ibandronate (intravenous) was introduced, a comparison trial in 66 cancer patients (most commonly breast, lung, and head/neck) with hypercalcemia was undertaken.[60**]

A range of ibandronate and pamidronate doses were administered commensurate with the initial calcium level. Normocalcemic response rates for ibandronate and pamidronate were 76.5 percent and 75.8 percent, respectively. The median time to relapse was significantly longer for ibandronate than pamidronate (14 vs. 4 days, respectively). Ibandronate appeared to be as effective as pamidronate, and potentially achieved a longer duration of response.

The optimal dose of ibandronate has not been established. In a dose–response study by Ralston, ibandronate 2 mg was significantly less effective than a 4 mg or 6 mg dose.[76*] The duration of ibandronate infusions in the published HCM literature range from 1 to 4 hours. Shorter infusion times and rapid bolus injection have been shown to be safe in other patient populations.[77*] Ibandronate (intravenous form) has been approved for the treatment of HCM by the European Union since 1997.[60**]

Zoledronic acid

Phase I clinical trials were first reported for the bisphosphonate zoledronate in 1996.[78*] Animal model studies found the antiresorptive potency of zoledronate to be at least 100 times that of pamidronate.[57*] The recommended dosage and administration of zoledronic acid is 4 mg (with 100 mL of normal saline) given intravenously over a minimum of 15 minutes. Higher doses and shorter infusion times have been associated with renal dysfunction.[79***]

Zoledronic acid has gained worldwide regulatory approval for the treatment of HCM based upon the pooled results of two identical, randomized, double blind, comparison trials of zoledronic acid and pamidronate.[59**] A total of 275 cancer patients with HCM were randomized to zoledronic acid 4 mg or 8 mg, or pamidronate 90 mg. Normocalcemia by day 10 was achieved in 88.4 percent, 86.7 percent, and 69.7 percent of patients in the zoledronic acid 4 mg and 8 mg, and pamidronate 90 mg arms, respectively. The median duration of response was 32, 43, and 18 days in the zoledronic acid 4 mg and 8 mg, and pamidronate 90 mg arms, respectively. Although the study was designed to show equivalence between the three arms, the response rate to pamidronate was significantly lower than expected and an advantage to using zoledronic acid is inferred.

Gallium nitrate

The hydrated nitrate salt of gallium was historically utilized in the treatment of lymphoma, where it was found to cause hypocalcemia in cancer patients.[56] Gallium nitrate impairs the ability of osteoclasts to resorb bone by interfering with a membrane proton pump and binds to the surface of hydroxyapatite decreasing its solubility.[80*,81***]

A randomized, double blind comparison of pamidronate versus gallium nitrate for HCM was presented at the European Organization for Research and Treatment of Cancer (EORTC) symposium in March 1996.[82**] In this

study patients were randomized to receive either gallium nitrate ($200 \, \text{mg/m}^2$, 5-day continuous intravenous infusion) or pamidronate (60–90 mg, 24-hour intravenous infusion) along with an intravenous placebo infusion for 4 days. Normocalcemia was achieved in 72 percent and 59 percent of patients in the gallium nitrate and pamidronate groups, respectively. Gallium nitrate has been shown to have a superior rate and duration of response to that of etidronate and calcitonin in treating HCM. Nephrotoxicity is a concern with gallium nitrate use, although the incidence of renal dysfunction with gallium nitrate is similar to that of comparator agents.[80*]

Calcitonin

Calcitonin plays a physiological role in maintaining the skeletal integrity by inhibiting osteoclast function. Although calcitonin is found in many tissues, calcitonin is primarily released into the circulation from the C cells (parafollicular cells) within the thyroid in response to elevations in serum calcium.[83] Synthetic salmon calcitonin is preferred over the human variety due to its greater hypocalcemic potency, along with a slower rate of degradation and clearance.[84***]

Calcitonin remains useful in the first few days of severe and life-threatening HCM. Unlike bisphosphonates which exert their effect mainly on bone, calcitonin inhibits both osteoclast activity and renal tubular calcium reabsorption.[49***] A dosage of 1–8 units/kg subcutaneously every 6–12 hours is recommended and can be administered parenterally or intranasally. Calcitonin's effect is rapid in onset (within 48 hours of administration); however, the net effect in reducing serum calcium tends to be modest in magnitude (0.5–1 mmol/L) and exhibits tachyphylaxis due to downregulation of osteoclastic calcitonin receptors.[56***] Side effects include nausea, flushing, abdominal pain, and local irritation at the injection site. Calcitonin is indicated in the first 48 hours of severe and life-threatening hypercalcemia, and it is used in conjunction with hydration and bisphosphonates.

Other agents

Corticosteroids have a negligible role in the treatment of HCM associated with solid tumors. In patients with multiple myeloma or lymphoma, in whom the underlying malignancy is considered to be steroid responsive, a trial of corticosteroids may be indicated.[67*] Although plicamycin (mithramycin) remains indicated in the treatment of HCM, its poor rate of inducing normocalcemia (range 30–50 percent), limited duration of response, and significant adverse effects, make it an undesirable agent for HCM.[56***,67***] Oral and intravenous phosphate use in the treatment of HCM has become obsolete due to the advent of safer and more potent therapies.[35]

Key learning points

- Hypercalcemia is a common, treatable complication of malignant disease.

- HCM may develop in the absence of overt metastatic bone disease.

- Treatment of HCM can result in improved overall palliation.

- The clinical symptoms and signs of HCM may be subtle and serum calcium should be measured even with low index of suspicion.

- Rehydration is an important initial step in the management of HCM.

- Intravenous bisphosphonates are the agents of choice in the treatment of HCM.

- The aminobisphosphonates provide the most rapid and the most durable normalization of serum calcium levels.

Hemorrhage

SRIRAM YENNURAJALINGAM, EDUARDO BRUERA

INTRODUCTION

Patients in palliative care who have advanced cancer experience a wide variety of bleeding problems. Bleeding occurs in approximately 10 percent of patients with advanced cancer[1,2] and is manifested as hemoptysis, hematuria, vaginal bleeding, rectal bleeding, hematemesis, melena, or bleeding from tumors fungating through the skin. It is the immediate cause of death in 6 percent of cancer patients and its management may pose a challenge to the healthcare provider. Bleeding is very distressing to the patient and his or her family.[3] Many of these patients require admission to the palliative care unit for various reasons such as transfusions, administration of medications like midazolam, or psychological reasons. In addition, it is difficult to predict which patients will suffer a catastrophic event; hence, a clear plan of action must be established in advance to prepare for a possible distressing circumstance.

This chapter will focus on the causes and management of bleeding in patients with advanced cancer.

CLINICAL PRESENTATION AND UNDERLYING PATHOPHYSIOLOGY OF BLEEDING IN PATIENTS WITH ADVANCED CANCER

Hemoptysis

Hemoptysis, a common symptom of bronchial carcinoma, is present in approximately 50 percent of patients at presentation[4] and may also accompany pulmonary metastasis.

Although rarely of hemodynamic significance, hemoptysis is distressing for the patient and an indication for local radiotherapy.[5**] There is no proved advantage, in terms of survival, for treating asymptomatic patients with inoperable lung cancer, but some evidence suggests that tumors greater than 10 cm in diameter, whether primary or metastasized, carry a significant risk of hemorrhage. It has been suggested that patients with such lesions should receive prophylactic treatment.[6]

Vaginal bleeding

Ninety percent of patients with endometrial cancer report vaginal bleeding at the time of their diagnosis. Vaginal bleeding is rarely excessive and can be managed conservatively. Occasionally, a patient with uterine tumor may present in the form of a major hemorrhage requiring urgent resuscitation and vaginal packing before urgent treatment to stop the hemorrhage is investigated. Hemorrhage in patients with advanced or metastatic cancer may be due to recurrent or locally advanced tumors of the cervix or uterus. Local infiltrations of advanced cancers of the bladder and rectum or mucosal deposits along the vaginal wall are the typical pattern of spread from endometrial cancer. Radiotherapy using either external beam irradiation or intracavitary treatment is of value in obtaining definitive control of bleeding.

Gastrointestinal hemorrhage

Symptomatic gastrointestinal hemorrhage may arise from either the upper or lower gastrointestinal tract and result in

hematemesis and melena, or rectal bleeding. Rectal bleeding is reported by 10 to 20 percent of patients with colorectal cancer. The underlying tumor may be a primary neoplasm arising within the gastrointestinal tract, most commonly from the stomach, large bowel, or rectum, or as a result of direct invasion of a locally advanced tumor from adjacent structures such as the uterus, bladder, or the prostate that has invaded the rectum. Modest doses of radiation at the bleeding sites will often control the bleeding effectively and durably.

Hematuria

Hematuria is a frequent symptom and sign of underlying urological disease. In patients with advanced cancer, hematuria may be secondary to an underlying malignancy, a possible major coagulation disorder, or as a result of interventions such as pelvic irradiation and cyclophosphamide treatment. Hematuria usually manifests as the passage of brown or red urine or could involve the passage of large clots, clot retention, or colic.

Patients who retain clots require immediate intervention before specific studies are initiated. On clinical confirmation of a palpable bladder as a result of a clot, complete evacuation can be achieved by inserting a multi-eyed Robinson catheter (24 F or 26 F) into the urethra. Once the catheter has passed into the bladder, vigorous irrigation with water or saline using a Toomey syringe will permit removal of all clots. Irrigation of the bladder can be uncomfortable, however, and may require analgesia. Unsuccessful initial placement of the catheter or continued bleeding and recurrent obstruction of the irrigating catheter are the specific indications for endoscopic evaluation. If the bleeding is refractory to conservative measures, instillation of silver nitrate, alum, or aminocaproic acid into the bladder, with formalin under general anesthesia (with help from a urologist) may be tried. Bleeding as a result of radiation cystitis may be stopped by hyperbaric oxygen, and in chronic cases, oral pentosan polyphosphate may be used. For palliation, local irradiation and oral tranexamic acid may be helpful.

Causes of bleeding due to cancer may be anatomical, generalized, or combined (Box 85.1). Bleeding may involve damage to local vessels, invasion of vessels, mucositis, a systemic process such as disseminated intravascular coagulation (DIC), or abnormalities in platelet number and function. The underlying causes of these abnormalities are varied and include liver failure, medications such as anticoagulants, chemotherapy, radiotherapy, surgery, and the cancer itself.

Disseminated intravascular coagulation

Disseminated intravascular coagulation, also called consumption coagulopathy and defibrination syndrome, is a systemic process producing both thrombosis and hemorrhage.

Box 85.1 Etiology of bleeding in patients with cancer

Anatomical

- Local tumor invasion (tumor erosion to a major vessel)
- Tumor surface bleeding
- Mucositis (infection, drug-related, chemotherapy-induced, radiation-therapy–induced, peptic-acid–related, and stress)

Generalized

- Platelet disorders
  - (i) Thrombocytopenia – due to bone marrow involvement by the tumor (hematological malignancies), drug-induced, radiation-therapy–induced, viral, vitamin deficiency, autoimmune
  - (ii) Platelet function defect – drug-induced, uremic, paraprotein effect
- Bone marrow involvement by the tumor (hematological malignancies)
- Bone marrow suppression (chemotherapy or radiotherapy)
- Disseminated intravascular coagulation (sepsis, prostate cancer, etc.)
- Liver failure
- Medications (anticoagulants, acetylsalicylic acid, nonsteroidal anti-inflammatory drugs, etc.)
- Concomitant disease (liver cirrhosis, von Willebrand disease, etc.)

Combined

- Local and systemic factors

It is initiated by a number of defined disorders and consists of the following components:

1 exposure of blood to procoagulants such as tissue factor and procoagulant
2 formation of fibrin in the circulation
3 fibrinolysis
4 depletion of clotting factors
5 end-organ damage.

Common manifestations of acute DIC, in addition to bleeding, include thromboembolism and dysfunction of the kidney, liver, lungs, and central nervous system (CNS). In one series of 118 patients with DIC, the main clinical manifestations were bleeding (64 percent), renal dysfunction

(25 percent), hepatic dysfunction (19 percent), respiratory dysfunction (16 percent), shock (14 percent), thromboembolism (7 percent), and CNS involvement (2 percent).[7]

Petechiae and ecchymoses are common in conjunction with blood oozing from wound sites, intravenous lines, catheters, and, in some cases, mucosal surfaces. Such bleeding can be life threatening if it involves the gastrointestinal tract, lungs, or CNS. In patients who develop DIC after surgical procedures, hemorrhage may develop around indwelling lines, catheters, drains, and tracheotomies, and blood may accumulate in serous cavities.

Although malignancy often causes chronic DIC, it can also produce acute DIC, particularly in patients with acute promyelocytic leukemia. Disseminated intravascular coagulation is often present at the time of diagnosis or soon after the initiation of cytotoxic chemotherapy in patients with this disorder. It can cause pulmonary or cerebrovascular hemorrhage in up to 40 percent of patients, and some studies have shown early hemorrhagic death in 10–20 percent of these patients.[8] The induction of tumor cell differentiation with all-*trans*-retinoic acid can rapidly alleviate the coagulopathy.[8]

CHRONIC DISSEMINATED INTRAVASCULAR COAGULATION

Compensated or chronic DIC develops when blood is continuously or intermittently exposed to small amounts of tissue factor, and compensatory mechanisms in the liver and bone marrow are largely unable to replenish the depleted coagulation proteins and platelets, respectively. Under these conditions, the patient is either asymptomatic with increased levels of fibrin degradation products or has manifesations of venous or arterial thrombosis, or both. Patients with chronic DIC may also have minor bleeding from the skin and mucosal membranes.

Malignancies, particularly solid tumors, are the most common cause of chronic DIC. Venous thromboses commonly present as deep venous thrombosis in the extremities or superficial migratory thrombophlebitis (Trousseau syndrome), where arterial thromboses can produce digital ischemia, renal infarction, or stroke. Arterial ischemia can also be due to embolization from nonbacterial thrombotic (marantic) endocarditis.

The diagnosis of acute DIC is suggested by the history (e.g., sepsis, trauma, malignancy), clinical presentation, moderate to severe thrombocytopenia (less than 100 000 platelets/μL), and the presence of microangiopathic changes on the peripheral blood smear. The diagnosis is confirmed by the findings of increased thrombin generation (e.g. decreased fibrinogen) and increased fibrinolysis (e.g. elevated fibrin degradation products and D-dimer). The extent of these abnormalities may correlate with the extensiveness of organ involvement. The laboratory values in the abovementioned studies are variable in chronic DIC because a slower rate of the consumption of coagulation factors may be offset by enhanced synthesis of these proteins. In such patients, the diagnosis may be largely based upon the finding of microangiopathy in the peripheral blood smear and increased levels of fibrin degradation products and, in particular, D-dimer.

TREATMENT

Treatment of the underlying disease (e.g. sepsis) is of central importance in controlling acute or chronic DIC. Hemodynamic support is essential, but many patients do not require specific therapy for the coagulopathy, because it is either short lived or not severe enough to pose a major risk for bleeding or thrombosis. In select instances, blood component replacement therapy or heparin may be of value, although there are no controlled studies showing the definitive benefit of either. In contrast, the administration of antifibrinolytic agents, such as ε-aminocaproic acid (EACA) or aprotinin, are generally contraindicated, because blockage of the fibrinolytic system may increase the risk of thrombotic complications.[9*] Disseminated intravascular coagulation associated with acute promyelocytic leukemia responds to treatment with all-*trans*-retinoic acid.

Platelet transfusion and fresh frozen plasma

Patients with DIC bleed because of thrombocytopenia and coagulation factor deficiency. There is no evidence to support the administration of platelets and coagulation factors in patients who are not bleeding or at high risk of bleeding. However, treatment is justified in patients who have serious bleeding, are at high risk for bleeding (e.g. after surgery), or require invasive procedures.

Patients with marked thrombocytopenia (less than 20 000 platelets/μL) or those with moderate thrombocytopenia (less than 50 000 platelets/μL) and serious bleeding should be given platelet transfusions (1–2 units/10 kg per day). Such patients typically show a less-than-expected rise in platelet count, due to the ongoing consumption. With respect to replacement therapy, patients who are actively bleeding with a significantly elevated prothrombin time, international normalized ratio (INR), or a fibrinogen concentration <50 mg/dL, or both should receive fresh frozen plasma or cryoprecipitate, the latter for fibrinogen replacement. It is preferable to keep the fibrinogen level above 100 mg/dL.

Heparin

The administration of heparin or other anticoagulants to interrupt the underlying coagulopathy in DIC would appear to be a logical therapeutic approach. However, there are no controlled trials indicating a benefit to these, and there is little evidence that the use of heparin improves organ function.[10,11]

THROMBOCYTOPENIA AND HEMORRHAGIC RISK IN PATIENTS WITH CANCER

The direct relationship between the platelet count and bleeding episodes in patients with malignant diseases was first

documented in 1962 by Gaydos *et al.*,[12] in patients with acute leukemia. Since then it has become well known that a spontaneous hemorrhage rarely occurs when the patient's platelet count exceeds 50 000/μL, but the risk of bleeding increases considerably as the count falls below 20 000/μL. The most feared complication of thrombocytopenia is intracranial hemorrhage. In this study major bleeding rarely occurred when the platelet count exceeded 20 000/μL but gradually the incidence increased as the platelet count ranged between 20 000/μL and 5000/μL, and became more dramatic when the platelet count fell below 5000/μL. In particular, Gaydos *et al.* observed that bleeding episodes associated with thrombocytopenia frequently follow a decline in platelet count, especially in cases in which the bleeding occurred when platelet counts exceeded 5000/μL. Moreover, no intracranial bleeding was observed at a platelet count exceeding 10 000/μL. Despite these data, Gaydos *et al.*'s study has been widely misinterpreted and overinterpreted, and for years it became the practice to administer platelets prophylactically to maintain the platelet count above a level of 20 000/μL.[13] Aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs) and some antibiotics, such as high-dose penicillin, taken by patients with malignant disease may impair platelet function. In 1978, Slichter and Harker[14] published that the threshold for spontaneous bleeding, as measured by fecal blood loss, was at approximately 5000 platelets/μL in patients with aplastic anemia. This finding was confirmed by the randomized study of Solomon *et al.*[15] showing that patients routinely transfused with platelets at 20 000/μL fared no better than those who were transfused only if they were bleeding or if their platelet count was decreasing rapidly.

The incidence of hemorrhagic complications in patients with solid tumors was first studied by Belt *et al.*[16] in a cohort of 718 patients receiving myelosuppressive chemotherapeutic agents. (Seventy-five patients [10.4 percent] experienced one or more episodes of hemorrhage. Bleeding was due to tumor invasion in 25/75 patients [33.3 percent] and DIC in 7 patients [9.3 percent] and was unrelated to malignant neoplasms or drug treatment in 6 patients [8 percent]. Thirty-seven patients [49.3 percent] had hemorrhages associated with drug-induced thrombocytopenia.) These results confirmed that there was a quantitative relation between the incidence of hemorrhage and the platelet count for both the group with thrombocytopenia and the group with hemorrhage resulting from all causes. However, the incidence of hemorrhage was low until the platelet count decreased below 10 000/μL, and fatal bleeding was unlikely to occur at platelet counts above 5000/μL.[16]

In 1984, Dutcher *et al.*[17] reviewed the records of 1274 patients treated between 1972 and 1980 on protocols known to produce significant myelosuppression to evaluate the incidence of thrombocytopenia and bleeding among patients with solid tumors, who had been treated intensively with chemotherapy. Of these, 301 patients experienced 5063 days of thrombocytopenia <50 000 platelets/μL and 670 days of

severe thrombocytopenia <20 000 platelets/μL. The median number of days with thrombocytopenia was 6 (range 1–250). There were only 44 episodes of clinically detectable serious bleeding, primarily gastrointestinal (26/44), during thrombocytopenia and all but 7 episodes first occurred at platelet counts between 20 000/μL and 50 000/μL. Fifteen of the 44 bleeding episodes were associated with coagulation abnormalities, 24 occurred during serious infection, and 12 occurred at the sites of tumors. Of the 301 patients, 147 (49 percent) received platelet transfusions. In 86 patients with thrombocytopenia who had CNS tumors, there was no evidence of CNS bleeding during thrombocytopenia. Hemorrhagic deaths were uncommon; of the 12 patients who died of bleeding, seven had normal platelet counts.[17]

Ten years later, Goldberg *et al.*[18] retrospectively studied the clinical impact of thrombocytopenia in patients with gynecological cancer who received chemotherapy. Thrombocytopenia, which was defined as having a platelet count below 100 000/μL, occurred in 182/501 (36.3 percent) patients. No intracranial or life-threatening bleeding occurred in any patient. Of these 182 patients, 139 (76.4 percent) had no clinical bleeding. Minor bleeding occurred in 34 patients (18.7 percent) and 44 cycles of chemotherapy (5.4 percent). Major bleeding occurred in nine patients (4.9 percent) and 10 cycles (1.3 percent). Of the major bleeding events, five occurred in 49 patients with platelet counts between 0 μL and 10 000/μL. Forty-three of these patients received platelet transfusions, and 38 of these 43 patients (88.3 percent) had no bleeding. Of the remaining five patients, two received prophylactic transfusions with no effect. Three major bleeding events occurred in patients with platelet counts that ranged from 11 000/μL to 20 000/μL, but these were due to chronic instrumentation or trauma. In patients with platelet counts exceeding 20 000/μL, major bleeding occurred only from necrotic metastatic lesions. Therefore, in this study, platelet counts of 10 000/μL were not associated with spontaneous major bleeding.[18]

To evaluate the conservative management of chemotherapy-induced thrombocytopenia, prophylactic transfusions were administered only to patients with platelet counts <5000/μL. Fanning *et al.*[19] evaluated 179 episodes of thrombocytopenia in 46 women with gynecological cancers who were enrolled in four dose-intense chemotherapy trials. Of the 179 episodes of thrombocytopenia evaluated, 100 were severe (<20 000/μL). None of the 179 episodes of thrombocytopenia resulted in major bleeding, including 70 that occurred in patients with platelet counts below <20 000/μL who were not receiving prophylactic platelet transfusions and 14/70 in patients who had platelet counts between 5000/μL and 10 000/μL.[19]

From these studies, it is evident that the risk of bleeding depends not only on the platelet count, but also on the underlying disease, the use of drugs interfering with platelet function, and complications such as fever and infection or the presence of coagulation defects. As a consequence, it is not just the absolute platelet count, but rather the number

of functional platelets that is important for the prevention of bleeding. Despite this, there are no studies showing that the bleeding time may aid in defining the risk of bleeding.

CLINICAL APPROACH (BOX 85.2)

A broad, open, and inquisitive frame of mind is a must when approaching the bleeding patient. The history and physical examination should provide important baseline information. Key laboratory tests must be quickly ordered and interpreted. Using this database, one can quickly determine whether the hemorrhagic disorder is congenital or acquired, severe or mild, and progressive or stable. Hemostasis may fail because of the deficiencies of platelets, the plasma coagulation protein system, or endothelial disturbances.

Box 85.2 Management of hemorrhage

- Identify patients at risk, if possible (such as patients who have already had a previous episode of bleeding)

- Identify the cause (detailed history and laboratory tests including cancer history, surgical history, medications, platelet disorder, coagulation disorders to determine whether it is anatomical, generalized, or both)

- Formulate a management plan and communicate it to the patient, family, and the medical team. Emphasize a caring approach and empathic listening to the fears of the patient and family that may help to resolve any conflicts arising from the situation

- Provide dark towels and a dark basin at the patient's bedside

- Prepare an emergency pack of a sedating drug (e.g. midazolam 5 mg in a prefilled syringe) to be given subcutaneously or intravenously

- Treat the bleeding, if appropriate, with several local modalities (such as topical hemostatic agents, radiotherapy, or interventional radiology) or systemic treatments (such as tranexamic acid)

- Consider transfusions or erythropoietin for the management of hypovolemia and anemia

---

In the palliative setting, many factors must be considered with regard to the management of bleeding. The clinician has to not only consider the underlying cause and the clinical presentation, including the severity and nature of each event, but also take into account other salient factors such as the setting of care, availability of various resources, overall disease burden, predicted life expectancy, the patient's overall quality of life, and wishes of the patient and family.

The choice of treatment modality must balance the risk of aggressive management with increased treatment-related toxicity, i.e. against the failure to use treatments that have potential symptomatic benefit. Although the staff providing palliative care can initiate many simple treatments, a definitive approach to management requires an interdisciplinary approach and sometimes expertise of various specialists.

As an example of the need to set priorities, it is evident that interventional radiology or surgical ligation of the pelvic vessel would be less likely to be considered in a homebound, cachectic patient who has expressed the desire to remain at home, particularly if the patient has an estimated life expectancy ranging from a few days to a few weeks. On the other hand, if the same patient presented soon after significant hemorrhaging began, it would be reasonable to at least consider the aforementioned treatments, particularly if specialists with the required skills and equipment are available. The patients and families facing the prospect or reality of massive bleeding require extensive psychological support.

Management of bleeding

General management of bleeding needs to be individualized and depends on the underlying cause, the likelihood of reversing or controlling the underlying cause, and the burden-to-benefit ratio of the treatment. If the patient's disease burden and life expectancy warrant it, then the management of a bleeding episode consists of general resuscitative measures, such as volume and fluid replacement, and specific measures to stop the bleeding. On the other hand, palliative measures may be most appropriate in end-stage patients. Appropriate management involves a detailed assessment via a history that includes a review of prior bleeding episodes, past illness, psychosocial stressors (including level of family support), and medications such as NSAIDs and anticoagulants. Physical examination should focus on whether the bleeding is focal or occurring at multiple sites. Investigations such as a hemogram and clotting profile may reveal a systemic disease, whereas endoscopic studies or angiography may reveal the site of the bleeding.

LOCAL INTERVENTIONS (BOX 85.3)

Packing can be used with or without pressure to achieve hemostasis when bleeding originates in the nose, vagina, or rectum. Surgical swabs of various sizes may be used for this purpose. Nonadherent dressings should be used. A variety of hemostatic agents and dressings, mostly designed for surgical procedures, are beneficial for exterior topical use in patients with advanced cancer.[21] Thromboplastin, a

Box 85.3 Local measures

- Epinephrine – may be used topically, but its liberal use is discouraged

- Prostaglandins E_2 and F_2 – used in intractable hemorrhagic cystitis

- Silver nitrate – induces chemical cauterization and has been used to control hemorrhages in the bladder and epistaxis

- 2–4 percent formalin – acts as a chemical cautery and has been used to control intractable rectal and bladder hemorrhaging

- Aluminum astringents – an example is 1 percent alum, which can be delivered by continuous irrigation of the bladder

- Sucralfate – controls cancer-related gastrointestinal bleeding and cutaneous oozing

- Tranexamic acid – controls bleeding when used locally[20*]

natural blood-clotting agent obtained from bovine plasma, is available as a powder for topical preparation.[22*]

Absorbable gelatin is available as a sterile spongelike dressing or sterile powder that can be applied dry or saturated with sterile sodium solution and is absorbed within 4–6 weeks. When the gelatin is applied, fibrin is deposited in the interstices of the foam, resulting in the swelling of the sponge, thereby forming a large synthetic clot. When the gelatin is applied to nasal, rectal, or vaginal mucosa, it liquefies within 2–5 days. Other bioabsorbable topical hemostatic agents include fibrin sealants and oxidized cellulose.[23**,24*] Fibrin sealants are derived from human plasma and reproduce the final steps in the coagulation pathway to form a clot. The inherent hemostatic activity of absorbable collagen agents provokes a clotting cascade when the bovine-derived mesh comes into contact with blood, and forms a clot. Other available hemostatic agents are oxidized cellulose compounds and highly absorbent alginate dressings derived from seaweed. Vasoconstricting or cauterizing agents are used to manage localized capillary-based bleeding.

RADIOTHERAPY

External beam radiotherapy is used to decrease the hemoptysis caused by lung cancer and is effective in 80 percent of patients.[5**,6**,25***] It also controls bleeding in 85 percent of patients with rectal bleeding and 60 percent of those with hematuria from bladder cancer.[6**,26**] Radiotherapy should

also be considered for treating bleeding from cancerous lesions in the vagina, skin, rectum, and bladder. Although radiotherapy can be useful in controlling the bleeding in patients with head and neck cancers, many patients have already received the maximal allowable doses of radiotherapy by the time bleeding occurs and cannot receive further radiation. Single or reduced fraction regimens appear to be as effective as multiple fractions in controlling bleeding. Upper gastrointestinal hemorrhaging from a malignant process is less amenable to radiotherapy.

ENDOSCOPY (TABLE 85.1)

Endoscopy-based treatments have, for a long time, been used to manage the bleeding from upper gastrointestinal varices, particularly after systemic therapies with agents such as vasopressin or somatostatin analogs have failed.[27, 28*]

INTERVENTIONAL RADIOLOGY

Embolization may be useful in well-selected patients whose blood vessels are accessible by catheter, and have not resulted in ischemia. The benefits of embolization have been reported in patients with cancers involving head and neck, pelvis, lung, liver, and gastrointestinal tract.[29–42*]

Transcutaneous arterial embolization is the technique used in some of these patients to control bleeding in select cases of intractable hemorrhage resulting from advanced pelvic urological malignancies, carotid artery rupture due to cancer, and spontaneous rupture of hepatocellular carcinoma.

Table 85.1 *Endoscopic interventions*

Procedure	What it does
Upper gastrointestinal endoscopy	Argon beam plasma coagulation has been shown to control bleeding in esophagogastric cancer
Cystoscopy	Cystoscopic-assisted cautery by either heat or laser probes has been used in the treatment of hematuria patients with bladder cancer
Bronchoscopy	In case of hemoptysis, bronchoscopy allows for ice-cold saline lavages and/or the use of balloon tamponade, laser photocoagulation, or topical application of thrombin or fibrinogen at the site of the bleeding
Colonoscopy	Techniques such as bipolar electrocoagulation, heater probe, argon, and Nd:YAG lasers are used to control bleeding in the lower gastrointestinal tract

SURGERY

Surgery may be appropriate for select patients for whom conservative measures have failed, and for those who are deemed fit for surgery. Bleeding has been controlled with surgery in patients with head and neck cancers who presented with acute or imminent carotid artery rupture and in radiation proctitis in whom the bleeding was not controlled by topically applied formalin.[43,44*]

SYSTEMIC INTERVENTIONS

Vitamin K

Vitamin K (phytonadione, menadiol) may be useful in the treating a derangement in vitamin K-dependent coagulation factors, such as factors II, VII, IX, and X, or for treating bleeding in patients with advanced cancer caused by excessive therapy with warfarin. The preferable route of administration would be oral or subcutaneous, but the intravenous route should be considered when rapid correction is required. The recommended doses vary from 2.5 mg to 10 mg depending on the severity.[45**]

Vasopressin/desmopressin

Vasopressin/desmopressin is a hormone in the posterior pituitary gland that causes splanchnic arteriolar constriction and reduction in portal pressure when it is injected intravenously or intraarterially. It has been used in a controlled trial to manage bleeding in selected patients with upper gastrointestinal bleeding related to a malignancy.[46*]

Somatostatin analogs

Octreotide, an analog of somatostatin, has been used in palliative care for reducing secretions in patients with a gastrointestinal obstruction. It also reduces the splanchnic flow and pressure by causing venous dilatation, thereby reducing portal pressure and portal venous flow and may reduce bleeding.[47***] Its use for controlling bleeding in cancer patients has not been reported.

Antifibrinolytic agents

Tranexamic acid and EACA are synthetic antifibrinolytic agents that block the binding sites of plasminogen, thereby inhibiting the conversion of plasminogen into plasmin by tissue plasminogen activator. The end result is the decreased lysis of fibrin clots.[48,49] Tranexamic acid and EACA have been administered orally and intravenously. Tranexamic acid is 10 times more potent than EACA in vitro. The suggested intravenous dose of tranexamic acid is 10 mg/kg three to four times a day, infused over about 1 hour. The suggested intravenous dose of EACA is 4–5 g in 250 mL over the first hour and then 1 g/hour in 50 mL administered continuously for 8 hours, or until the bleeding is controlled.[50*] The most common adverse effects of tranexamic acid and EACA are gastrointestinal in nature (nausea, vomiting, and diarrhea) and occur in 25 percent of cases. The adverse effects appear to be dose dependent. Thromboembolism is uncommon.[51,52]

BLOOD PRODUCTS

Transfusions of blood products should be undertaken on a selective basis. There is no scientific basis for the 20 000/μL cut to transfuse platelets. Lassauniere and colleagues proposed criteria for platelet transfusions in patients with advanced hematological malignancies.[53***] These criteria include continuous bleeding of the mouth or gums, epistaxis, extensive and painful hematomas, severe headaches, or disturbed vision of recent onset, as well as continuous bleeding through the gastrointestinal, gynecological, or urinary systems. The continuation of platelet transfusion in patients with end-stage thrombocytopenia poses an ethical dilemma. Even through the ongoing transfusions may be futile, the patients and their families may perceive the cessation of transfusions as the withdrawal of life-sustaining therapy. Sensitive and empathic discussions between patients, their families, the attending physician and the health team are essential in order to explore their expectations, fears, and concerns and to engage in advanced end-of-life planning while ensuring ongoing support and providing optimal comfort care.

Transfusions of fresh frozen plasma are indicated in patients:

- who are bleeding and have specific deficiencies in certain coagulation factors
- in whom the effects of warfarin urgently need to be reversed
- who require urgent invasive interventions such as thoracenteses or surgery
- with DIC, when appropriate.

Transfusions of packed red cells are indicated when anemia resulting from blood loss causes or aggravates symptoms such as fatigue and dyspnea.

CONCLUSIONS

Massive bleeding, which occurs in 6–10 percent of patients in palliative care settings, can be extremely distressing for both the patients and caregivers. These episodes require an individualized approach based on the specific needs of the patient and family, which include the level of distress, the stage of disease, and the expertise available. A multidisciplinary approach that makes use of various modalities may be required. Treatments range from simple hemostatic techniques to more invasive and sophisticated modalities. Minimal management requires the identification of patients at risk and preparatory measures to empower caregivers to deal appropriately with massive bleeding if it occurs.

Key learning points

- Bleeding occurs in approximately 10 percent of patients with advanced cancer.

- It is the immediate cause of death in 6 percent of patients with cancer.

- Bleeding is very distressing to the patient and his or her family.

- Thorough clinical assessment is essential to identify the risk of bleeding and the cause when it occurs.

- Formulate a management plan and communicate it to the patient, family, and the medical team.

- Emphasize a caring approach and empathic listening to the fears of the patient and family that may help to resolve any conflicts arising from the situation.

Spinal cord compression

NORA A JANJAN, ANITA MAHAJAN, ERIC L CHANG

INTRODUCTION

In the past decade, 11 million cases of cancer were diagnosed and 5 million people have died from cancer in the US. Approximately half the patients diagnosed with cancer will develop metastatic disease. Over 70 percent of all cancer patients develop symptoms from either their primary or metastatic disease.[1–5] Prognosis is influenced by the overall metastatic burden, and the number and location of the sites involved by disease. When metastases are found also in the lung, liver and/or central nervous system, the prognosis is especially poor.[6–15]

Spinal cord compression generally results from bone metastases rather than as a result of leptomeningeal or intramedullary metastases. Prognosis after the development of metastatic disease is important to the type of radiation therapy administered. After bone metastases are diagnosed, the median survivals are 12 months for breast cancer, 6 months with prostate cancer, and 3 months with lung cancer.[7–9] The site of the primary disease and the presence of a solitary metastatic site are predictive of a more prolonged survival.[16–19] The distribution of bone metastases in prostate cancer has prognostic significance. The rate of survival is significantly longer when the metastases are restricted to the pelvis and lumbar spine, and among patients who respond to salvage hormone therapy.[10–12] Any metastatic involvement outside the pelvis and lumbar spine results in lower rates of survival irrespective of response to salvage hormone therapy.

A bone scan index (BSI) has been formulated based on the weighted proportion of tumor involvement in individual bones. The BSI was then related to known prognostic factors and survival in patients with androgen-independent prostate cancer.[13] In multivariable proportional hazards analyses, only the BSI, age, hemoglobin level, and lactate dehydrogenase level were associated with survival. Survival rates were 18.3 months for a BSI of <1.4 percent, 15.5 months for a BSI of 1.4–5.1 percent, and 8.1 months for a BSI > 5.1 percent. Elevations in the bone resorption marker N-telopeptide (NTx) have been associated with a 20 times higher risk for the development of a skeletal complications within 3 months, and shorter times to first disease progression and death.[20,21] These identified prognostic factors should be considered, as a surrogate to a staging system for metastatic disease, so that palliative treatment is appropriate to prognosis based on the extent of disease.

Bone metastases are the most common cause of cancer-related pain, and over 70 percent of patients with bone metastases have symptoms. Among hospitalized patients, over 50 percent of patients experience severe pain due to bone metastases.[4] One of the most important goals in the treatment of bone metastases is to relieve suffering and return the patient to independent function.[22,23] The location of the metastasis influences the types of palliative intervention necessary, especially in weight-bearing bones and bones responsible for ambulation and activities of daily living. Complete pain relief after radiation is achieved in 88 percent of limb lesions, 73 percent of spine metastases, and 67 percent of pelvic metastases.[24]

Bone scans are the most sensitive and specific method of detecting bone metastases, but magnetic resonance imaging (MRI) is the best available technique for evaluating the bone marrow, neoplastic invasion of the vertebrae, the central nervous system and peripheral nerves.[25–27] In a study of melanoma patients, positron emission tomography (^{18}F-fluorodeoxyglucose PET) also found unsuspected spinal cord compression, later confirmed on MRI.[28] Bone or other metastases rarely fail to be detected when radiographic diagnosis is pursued. When radiographic confirmation of malignancy is equivocal, bone biopsy should be considered.[29]

Pain, risk for pathological fracture, and spinal cord compression are the most common indications to treat bone metastases with localized therapy including radiation and surgery. Because external beam radiation provides treatment only to a localized symptomatic site of disease, it is frequently used in coordination with systemic therapies such as chemotherapy, hormonal therapy, and bisphosphonates.

PRINCIPLES OF RADIATION THERAPY

Radiotherapy techniques vary considerably based upon the involved and adjacent normal structures. Basic to an understanding of applied techniques and potential morbidity during a course of radiation are the following principles:[30] radiation therapy is delivered in units designated as the Gray. Relating this to the previously used term rad, equivalent doses can be expressed as 1 Gray (Gy), 100 centigray (cGy) and 100 rad; 1 rad equals 1 cGy.

Radiation for spinal cord compression is delivered by external beam therapy (linear accelerators, cobalt-60 units) that is administered with a prescribed number of daily fractions over several weeks. A variety of radiation energies and biological characteristics are now available to help localize treatment to the areas at risk and exclude uninvolved normal tissues.

External beam irradiation

Included within the classification of external beam radiation are *photons* that are penetrating forms of radiation, and *electrons*, delivering treatment to superficial areas. Other specialized types of external radiation beams are available at only a few centers and they include *proton beam* therapy (administering radiation with high precision to well-defined small areas of tumor involvement, e.g. pituitary or midbrain lesions) and *neutrons* (used by a few centers to treat bulky unresectable or recurrent tumors). Generally photons are used to treat spinal cord compression. Occasionally, electron beam therapy is used in children, and proton beam radiation is now becoming available for the treatment of spinal cord tumors at many centers in the USA.

The concept of integral dose relates the amount of radiation deposited to uninvolved normal tissues located between the skin surface and tumor; the goal in any radiation plan is to minimize integral dose by selecting the appropriate beam energy (Table 86.1). The D_{max} radiation dose is the depth at which 100 percent of the prescribed radiation is deposited. Higher-energy photon radiation, e.g. 18 MeV photons, reduces integral dose because it deposits more radiation to deeper structures while delivering relatively little radiation to superficial tissues.

Multiple radiation portals, each of which is treated daily, are also routinely used in radiotherapy to reduce integral dose. Table 86.2 gives an example of the impact on integral

radiation dose when 200 cGy are prescribed at 10 cm depth from a 6 MeV linear accelerator. When only the posterior radiation portal is used to deliver radiation in the example, the integral dose is high because more superficial tissues receive nearly 50 percent more than the prescribed radiation dose at the site of the tumor located 10 cm below the skin surface; at 1.5 cm from the skin surface the daily radiation dose is 294 cGy per fraction and the total dose is 5880 cGy as compared to the 200 cGy per fraction and total radiation dose of 4000 cGy at the tumor. Radiation tolerance is primarily based on the daily radiation dose; as the

Table 86.1 *The concept of integral dose is demonstrated by the following radiation dose distributions for three different energies including cobalt-60, 6 and 18 MeV photons. D_{max}, the maximum dose, refers to the depth at which 100 percent of the prescribed dose is located below the skin surface. The greater the D_{max}, the greater the skin sparing associated with less of an integral dose*

Skin surface (cm)	Cobalt-60 (%)	6 MeV (%)	18 MeV (%)
0.5	100	30	25
1.0	98	90	50
1.5	95	100	90
2.0	93	98	96
2.5	90	97	98
3.0	88	95	98
3.5	85	92	100
5.0	80	88	96
10.0	55	68	80

Table 86.2 *The impact on integral radiation dose when 200 cGy are prescribed at midline (10 cm depth; patient diameter is 20 cm) from an 6 MeV linear accelerator*

Distance from skin surface (cm)	6 MeV photons (%)
0.5	30
1.0	90
1.5	100
2.0	98
2.5	97
3.0	95
3.5	92
5.0	88
10.0	68
15.0	51
16.5	48
17.5	44
18.5	42
19.5	40

Radiation dose = 200 cGy at 10 cm depth; percentage depth dose = 68%. Radiation dose at 1.5 cm (D_{max} or 100%) is the radiation dose prescribed/0.68. Radiation dose at other depths is the D_{max} dose × % isodose (see Table 86.1).

daily radiation dose increases, the total radiation dose that can be given to normal tissues decreases. Because of this, treatment with a posterior field alone would result in significant side effects due to the high integral dose manifested by skin fibrosis that outlines the radiation field. It is important to realize that giving the first half of the radiation course from the anterior (AP) field alone, and the second half of the radiation course from the posterior (PA) field alone would not reduce radiation side effects. Although the total radiation dose would be more even using an AP field during the first half and a PA field during the last half of a radiation dose, side effects still may be severe because of the high daily (integral) dose of radiation.

When the radiation is delivered each day from an AP and PA radiation portal, the radiation dose given in the portal is the sum of the radiation dose from each field (Fig. 86.1). The integral dose in the case presented decreases significantly with AP and PA treatment fields because the daily radiation dose throughout the treatment field is within 6 percent (with a daily dose of 211 cGy per fraction at 16.5 cm below the anterior skin surface) of the prescribed dose of 200 cGy per fraction (Fig. 86.2). Likewise, the maximum total radiation dose in the field is 4220 cGy, just 220 cGy more than the prescribed radiation dose at the tumor (Fig. 86.3). Newer treatment approaches, like conformal radiation therapy, exploit this relation by treating up to eight different radiation fields each day. Reducing integral dose is a principal concept of radiation treatment planning because it allows higher radiation doses to the tumor and less radiation to the surrounding normal tissues.

A wide variety of photon energies are available. This allows selective administration of treatment to the tumor and minimizes radiation to uninvolved tissues. As a standard, available photon beam energies range from cobalt-60 to 22 MeV photons. Cobalt-60 delivers 100 percent of the prescribed radiation dose, indicated as the maximum radiation dose (D_{max}), 0.5 cm below the skin surface; 6 MeV X-rays from a linear accelerator have a D_{max} of 1.5 cm, and 18 MeV photons have a D_{max} of 3.5 cm below the skin. Tissues 0.5 cm below the skin surface treated with 18 MeV photons receive only 30 percent of the prescribed radiation dose (Fig. 86.4). This demonstrates the relation in radiation physics that there is more sparing of superficial structures (skin and subcutaneous tissues) from radiation with higher photon energies even though the beam deeply penetrates into the tissue. In contrast to the 18 MeV linear accelerators currently available, the low radiation energy of orthovoltage radiation ranges between 125 keV and 250 keV.

Figure 86.1 *The radiation isodose distribution for a 15 cm × 15 cm radiation field using anterior and posterior (AP and PA) parallel opposed portals with cobalt-60. In this case the patient has a 24 cm diameter. Each number represents a percentage of the prescribed radiation dose. If 200 cGy was prescribed to the 100 percent isodose line, then 240 cGy would be delivered to the 120 percent isodose line near the skin surface and only 180 cGy would be given at the edge of the radiation field at the 90 percent isodose line. The edges of the field receive less radiation dose because there is less opportunity for radiation dose contributed by interactions with adjacent radiated tissue at the blocked edge than in the middle of the field.*
Figure 86.2 *Graphic comparison of the integral radiation dose, defined as the radiation dose deposited between the skin surface and the tumor. In this case, the tumor is 10 cm below the skin surface. If radiation were only given from the anterior treatment portal the radiation dose to the skin would result in complications because of the high radiation dose per fraction as well as the high total dose of radiation.*

Figure 86.3 *Graphic comparison of the total radiation dose given when a single anterior radiation field is used instead of parallel opposed radiation fields (AP and PA fields) treated every day. With the AP field alone, the skin would receive 30 percent more radiation than the parallel opposed treatment approach to achieve the same radiation dose at the tumor.*
Figure 86.4 *The different radiation isodose distributions for 10 cm × 10 cm radiation fields. The three beams compared include orthovoltage radiation with a 250 keV radiation beam (left), a cobalt-60 unit (middle), and a 22 MeV linear accelerator (right). The 250 keV unit has no skin sparing and little depth of penetration of the radiation beam. The cobalt-60 unit is ideal for treating head and neck cancers in that adequate radiation is given to superficial lymph nodes and scars in the postoperative setting. Because the diameter of the head and neck region is limited, a highly penetrating photon beam is not advisable. Photons of 22 MeV are ideal for deep-seated tumors such as in the pelvis and abdomen because of skin sparing and deep penetration of the photon beams.*

Using conventional radiation techniques, radiation for vertebral metastases commonly were prescribed to 5 cm below the skin surface using cobalt-60 or 6 MeV photons. However, mean depths from MRI scans of 20 patients equaled 5.5 cm for the posterior spinal canal, 6.9 cm for the anterior spinal canal, and 9.6 cm for the anterior vertebral body. Based on the radiation dose distributions, a metastatic lesion in the anterior vertebral body could receive a radiation dose that is significantly lower than that prescribed.[31]

External beam irradiation is administered from specialized machines which emit gamma rays from a housed isotope (cobalt-60) or X-rays (linear accelerators), which are more than 1000 times as powerful as those used in diagnostic radiology, and are generated by electricity. The availability of higher-energy radiation beams, and the development of

a variety of different radiation energies was critical to the advancement of radiation therapy. These advancements allowed more precise deposition of the radiation in the area of the tumor while sparing surrounding uninvolved normal tissues.

Radiation beams diverge as they penetrate through the beam such that the field that exits the body is larger than the field that enters the body. If spinal metastases occur near a previously radiated area of the spinal cord, the new radiation field must be matched to the prior radiation field, accounting for the divergence of the radiation beam. Extreme precision is required when administering radiation, especially when the radiation treatment must match a previously radiated segment of the spinal cord.[32,33] A computed tomography (CT) scanner on rails with a linear accelerator has been
Figure 86.5   *A computed tomography (CT) scanner on rails with a linear accelerator has been used to verify the position of the patient immediately before the administration of the radiation treatment. (a) A carbon fiber base plate; (b) a whole-body vacuum cushion; (c) a vacuum system; (d) a plastic fixation sheet; (e) a stereotactic localizer; and (f) an arm-support system.*

used to verify the position of the patient immediately before the administration of the radiation treatment; once the patient position is verified on the treatment table by a CT scan, the treatment table is rotated to administer the intensity modulated radiation therapy (IMRT) treatment (Fig. 86.5). Treatment accuracy is within 1 mm of the planned treatment center and the dose variation in the high-dose region is 2 percent or less. Five IMRT treatments delivered 30 Gy to the tumor, limiting the spinal cord radiation dose to 10 Gy or less (Fig. 86.6).

Stereotactic radiosurgery provides a high dose of photon radiation to a small, well-defined area. Using radiosurgery, the vertebral body can receive 20 Gy while less than 0.5 cm^3 of the spinal cord is exposed to 8 Gy of radiation.[34,35] Combined with kyphoplasty, radiosurgery is able to relieve pain in 92 percent of patients during a 7–20-month follow-up period.

Proton beam therapy and 'radiosurgery' are more limited in application and availability, however, the concept is to precisely deposit a large amount of radiation to a well defined volume of tumor while sparing intervening tissues. Precision of proton beam therapy is to the level of the millimeter, requiring exact mapping of the tumor volume and potential microscopic areas of involvement. An additional advantage of proton irradiation is the improvement of relative biological effectiveness of this type of radiation because of the characteristic Bragg–Peak distribution of radiation within a narrow volume of tissue (Fig. 86.7). Chordomas and localized intracranial tumors, especially

around the optic chiasma, have been treated with proton irradiation. Because of its precision, research is ongoing to define further applications of proton therapy, especially in pediatric tumors and previously irradiated recurrent tumors.

The clinical status of the patient is accounted for in the treatment set-up and in the number of radiation treatments that are prescribed. The radiation dose-fractionation schedule and technique also considers the site and volume irradiated, and the integration of other therapies. Conformal, IMRT and proton therapy are all techniques that can better localize radiation dose and reduce side effects, especially in a previously irradiated area.

Reirradiation

Issues regarding reirradiation are especially important in palliative therapy. Experimental data suggest that acute responding tissues recover from radiation injury in a few months and can tolerate additional radiation therapy. However, there is considerable variability in recovery from radiation among late-reacting tissues such as the spinal cord.[36,37] This recovery depends on the technique used, the organ irradiated, the volume irradiated, the initial total dose of radiation, the radiation dose given with each fraction, and the time interval between the initial and second courses of radiation.[38]

Correlating with existing clinical experience, limited toxicities occur with reirradiation when there is careful attention to treatment techniques and radiobiological factors. Radiotherapeutic techniques that localize the radiation dose to the recurrent tumor and limit the dose to the surrounding normal tissues allow the reirradiation of recurrent tumors. Other techniques include conformal external beam radiation, IMRT, and proton therapy.[39,40]

Conformal radiation therapy/IMRT

Conformal radiation techniques precisely localize the radiation dose using external beam radiation from a linear accelerator. Because very low doses of radiation are given through a number of beams, no one area of normal tissues receives a significant dose of radiation. The tumor, though, is given the sum of the radiation from the beams and receives a high dose of radiation. This technique has allowed high doses of radiation to be given, and has allowed for reirradiation of normal tissues without significant side effects.

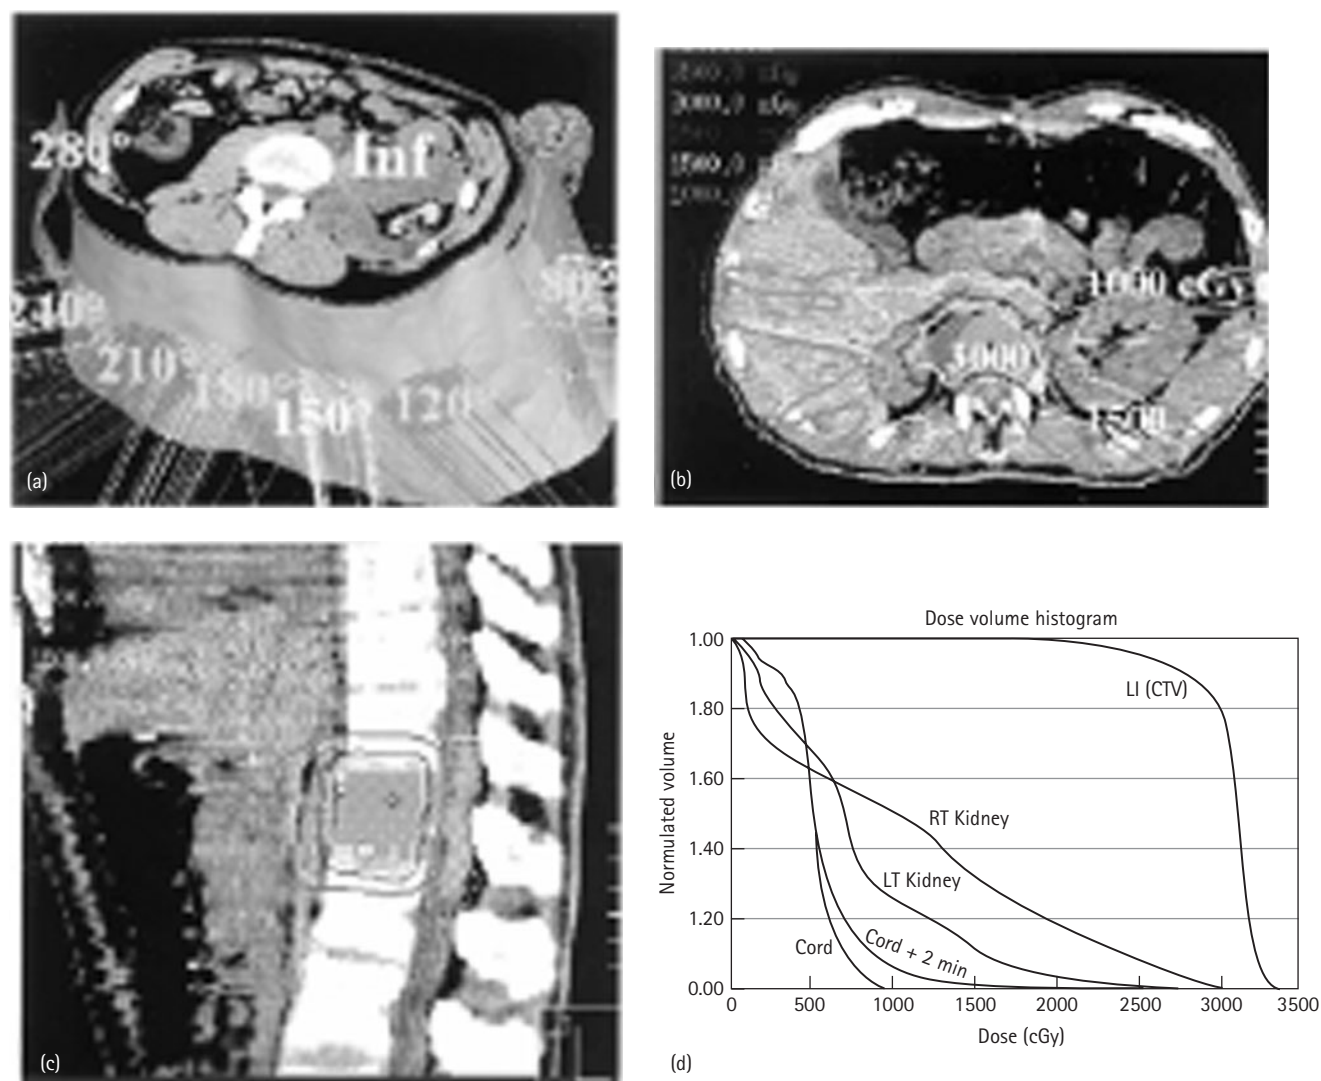
Intensity modulated radiation therapy is a form of conformal external beam radiation that even more precisely administers radiation. It is possible to deliver different doses of radiation to specific areas in a single radiation fraction. For example, with IMRT the center of the tumor may receive 2.20 Gy with each radiation treatment to a total dose of 66 Gy over 30 fractions in 6 weeks, while the periphery of the tumor may receive 2.0 Gy with each radiation treatment


Figure 86.6 *(a–d) Five intensity modulated radiation therapy (IMRT) treatments delivered 30 Gy to the tumor in the patient in Figure 86.5, limiting the spinal cord radiation dose to 10 Gy or less.*

to a total dose of 60 Gy. At the same time, the normal tissues within 2 cm of the tumor (clinical tumor volume to account for possible microscopic tumor extension) may receive 1.8 Gy with each radiation treatment to a total dose of 54 Gy. Thus, IMRT provides the radiobiological advantage of giving a high daily dose of radiation localized within a tumor while giving a well-tolerated lower daily dose of radiation to the surrounding tissues at the same time. By localizing high daily and total doses of radiation in the tumor, IMRT is able to kill more cancer cells with higher radiation doses without harming the surrounding tissues. Any shape or configuration of radiation dose, like an hourglass, can be designed with IMRT. Because of these factors, this radiotherapeutic tool is extremely helpful in delivering high radiation doses to inoperable tumors over a shorter period of time, and in treating tumors that recur in a previously irradiated field.

Normal tissue tolerance with radiation

A balance is required between the dose required to kill the tumor and the radiation dose tolerated by the normal tissues. The concept of fractionated radiation allows treatment of the cancer while not exceeding the tolerance of the surrounding normal tissues. The four 'Rs' of radiation biology are repair of sublethal damage, reoxygenation, repopulation, and reassortment of cells within the cell cycle.[36] These four factors are key to deciding the radiation schedule to optimize tumor regression while minimizing effects to normal tissues.

With fractionated radiation normal tissues are able to *repair* sublethal radiation effects between treatments. With large daily doses of radiation, a large number of tumor cells are killed, but repair of normal tissues is lower (Fig. 86.8). Because the normal tissues are unable to repair the radiation
Figure 86.7 *The Bragg–Peak effect in radiation associated with proton radiation. Only the designated tumor area receives radiation and the surrounding normal tissues are spared radiation. Although currently used to treat intracranial tumors and children, proton radiation may have application in palliative care for the re-treatment of tumors.*
Figure 86.8 *Cell survival curve for single and multiple fraction radiation schedules. A large single dose of radiation, like a single 8 Gy radiation fraction, proportionately kills more tumor cells than equivalent total doses of radiation spread out over multiple fractions, like four 2 Gy fractions, because of repopulation of tumor cells and repair of sublethal damage.*

damage of large daily doses of radiation, the total radiation dose that can be given is also much lower.[36]

Equivalent normal tissue effects can be achieved with a variety of radiation treatment schedules. The following clinical radiation schedules are used to treat spine metastases: 2000 cGy is delivered in five fractions, 3000 cGy is administered in 10 fractions, 3500 cGy in 14 fractions or 4000 cGy in 20 fractions. The late radiation effects on the spinal cord would be equal to giving 2800 cGy, 3600 cGy, and 3900 cGy, respectively, at 200 cGy per fraction. This shows that as the radiation dose per fraction increases, the late radiation toxicities biologically exceed the total radiation dose administered. This effect is more exaggerated as the radiation dose per fraction increases from the standard 200 cGy per fraction.[41] Relating back to the example on integral dose in Table 86.2, administration of 5880 cGy at 294 cGy per fraction would result in severe long-term radiation effects because this would be biologically equal to a total radiation dose of 7200 cGy at 200 cGy per fraction to a large area of small bowel.[42]

The total dose of radiation necessary to eradicate a tumor is a function of the volume of disease and the number of tumor cells killed with each radiation fraction. The tumor volume is the sum of viable and nonviable cells. In most tumors, the potential number of tumor cells is directly proportional to the tumor volume. In some tumors, e.g. soft tissue sarcomas, there is a large necrotic fraction and the rate of cell loss and removal of dead tumor cells from the tumor volume is low. The viable cells may be less responsive to radiation because of the low oxygen tension in the nearby necrotic region. The radiosensitivity of cells also varies during the cell cycle. Cells are most resistant to radiation when they are in the late S-phase, and in the late G1/G0 phase. Radiation resistance results from either rapidly proliferating tumors that spend most of their time in S-phase or a slowly proliferating tumor where many cells are in G1/G0.

Less total radiation dose is required to control microscopic residual disease than bulk disease. For example, the 2-year rate of local control following radiation alone in the treatment of cervical node metastases in head and neck cancer is directly related to the node diameter and total dose. Using 200 cGy per daily fraction of radiation, over 95 percent of patients with only microscopic residual cancer achieve tumor control, and over 85 percent of patients with lymph node diameters of less than 2 cm in size are controlled with a median dose of 6600 cGy. But only 69 percent of nodes measuring between 2.5 cm and 3.0 cm are controlled after 6900 cGy and 59 percent of nodes larger than 3.5 cm are controlled after 7000 cGy. Large tumors have a large hypoxic fraction of cells.[36] Hypoxic cells are relatively resistant to radiation effects; it takes three times the dose of radiation to control hypoxic tumors as it does well-oxygenated tumors (Fig. 86.9). With fractionated radiation, hypoxic areas are able to reoxygenate to some degree during the course of treatment.

Additionally, tumor cells and normal tissues vary widely in their tolerance to radiation because of cellular repopulation.

Radiation doses need to be high enough to kill tumor cells but low enough to allow normal tissues to repair and repopulate. Very low doses of radiation have limited acute effects on normal tissues. No inflammation of the skin or mucosa occurs when the radiation dose is less than 2000 cGy when given in 200 cGy fractions over 2 weeks. But this total dose of radiation is not sufficient to permanently kill tumor cells due to repopulation of the tumor cells. In the past, a course of radiation was interrupted after 2 weeks of treatment to minimize the side effects of treatment. These so-called 'split-courses of radiation' that allowed repair and repopulation of normal tissues and improved tolerance to radiation have been abandoned because tumor control rates were compromised by tumor repopulation during the interruption in the treatment.[43,33] In fact, tumor repopulation was found during radiobiological evaluations to be accelerated after 2 weeks of radiation because of tumor reoxygenation.

Tolerance to radiation also depends on the type of tissue treated. There are two types of normal tissue:

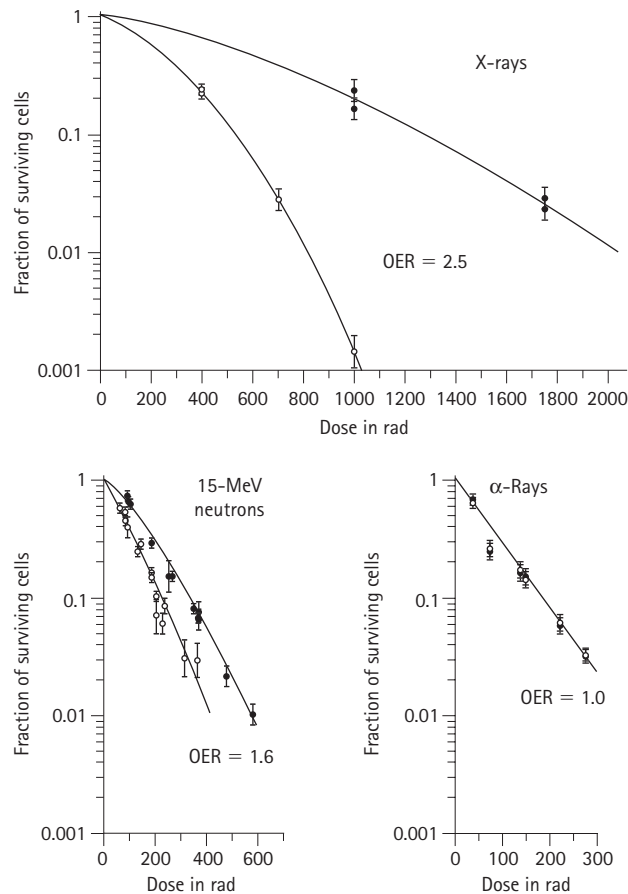
- *Acute reacting tissues*. These are rapidly proliferating tissues, e.g. mucosal surfaces, and usually develop an inflammatory radiation reaction during the course of treatment.


Figure 86.9 *Influence of oxygen on the ability of radiation to kill tumor cells. Open symbols represent hypoxic cells; closed symbols represent oxygenated cells. OER, oxygen enhancement ratio.*

- *Late reacting tissues*. These do not proliferate, e.g. brain and spinal cord, liver, and muscle, and generally do not develop a significant inflammatory reaction during the radiation course.

Acute radiation reactions do not predict the extent of late radiation effects. Scar tissue is the most common form of late radiation effect. These effects are similar to those seen in wound healing. The alpha-beta ratio is a calculation that relates to the ability of normal tissues to repair the damage caused by radiation.[36] With low daily doses of radiation over several weeks, more acute radiation effects are seen during the course of radiation. When high daily doses of radiation are given over a short period of time, the most significant radiation side effects occur months to years later after the radiation is completed.

Relating normal tissue tolerance to a 5 percent risk of a treatment-related complication at 5 years, the tolerance doses (TD 5/5) of each organ have been reported by a National Cancer Institute task force. The TD 5/5 ranges from 1000 cGy for the eye, to 1750 cGy for the lung, 4500 cGy for the brain, and 7000 cGy for the larynx when the entire organ is treated. Radiation tolerance is a function both of the type and the volume of tissue irradiated. When only a third of the organ is irradiated, these values equal 4500 cGy for the lung, 6000 cGy for the brain and 7900 cGy for the larynx. The normal tissue tolerance for spinal cord is more limited.

RADIATION TOLERANCE OF THE SPINAL CORD

The potential for the development of radiation myelitis with total radiation doses which exceed 40 Gy at 2 Gy per fraction represents the limiting factor in the treatment of large tumor burdens near or involving the spinal canal. Furthermore, the length of spinal cord that needs to be irradiated significantly affects the radiation tolerance of the spinal cord.[45–49] Changes seen in the bone marrow on MRI after palliative radiotherapy initially includes decreased cellularity, edema, and hemorrhage followed by fatty replacement and fibrosis. These well-defined changes on MRI after radiotherapy can be distinguished from those seen with progressive disease.[50–52]

Clinical and experimental experience has failed to demonstrate any difference in radiosensitivity in different segments of the spinal cord.[45,48] The risk of radiation myelitis in the cervicothoracic spine is less than 5 percent when 6000 cGy is administered at 172 cGy per fraction, or 5000 cGy is given with daily fractions of 200 cGy per fraction. Especially among patients who have received chemotherapy or need to have a significant length of spinal cord irradiated, the total dose to the spinal cord is generally limited to 4000 cGy administered at 200 cGy per fraction to minimize any risk of irreversible radiation injury to the spinal cord. A steep curve based on total radiation dose predicts the risk of developing radiation myelopathy; a small increase in total radiation dose can result in a large increased risk for radiation myelopathy.[45,47,49]

Re-treatment of a previously irradiated segment of spinal cord results in high risk for radiation-induced myelopathy because other neurological pathways cannot compensate for an injury to a specific level of the spinal cord. Experimental data also have shown that the time course and the extent of long-term recovery from radiation are dependent on the specific type and age of tissue.

The radiation tolerance of the spinal cord can be compromised by prior injury. Difficulty arises in separating traumatic, pathological, and radiotherapeutic injury to spinal cord compression. Vasogenic edema of the spinal cord and nerve roots can be caused by compression injury. Metastatic epidural compression results in vasogenic spinal cord edema, venous hemorrhage, loss of myelin, and ischemia. Other consequences of pathological compression include hemorrhage, loss of myelin, and ischemia.[45–49]

PALLIATIVE RADIATION

With palliative radiation, shorter external beam radiation schedules are generally used that administer a higher radiation dose with each radiation fraction. This is known as *hypo*fractionation (Table 86.3). Tumor cell kill is proportional to the radiation dose that is administered. Therefore, symptomatic relief is more quickly achieved because of the large number of tumor cells that are killed in a short period of time with large daily doses of radiation (see Fig. 86.8).

A shorter course of therapy also has a significant impact on quality of life. This short course of treatment not only provides more prompt relief of tumor-related symptoms, but it limits the amount of time needed for the patient to come back and forth for radiation treatments. This is particularly important because the median survival is less than 6 months among patients with poor prognostic factors. However, higher radiation doses, that provide more durable pain relief, are considered warranted for patients with good prognostic factors who require treatment over the spine and other critical sites. It is important to recognize that palliative radiation only results in tumor regression and does not eradicate the tumor. With prolonged survival, the site of metastatic disease may require re-treatment due to regrowth of the tumor.

In contrast to the low daily radiation doses (1.8–2 Gy) given with each treatment during conventional radiation schedules to total radiation doses of 50–60 Gy over 5–6

weeks, large daily radiation fractions are given with hypofractionated radiation schedules used for palliative radiation. Because of normal tissue tolerance to radiation, the total radiation dose that can be administered is low when high doses of radiation are given with each daily fraction. Hypofractionated radiation schedules can range from 2.5 Gy per fraction administered over 3 weeks for a total radiation dose of 35 Gy to a single 8 Gy dose of radiation.[53,54] Most frequently, 30 Gy is administered in 10 fractions over 2 weeks. The decision for the radiation schedule depends on the radiation tolerance of the tissues in the field and the prognosis. The radiation schedule used to relieve symptoms must be indexed to the types of tissues treated, the potential for tumor resection, and/or overall prognosis.

Radiopharmaceuticals are another systemic option that treat diffuse symptomatic bone metastases. Radiopharmaceuticals, such as strontium-89 or samarium-153, can also be used to treat bone metastases when symptoms recur in a previously irradiated site but are contraindicated with epidural disease because the radiation is deposited directly at the involved area in the bone.[55–60] Radiopharmaceuticals can also act as an adjuvant to localized external beam irradiation and reduce the development of other symptomatic sites of disease.

Control of cancer-related pain with the use of analgesics is imperative to allow comfort during and while awaiting response to antineoplastic interventions. Pain represents a sensitive measure of disease activity. Patients should be closely followed up to ensure control of cancer and treatment-related pain, and to initiate diagnostic studies to determine the cause of persistent, progressive or recurrent symptoms. The limited radiation tolerance of the normal tissues, like the spinal cord, that are adjacent to a bone metastasis make it impossible to administer a large enough dose of radiation to eradicate a measurable volume of tumor. Palliative radiation should result in sufficient tumor regression off critical structures to relieve symptoms. Symptoms that recur after palliative radiation most commonly result from localized regrowth of tumor in the radiation field.

Localized bone metastases

Radiation of localized bone metastases relieves symptoms and helps prevent spinal cord compression and pathological fractures. There has been much controversy about palliative radiation schedules for localized symptomatic bone metastases. The Radiation Therapy Oncology Group (RTOG) conducted a prospective trial that included a variety of treatment schedules. In order to account for prognosis, patients were stratified on the basis of whether they had a solitary or multiple sites of bony metastases. The initial analysis of the study concluded that low-dose, short-course treatment schedules were as effective as high-dose protracted treatment programs.[61] For solitary bone metastases, there was no difference in the relief of pain when 20 Gy using 4 Gy fractions was compared with 40.5 Gy delivered as 2.7 Gy per fraction. In patients with multiple bone metastases, the following dose

schedules were compared: 30 Gy at 3 Gy per fraction, 15 Gy given as 3 Gy per fraction, 20 Gy using 4 Gy per fraction, and 25 Gy using 5 Gy per fraction. No difference was identified in the rates of pain relief between these treatment schedules (Table 86.4). Partial relief of pain was achieved in 83 percent, and complete relief occurred in 53 percent of the patients studied. Over 50 percent of these patients developed recurrent pain, and 8 percent of patients developed a pathological fracture.

In a reanalysis of the data, a different definition for complete pain relief was used and excluded the continued administration of analgesics. Using this definition, the relief of pain was significantly related to the number of fractions and the total dose of radiation that was administered.[62] Complete relief of pain was achieved in 55 percent of patients with solitary bone metastases who received 40.5 Gy at 2.7 Gy per fraction as compared with 37 percent of patients who received a total dose of 20 Gy given as 4 Gy per fraction. A similar relation was observed in the reanalysis of patients who had multiple bone metastases. Complete relief of pain was achieved in 46 percent of patients who received 30 Gy at 3 Gy per fraction versus 28 percent of patients treated to 25 Gy using 5 Gy fractions.

Three important issues are identified from this RTOG experience. First, the results of the reanalysis demonstrate the importance of defining what represents a response to therapy. Second, this revised definition of response showed that the total radiation dose did influence the degree that pain was relieved. Third, the RTOG experience identified the amount of time that was needed to experience relief of pain after radiation for bone metastases (Tables 86.5 and 86.6). It is important to note that only half of the patients who were going to respond had relief of symptoms at 2 weeks to 4 weeks after radiation.[61,62] This underscores the need for continued analgesic support after completing radiation. Consistently, it took 12 weeks to 20 weeks after radiation to accomplish the maximal level of relief. That period of time may reflect the time needed for reossification.

Radiographic evidence of recalcification is observed in about a fourth of cases, and in 70 percent of the time recalcification is seen within 6 months of completing radiation and other palliative therapies.[63–65] Therefore, it is critical to determine the time and parameters of response. Pretreatment characteristics also can influence the level of response. Neuropathic pain is a significant clinical variable that reduces the response to palliative radiation.[67,68]

The projected length of survival is the critical issue for radiation dose and schedule for palliative radiation. In one study, only 12 of 245 patients were alive at the time of analysis with approximately 50 percent alive at 6 months, 25 percent at 1 year, 8 percent at 2 years, and 3 percent at 3 years after palliative radiation. For breast cancer patients the survival rates at these time points after palliative radiation were 60 percent, 44 percent, 20 percent, and 7 percent, respectively. For prostate cancer, the survival rates were 60 percent at 6 months, 24 percent at 1 year, and there were no patients who survived 2 years.[69] In the RTOG trial

Table 86.4   *(A) Different radiation schedules. Arrows represent a comparison to conventional fractionation*

	Conventional	Hyperfractionation	Accelerated	Hypofractionation
Intent	Curative	Curative	Curative	Palliative
No. of fractions per day	1	2 (↑)	1/day for the first 3 to 4 weeks of XRT (↔) Then 2/day (large field + boost field around the tumor) for the last 1 to 2 weeks of XRT (↑)	1 [↔]
No. of fractions	25–30	60–70 (↑)	30–35 (↑)	1–15 (↓)
Dose per fraction	1.8–2 Gy	1.2 Gy BID (↓)	1.8 to 2 Gy to a large field (↔) 1.5 Gy to a boost field (↓)	8 Gy (1 fraction) to 2.5 Gy (15 fractions) (↑)
No. of weeks	5–6	7–9 (↑)	5–6 (↔)	1–3 (↓)
Total radiation dose	45–60 Gy	70–84 Gy (↑)	52–65 Gy (↑)	8–35 Gy (↓)

(B) Relative relations of radiation dose per fraction, and total dose in a variety of radiation schedules. When a high dose of radiation is given per fraction, the total dose must be low and given in a small number of fractions

Low		High	
Hypofractionation	Conventional fractionation	Hyperfractionation	Accelerated fractionation
20–30 Gy	50–60 Gy	70–80 Gy	55–65 Gy
5–10 fractions	25–30 fractions	60–70 fractions	28–35 fractions
1–2 weeks	5–6 weeks	7–8 weeks	5–6 weeks

Table 86.5   *Dose–response evaluation from the reanalysis of the RTOG Bone Metastases Protocol.[90] Listed are the dose per fraction (dose/fx), total radiation dose, the radiobiological equivalent dose if administered at 2 Gy/fx, the complete response rate (CR) using the definition that excludes the use of analgesics and that accounts for re-treatment*

	Dose/fx (Gy)	Total dose (Gy)	Tumor dose at 2 Gy/fx	CR (%)	P value
Solitary bone metastases					0.0003
	2.7	40.5	42.9	55	
	4.0	20.0	23.3	37	
Multiple bone metastases					0.0003
	3.0	30	32.5	46	
	3.0	15.0	16.2	36	
	4.0	20.0	23.3	40	
	5.0	25.0	31.25	28	

Table 86.6   *Percentage of patients who responded to radiation relative to time, designated in weeks after completion of radiation therapy. This prospective trial, conducted by the RTOG, randomized radiation dose and number of fractions and stratified the randomization on the basis of solitary or multiple bone metastases.[79,80] Also listed is the radiobiological equivalent dose if administered at 2 Gy per fraction*

Total dose (Gy)	Dose per fraction (Gy)	Tumor dose at 2 Gy/fx	Weeks after radiation therapy (%)			
			<2	2–4	4–12	12–20
Solitary metastasis						
40.5	2.7	42.9	7	29	53	77
20.0	4	23.3	16	50	66	82
Multiple metastasis						
30.0	3	32.5	19	48	73	84
15.0	3	16.2	34	70	84	93
20.0	4	23.3	28	53	75	88
25.0	5	31.25	22	41	72	80

the median survival for solitary bone metastases was 36 weeks and was 24 weeks for multiple bone metastases.[61,62] The RTOG study also demonstrated that the level of pain correlated with prognosis among patients with multiple bone metastases. This survival difference may be an important observation because unrelieved pain and the resultant sequelae of immobility may contribute to mortality as well as morbidity.

Spinal cord compression

The time from the original diagnosis to the development of metastatic spinal disease averages 32 months, and the average time is reported to be 27 months from diagnosis of skeletal metastases to spinal cord compression. Median survival among patients with spinal cord compression ranges between 3 and 7 months with a 36 percent probability for a 1-year survival. The vertebral column is involved by metastatic tumor in 40 percent of patients who die of cancer, and approximately 70 percent of vertebral metastases involve the thoracic spine, 20 percent the lumbosacral region, and 10 percent the cervical spine. From a tumor registry of 121 435 patients, the cumulative probability of at least one episode of spinal cord compression occurring in the last 5 years of life was 2.5 percent.[72] The diagnosis of spinal cord compression was associated with a doubling of the time spent in hospital in the last year of life.

The demographics of spinal cord compression were: 37 percent of patients had breast cancer, 28 percent had prostate cancer, 18 percent had lung cancer, and 17 percent had other solid tumors. The time between primary tumor diagnosis and development of spinal cord compression is dependent on tumor type with the shortest time associated with lung cancer and the longest time for breast cancer. Lung cancer patients have the most severe functional deficit with more than 50 percent totally paralyzed. Breast cancer patients are ambulatory 59 percent of the time. More severe disturbances in gait occurred when the time between the interval from the diagnosis of the primary tumor and spinal cord compression was short.[70–75] The mean survival time after the diagnosis of spinal cord compression is 14 months for breast cancer, 12 months in prostate cancer, 6 months in malignant melanoma, and 3 months in lung cancer.[70–72]

In a series of 153 consecutive patients with spinal cord compression, total paralysis was present in 28 percent of patients presenting for radiation, 20 percent were able to move their legs but could not walk, 12 percent were able to walk with assistance, and 40 percent could walk unassisted. Sensory exam of the legs was normal in 34, slight disturbances were present in 84, and total lack of pain perception occurred in 35 patients. After radiation, 26 percent were totally paralyzed, 13 percent were able to move their legs without being able to walk, 11 percent were able to walk with assistance, and 50 percent had unassisted gait.[76] Survival in this series was dependent on time from primary tumor diagnosis,

ambulatory function at diagnosis and after radiation therapy, and median survival was 3.5 months. The type of primary tumor also has a direct influence on the interval between the diagnosis of the primary tumor and the diagnosis of spinal cord compression due to metastatic disease.[77] Factors such as age, discharge destination, primary tumor site, other metastases, comorbidities, and hemoglobin and albumin levels had no significant influence on survival time in a study of 60 consecutive patients with metastatic spinal cord compression.[78]

RADIATION SCHEDULE FOR SPINAL CORD COMPRESSION BASED ON PROGNOSIS

The time under radiation needs to be considered as the opportunity cost of palliative treatment.[79] If the median survival of a patient with spinal cord compression is 6 months (180 days), the patient will spend 0.6 percent of the remaining survival time under radiation treatment when a single fraction of radiation is given. If 10 radiation fractions are given, 8 percent of the remaining survival and if 20 fractions are prescribed 16 percent of the remaining survival will be consumed by radiation therapy. Even if re-treatment with a second single fraction is required, the patient will continue to spend about 1 percent of the survival time under radiation therapy. For lung cancer patients with a 3 month survival rate, 1 percent of the remaining time is spent with a single fraction of radiation as compared to 16 percent if 10 fractions are given, or 30 percent if 20 fractions are prescribed.

A more protracted course of radiation is still used for patients with a more prolonged prognosis who require treatment over the spine and other critical sites. With a more limited prognosis, metastatic spinal cord compression has been treated either with a single 8 Gy fraction or five 4 Gy fractions. The median time to recurrence was 6 months among 62 patients with a range of 2–40 months.[73] Re-treatment consisted of another single 8 Gy fraction, or five more fractions of either 3 Gy or 4 Gy. Motor function improved in 40 percent, and it was stable in an additional 45 percent; 38 percent of the nonambulatory patients regained the ability to walk.[80,81] Use of a single fraction of radiation provided sufficient tumor regression for neurological improvement while minimizing time under radiation.

Arguments against the use of a single fraction of radiation in patients with a more limited prognosis involve gastrointestinal toxicity from the exit dose of radiation. Using a single posterior radiation field, about two-thirds of the radiation dose causes toxicity as it exits through the esophagus, stomach, and bowel (Fig. 86.10). Acute radiation toxicities are a function of the dose per fraction, total dose, and the area and volume of tissue irradiated. If mucosal surfaces like the upper aerodigestive tract, bowel and bladder can be excluded from the radiation portals, acute radiation side effects can be significantly reduced whether a single or multiple fractions are prescribed.[82–90] Gastrointestinal toxicities, like esophagitis, nausea and vomiting, and small bowel
Figure 86.10 *Typical radiation portal to treat disease involvement in the vertebral bodies and epidural region.*
Figure 86.11 *Radiation plan that reduces exit beam and toxicity to adjacent visceral structures.*

toxicity, can be avoided when a high dose of radiation, is administered with the use of more conformal radiation that localizes the radiation to the vertebra and minimizing dose to adjacent normal structures (Fig. 86.11).

RESPONSE TO RADIATION THERAPY

Pain is the initial symptom in approximately 90 percent of patients with spinal cord compression, and the development

of spinal cord compression is associated with a poor overall prognosis. Paraparesis or paraplegia occurs in over 60 percent, sensory loss is noted in 70 percent to 80 percent, and 14 percent to 77 percent have bladder and/or bowel disturbances.[73,77,91–100] Among 102 consecutive patients with metastatic spinal cord compression, only 51 percent were fully ambulatory at the time of radiotherapy, and 41 percent had paraparesis. Median survival was 3.5 months, with normal gait returning in 58 percent, 2 weeks after completing radiation, and in 71 percent, 2 months after radiation. No paraplegic patient regained function.[91]

The rate of development of motor symptoms correlates with the possibility of recovering neurological function after radiation therapy. Weakness can signal the rapid progression of symptoms and 30 percent of patients with weakness become paraplegic within 1 week. Rapid development of weakness, defined as occurring in less than 2 months, most commonly occurs in lung cancer whereas breast and prostate cancers can progress more slowly. Neurological deficits can develop within a few hours in up to 20 percent of patients with spinal cord compression.[70–72,76,77,91,93,95–100] Motor function improved among 86 percent of patients who had >14-day time to development of symptoms. Only 29 percent improved when motor deficits developed over 8 to 14 days before the diagnosis of spinal cord compression. Improvements occurred in only 10 percent if motor deficits developed over 1 to 7 days. The severity of weakness at the time that radiation therapy is initiated is the most significant factor for recovery of function. Ninety percent of patients who are ambulatory at presentation will be ambulatory after radiation. Only 13 percent of paraplegic patients will regain function, particularly if paraplegia is present for more than 24 hours before the initiation of radiation.

The degree and rate of pain relief is also dependent on the level of pain at the time radiation is administered.[77,76,77,91,93,95–100] Pain relief is accomplished in 73 percent of patients, and the mean time to pain relief was 35 days in 108 breast cancer patients. Recurrent symptoms at a different spinal level occur in more than three-fourths of patients and within 6 months of radiation.[72]

Without motor impairment, corticosteroids are unnecessary when radiation therapy is administered to relieve pain from vertebral involvement.[101] Elimination of steroids from the standard treatment avoids cortisone side effects above all in those patients with diabetes, hypertension, peptic ulcer, and other steroid-sensitive medical problems. However, corticosteroids should be initiated with clinical and/or radiographic evidence of spinal cord compromise prior to the start of radiotherapy to reduce disease-related edema and pain. Oral dexamethasone (4 mg) generally is administered four times daily, but intravenous dexamethasone should be considered with severe and/or rapid neurological impairment. Experimental studies have shown that high-dose steroids are more effective than lower doses in reversing edema and improving neurological function.

Consistent with this are clinical data including a well-designed randomized trial that administered radiation therapy either with high-dose corticosteroids or placebo. In that trial the group that received corticosteroids were more likely to retain or regain ambulation.[102] Pain relief is also more rapid and complete with high-dose steroids (initial bolus of 100 mg followed by 4 mg dexamethasone four times daily for the duration of radiation therapy) among patients suspected to have spinal cord compression.

The radiation tolerance of the spinal cord can be compromised by prior injury. Difficulty arises in separating the pathological and radiotherapeutic injury to spinal cord compression. Vasogenic edema of the spinal cord and nerve roots can be caused by compression injury. Metastatic epidural compression results in vasogenic spinal cord edema, venous hemorrhage, loss of myelin, and ischemia. Vasogenic edema results in an increased synthesis of prostaglandin E_2 that can be inhibited by steroids or nonsteroidal anti-inflammatory agents. Other consequences of pathological compression include hemorrhage, loss of myelin, and ischemia.[45–47]

A statistically significant improvement in functional outcome occurs with laminectomy and radiotherapy in treatment of epidural spinal cord compression over either modality alone for selected clinical presentations. Laminectomy has been recommended to promptly reduce tumor volume in an attempt to relieve compression and injury of the spinal cord and provide stabilization to the spinal axis. The rate of tumor regression following radiotherapy is too slow in these cases to effect recovery of lost neurologic function, and radiation therapy cannot relieve compression of the spinal column due to vertebral collapse. After radiation alone to treat a partial spinal cord block, 64 percent of patients regain ambulation, 33 percent have normalization of sphincter tone, 72 percent are pain free, and median survival is 9 months.[70,76,86,89,90,103,104] With a complete spinal cord block only 27 percent will have improvement in motor function and 42 percent will continue to have pain after radiation alone. In paraparetic patients who undergo laminectomy and radiation, 82 percent regain the ability to walk, 68 percent have improved sphincter function, and 88 percent have relief of pain.

Laminectomy is indicated with rapid neurological deterioration, tumor progression in a previously irradiated area, stabilization of the spine, paraplegic patients with limited disease and good probability of survival, and to establish a diagnosis. Adjuvant radiotherapy is often given after laminectomy to treat microscopic residual disease after neurosurgical intervention.[70,84–86,88–90,103,104] Surgical restoration of the vertebral alignment may be required due to neurologic compromise and pain caused by progressive vertebral collapse. Vertebral collapse may occur due to cancer or vertebral instability after cancer therapy, e.g. radiation (Fig. 86.12). Appropriate diagnostic studies and intervention should be pursued with persistent pain because the neurological compromise and pain from vertebral instability

Figure 86.12 *Compression fraction of the twelfth thoracic vertebral body following an initial pain-free interval after palliative radiation. Vertebral weakness with rapid tumor regression resulted in the compression fracture which caused recurrent back pain due to spinal instability.*

can be as devastating as that with epidural spinal cord metastases.[89,104]

Based on clinical and radiographic grounds, leptomeningeal carcinomatosis must also be considered in the diagnostic evaluation. Leptomeningeal carcinomatosis occurs more commonly than expected. For example, only half of breast cancer patients with leptomeningeal carcinomatosis will be diagnosed before death.[70,75,84,90,97] Radiation therapy is indicated in localized regions of nodular leptomeningeal involvement.[97]

THERAPEUTIC RECOMMENDATIONS

The primary goals of palliative treatment are to efficiently relieve disease-related symptoms and maintain function, while minimizing treatment-related symptoms and time under therapy. Spine metastases cause significant pain and can result in irreversible paralysis. Patients with known vertebral metastases require frequent clinical evaluation to

identify any change in symptoms and/or radiographic findings suggesting risk for spinal cord compromise. Early detection of vertebral compromise is paramount to preventing an oncological emergency with severe pain and neurological compromise from spinal cord compression. Emergent oncological care involves either surgical decompression and/or radiation therapy.

To prevent disease progression resulting in spinal cord compression, radiation should be considered to treat extensive and/or painful vertebral metastases, and with limited asymptomatic epidural involvement. Radiopharmaceuticals, administered by a single injection, are an important option with multifocal bone metastases, especially if symptoms and disease recurs in a previously irradiated area in the absence of epidural involvement.

Radiation remains an important modality in palliative care. A number of clinical, prognostic and therapeutic factors must be considered to determine the most optimal treatment regimen in palliative radiotherapy in general. Symptoms that persist after palliative radiation should be evaluated to exclude progression of disease in the treated area, and possible extension of disease outside the radiation portal especially if there is an associated paraspinal mass. Pain may also persist due to reduced cortical strength after treatment of spinal metastases that can result in vertebral compression or stress microfractures.

A wide range of radiotherapeutic options are available for the treatment of spinal cord compression. Radiobiological principles, the radiation tolerance of adjacent normal tissues, and the clinical condition influence the selection of radiation technique, dose, and fraction size. As a late-reacting tissue, the radiobiological tolerance of the spinal cord to radiation is finite. Technological advances, however, have increased our ability to treat spinal metastases with greater precision, and have allowed consideration of retreatment with radiation to selected patients.

Prevention or early treatment of symptoms is often the most important care administered. The treatment of vertebral metastases and spinal cord compression to prevent or relieve symptoms of pain and paralysis is one of the most important services rendered to cancer patients.

Key learning points

- Spinal cord compression results in significant morbidity, constitutes an oncological emergency, and is associated with a poor overall prognosis.

- Early diagnosis and treatment prevents lasting neurological dysfunction.

- New therapeutic modalities are now available to prevent and treat spinal cord compression.

Superior vena cava syndrome

MARÍA LUISA DEL VALLE, CARLOS CENTENO

INTRODUCTION

Superior vena cava syndrome (SVCS) is an array of symptoms resulting from the impairment of blood flow through the superior vena cava to the right atrium. It is present at diagnosis in 10 percent of patients with small cell lung cancer and less than 2 percent of patients with nonsmall cell lung cancer. There are no reliable data on the risk of subsequent development of SVCS in patients with lung cancer or on its prevalence in a terminal setting. However, clinically relevant SVCS can develop in more than 10 percent of patients with right-sided malignant intrathoracic tumors.[1]

ETIOLOGY

The spectrum of underlying conditions associated with SVCS has shifted from tuberculosis and other benign diseases such as mediastinal fibrosis or histoplasmosis to malignant disorders. Almost 95 percent of SVCS cases described in recent studies are due to cancer. The most common cause is small cell lung cancer,[2*] followed by nonsmall cell lung carcinoma – in different proportions for each histological subtype (Table 87.1). Additional causes of

Table 87.1 *Histologic subtypes of lung cancer in superior vena cava syndrome*

Histology	Patients (%)
Small cell	40
Squamous	25
Adenocarcinoma	15
Large cell	10
Unknown	10

SVCS include cancers, such as germ cell tumors, lymphoma, thymoma, esophageal cancer or mediastinal metastases from other tumors, and nonmalignant diseases, such as sarcoidosis.[3] A nonmalignant cause of SVCS in patients with cancer that is becoming more frequent is thrombosis, sometimes due to intracaval catheters.

PHYSIOPATHOLOGY

Superior vena cava syndrome results from the compression of the superior vena cava by:

- tumor arising in the mediastinum or in the right main or upper lobe bronchus
- large-volume mediastinal lymphadenopathy (most commonly from the right paratracheal or precarinal lymph nodes).[4]

The superior vena cava is formed by the junction of the left and right brachiocephalic veins in the mid-third of the mediastinum. It extends caudally for 6–8 cm, coursing anterior to the right mainstem bronchus and terminating in the superior right atrium. It is joined posteriorly by the azygos vein as it loops over the right mainstem bronchus and lies posterior to and to the right of the ascending aorta. The right mediastinal parietal pleura is lateral to the superior vena cava, creating a confined space, and the superior vena cava lies adjacent to the right paratracheal, azygous, right hilar and subcarinal lymph node groups. It is a thin-walled vessel and the blood flows in it under low pressure. Thus, when the nodes or ascending aorta enlarge and the superior vena cava is compressed, partial occlusion may occur leading to slowing of blood flow, and eventually, complete superior vena cava occlusion may develop.

The severity of the syndrome depends on the rapidity of onset of the obstruction and its location. The more rapid the onset, the more severe the symptoms because the collateral veins do not have time to distend to accommodate the increased blood flow. If the obstruction is above the entry of the azygos vein, the syndrome is less pronounced because the azygous system can readily distend to accommodate the shunted blood, allowing a reduction of the venous pressure in the head, arms, and upper thorax. If the obstruction is below the entry of the azygos vein, more florid and severe symptoms and signs are seen because the blood pressure increases in order to return to the heart via the upper abdominal veins and the inferior vena cava.[5] Other patterns of venous collateral return have been described, but their significance is less relevant.[6]

CLINICAL PRESENTATION

The diagnosis of SVCS is usually made clinically in the first instance. The most frequent symptoms that prompt suspicion of this syndrome include swelling of the face, neck, upper trunk and extremities, coughing, and dyspnea. Several other symptoms may be associated, such as chest pain, dysphagia and less frequently, lethargy and headache. More rarely, cyanosis, Horner syndrome, and paralysis of the vocal chords may also be present. Physical signs usually noted on presentation are neck and thoracic vein distension, edema of the face and upper extremities, venous regurgutation, hoarseness, and tachypnea (Table 87.2).

Although SVCS may present with different manifestations depending on the severity of obstruction and the rate of progression of disease, there is no commonly accepted scoring system to assess its risk and provide adequate treatment.

DIAGNOSIS

Once SVCS is recognized, prompt clinical attention is important. In the absence of a histological diagnosis, however, it

Table 87.2 *Most frequent symptoms and physical signs in superior vena cava syndrome*

Symptoms	Percent	Signs	Percent
Dyspnea	65	Venous distension of neck	65
Swelling of the face and neck	50	Venous distension of upper trunk	55
Cough	25	Facial edema	45
Swelling of the extremities	20	Cyanosis	20
Chest pain	15	Venous regurgitation	20
Dysphagia	10	Arm edema	15

is advisable that this should be established prior to initiating therapy. Usually there is time to obtain a histological diagnosis, chiefly because 3–5 percent of the patients diagnosed with SVCS do not have cancer. Even when SVCS is evidently an oncological complication, generally no emergent therapeutic interventions are required. This is because this syndrome usually presents with slow progressive development of clinical manifestations as a chronic or at least, as a subacute disease. In fact, up to 75 percent of patients present symptoms and signs of SVCS for over a week before seeking medical attention.[7] In addition, it must be borne in mind that SVCS is rarely lethal by itself. Cancer patients diagnosed with SVCS (even more, those patients with advanced and refractory tumors) do not die because of this syndrome itself but from the extent of underlying disease. Only in exceptional cases, where tracheal obstruction or cerebral edema is present, could SVCS be considered as an oncological emergency requiring immediate therapy. In the rest, treatment prior to definitive diagnosis does not seem to be justified.[8]

The initial evaluation of the patient should include a chest radiograph to look for mediastinal masses and other possible associated findings, such as pleural effusion, lobar collapse, or cardiomegaly. Computed tomography (CT) or magnetic resonance imaging (MRI) is of a great value in defining the extent of the disease and even in planning the treatment.[9] Both yield the most useful diagnostic information and can define the anatomy of the involved mediastinal nodes. They might assist in radiotherapy planning or act as a baseline for assessment of response to treatment such as chemotherapy. Venous patency and the presence of thrombus are assessed by using contrast and rapid scanning techniques.[10] For example, contrast-enhanced spiral or multislice CT and MRI are now able to identify accurately the level of the obstruction and the presence of associated intravascular thrombus. Depending on local expertise, contrast and nuclear venography and ultrasound may help in further assessment of the nature and location of the obstruction.

After the first clinical and radiographic approach, a histological diagnosis is essential for appropriate treatment planning. This is because in SVCS due to cancer, the treatment depends on tumor histology. When the syndrome appears within the framework of a tumoral disease but without defined histology, the biopsy specimen should be taken from the most accessible site that is clinically involved with disease. The protocol for biopsy is based on the location of the tumor, the performance status of the patient, and the expertise available. It may include bronchoscopy, biopsy of palpable cervical or supraclavicular lymph nodes or needle biopsy of a lung mass or mediastinal nodes using either CT or ultrasound guidance. In a number of patients, more aggressive tools such as mediastinoscopy, mediastinotomy, median sternotomy, video-assisted thoracoscopy, or conventional thoracotomy may be required.

TREATMENT

The treatment of SVCS depends on the cause of the obstruction, the severity of the symptoms, the prognosis of the patient, and the patient's preferences and goals for therapy. In patients with advanced cancer, treatment is generally purely symptomatic. Yet in some patients, the best palliation, measured as both symptom control and quality of life and even prolongation of survival, is achieved not only by 'symptomatic' treatment but also by treatment specifically directed against the tumor.

It is advisable to withhold both radiation therapy and chemotherapy until the etiology of the obstruction is clear. Since treatment of a malignant obstruction may depend on tumor histology, a histological diagnosis, if not made earlier, should be made immediately prior to initiation of treatment.[11] Unless there is airway obstruction or cerebral edema, there appears to be no detriment in outcome when treatment is delayed until these data are obtained.

Response rates to therapy are difficult to evaluate. Radiographic measures of tumor may not directly correlate with the severity of symptoms or the clinical status of patients and criteria for relief are not well defined. As the diagnosis of SVCS is made clinically, the clinical response and subsequent relapse need to be assessed in the same way. Although a number of studies have described the range of symptoms prior to treatment, response assessment was limited to whether SVCS had been relieved or not. In other studies different scoring systems have been proposed,[12,13*] but as of now there is no standard scoring system.

Medical management

A patient with sufficient collateral blood flow and minimal symptoms may not need treatment other than postural advice and appropriate prevention of further complications such as thrombosis. If the occlusion is small enough to allow sufficient collateral circulation, the symptoms and signs may stabilize and the patient may be comfortable enough without further therapy.

As mentioned above, in 10 percent of patients with small cell lung cancer and less than 2 percent with nonsmall cell lung cancer SVCS is present at diagnosis. In these patients the specific treatment directed toward relieving SVCS is commenced at the same time as treatment for the disease. This is preferred even when medical management may be adequate at least until the time the antitumor therapy works. However, a proportion of patients have SVCS relapse after the initial antitumor treatment, usually chemotherapy. In such patients only second-line therapy may be suitable, but it is hardly successful. Thus in most patients, palliative therapy is preferred as the tumor becomes resistant to treatment. In symptomatic advanced cancer patients with poor performance status or in patients who do not want aggressive treatment, palliation may be achieved by medical interventions such as postural advice, since a raised head may help blood to flow better through the superior vena cava to the heart, and drugs.[14]

Traditionally, treatment has included systemic steroids (prednisolone or dexamethasone) to alleviate respiratory compromise. These are also recommended to prevent radiation-induced edema when radiotherapy is used but there is no strong evidence of such an inflammatory reaction or edema after radiotherapy for SVCS. There are no definitive studies that prove the effectiveness of steroids,[15*] although they are potentially useful to treat respiratory compromise. If steroids are to be prescribed, high doses should be used for a limited duration. Diuretics have been used in the treatment of SVCS with anecdotal reports of benefit. There may be symptomatic relief of edema but ultimately these can lead to systemic complications, such as dehydration.

Other usual measures such as oxygen or antithrombotic therapy are not established enough but may help to alleviate some problems. For instance, oxygen may palliate dyspnea in some cancer patients.[16] Low-molecular weight heparin may prevent further thrombosis in a cancer patient with slow flow in the vena cava.

Chemotherapy

Chemotherapy is the anticancer treatment of choice for sensitive tumors such as small cell lung cancer, lymphoma, and germ-cell tumors. In these cases, SCVS does not appear to be an independent prognostic factor, and its presence should not be used to change the treatment approach. The response rates to chemotherapy in sensitive tumors such as small cell lung cancer approaches 80 percent,[17,18] but in more than 15 percent of those there was a recurrence of SVCS.

In tumors which are less chemosensitive, such as nonsmall cell lung cancer, chemotherapy can relieve SVCS in 60 percent of the patients.[19,20**] The proportion of recurrences of SVCS after response to chemotherapy is about 20 percent.

Radiation therapy

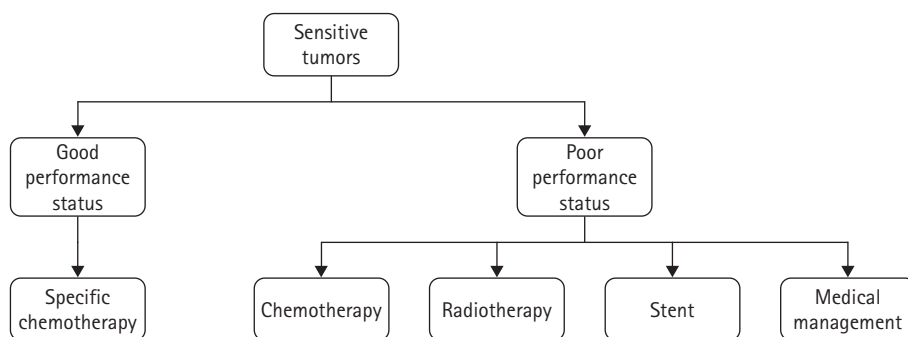
If the obstruction of the superior vena cava is caused by a tumor that is or has become refractory to chemotherapy, radiation therapy remains highly effective as symptomatic treatment.[21] Historically, treatment started with larger fractions of 4 Gy for the first few days, because it was thought that this led to a more rapid response, and then continued with smaller fractions until the desired total dose was reached.[22**,23] However, there is no obvious need for large radiation fraction sizes in the first few days.[24] Many fractionation schemes have been used,[25,26] with doses ranging from 20 Gy in five fractions to 50 Gy in 25 fractions. Single dose (6–8 Gy) has been recommended for rapid relief in patients with poor performance status or short life expectancy. Overall, in 60 percent of nonsmall cell lung cancer and 80 percent of small cell lung cancer, SVCS responds to radiotherapy.[27]


Figure 87.1 *Algorithm of treatment of malignant superior vena cava syndrome in patients with potentially sensitive tumors.*

There are no definitive data regarding a fractionation scheme of choice. The fractionation scheme will depend on histology, previous therapy, disease extent, prognosis, and performance status. In previously treated patients with short life expectancy who have now become resistant, and in disseminated disease and poor performance status, a short-term schedule would be preferable with a total dose of 20–30 Gy, or a single-fraction treatment. However, patients in whom the disease is limited to the thorax or in those with good performance status might benefit by conventional fractionation treatment and higher total doses (50–60 Gy).

In lung cancer, there appears to be no distinction between radiotherapy and chemotherapy with regard to speed of palliation. Median time to response ranges from 10 to 15 days, with 75 percent of responses occurring within 3 weeks of starting treatment.[24]

Stent placement

There has been rapid increase in experience with intravascular expandable stent to reopen the occluded superior vena cava. However, no prospectively designed comparative studies have been published. The procedure allows rapid restoration of the normal flow pattern with rapid resolution of symptoms. Response rates are very high, at around 95 percent, with phlebographic resolution in the majority of patients,[28,29] independent of the type of stent used (Wallstent, Gianturco, or Palmaz). Following stent insertion, relief of headache can be immediate,[30] and facial edema may be resolved within 24 hours.[31] The proportion that relapse following stent placement approaches 10 percent, frequently due to thrombus within the stent.

There is no agreement about the optimal timing of this procedure: at diagnosis, as the first choice treatment, or after failure of other treatment modalities. Nevertheless, we should not forget that there is associated morbidity (hematoma, bleeding or stent migration), and that stenting is time consuming and costly. Thrombolytic agents such as streptokinase or urokinase can be administered prior to stent insertion to help with this procedure.[32] Morbidity following stent insertion is greater if thrombolytics are administered. In any case the relapse rate with thrombolytics administered prior to stent insertion does not seem to increase when those drugs are not used.[33***] In the same way,

there is no agreement on the need for the indication or the duration of anticoagulant or antiaggregant therapy after stent placement. However, this policy seems to be related to a lower rate of reocclusion[34] but there is not enough evidence to reach solid conclusions.

In summary, stenting of superior vena cava syndrome is an effective procedure resulting in rapid alleviation of symptoms in almost all patients and allowing for full dose anticancer treatment after stent insertion.

Surgery

There are just a few reports on palliative surgery for malignant SVCS. Surgical bypass is more appropriate for patients with a benign obstruction, although surgical bypass has also been used for some selected patients with malignant obstructions.[35] The indications are limited by the prognosis of patients and the severe complications of the procedure.

Clinical management

In patients with good performance status, several variables have to be considered before the choice of treatment can be made. Tumor histology, extent of disease, prognosis, and type of the vena cava obstruction influence the choice. In very sensitive tumors where systemic therapy modifies survival and may even result in cure, such as lymphoma, germ-cell tumor and even limited disease small cell lung cancer, aggressive therapy aimed at achieving a quick response and improving survival is warranted. In these cancers, radiotherapy can be included as part of the protocol to improve local control. In extensive small cell lung cancer, chemotherapy is the treatment of choice even when cure is not possible (Fig. 87.1).

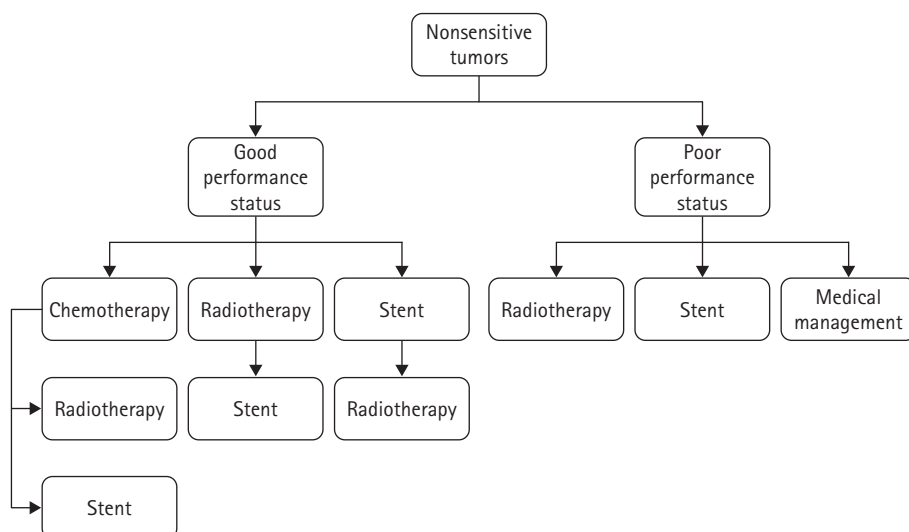
In other tumors where the benefit of chemotherapy is not so impressive, such as locally advanced or metastatic cancer, radiotherapy is the anticancer treatment of choice for SVCS. Systemic therapy may produce relevant palliation of symptoms in some cases. In patients with potentially sensitive disease but with poor performance status chemotherapy remains a choice.[36] Stent insertion appears to provide relief in a higher proportion and more rapidly (Fig. 87.2). Even when the response is more frequent and faster, stenting is a more aggressive approach than just single-fraction palliative


Figure 87.2 *Algorithm of treatment of malignant superior vena cava syndrome in patients with non-sensitive tumors.*

radiotherapy for patients with very poor survival expectancy. There are no data supporting a particular schedule or timing for the combination of different treatments, in particular, local approaches such as radiotherapy and stents.

However, a majority of such patients will require only palliative treatment that is not directed at the tumor. These people can achieve significant relief with medical treatment and a short-term radiotherapy schedule.

Key learning points

- In the absence of histological diagnosis, it is advisable that this should be established prior to initiating therapy because between 3 percent and 5 percent of the patients diagnosed with SVCS do not have cancer.

- Almost 95 percent of SVCS cases described in recent studies are due to cancer.

- No emergent therapeutic interventions are required, and SVCS is rarely lethal by itself. Only in exceptional cases where tracheal obstruction or cerebral oedema is present, could it be considered as an oncological emergency.

- There is no standard scoring system as yet: diagnosis, response and subsequent relapse of SVCS are usually clinically assessed.

- Anticancer therapy, chemotherapy and/or radiotherapy form the basis of treatment (scheme depends on histology and clinical situation).

- Patients with poor performance status or short life expectancy may be managed by medical treatment and a short-term radiotherapy schedule.

- Stent insertion appears to provide relief in a higher proportion and more rapidly. There is no agreement about the timing of stenting.

Seizures

FABIO SIMONETTI, AUGUSTO T CARACENI

INTRODUCTION

Seizures are not infrequently encountered in palliative medicine. They may be caused by metastatic cerebral lesions in advanced cancer, by acquired immune deficiency syndrome (AIDS), or as a consequence of metabolic derangement or drug toxicity. Nonstructural causes of seizures are quite common,[1] and they can occur in patients with brain metastases (Table 88.1).

DEFINITIONS AND CLASSIFICATION OF SEIZURES[2]

Epileptic seizures are classified according to their electroencephalographic features into partial seizures (when an initiating focus can be identified in a specific brain area) and generalized seizures (when the seizure seems to have bilateral onset). Partial seizures can evolve into generalized tonic-clonic seizures, and in this case the term secondarily generalized seizures is used.

Depending on the level of consciousness during attacks, seizures can be classified as follows:

- *Simple partial seizures.* These are associated with a normal level of consciousness. Only a selective area of the cortex participates in the seizure activity causing symptoms that are therefore typical of the function of the cortical area involved: partial motor, sensory, autonomic, and affective may occur. At times when symptoms of this kind precede the onset of a generalized seizure they are called an 'aura'.

- *Complex seizures.* These are associated with impaired consciousness and may be:
  - *Absence (petit mal) seizures.* These are typical of infancy and can last for 5–10 seconds and occur ten to hundreds of times a day. The patient stops whatever they are doing, with fixed unresponsive eyes. If the seizure lasts for more than 10 seconds he or she may blink or smack the lips repetitively. Atypical absences can be of longer duration and can be associated with flaccidity or muscle rigidity and usually have onset after age of five.
  - *Partial complex seizures.* These combine focal symptoms with an altered state of consciousness. These are the most common type of seizures seen in adults and probably also the most common in the palliative care setting. The patient seems to be awake but has no contact with the environment. He or she does not answer questions appropriately, the eyes can be fixed or rolling purposelessly around, the patient is immobile or engaged in repetitive behaviors (motor automatisms), repeats words or sentences and may be grimacing, snapping fingers, chewing, running or undressing. If physically restrained, the patient can become hostile or aggressive. These attacks can be preceded by auras that are similar to simple partial seizures. The seizure lasts on average 3 minutes and is followed by a post-ictal phase with symptoms as somnolence, delirium, or headache, which can last for several hours. After complete recovery the patient has no recollection of the event, but sometimes may remember the aura.
  - *Generalized tonic-clonic (grand mal) seizures.* These start with a sudden loss of consciousness, at times

Table 88.1 *Causes of seizures in palliative care*

Cause	Comment
Brain metastases	More frequent when involving gray matter
	Due to bleeding
	Particularly frequent with melanoma
Meningeal metastases	Due to cerebral cortex infiltration
AIDS	Frequent in AIDS dementia complex (50%)
	Due to CNS infection
	Due to primary brain lymphoma
	Metabolic
	In 20% of cases cause remains unknown
Drug toxicity	Chemotherapy with vincristine, ifosfamide,[a] thiothepa, methotrexate, busulfan
	Antiviral therapy
	Opioids (very high doses)
	Quinolonic antibiotics
	Penicillin and derivatives
	Imipenem
