	Hypoglycemia
Neurologic disease	Primary brain tumor
	Multiple sclerosis
	Tuberous sclerosis
	Cerebrovascular accident
	Leukodystrophies
	Alzheimer disease

[a] Ifosfamide high dose infusion typically causes nonconvulsive status epilepticus.

accompanied by shouting (due to forced air expiration by sudden contraction of the diaphragm). Diffuse muscle rigidity and cyanosis follow, and after a minute myoclonus and muscle fasciculations occur for 1–2 minutes. In this phase the patient can bite his or her tongue. At the end, the post-ictal phase, the patient is in deep sleep, and breathing slowly and deeply when they gradually awaken, and often complain of headache.

Absence and tonic-clonic seizures are the most typical clinical manifestations of generalized seizures which also include *clonic seizures* (rhythmic contractions of upper limb, neck and face muscles), *myoclonic seizures* (brief segmental contractions of the limbs, occurring alone or in clusters without loss of consciousness), *tonic seizures* (sudden generalized muscle rigidity associated with loss of consciousness and falls), and *atonic seizures* (sudden muscle tone resolution).

TREATMENT OF SEIZURES[3,4]

Prophylactic anticonvulsant treatment in patients with brain tumors or metastases is controversial and in fact few studies have addressed the efficacy of prophylactic anticonvulsant therapy in these patients. In noncontrolled clinical series prophylactic treatment has not been shown to give any advantage. One randomized clinical trial confirmed that in patients with brain metastases who had never had seizures prophylactic treatment did not prevent seizure development.[3,4**] In patients with primary brain tumors without seizures it is suggested that anticonvulsant therapy be withdrawn 1 week after surgery.[4] Metastases from melanoma, choriocarcinoma, and cancer of the testis are more often associated with seizures, possibly because these lesions are often hemorrhagic and, in the case of melanoma, tend to invade the cortical gray matter. Many anticonvulsants have potentially serious side effects and may interact with chemotherapeutic drugs and steroids. They can be sedative and can produce cognitive impairment. Prophylaxis is therefore only recommended in patients who have already had seizures. Seizures worsen brain edema and vice versa, therefore, in patients who develop new seizures in spite of anticonvulsant therapy it is advisable to optimize antiedema therapies before modifying the anticonvulsant regimen.

It is worth emphasizing that in every other case of seizures secondary to medical or metabolic causes in palliative care patients without brain tumor lesions there is no indication to start long-term anticonvulsant therapy.

Pharmacological therapy[5–8]

This section summarizes the general characteristics of anticonvulsants. One must bear in mind that blood levels, when available, should be monitored because of the unpredictability of metabolic changes and drug interactions, although it

should also be remembered that clinical response and not blood levels will guide dosage.

PHENYTOIN

Phenytoin is a first-line drug in simple and complex partial seizures and in generalized tonic-clonic seizures. It is metabolized by a saturable hepatic enzyme so it has non-linear kinetics making dosage adjustments difficult. It is available in two different intravenous formulations (phenytoin and fosphenytoin) suitable for emergencies or when administration by the oral route is not possible. The dose varies from 4 mg/kg per day to 8 mg/kg per day. Its long half-life allows the dose to be given once daily, but it may be divided into two to three doses daily to avoid gastric discomfort.

Phenytoin has some drawbacks. Blood levels of phenytoin are quite variable as a consequence of the administration of many other drugs interfering with liver metabolism, absorption, or protein binding. Interference has been demonstrated with ciclosporin, cisplatinum, and paclitaxel. Significant pharmacokinetic interactions can occur with concurrent dexamethasone which can reduce phenytoin plasma levels by 50 percent. Advantages of phenytoin include the lack of sedative effects and good tolerability even at higher than recommended doses.

Side effects due to long-term use include ataxia, gastrointestinal disturbances, gingival hypertrophy, hirsutism, osteoporosis, and megaloblastic anemia. Severe allergic reactions involving rash, hypersensitivity reactions, liver toxicity and myelo-suppression have been reported but are rare.

PHENOBARBITAL

Phenobarbital is effective in both partial and generalized tonic-clonic seizures. It is metabolized by liver cytochrome P450, and has very slow plasma clearance (4–5 days), that can be affected by liver disease. It is a safe drug with a wide therapeutic index but it can cause drowsiness, ataxia, and severe rash (Stevens–Johnson syndrome and Lyell syndrome). It interferes with the metabolism of several chemotherapeutic agents and long-term use is associated with pseudorheumatism which can worsen the symptoms of a concurrent steroid-induced osteoporosis.

It is available in oral and parenteral formulations; the dose varies from 1 mg/kg per day to 5 mg/kg per day, given once daily. It can be used in subcutaneous infusions.

SODIUM VALPROATE

Sodium valproate is active in most types of generalized seizure (tonic, myoclonic, absence, tonic-clonic) including secondarily generalized partial seizures. It is also effective in treating neuropsychiatric disturbances commonly seen in palliative care situations. Doses start at 250–500 mg/day and are increased by 250 mg per week up to 1000–3000 mg/day. In children the initial dose is 10–15 mg/kg per day, increased by the same incremental doses. It has the potential for drug–drug interactions.

Common side effects of sodium valproate include tremors, weight gain, sedation, ataxia, gastrointestinal symptoms and thrombocytopenia. Liver enzymes and blood ammonia can be increased. Severe liver toxicity can occur (usually in the first 6 months of therapy); most cases occur in children and in association with other anticonvulsants.

CARBAMAZEPINE

Carbamazepine is effective in the treatment of simple and complex partial seizures, and in tonic-clonic generalized seizures. It is available only in oral formulations and the dose should start at 200 mg/day, increasing by 200 mg per week.

Acute intoxication can cause stupor and coma, convulsions, and respiratory depression. After chronic administration sedation, vertigo, ataxia, double vision, and myelo-suppression can occur. Severe myelotoxicity has been found (1 case of aplastic anemia/200 000 patients).

CLONAZEPAM

Clonazepam is approved by the US Food and Drug Administration (FDA) for the prophylaxis of absence, atypical absence, and myoclonic epilepsy. It can also be used as a temporary treatment to control and prevent seizures not controlled by ongoing therapy. In children initial doses start at 0.01–0.03 mg/kg per day and are increased by 0.25–0.5 mg every 3 days. The most relevant side effect is sedation. Paradoxical excitation is rare.

NEWER ANTIEPILEPTIC DRUGS[9,10]

Oxcarbazepine

Oxcarbazepine can be used as monotherapy in patients with refractory partial epilepsy. It is chemically related to carbamazepine, but it has less pharmacological interaction liability because it is a poor inducer of liver enzymes, although a decrease in serum ethinyl estradiol has been seen. Its mechanism of action also seems to be linked to sodium channel modulation. It is approved for partial seizures in adults both as monotherapy and add-on therapy. Side effects are similar to carbamazepine but it is usually better tolerated. Initial doses range from 300 mg to 600 mg in two to three daily doses and is usually titrated up to 600–1800 mg per day. Patients taking this drug can have clinically significant hyponatremia (more common in older people) and rash.

Gabapentin

Gabapentin is approved for adjunctive therapy of partial seizures with or without secondary generalization. Its use is facilitated by the lack of binding to plasma protein and

pharmacological metabolic interferences. Because of its short half-life multiple doses are required per day. Elimination is renal and influenced only by renal function. Daily doses are 900–1880 mg/day in three divided doses but doses as high as 3600–6000 mg/day in adults have been used without severe side effects. Gabapentin is also considered effective as monotherapy in epilepsy but its use in neurooncology has never been studied. There are no serious adverse events, minor events include sedation, ataxia, weight gain, peripheral edema, dizziness, and behavioral changes.

Topiramate

Topiramate is indicated in partial and generalized seizures in children and adults. Initial dose should be low (25 mg) and increased by 25–50 mg per week. Minimal daily doses range from 200 mg to 400 mg. In children the initial dose is 0.5–1 mg/kg per day, and it is increased weekly by the same amount up to 5–9 mg/kg. Side effects are of the central type, sedation, unsteadiness, memory and concentration problems; serious adverse events include nephrolithiasis, open angle glaucoma, and hypohidrosis. Topiramate 6 mg/kg per day is effective in reducing drop attacks (tonic and atonic seizures) in patients with the Lennox–Gastaut syndrome.

Topiramate can also be used as monotherapy in patients with refractory partial epilepsy and at 6 mg/kg per day is effective for the treatment of refractory generalized tonic-clonic convulsions and in other seizure types in adults and children. Topiramate causes a decrease in the serum concentration of ethinyl estradiol.

Lamotrigine

Lamotrigine has been approved for partial seizures in adults in association with other drugs. It is effective also as monotherapy in patients with refractory partial epilepsy and also for the treatment of absence seizures in children. It is metabolized by the liver and has significant interactions with all the classic anticonvulsants (phenobarbital, phenytoin, carbamazepine). Serious adverse events are rashes including Stevens–Johnson syndrome and toxic epidermolysis, more so in children and with concomitant valproate use. They are related to a rapid titration of the drug dose. With slow initiation of therapy the risk of skin rash is comparable with that seen with phenytoin. It is therefore important to titrate the dose slowly with weekly increments of 25 mg or 50 mg up to 300–500 mg/day. In patients who are already taking liver enzyme-inducing antiepileptic drugs (with the exception of valproic acid) the starting dose should be 50 mg/day for 2 weeks, then increased by 100 mg/day (in two divided doses) to a maintenance dose of 300–500 mg/day. If added to a regimen consisting of valproic acid, lamotrigine should be started at 25 mg every other day for 2 weeks and titrated even more carefully. Nonserious adverse events include tics, predominantly in children and insomnia. It is available only in oral formulation. A decrease in lamotrigine serum concentrations has been observed with oral contraceptives.

Summary and practical guidelines for management in palliative care

The ideal antiepileptic drug for palliative care is not easy to establish as the classic anticonvulsants cause a variety of metabolic interactions and significant side effects. Among the newer drugs there is little experience in this indication. On the basis of our experience we suggest some practical management guidelines:

- The need for slow titration schedules limits the usefulness of topiramate and lamotrigine, which is also a strong inducer of liver enzymes.[7,8] In our experience oxcarbazepine and valproate seem to have a more favorable profile compared with other available drugs.
- Prophylactic treatment should be started only in patients with structural brain disease who have had a seizure before. In cases of metabolic or toxic causes that have been successfully managed there is no need for prophylaxis.
- In case of brain lesions we do not counsel the family or patients about the risk of seizures unless risk is very high, such as in case of brain metastases from melanoma, for which we also recommend prophylaxis.
- If the patient had a seizure due to structural brain lesion, the family should be informed about how to react in case of another seizure. They should position the patient on one side to protect from injury and aspiration and they should not try to force open the mouth in case of 'morsus'.
- The seizure is usually a self-limiting event, and the family should wait for spontaneous resolution unless the seizures are prolonged (more than a few minutes) or repetitive. Although recovery from a seizure or recognition of recurrence may be difficult for family members, in these circumstances they can be instructed to use rectal diazepam preparations while waiting for medical assistance. If in the same situation medical or nursing care is available lorazepam 2–4 mg intravenously should be given if intravenous access is available.
- In patients with poor oral intake phenobarbital subcutaneous infusion is the best alternative for home and hospice care. Midazolam can be added in case of difficult-to-control seizures.
- Blood levels should be checked only if under- or overdosing are suspected, which lead to poor seizure control or toxicity, respectively. Toxicity from antiepileptic agents can be difficult to distinguish from worsening of the underlying brain disease. If feasible, it is also advisable to check blood levels at least once after initial titration of phenobarbital, carbamazepine, phenytoin, oxcarbazepine, or sodium valproate.

STATUS EPILEPTICUS

The most commonly accepted definition of status epilepticus (SE)[2] is continuous seizure activity persisting for more than 30 minutes or two or more seizures without full recovery of neurological function in between. Another definition of SE is continuous generalized seizures lasting longer than 5 minutes or, of course, two or more seizures during which the patient does not return to baseline consciousness; this is more practical in palliative care setting because patients are usually more ill; moreover if a seizure lasts more than 5 minutes the likelihood of spontaneous termination decreases. A patient who has not responded to first-line therapy in an hour is said to be in *refractory status epilepticus.*

Clinical characteristics

Status epilepticus may be characterized by motor convulsions (convulsive SE) or by absence of motor phenomena (nonconvulsive SE); and may affect the whole brain (generalized SE) or only part of the brain (partial SE). Depending on the type of seizures SE can be also defined as:

- Tonic-clonic SE
- Tonic SE
- Clonic SE (only in children)
- Myoclonic SE
- Simple partial SE or SE epilepsia partialis continua (without impairment of consciousness)
- Nonconvulsive status epilepticus (NCSE).

NONCONVULSIVE STATUS EPILEPTICUS

This particular condition is characterized by electroencephalogram (EEG) seizure activity without convulsive activity. It is a significant cause of impaired consciousness in patients with complex toxic-metabolic encephalopathies, occurring in 8 percent[11*] of comatose patients according to recent data. According to some authors most patients with altered state of consciousness and mild motor signs have EEG findings compatible with SE. Manifestations of NCSE include absence type NCSE and partial complex NCSE. Although no data are available we consider this condition not to be totally rare in palliative care and its differential diagnosis may apply more often than usually thought.

Partial complex NCSE is a particularly challenging situation. Seizure activity fluctuates and recurs, often originating from temporal cortical areas and causes a confusional state with variable clinical findings. This condition can be continuous, with longlasting delirium, with or without psychotic behaviors and automatisms, and, in this case, is sustained by continuous focal seizures, or discontinuous with recurrent partial complex seizures, but with recovery of consciousness between the single seizure episodes. Clinical aspects may be baffling with minimal abnormalities in

answering questions but affective manifestations of fear or paranoid ideation.

Duration can vary from 30 minutes to 2 weeks. In 40 percent of cases the episode is shorter than 24 hours; in another 40 percent the episode lasts from 1 to 10 days. In one case report a partial complex status lasted for 7.5 months.[12*]

Treatment

Convulsive SE is a neurological emergency associated with significant mortality and morbidity and thus requires rapid and aggressive treatment.[13] In terminally ill patients the treatment must be weighted. The first priority is that the cardiocirculatory and respiratory functions are supported. Intravenous infusion of benzodiazepines and phenytoin are the first-line pharmacological approaches (Fig. 88.1). Treatment has a high rate of success (80 percent) if initiated within 30 minutes. If delayed for more than 2 hours these drugs fail in 60 percent of cases.

CHARACTERISTICS OF DRUGS USED IN SE

The drugs used for the acute control of epileptic seizures also have other indications in palliative care when they are used primarily for their sedative effects.

Lorazepam
Lorazepam is considered the drug of choice.[15**] The mean time to clinical effect is 3 minutes, the half-life is 10–15 hours but effective brain levels are maintained for 8–24 hours. It has no active metabolites. It should be infused intravenously not faster than 2 mg/minute. It is rapidly absorbed after rectal administration. Intramuscular administration is not recommended. In acute administration the main risk is respiratory depression. Refrigeration is usually necessary, but some authors have observed that lorazepam retained 90 percent of its original concentration when stored without refrigeration in ambulances for 5 months.

Diazepam
Diazepam enters the brain in a few seconds but because of its high lipid solubility, redistribution to all body tissues is rapid with a consequent fall of brain concentrations. Its anticonvulsant effect is therefore very brief and a second dose may be necessary after only 20–30 minutes. Rectal formulations are available. Recommended doses are 10 mg in adults and 5 mg (0.5 mg/kg) in children. Rectal administration at these doses does not cause respiratory depression. After intramuscular administration absorption is variable and unpredictable and this route should generally be avoided.

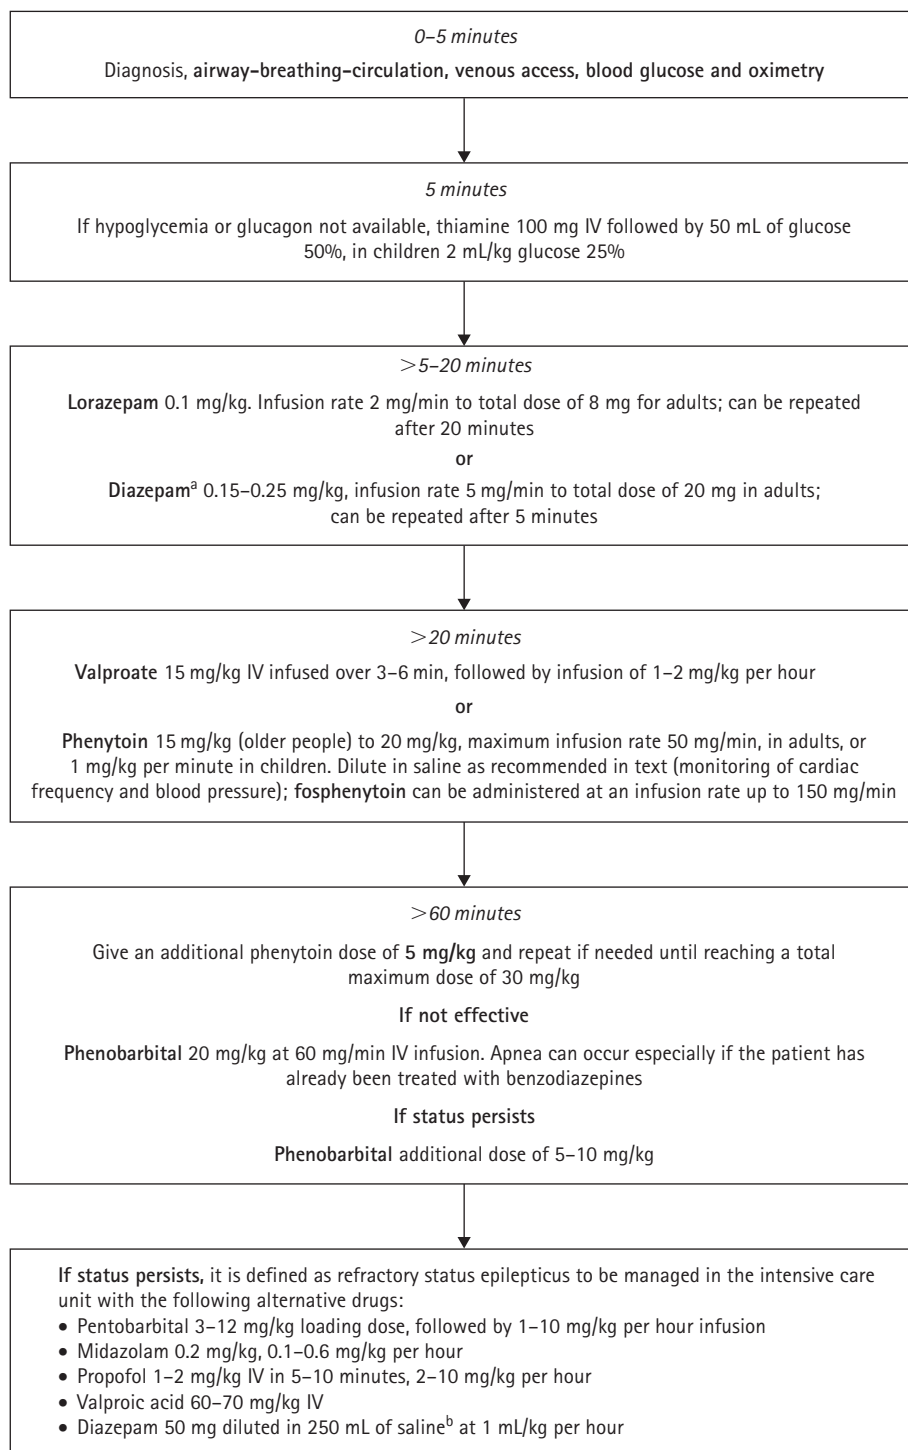
Phenytoin
The onset of action of phenytoin is short (10–20 minutes), it has no sedative effects, does not cause respiratory depression, and has a long duration of action.


Figure 88.1 *Algorithm for the management of status epilepticus.* *[a]Diazepam is now considered an undesirable second choice. [b]Solution should be freshly prepared every 6 hours. IV, intravenous. Modified from Working Group on Status Epilepticus recommendations.[14]*

It should be used in benzodiazepine-refractory SE by intravenous infusion, at 20 mg/kg, not more than 50 mg/minute. In older patients the dose should be reduced to 15 mg/kg. After a loading dose has been infused the duration of the therapeutic effect is about 24 hours. Blood levels can be checked 120 minutes after the end of the infusion. A loading dose of 15–20 mg/kg can be also administered orally but poor gastric tolerability limits the use of this route in some patients.

After diluting phenytoin in saline, the solution should be infused within 1 hour. A concentration of 6.7 mg/mL (1000 mg/130 mL) is suggested although the drug is stable in solutions of up to 10 mg/mL. Side effects may be related to excessively fast infusion rates, as may be required in emergency situations and include cardiac arrhythmias, arterial hypotension and central nervous system depression. The 'purple glove syndrome' is due to the high pH of the drug (−13) causing local toxicity at the site of infusion

which manifests with blue discoloration, and distal edema, 2 hours after administration.[16]

Sodium valproate

The availability of a parenteral formulation of valproate provides an alternative to phenytoin. Many reports confirm the efficacy and safety of valproate infusion (up to 6 mg/kg per minute and dose of up to 30 mg/kg followed by a maintenance dose of 1–2 mg/kg per hour) in emergency situations.[17*]

Midazolam

Midazolam is water soluble, has a very short half-life, and has no active metabolites. Its onset of action is 3 minutes, 5 minutes, and 15 minutes after intravenous, intramuscular, and oral administration, respectively. The good intramuscular and subcutaneous absorption is an important advantage in cases of difficult venous access and therefore can be indicated is some palliative care settings. In refractory SE the initial dose is 0.2 mg/kg, followed by 0.05–0.5 mg/kg per hour intravenous infusion.[18*,19*]

Propofol

Propofol has an effect on γ-aminobutyric acid (GABA) receptors similar to that of benzodiazepines and barbiturates. Its use requires intensive care support and is reserved for SE which is refractory to standard treatment. Hypotensive effects should be carefully managed. A loading dose of 3–5 mg/kg IV followed by a continuous infusion at a rate which can cause a burst suppression pattern on the EEG, usually 30–100 μg/kg per minute (maximum dose = 108 g in 9 days in one patient who had one single asymptomatic episode of hypertriglycidemia without rhabdomyolysis).[20*]

Phenobarbital

This is an option if benzodiazepines and phenytoin fail. The peak clinical effect is delayed for 20–60 minutes after administration.

Thiopental

Thiopental is highly lipid soluble and for this reason undergoes rapid redistribution, resulting in a state of coma that is less prolonged than with phenobarbital. It is partially metabolized to pentobarbital. Thiopental lowers the intracranial pressure but is associated with severe hypotension, edema, ileus, sepsis, immune depression and an increase in P_{CO_2}.

Awakening is complicated by longlasting side effects and function recovery has a long and variable profile: recovery of motor function occurs within 1–72 hours after the end of treatment, eye-opening after 1–3 days, and cognitive function after 2–18 days.

Differential diagnosis

It is important to keep in mind that acute conditions with an altered state of consciousness at times associated with motor or behavioral abnormalities are often erroneously considered seizures. The most frequently occurring of these conditions are listed in Box 88.1.[21]

Box 88.1 Differential diagnosis of seizures

- Psychiatric disturbances: somatoform reactions, anxiety panic attacks, psychotic dissociative episodes, Munchausen syndrome

- Cardiovascular disorders: syncope, arrhythmia, transient ischemic attacks

- Headache: hemicrania comitata, basilar migraine

- Movement disorders: tremor, dyskinesia, tic, myoclonus

- Parasomnias and sleep disturbances: nightmares, somnambulism, narcolepsy, cataplexy, nocturnal paroxysmal dystonia

- Gastrointestinal symptoms: nausea or colic

- Delirium

- Progressive worsening of intracranial hypertension or herniation with opisthotonus or other acute neurological findings

---

Key learning points

- Secondary epilepsy is common in palliative care and has complex multifactorial etiologies.

- Prophylactic anticonvulsants in patients with primary or metastatic brain tumor who have never had seizures is not recommended.

- All anticonvulsants offer effective protection against seizures in patients with brain tumor and a seizure disorder but have varying profiles of toxicity and metabolic interactions. Sodium valproate, oxcarbazepine and topiramate offer a favorable therapeutic index in these patients.

- Generalized SE is a medical emergency while nonconvulsive SE is an important differential diagnosis in patients with changes in behavior and mental status.

- Lorazepam and sodium valproate are first-line therapies of generalized SE with low risk of administration. Midazolam is an important alternative if venous access is not available.

Acute pain syndromes*

MELLAR P DAVIS

WHAT IS ACUTE PAIN?

There is an implicit understanding of what acute pain is (or at least an assumed understanding), yet few reviews define acute cancer pain and most treatment strategies intermingle chronic and acute cancer pain management without a clear separation. Almost all published reviews are about postoperative or procedural-related pain management. If we can borrow from the cardiology nomenclature of unstable angina, then acute cancer pain (unrelated to procedures) is a new onset or a change in the pattern of chronic pain which evolves over hours to days. Acute pain in cancer usually signifies new metastases, a complication from existing metastases, an indirect complication from treatment such as herpes zoster or mucositis, an evolving chronic comorbidity or developing comorbidity. Patients are more likely to seek medical attention in the emergency rooms with acute cancer pain than with chronic cancer pain (unless chronic cancer pain is grossly under-treated). The change in pain may be related to the frequency of breakthrough pain or a sharp increase in the intensity of the underlying chronic pain, a change in pain referral pattern or new pain upon chronic pain, or associated new symptoms (such as nausea and vomiting) upon a background of chronic (abdominal) pain. The general assumption most physicians have is that acute pain is severe, however some patients will experience acute, mild, or moderate pain or the pattern of pain may change but severity remains the same (e.g. continued moderate back pain but new onset of radicular pain with spinal cord compression).

TEMPORAL CLASSIFICATION OF PAIN

Acute pain has most often been classified as transient pain due to procedures or postoperative pain. But acute pain may also crescendo 'acute on chronic' pain from rapidly evolving tumor cancer complications such as hemorrhage or infection within the tumor, pathological fracture, bowel obstruction, or perforation of the hollow viscous. Acute pain draws attention to the injury typified by a 'fight or flight' response. The 'fight or flight' response results in pupillary dilation, sweating, tachycardia, tachypnea, or shunting of blood from viscera.[1] Responses to chronic pain differ significantly from acute pain. Chronic persistent pain is generally purposeless, poorly related to the degree of tissue injury and has a significant component of neuroplasticity resulting in abnormal pain processing. Patients tend to be somnolent, hypokinetic and anorexic. Libido is reduced (independent of opioids), constipation, anhedonia, and somatic preoccupation and personality changes may supervene.[1] In one sense breakthrough pain is a type of acute pain (usually upon a background of chronic pain) but is not 'acute pain syndrome' and is generally discussed under chronic cancer pain.

The temporal nature and severity of pain dictate the speed with which the cycle of assessment, analgesic choice, application and reassessment occurs.[2] Among the errors cited in treatment strategies, failure to escalate in a timely fashion with adequate doses of opioids is common.[2] This may

---

*A World Health Organization project in palliative medicine.

be due in part to the use of chronic pain dosing strategies in the management of acute pain. Chronic pain is evaluated at intervals of days whereas acute pain requires reassessment within minutes to hours. The strategy of continuous opioid parenteral infusion or every 4-hour oral dosing with provision for breakthrough for chronic pain is simply inadequate for acute pain.[3] Parenteral titrated opioids are preferred in the face of crescendo pain.[4] The importance of providing expedited pain relief in acute pain syndromes goes beyond the ethical principle of limiting suffering. The neurohumoral response to acute pain particularly in the setting of comorbidities and limited cardiopulmonary function leads to quick demise of the patient. Immobility due to acute pain increases the risk for thromboembolism. Acute oropharyngeal pain from mucositis accelerates nutritional deficiency. Acute pain leads to anxiety and fear which worsens pain and may precipitate an existential crisis.[5] Uncontrolled acute pain, if treated ineffectively will lead to abnormal central pain processing through neuroplasticity, which ends up as refractory chronic pain. Uncontrolled acute pain increases medical expenditures and prolongs hospitalization.[5,6] Acute crescendo pain accounts for only 4 percent of cancer pain visits to the emergency room but its overall incidence is relatively underreported.[7]

ASSESSMENT OF ACUTE PAIN SYNDROMES

> The management of cancer pain depends on a comprehensive assessment. This needs to characterize the symptoms in terms of phenomenology and pathogenesis, and assess the relationship between pain and disease and clarify the impact of pain and co-morbid conditions on the patient's quality of life.[8]

Acute pain as transient flares of pain due to procedures is unlikely to influence overall quality of life but acute pain as a complication of cancer will significantly affect a patient's quality of life. A pain history should include documentation of the temporal pattern, location, severity, quality, and palliative factors to pain. Procedural-related pain is quite obvious. The focus of assessment in this situation will be pain severity, duration, and response to analgesia. However, acute or chronic or crescendo pain will require a full history as has been outlined for chronic cancer pain.[8]

Cancer pain syndromes are well defined for chronic cancer pain.[8–11] Most cancer pain classification systems are based upon chronic pain where the prevalence and etiology are well defined. This is not true for acute pain syndromes. Acute pain syndromes have been listed by various authors but remain incomplete due to lack of definition.[8,10] Prevalence of acute pain in cancer pain is less well defined. Boxes 89.1 and 89.2 represent the author's attempt to classify acute pain based upon clinical experience and from the literature.[12,13]

Box 89.1 Acute pain syndrome in advanced cancer

Directly related to cancer

- Destruction of joints
- Pathologic fracture of long bone
- Vertebral fracture with mechanical instability and/or cord compression
- Visceral infiltration with obstruction of a hollow organ
- Visceral perforation and secondary peritonitis
- Hepatic capsule infiltration and/or rupture or acute bleed
- Splenic infarct
- Pulmonary artery tumor infiltration and pulmonary infarct

- Tumor-induced pericarditis or cardiac tamponade
- Budd–Chiari syndrome from hepatic venous cancer invasion

Acute pain related to treatment or procedures

- Acute postoperative pain
- Postradiation: mucositis, esophagitis, brachial plexopathy, arachnoiditis (Lhermitte syndrome), enteritis, cystitis, proctitis
- Chemotherapy: extravasation, endophlebitis, neuropathy (oxaliplatin, taxanes, vinca alkaloids), acute jaw pain (vincristine), mucositis (radiation or chemotherapy)
- Steroid withdrawal and arthralgia-myalgia
- Dexamethasone-induced rectal pain
- Luteinizing hormone-releasing hormone agonist or hormone-induced bone pain flare (prostate cancer and breast cancer)
- Chemical pleuritis from pleurodesis
- Hepatic pain from hepatic artery embolization and/or chemotherapy
- Chest pain from pericardiocentesis + sclerosis

- Paracentesis and chemotherapy lavage
- Post lumbar puncture headaches
- Post bone marrow biopsy pain
- Venipuncture
- Stent placement (biliary or ureteral, esophageal)
- Percutaneous endoscopic gastrostomy tube placement
- Nephrostomy tube placement
- Transhepatic biliary drainage tube

Indirect complications of cancer

- Pulmonary embolism
- Venous thrombosis
- Arterial thrombosis
- Marantic endocarditis with multiple infarcts
- Shingles
- Oropharyngeal candidosis
- Clostridium enterocolitis
- Acute myalgias from sepsis
- Ascending cholangitis
- Pyelonephritis
- Graft vs. host disease
- Hepatic venous occlusive disease after bone marrow transplant
- Typhlitis

Box 89.2 Acute neuropathic pain syndromes

- Vinca-induced lancinating pain

- Radiculopathy from plexopathy, vertebral collapse or spinal cord compression
- Postherpetic neuralgia

Unidimensional pain scales, either verbal rating scales or visual numerical rating scales (VNRS), visual analog scales (VAS) or category scales (CS) are used to assess acute pain severity and pain response.[8,14] A pain relief scale is frequently combined with unidimensional scales to assess the adequacy of response. The algorithm of assessment, treatment, and reassessment is more rapid than with chronic pain since the acute nature, pain severity and dosing strategy dictates the need for a quick response.[2] Failure to escalate analgesics in a timely manner can be due to failure to reassess at appropriate intervals.[2] A lack of uniform and timely assessment influences comparisons of opioid dosing strategies for acute pain.

RESPONSE CRITERIA

The response criteria in acute pain are defined by several parameters (Box 89.3). Area under the curve (AUC) for time-analgesic response for pain intensity is one parameter. This requires measurements prior to intervention and at multiple occasions thereafter.[15] This is similar to pharmacokinetics during drug trials with subjective pain relief substituted for plasma drug levels. The sum of pain intensity differences is measured by calculating the AUC. Both of these measures reflect a cumulative response to analgesics but do not provide information about the onset to peak pain relief or duration of relief, both of which are clinically relevant to acute pain.[15] 'Half pain relief' (the percentage of patients who obtain at least a 50 percent relief of their pain) over a 4–6-hour interval as an outcome distinguishes effectiveness of analgesics for acute pain. 'Half pain relief' is governed by three factors: analgesic potency, analgesia dose, and frequency of dosing. To adequately detect a difference between two different methods of pain control, either timing frequency, route, dose, or drug should vary as a single variable and an adequate number of patients should be included in each arm (estimated to be 40) of the study.[15] This is a rarity in cancer pain trials.

Box 89.3 Outcome measures for acute pain

- Peak pain relief
- Number of patients who experience 50 percent reduction in pain intensity
- Summed pain intensity differences (numerical or visual analog scale)
- Total pain relief (numerical or visual analog scale)
- The proportion of patients with 50 percent pain relief
- The proportion of patients who rate their relief as good or excellent
- Time to analgesia (or the time to rescue dose after pain intervention)[15]

The clinically significant changes in VAS or VNRS for acute pain are debated in the literature. There is a significant difference in opinion about the degree of change in unidimensional scales which is relevant to pain relief. That is, if patients have severe pain (VNRS > 7 or a VAS > 70) do these scales need to change to a greater degree for the similar degree of pain relief as compared with mild or moderate pain to be able to detect a meaningful change in pain severity? Gallagher *et al.* found that a significant detectable difference in VAS for acute abdominal pain was 16 mm (VAS).[16] Myles *et al.* found that the VAS was linear for mild to moderate acute postoperative pain. The change in the VAS scale with pain relief represented a linear magnitude in change of pain intensity by unidimensional scales.[17] Kelly found that the minimal significant difference in VAS appeared not to vary with pain intensity. Mild pain required an 11 mm decrease in VAS, which was 15 mm for moderate pain and 11 mm for severe pain.[18] Farrar and colleagues found that a ≥2.0 difference in the VRNS (0–10) was indicative of perceived significant pain relief with oral transmucosal fentanyl citrate for acute breakthrough cancer pain.[19,20] On the other hand, Cepeda *et al.* found a nonlinear relation between decreases in pain intensity and pain relief. Minimally detectable pain relief required a decrease in the VNRS of 1.8 for severe pain. The VNRS decreased on an average of 2.4 or greater to detect 'much pain relief' when patients had moderate pain and average of 4.0 if patients had severe intense pain. Pain had to decrease by 3.5 (VNRS) for 'very much pain relief' if the initial pain was moderate and by 5.2 if pain was severe.[21] Aubrun and colleagues found that the relation between VNRS and morphine was not linear but sigmoid. Higher pain intensity required greater doses of morphine in order to reduce the VNRS to the same degree.[22] A nonlinear relation was found by Bird and Dickson.[23] This appears to be independent of gender and age. Acute pain perception differs with age; procedural-related pain is perceived by older patients as less painful than younger patients.[24] In general, the VNRS and VAS correlate but there is a tendency for the VNRS to be higher than the VAS for pain intensity. However, wide interindividual differences exist in distribution between VAS and VNRS.[25]

Satisfaction scales are inaccurate in determining pain response. Patients tend to be satisfied with pain treatment even when pain is not relieved.[26] The VAS cannot adequately discriminate between those patients in acute pain who do and do not want analgesics.[27] Patients can present with severe pain and refuse or be reluctant to take analgesics.

BARRIERS TO ACUTE PAIN MANAGEMENT

The reluctance on the part of the patients in acute pain to take opioids may be due to fear of addiction, sedation, or adverse effects. Pain intensity is perceived as the need for prolonged hospitalization which will be 'shortened' if analgesics are minimized or avoided.[28] Pain may signify that the cancer is progressing and this perception can be 'minimized'

by avoiding analgesics as a means of denial. Patients hope that pain will spontaneously resolve. Acute pain management involves high technology, and for some, the use of patient-controlled analgesia (PCA) devices. A significant number of patients have fears about the technology of PCA or fear of self-induced overmedication.[28] Half of the patients are concerned about opioid dose titrations and half receive anxiolytics and adjuvants during acute pain management for that reason.[28]

The majority entering an emergency room with acute cancer pain will not receive sufficient opioids for pain relief (77 percent).[3] This is not related to pain intensity and in fact relief is inversely related to the initial intensity of the pain upon entering the emergency room. Patients with mild to moderate pain are more likely to have their pain ignored and undertreated. Usually no analgesics are given prior to procedures or examinations. There is a lack of training for emergency room physicians in acute pain management. Patients refuse analgesics 15 percent of the time for fear of masking important clinical findings and physicians provide minimal analgesics for the same reason despite randomized trials which have demonstrated that effective analgesics do not prevent good assessment.[3,29,30] Finally, the wrong treatment strategy is chosen to manage acute pain, such as continuous infusions of opioids, resulting in a delayed onset to analgesia.

Physicians initially underrate acute pain relative to the patient's rating. The physician's assessment will be more congruent with the patient's perceived pain severity if assessment is repeated.[31–33]

TREATMENT

The traditional method of fixed doses of oral immediate-release morphine every 4 hours or parenteral continuous infusion with rescue dosing is largely inadequate in acute pain management.[3,34] Patient-controlled analgesia developed in the 1970s and 1980s established the fundamental acute dosing strategy of small opioid doses administered at short intervals. In postoperative patients, PCA is both safe and effective. Opioids are titrated against pain intensity, then PCA is used as maintenance. Excessive self-administered doses by PCA are limited by sedation (which occurs before respiratory depression). Two insights are gained with PCA: (i) most patients like to participate in the management of pain and (ii) there is an 8–10-fold difference in opioid requirement between individuals in acute pain such that there is no 'standard' dose.[3,35] Age, not body weight, predicts opioid doses in acute pain management.[3] Women in certain studies required 30 percent (median) more morphine than men.[36,37]

The goals in acute pain management are pain relief balanced by side effects whereas the goals in chronic pain management balance pain relief with function (i.e. activities of daily living and social interactions).
Figure 89.1   *The physicochemical properties of an opioid will determine in part the onset to analgesia (time to effective central nervous system (CNS) concentrations or hysteresis) and duration of effect. Lipophilic opioids initially will have a rapid onset to active and rapid redistribution whereas hydrophilic opioids will have a delayed hysteresis but slower egress from the CNS. The level of P-glycoprotein may also play a role in determining CNS levels for certain opioids.[38]*

Pharmacology and the management of acute pain

Opioid pharmacology is important in the understanding of treatment strategies for acute pain and opioid titration (Box 89.4). The time course to analgesia is not reflected by the change in opioid blood concentrations. Opioid blood concentrations play little role in the management of acute pain, nor do blood levels provide insight into the clinical use of opioids.[3] There is a temporal delay between the drug concentration in plasma and the time to analgesia (frequently called drug hysteresis) related in part to the partition coefficient (lipid solubility) of the opioid (Fig. 89.1 and Box 89.5). The longer the effect delay (hysteresis) the greater the dissimilarity between plasma levels and analgesia. Among phenylpiperidine opioids (alfentanil, fentanyl, and sufentanil) there is a strong association between lipid solubility and minimal effective plasma concentrations, suggesting that the onset to analgesia and potency are related to the ability to cross the blood–brain barrier.[3,38,39] The ability to approach the opioid receptor from multiple directions through the lipid membrane by lipophilic opioids is another factor. Lipophilic opioids give greater access to opioid receptors relative to hydrophilic opioids which are limited to the aqueous phase.

Box 89.4 Factors influencing opioid responses in acute pain

- Differences in tissue damage
- Variability in opioid pharmacokinetics (which range twofold to fourfold between individuals)
- Differences in permeability due to the blood–brain barrier (partition coefficient of each opioid)
- Differences in opioid receptor genetics between individuals
- Variability in perception, meaning of, and attitude toward the pain experience[3]

Box 89.5 Effect delay[3,30,38]

- Morphine – 17–34 minutes
- Fentanyl – 6 minutes
- Alfentanil – 1 minute

P-glycoprotein acts as an efflux pump along the blood–brain barrier that extrudes morphine and morphine 6-glucuronide from the CNS. Morphine 6-glucuronide is several-fold more potent than morphine but its CNS concentrations are significantly less than morphine due to its hydrophilic character and perhaps P-glycoprotein.[38]

The effect delay for morphine has been based on the vocalization responses to electrical stimulation in rats and by the experiences with PCA in humans. However, the published experience of Mercandante and colleagues suggests that by morphine titration 2 mg every 2 minutes the onset to analgesia is less than 10 minutes.[40] Continuous infusions of opioids produce steady state concentrations at 5 half-life intervals resulting in a slow onset to analgesia and an unacceptably long time to reach effective CNS concentrations[3] (Fig. 89.2). Such an approach subjects patients to prolonged, uncontrolled pain.

The onset to analgesia does not correlate with duration of effective analgesia. The CNS dwell time of morphine is much longer than fentanyl, as fentanyl is rapidly redistributed from the CNS. Opioids with short CNS dwell times produce poor pain control with intermittent injections alone.[3] Thus, the need for rescue doses (which reflects CNS levels below effective analgesia) differs between lipophilic opioids and hydrophilic opioids. Traditional methods using 1–2-hour intervals are suitable for opioids with longer CNS dwell times. With PCA, lockout intervals of 6–10 minutes if demand only or continuous infusion plus patient activated rescue doses are more suitable for fentanyl and other lipophilic opioids.[3]

Patient-controlled analgesia has been recommended for unstable acute cancer pain. The cardinal principle of PCA is
Figure 89.2 *Parenteral titration or bolus infusions of morphine will achieve effective central nervous system concentrations quickly depending upon the dosing strategy. Continuous infusions of morphine require 420 minutes to relative onset of analgesia.*[3]

patient-directed opioid titration to analgesia. Patients vary widely in the dose needed for pain control.[3] However, in reality, patients frequently wait to activate the device until pain resurges to its original intensity, and some will not activate the device at all for fear of causing sedation. This delays analgesia despite the prescribed short lockout intervals. In fact the present evidence suggests that oral titration at 2-hour intervals produces pain relief in the same time as PCA. Physician-controlled titration to relief followed by maintenance increases pain relief in a significantly shorter time compared with PCA alone.[40] In studies using PCA patients were not titrated to pain control prior to using PCA and thus differ from usual guidelines for postoperative pain.[41,42]

MANAGEMENT OF ACUTE PAIN IN CANCER: REVIEW OF THE LITERATURE

Severe, unstable, or crescendo pain requires aggressive opioid titration.[43] Titration schedules can consist of either planned dose escalation of opioids at fixed intervals or loading doses of opioids to pain relief followed by maintenance.[3] The evidence supporting dosing strategies is weak due to the paucity of randomized trials.[44,45] The French National Federation of Cancer Centers working group recommends that 'in the presence of very unstable intense pain, preference should be given to intravenous or subcutaneous patient controlled analgesia' as an expert opinion with little evidence for such recommendations.[46] On the other hand reviews of PCA for acute pain state that PCA is essentially a maintenance therapy and therefore acute pain should be controlled prior to starting PCA.[47,48] Discrepancies between guidelines and expert opinion are due to the lack of strong evidence to support such guidelines.

A systematic review of opioid dosing strategy for acute pain has been published.[3,40–42,45] Since that publication, three additional studies have become available for review.[7,45,49,50] A total of 12 studies are now available in the English literature, providing clinical evidence with regards to dosing strategies. Eight of the 12 trials were prospective, two retrospective, and only two were randomized. Evidence-based guidelines and meta-analyses are not possible due to population heterogeneity and study methodologies. Patients were opioid naïve or on weak opioids and in some studies patients were on potent opioids.[45] Routes, dosing schedules, and outcome parameters also differed. While there are no strong evidence-based recommendations some wisdom can be gleaned from these 12 studies. All reported methods and strategies were safe. Respiratory depression was not observed. Drop-out due to toxicity from opioid titration was rare but some patients developed nausea and mild sedation. Hallucinations, myoclonus, constipation, and hypotension were not observed during titration.

Traditional intravenous titration for acute or crescendo cancer pain

All six trials that studied intravenous titration for acute or crescendo cancer pain used a numerical rating scale. 'Responses' differed and ranged from 'initial onset of analgesia' to <5 out of 10 on a VNRS to complete pain relief.[40,45,49,51–53] Time to response ranged between 9.7 to 89 minutes and all were within 100 minutes (Tables 89.1 and 89.2).

Traditional titration leads to rapid pain relief within 2 hours and in several studies within minutes of starting titration. Responses occurred in over 80 percent. This is true both for opioid-tolerant and opioid-naïve patients. Assessment is done frequently, usually at several minute intervals. Close monitoring is necessary with traditional opioid titration.

For maintenance, the total titrated dose is the 4-hourly dose. The titrated dose can be converted to the oral morphine dose by using a 1:3 ratio (parenteral:oral). If patients require high doses of morphine the recommended ratio is 1:2.[40]

Table 89.1 *Intravenous titration for acute or crescendo cancer pain*

Study	Method	Pretrial opioid	Dose	Pain measure and response
Hagen et al.[51]	Prospective case series	Morphine	Morphine 10–20 mg/15 minutes Double the dose every 30 minutes if no response	VNRS; response: ≤5
Kumar et al.[53]	Retrospective case series	NSAIDs, 'weak' opioids	Morphine 1.5 mg/10 minutes	VNRS; response: complete relief
Harris et al.[52]	Prospective randomized trial	NSAIDs, 'weak' opioids	Morphine 1.5 mg/10 minutes	VNRS; response: complete relief
Mercadante et al.[40]	Prospective case series	NSAIDs, 'weak' potent opioids	Morphine 2 mg/2 minutes	VNRS; initial onset of significant analgesia
Soares et al.[49]	Prospective case series	Oral morphine	Fentanyl 10% of MEDD 95 minutes × 2 then 5% increase 95 minutes × 2	VNRS <4 on 0–10 scale
Davis et al.[45]	Retrospective case series	Morphine	Morphine 1 mg/min × 10 minute followed by 5-minute respite then repeat × 3	VNRS; response: pain relief

NSAID, nonsteroidal anti-inflammatory drug; VNRS, visual numeric rating scale; MEDD, mean equivalent daily dose.

Table 89.2 *Intravenous titration for acute pain*

Study	No. of patients	Response time
Hagen et al.[51]	9	89 minutes
Kumar et al.[53]	491	<100 minutes
Harris et al.[52]	62	<1 hour
Mercadante et al.[40]	49	9.7 minutes
Soares et al.[49]	18	11 minutes
Davis et al.[45]	3	20 minutes

Maintenance doses will also depend upon chronic opioid doses in opioid-tolerant patients.[54] Our group has used fentanyl 20 μg or hydromorphone 0.2 mg in substitution for morphine 1 mg in those who cannot take morphine.[54,55]

Patient–controlled analgesia in acute cancer pain

Patient-controlled analgesia has been used to improve relief from cancer pain, and in a small number of studies PCA has been used for relief of acute crescendo cancer pain. It has been stated that PCA improves the titration of opioids to pain relief and minimizes individual pharmacokinetic and pharmacodynamic differences. It reduces patient anxiety about delays in dosing and is said to foreshorten the slow onset to pain relief associated with continuous infusions. Overdose is minimized by small bolus doses and mandatory lockout intervals.[56–58]

A syringe driver, disposable plastic cylinder, or a battery operated computer-driven pump and multiple routes, intranasal, subcutaneous, intravenous, and spinal can be used for PCA.[57] However, regardless of technique, if the patient receives an adequate dose in a timely fashion, a good outcome will occur. The proposed success of PCA over conventional (traditional) methods is related to (i) the nurse to patient ratio, and (ii) the dedication of the nursing staff to pain control. The assessed response benefit of PCA may be missed if assessment is not related to the timing of the dose.[47] Assessment at 2–4-hour intervals or once daily (as occurs in most acute cancer pain trials) will miss the temporal benefits to PCA.[47] The risk of respiratory depression is small (ranges between 0.1 and 0.8 percent). Patient satisfaction, rather than pain relief with PCA is misleading as an outcome measure. Patients generally do not like to criticize those caring for them even if pain is suboptimally controlled. Expectations for pain relief by patients may be low and some pain relief may be better than anticipated.[47] Continuous infusion PCA with demand rescue dosing should be avoided in opioid-naïve patients.

Contraindications to PCA include: dementia or delirium, renal failure, dehydration, obesity, and obstructive sleep apnea.[47] A prescription for PCA requires (i) drug, (ii) bolus dose, (iii) background infusion (if applicable), (iv) lockout interval, and (v) maximum hourly or 4-hourly dose.[47] Patients cannot be expected to activate the demand device frequently to make up for inadequately small bolus doses to sustain pain relief.[47] However most importantly, PCA is essentially a maintenance therapy and pain should be under control prior to PCA.[47] PCA is not a 'one-size-fits-all' nor a 'set-and-forget' technology.[47] Patients need close observation and individualization. Appropriate doses based upon titration and short intervals make up for wide individual differences in opioid requirements. However, most PCA prescriptions are generally done without individualization, or differences in opioid physicochemical properties which influence effect delays, opioid clearance, opioid redistribution, and duration of pain relief.[47]

Table 89.3 *Patient-controlled analgesia in acute crescendo cancer pain*

Study	Method	Pretrial opioid	Dose	Pain measure and response
Radbruch et al.[42]	Prospective case series	Weak opioids	Morphine 1 mg/5-minute lockout interval	VNRS; response not defined; characterized by a decrease in VNRS at 24 hours
Zech and Lehmann[67]	Prospective case series	Morphine	Fentanyl 50 µg/5-minute lockout interval	VAS; response not defined but characterized by a decrease in VAS
Kornick et al.[50]	Prospective case series	Transdermal fentanyl	Fentanyl 100% of the transdermal fentanyl dose plus 50–100% of the hourly fentanyl dose lockout interval 15–20 minutes	VNRS; response not defined but characterized by a reduction in the VNRS score

VNRS, visual numerical rating scale; VAS, visual analog scale.

Table 89.4 *Acute pain management by patient-controlled analgesia for acute crescendo pain*

Study	No. of patients	Time to response
Radbruch et al.[42]	28	300 minutes (subset)
Zech and Lehmann[67]	20	24 hours (VAS from 68 to 34)
Kornick et al.[50]	9	Mild pain at rest 1.5 days
		Mild pain with movement 3 days

VAS, visual analog scale.

PCA AND ACUTE TRANSIENT PAIN

Transient procedural pain is frequently treated with PCA patterned after postoperative pain management and is most studied in mucositis associated with bone marrow transplantation. Interpreting PCA trials with mucositis induced by bone marrow transplantation is fraught with some difficulties.[59] Simply by participating in a trial, and assessment and management by the nursing staff, the control group will improve (Hawthorne effect).[60,61] The overall findings demonstrate that PCA has little advantage over conventional continuous opioid infusions in the treatment of painful mucositis.[61**,62**,63*,64**,65***] Morphine consumption is less with PCA than continuous morphine infusion, but is probably not a major measure of success. Patients develop rapid tolerance when alfentanil or sufentanil are used with PCA.[66**]

PCA MANAGEMENT OF CRESCENDO CANCER PAIN

There have been three trials on the management of acute crescendo pain (Tables 89.3 and 89.4).[42*,50,67*] These three studies illustrate the difficulty in evaluating the efficacy of PCA for crescendo pain. In all three studies assessments were done only once daily and unrelated to the dose. A small subset of patients were evaluated more frequently. All three used PCA without previous titration to pain control. Morphine and fentanyl were prescribed with the same demand interval despite differences in physicochemical properties.

Response to PCA appears to be slower than to traditional titration despite similar dosing intervals. This may be related to the need to frequently activate the device and the reluctance of the patient to activate the device until pain recurs. Many patients will lack a fundamental knowledge of PCA and require getting used to activating the device to effectively use PCA.

Oral opioid dose titration for acute crescendo pain

Oral titration studies have used morphine, except for one retrospective study which used oral transmucosal fentanyl citrate (Tables 89.5 and 89.6).[7*,45***,68**,69*] Morphine dosing intervals were at 12-hour intervals for sustained release and 4 or 2 hours for immediate release. Planned dose escalation depended upon pain relief at the time of the next dose or at 24-hour intervals. Oral transmucosal fentanyl citrate was prescribed at 30-minute intervals until pain relief.

The European Association of Palliative Care (EAPC) working group has recommended daily assessments during oral titration due to steady state concentrations of oral morphine (4–5 half-lives with a 4-hour single dose half-life). During titration the 4-hourly dose is used every 1–2 hours based upon consensus recommendation.[70] The only evidence for short oral titration intervals is a 2-hour interval in Lichter's study.[41*] The recommendation by the EAPC is the same dose hourly whereas Lichter used planned dose increments based upon hourly or every 2-hourly assessments.[41*] The 'titration' strategies of the EAPC appear to be based upon breakthrough pain whereas strategies in the Lichter study were based upon acute uncontrolled pain.[44*] This author has given fixed doses of morphine at 15–30-minute intervals until pain control in home hospice patients with severe crescendo with success (and with a hospice nurse in the home). At the present time there is little to guide us on the particular safe and effective oral dosing strategies (whether fixed doses at frequent intervals or dose escalation at fixed intervals).

Table 89.5 *Oral opioid titration for crescendo cancer pain*

Study	Method	Pretrial opioid	Dose	Pain assessment and response
Klepstad et al.[68]	Randomized controlled, double blind trial	Codeine and dextropropoxyphene	IR morphine or SR morphine at 4 or 24-hour intervals starting with 60 mg titrating to 90, 120, 180, 240, 360 mg depending upon response daily	VAS and VRS; response was less than 3 on a VRS (1–7)
Klepstad et al.[69]	Prospective case series	Codeine and dextropropoxyphene	IR morphine 10 mg every 4 hours × 6 increase by 33–50% every 24 hours	VAS and VRS; response was less than 3 on a VRS (1–7)
Lichter[41]	Prospective case series	Weak or potent nonmorphine opioid	IR morphine every 4-hour intervals starting with 5 mg and titrating to 10, 15, 20, 30, 40, 60, 80, 120, 160, 200 mg at 4-hour intervals or 2-hour intervals	Qualitative descriptor
Burton et al.[7]	Retrospective	Morphine	Fentanyl 200–600 μg every 30 minutes	VNRS

VAS, visual analog scale; VRS, verbal rating scale; VNRS, visual numerical rating scale; IR, immediate release; SR, sustained release.

Table 89.6 *Oral opioid titration for acute crescendo cancer pain*

Study	No. of patients	Time to response
Klepstad et al.[68]	120	2.1 days (SR) 1.7 days (IR)
Klepstad et al.[69]	40	2.3 days
Lichter[41]	50	1 day (every 4 hours) 6 hours (every 2 hours)
Burton et al.[7]	39	<30 minutes in 35 patients

IR, immediate release; SR, sustained release.

Key learning points

- Transient pain in patients with cancer occurs due to investigational procedures, interventions, or complications from treatment and cancer.

- Opioid dosing strategies on an as needed basis or by PCA are reasonable for procedure-related pain.

- Acute unstable and crescendo pain is managed by opioid titration followed by maintenance opioid dosing for quick pain relief.

- Titration consists of either small frequent doses to analgesia or planned dose escalation at fixed intervals.

- Response is assessed at short intervals (minutes to hourly).

- The effective titrated dose at which pain relief occurs provides the basis for maintenance doses.

- The pre-titration opioid dose in the opioid-tolerant patient needs to be added to maintenance doses.

- Rapid opioid titration is safe in those monitored closely.

- Assessment of the underlying cause is not impeded by effective opioid titration.

- Further studies are needed to develop guidelines for the management of acute crescendo cancer pain.

Suicide

WILLIAM BREITBART, CHRISTOPHER GIBSON, JENNIFER ABBEY, NICOLE IANNARONE, RONI BORENSTEIN

INTRODUCTION

Suicide is a tragic, but often preventable response, to the emotional challenges of terminal physical illness. Whitlock[1***] points out that when we consider the stressors that an individual must face in confronting such illnesses we might expect suicide to be a more common reaction, while in reality it is relatively uncommon. Such a realization may indicate that suicide in the terminally ill is a pathologic, and thus potentially treatable, coping response. The purpose of this chapter is to examine the prevalence of suicide in this population, factors that contribute to it, and potential interventions both to prevent it as well as to deal with the trauma that completed suicides have on family and significant others.

SUICIDAL IDEATION IN THE TERMINALLY ILL

Thoughts of suicide probably occur quite frequently, particularly in the setting of advanced physical disease, and may serve as a 'steam valve' for ideations often expressed by patients as 'no matter how bad things become, I always have a way out'. However, published reports have suggested that suicidal ideation is relatively infrequent in illnesses such as cancer and is limited to those who are significantly depressed. Silberfarb et al.[2**] found that only 3 of 146 patients with breast cancer had suicidal thoughts, while none of the 100 cancer patients interviewed in a Finnish study expressed suicidal thoughts.[3] A study conducted at St Boniface Hospice in Winnipeg, Canada, demonstrated that only 10 of 44 terminally ill cancer patients were suicidal or

desired an early death, and all 10 were suffering from clinical depression.[4]

At Memorial Sloan–Kettering Cancer Center (MSKCC), suicide risk evaluation accounted for 8.6 percent of psychiatric consultations, usually requested by staff in response to a patient verbalizing suicidal wishes.[5] Among 185 cancer patients with pain studied at MSKCC, suicidal ideation was found in 17 percent of the study population.[5] It should be noted that the actual prevalence of suicidal ideation may be considerably higher than these figures suggest, in that patients often disclose these thoughts only after a stable, ongoing physician–patient relationship has been established. It has been our experience that once patients develop such a trusting and safe relationship, they almost universally reveal occasional persistent thoughts of suicide as a means of escaping the threat of being overwhelmed by their illness.

SUICIDE AND TERMINAL ILLNESS

Patients suffering from terminal illnesses, such as cancer and acquired immune deficiency syndrome (AIDS), are at increased risk of suicide relative to the general population, particularly in the terminal stage of illness. Unfortunately, the frequency of suicide attempts in illnesses such as cancer has not been well studied. However, a recent study by Hem and colleagues examining data from the Cancer Registry of Norway is a step forward in this area.[6*] This study revealed standardized mortality ratios (SMRs) of 1.55 for males and 1.35 for females. In addition, risk was found to be greatest in the first months following diagnosis and was significantly

increased in male patients with respiratory cancers. While the overall frequency of suicidal thinking in the cancer setting may be in question, its relationship to suicide attempts or completions is clearer. Bolund[7*] reports that fully half of all Swedish cancer suicides had previously conveyed suicidal thoughts or plans to their relatives. In addition, many of the completed cancer suicides had been preceded by an attempted suicide. This is consistent with the statistics of suicide in general, which show that a previous suicide attempt greatly increases the risk of completed suicide.[8,9,10] A family history of suicide is of increasing relevance in assessing suicide risk.

Factors associated with increased risk of suicide in patients with advanced physical disease[5,11***] are listed in Box 90.1. Patients with advanced illness are at highest risk, perhaps because they are most likely to have such complications as pain, depression, delirium, and deficit symptoms. Psychiatric disorders are frequently present in hospitalized patients who are suicidal. For example, a review of consultation data from the psychiatry service at MSKCC revealed that one-third of suicidal cancer patients had a major depression, about 20 percent suffered from a delirium, and 50 percent were diagnosed as having an adjustment disorder with both anxious and depressed features at the time of evaluation.[5,11***]

Box 90.1   Factors associated with increased risk of suicide in patients with advanced physical disease

- Pain – aspects of suffering
- Advanced illness – poor prognosis
- Depression – hopelessness
- Delirium – disinhibition
- Control – helplessness
- Preexisting psychopathology
- Substance/alcohol abuse
- Suicide history – family history
- Fatigue – exhaustion
- Lack of social support – social isolation

Physically ill patients commit suicide most frequently in the advanced stages of disease.[7*,12*,13*,14] Eighty-six percent of suicides studied by Farberow et al.[15**] occurred in the preterminal or terminal stages of illness, despite greatly reduced physical capacity. Poor prognosis and advanced illness usually go hand in hand. It is thus not surprising that in Sweden, those who were expected to die within a matter of months were the most likely to commit suicide. Of 88 cancer suicides, 14 had an uncertain prognosis, and 45 had a poor prognosis.[16**] With advancing disease, the incidence of significant cancer pain increases. Uncontrolled pain in cancer patients is a dramatically important risk factor for suicide. The vast majority of cancer suicides in several studies showed that these patients had severe pain which was often inadequately controlled and poorly tolerated.[7*,17*]

Depression is a factor in 50 percent of all suicides. Those suffering from depression are at 25 times greater risk of suicide than the general population.[18*,19] The role depression plays in suicides among the seriously medically ill is equally significant. Approximately 25 percent of all patients with cancer experience severe depressive symptoms, with about 6 percent fulfilling the Diagnostic and Statistical Manual (DSM)-III criteria for the diagnosis of major depression.[20,21] Among those with advanced illness and progressively impaired physical function, symptoms of severe depression rise to 77 percent.[22***] Depression also appears to be important in terms of patient preferences for life-sustaining medical therapy. Ganzini and colleagues reported that among older depressed patients, an increase in desire for life-sustaining medical therapies followed treatment of depression in those subjects who had been initially more severely depressed, more hopeless, and more likely to overestimate the risks and to underestimate the benefits of treatment.[23*] They concluded that whereas patients with mild to moderate depression are unlikely to alter their decisions regarding life-sustaining medical treatment in spite of treatment for their depression, severely depressed patients – particularly those who are hopeless – should be encouraged to defer advance treatment directives. In these patients, decisions about life-sustaining therapy should be discouraged until after treatment of their depression.

Hopelessness is the key variable that links depression and suicide in the general population. Further, hopelessness is a significantly better predictor of completed suicide than is depression alone.[24] In a recent study[25] Chochinov and colleagues demonstrated that hopelessness was correlated more highly with suicidal ideation in terminally ill patients than was the level of depression. With the typical cancer suicide being characterized by advanced illness and poor prognosis, hopelessness is commonly experienced. In Scandinavia, the highest incidence of suicide was found in cancer patients who were offered no further treatment, and no further contact with the healthcare system.[7*,14] Being left to face illness alone creates a sense of isolation and abandonment that is critical to the development of hopelessness. The prevalence of organic mental disorders among seriously medically ill patients requiring psychiatric consultation has been found to range from 25 percent to 40 percent[26*,27*] and as high as 85 percent during the terminal stages of illness.[28] Although earlier work suggested that delirium was a protective factor in regard to suicide,[12*] clinical experience has found these confusional states to be a

major contributing factor in impulsive suicide attempts, especially in the hospital setting.

Loss of control and a sense of helplessness in the face of one's illness are important factors in suicide vulnerability. Control refers to both the helplessness induced by symptoms or deficits due to the illness or its treatments, as well as the excessive need on the part of some patients to be in control of all aspects of living or dying. Farberow noted that patients who were accepting and adaptable were much less likely to commit suicide than patients who exhibited a need to be in control of even the most minute details of their care.[15**] This need to control may be prominent in some patients and cause distress with little provocation. However, it is not uncommon for illness-related events to induce a great sense of helplessness even in those who are not typically controlling individuals. Impairments or deficits induced by the patient's illness or its treatments often include loss of mobility, paraplegia, loss of bowel and bladder function, amputation, aphonia, sensory loss, and inability to eat or swallow. Most distressing to patients is the sense that they are losing control of their minds, especially when they are confused or sedated by medications. The risk of suicide is increased in patients with such physical impairments, especially when accompanied by psychological distress and disturbed interpersonal relationships due to these deficit factors.[17*]

Fatigue, in the form of emotional, spiritual, financial, familial, communal, and other resource exhaustion increases risk of suicide in the seriously physically ill patient.[5] Due to advancements in treatment, illnesses such as cancer now often follow more of a chronic course. Increased survival is accompanied by increased number of hospitalizations, complications, and expenses. Symptom control thus becomes a prolonged process with frequent advances and setbacks. The dying process also can become extremely long and arduous for all concerned. It is not uncommon for both family members and healthcare providers to withdraw prematurely from the patient under these circumstances. A suicidal patient can thus feel even more isolated and abandoned. The presence of a strong support system for the patient that may act as an external control of suicidal behavior reduces the risk of suicide significantly.

Holland[29***] advises that it is extremely rare for a cancer patient to commit suicide without some degree of premorbid psychopathology that places them at increased risk. Farberow et al.[12*] described a large group of cancer suicides as the 'dependent dissatisfied'. These patients were immature, demanding, complaining, irritable, hostile, and difficult to manage on the ward. Staff often felt manipulated by these patients and became irritable due to what they saw as excessive demands for attention. Suicide attempts or threats were often seen as 'hysterical' or manipulative. Consultation data from MSKCC on suicidal cancer patients showed that half had a diagnosable personality disorder.[30]

ASSESSMENT AND MANAGEMENT OF THE SUICIDAL PATIENT

Assessment of suicide risk and appropriate intervention are critical. Early and comprehensive psychiatric involvement with high-risk individuals can often avert suicide in the cancer setting.[31**] A careful evaluation includes a search for the meaning of suicidal thoughts, as well as an exploration of the seriousness of the risk. The clinician's ability to establish rapport and elicit a patient's thoughts is essential as he or she assesses history, degree of intent, and quality of internal and external controls. The clinician should listen sympathetically, not appearing critical or stating that such thoughts are inappropriate. This is critical, in that allowing the patient to discuss suicidal thoughts often decreases the risk of suicide. The myth that asking about suicidal thoughts 'puts the idea in their head', is one that should be dispelled.[32***] Patients often reconsider and reject the idea of suicide when the physician acknowledges the legitimacy of their option and the need to retain a sense of control over aspects of their death.

The suicide vulnerability factors presented in Box 90.1 should be used as a guide to evaluation and management. Once the setting has been made secure, assessment of the relevant mental status and adequacy of pain control can begin. Analgesics, neuroleptics, or antidepressant drugs should be used when appropriate to treat agitation, psychosis, major depression, or pain. Underlying causes of delirium or pain should be addressed specifically when possible. Initiation of a crisis-intervention–oriented psychotherapeutic approach, mobilizing as much of the patient's support system as possible is important. A close family member or friend should be involved in order to support the patient, provide information, and assist in treatment planning. Psychiatric hospitalization can sometimes be helpful but is usually not desirable in the terminally ill patient. Thus, the medical hospital or home is the setting in which management most often takes place. Whereas it is appropriate to intervene when medical or psychiatric factors are clearly the driving force in a cancer suicide, there are circumstances when usurping control from the patient and family with overly aggressive intervention may be less helpful. This is most evident in those with advanced illness where comfort and symptom control are the primary concerns.

Ultimately the palliative care clinician may not be able to prevent all suicides in all terminally ill patients that he or she cares for. The emphasis of intervention should be to aggressively attempt to prevent suicide that is driven by the desperation of uncontrolled physical and psychological symptoms such as uncontrolled pain, unrecognized delirium, and unrecognized and untreated depression. Prolonged suffering caused by poorly controlled symptoms may lead to such desperation, and it is the appropriate role of the palliative care team to provide effective management of physical and psychological symptoms as an alternative to desire for death, suicides, or requests for assisted suicide by their patients.

REQUESTS FOR ASSISTED SUICIDE

A growing body of literature has emerged on the type of physical and psychological concerns that may give rise to a desire for hastened death and request for assisted suicide. Even if relatively little empirical research has addressed this issue, especially with medically ill patients, some authors found rates of support for legalization of assisted suicide that were roughly comparable to those published in studies on the general population. In Breitbart et al.'s survey study 64 percent of AIDS patients supported legalization of assisted suicide.[33*] In another study 55 percent of terminally ill AIDS patients indicated a possible interest in assisted suicide. In a 1996 study of oncology patients, 25 percent reported that they had thought seriously about euthanasia and 12 percent had discussed this option with their physicians.[34*] A number of social variables, such as fear of becoming a burden to family and friends and experience with the death of a friend or family, have been significant predictors of interest in assisted suicide among ambulatory patients with AIDS.[33*] This joins a growing evidence of research demonstrating an important relation between social support and desire for death, when no relation was found with pain, physical symptoms, or stage of disease.[32***]

DESIRE FOR HASTENED DEATH

Desire for hastened death may be thought of as a unifying construct underlying requests for assisted suicide or euthanasia, as well as suicidal thoughts in general. Literature has emerged on the type of physical and psychological concerns that may give rise to a desire for hastened death. Several studies have demonstrated that depression plays a significant role in the terminally ill patient's desire for hastened death. The precise intensity of this association between depression and desire for hastened death is still being investigated. Chochinov et al. found that of 200 terminally ill patients in a palliative care facility, 44.5 percent acknowledged at least a fleeting desire to die – these episodes were brief and did not reflect a sustained or committed desire to die.[35**] However, 17 patients (8.5 percent) reported an unequivocal desire for death to come soon and indicated that they held this desire consistently over time. Among this group, 10 (58.8 percent) received a diagnosis of depression, compared to a prevalence of 7.7 percent in patients who did not endorse a genuine, consistent desire for death. Patients with depression were approximately six to seven times more likely to have a desire for hastened death than patients without depression. Patients with a desire for death were also found to have significantly more pain and less social support than those patients without a desire for death. Breitbart et al.[36**] recently studied the relationships between depression, hopelessness, and desire for death in a sample of 92 terminally ill cancer patients. Sixteen patients (17 percent) were

classified as having a high desire for death, based on their scores on a validated self-report measure of desire for hastened death called the Schedule of Attitudes Toward Hastened Death,[37**,38**] and 16 percent met criteria for a current major depressive episode. Of the patients who met criteria for major depressive episode, 7 (47 percent) were classified as having a high desire for hastened death while only 12 percent without a desire for death met criteria for depression. Thus, patients with a major depression were four times more likely to have a high desire for hastened death. In addition, Breitbart and colleagues found that both depression and hopelessness, characterized as a pessimistic cognitive style rather than an assessment of one's poor prognosis, appear to be unique and synergistic determinants of desire for hastened death.[39***] No significant association with the presence or the intensity of pain was found. Desire for hastened death also appears to be primarily a function of psychological distress and social factors such as social support, spiritual wellbeing, quality of life, and perception of oneself as a burden to others. Recent data suggest that among dying patients 'will to live', as measured with a visual analog scale, tends to fluctuate rapidly over time and is correlated with anxiety, depression and shortness of breath as death approaches.[40]

INTERVENTIONS FOR DESPAIR AT THE END OF LIFE

The response of a clinician to despair at the end of life as manifest by a patient's expression of desire for death or request for assisted suicide has important and obvious implications on all aspects of care which impact on patients, family, and staff.[41***] These issues must be addressed both rapidly and thoughtfully, offering the patient a nonjudgmental willingness to engage in a discussion of the factors that contribute to the suffering and despondency that leads patients to express such a desire for death. Some investigators speak of this suffering in using such terms as 'spiritual' suffering, 'demoralization', loss of 'dignity', 'loss of meaning',[42***,43,44,45*,46] and have developed interventions based on these concepts/themes.

Palliative care practitioners have begun to deal with the issue of spirituality in the dying and interventions for spiritual suffering. Rousseau[43] outlines an approach for the treatment of spiritual suffering composed of the following steps

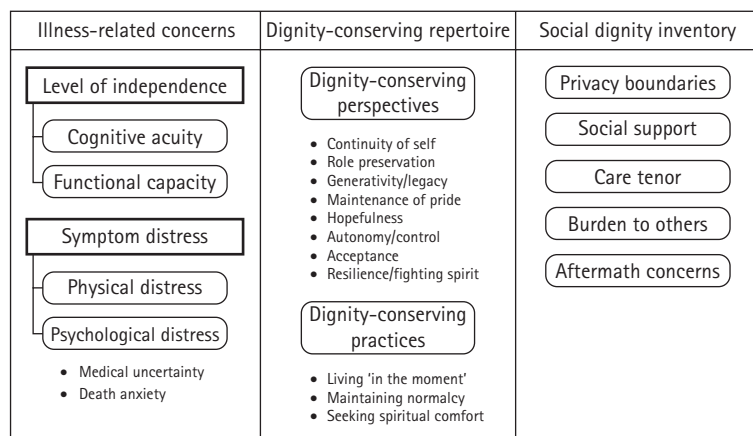
1 controlling physical symptoms
2 providing a supportive presence
3 encouraging life review to assist in recognizing purpose, value, and meaning
4 exploring guilt, remorse, forgiveness, reconciliation
5 facilitating religious expression
6 reframing goals
7 encourage meditative practices, focus on healing rather than cure.


Figure 90.1　*Major dignity categories, themes and sub-themes. Adapted from Chochinov* et al.[45]

Rousseau has presented an approach to spiritual suffering, which is an interesting blend of basic psychotherapeutic principles. Psychotherapeutic techniques that are particularly adaptive to psychotherapy with the dying such as life narrative and life review are also included. There is an emphasis on facilitating religious expression and confession that in fact may be extremely useful to many patients, but is not applicable to all patients and not necessarily an intervention that many clinicians feel comfortable providing. What Rousseau's work suggests is that novel psychotherapeutic interventions aimed at improving spiritual wellbeing, sense of meaning and diminishing hopelessness, demoralization, and distress, are critically necessary to develop at this stage in the development of palliative medicine.

Kissane and colleagues[44] have described a syndrome of 'demoralization' in the terminally ill which they propose is distinct from depression, and consists of a triad of hopelessness, loss of meaning, and existential distress expressed as a desire for death. It is associated with life-threatening medical illness, disability, bodily disfigurement, fear, loss of dignity, social isolation, and feelings of being a burden. Because of the sense of impotence and hopelessness, those with the syndrome predictably progress to a desire to die or commit suicide. Kissane and his group describe a treatment approach for demoralization syndrome.[44] This approach emphasizes a multidisciplinary, multimodal approach consisting of:

- ensuring continuity of care and active symptom management
- ensuring dignity in the dying process
- utilizing various types of psychotherapy to help sustain a sense of meaning, limit cognitive distortions and maintain family relationships (i.e. meaning-based, cognitive–behavioral, interpersonal, and family psychotherapy interventions
- using life review and narrative, and attention to spiritual issues
- using pharmacotherapy for comorbid anxiety, depression, delirium.

Ensuring 'dignity' in the dying process is a critical goal of palliative care. Despite use of the term 'dignity' in arguments for and against a patient's self-governance in matters pertaining to death, there is little empirical research on how this term has been used by patients who are nearing death. Chochinov et al.[45*] examined how dying patients understand and define the term 'dignity', in order to develop a model of dignity in the terminally ill (see Fig. 90.1). A semi-structured interview was designed to explore how patients cope with their advanced cancer and to detail their perceptions of dignity. Three major categories emerged from a detailed qualitative analysis, including illness-related concerns (concerns that derive from or are related to the illness itself, and threaten to or actually do impinge on the patient's sense of dignity); dignity-conserving repertoire (internally held qualities or personal approaches or techniques that patients use to bolster or maintain their sense of dignity); and social dignity inventory (social concerns or relationship dynamics that enhance or detract from a patient's sense of dignity). These broad categories and their carefully defined themes and sub-themes form the foundation for an emerging model of dignity amongst the dying. The concept of dignity and the notion of dignity-conserving care offer a way of understanding how patients face advancing terminal illness, and presents an approach that clinicians can use to explicitly target the maintenance of dignity as a therapeutic objective and principle of bedside care for patients nearing death. Chochinov, in fact, describes his technique of 'dignity-conserving care' in a recent review[47] which interested readers can read for further details (see also Chapter 13).

Interventions for hopelessness and loss of meaning and purpose in the terminally ill are of particular importance when addressing the issues of desire for death and despair at the end of life. Breitbart and colleagues[42***,46] have developed an intervention they term 'meaning-centered' group psychotherapy for advanced cancer patients; an intervention based on the concepts and principles of Viktor Frankl's writings and logotherapy. The intervention is designed to help patients with advanced cancer sustain or enhance a sense of meaning, peace and purpose in their lives even as they approach the end of life. Meaning-centered group

psychotherapy is a manualized, 8-week (one and a half hour weekly sessions) intervention which uses a mixture of didactics, discussion, and experiential exercises that focus around particular themes related to meaning and advanced cancer. The session themes include:

> Session 1 – Concepts of meaning and sources of meaning
> Session 2 – Cancer and meaning
> Session 3 – Meaning and historical context of life
> Session 4 – Storytelling, life project
> Session 5 – Limitations and finiteness of life
> Session 6 – Responsibility, creativity, deeds
> Session 7 – Experience, nature, art, humor
> Session 8 – Termination, goodbyes, hopes for the future

Patients are assigned readings and homework that are specific to each session's theme and which are utilized in each session. While the focus of each session is on issues of meaning/peace and purpose in life in the face of advanced cancer and a limited prognosis, elements of support and expression of emotion are inevitable in the context of each group session (but limited by the focus on experiential exercises, didactics and discussions related to themes focusing on meaning). Currently this intervention is undergoing a randomized controlled trial for efficacy.

Most palliative care clinicians believe that aggressive management of physical and psychological symptoms and syndromes that have been demonstrated to contribute to desire for death will naturally prevent such expressions of distress or requests for assisted suicide. For instance, there is a general consensus that individuals with major depression can be effectively treated in the context of terminal illness. No research has yet addressed if such treatment for depression directly influences desire for hastened death. There are currently two large trials in cancer and AIDS populations examining this specific question.[36**] Because depression and hopelessness are not identical constructs (although highly correlated) clinical interventions, such as those described above, developed to more specifically address hopelessness and related constructs such as dignity, loss of meaning, demoralization, and spiritual suffering or distress will be important to test empirically and utilize in general palliative care practice if they prove effective.

INTERVENTIONS FOR FAMILY MEMBERS FOLLOWING A COMPLETED SUICIDE

When a terminally ill patient chooses to end his or her own life, the treatment team must quickly turn its attention to addressing the needs of the patient's family so as to reduce the chances of complicated bereavement. In order to provide effective support, it is essential that the team is aware of the unique reactions commonly found among suicide survivors. A number of studies have compared the bereavement patterns of suicide survivors and nonsuicide survivors.[48**,49,50*]

Findings from these studies indicate that there are several distinguishing themes that arise in suicide bereavement.

Foremost among them is the desire for the survivor to make meaning of the suicide, or to answer the question 'Why?'.[48**,49,51] Van Dongen[52] calls this process 'agonizing questioning' given the impossibility of ascertaining the answer from the now deceased. Second, survivors often express feelings of guilt, blame, and responsibility for the death.[48**,49] Often they engage in a struggle to retrace the days and months leading up to the suicide in order to pick up clues that they 'missed'. Another documented theme is a heightened feeling of rejection or abandonment, which is often accompanied by anger toward the deceased.[48**,49,53**] Finally, perceived feelings of stigmatization, shame, and embarrassment are well documented.[48**,53**] These feelings may be warranted as there is much evidence in the literature showing that suicide survivors are in fact viewed more negatively by others in their social network in comparison with other mourners.[49] One study by Allen and colleagues[54**] found that individuals bereaved by suicide were viewed as more psychologically disturbed, less likable, more blameworthy, and more in need of professional mental healthcare than those bereaved by other causes. As a result it is not surprising that these individuals struggle with isolation and lack of social support at a time when it is needed most.

Although the aforementioned themes are likely to arise to some extent in all suicide survivors, some may be more or less likely when the suicide is completed by a terminally ill patient. First, on the positive side, family members of a terminally ill suicide completer may not struggle as restlessly with the meaning of the suicide, particularly if their loved one was in a large amount of physical pain or was somehow physically incapacitated. Second, family members may not feel as much responsibility for the suicide as there is a clear external factor, namely the terminal illness, to which one can assign blame. Finally, given that the suicide may not be as unexpected among such a population, the family member may have already started the anticipatory grieving process and may not feel as rejected and abandoned as other survivors. On the other hand, although suicide among the terminally ill may be more socially accepted and thus less stigmatizing for the survivor, this group may receive fewer offers of professional support in comparison with other mourners. Additionally, guilt feelings may be more common among this group of survivors as a consequence of the simultaneous feeling of relief they may experience at the end of a possibly long caregiving period.

Armed with an understanding of the key issues for suicide survivors in general, and for survivors of a terminally ill patient's suicide more specifically, the treatment team can now begin to intervene on behalf of the family. First and foremost, the physician and mental health professional on the team should contact the family immediately after hearing of the suicide. This will communicate that the treatment team does not criticize or blame the family, and that they will not abandon the family just because the patient has passed away.

Similarly, efforts should be made to attend the funeral or memorial services. These acts will serve to diffuse the family's feelings of isolation and stigmatization. Second, attempts should be made to connect the family member to a support group specifically designed for suicide survivors. Jordan[49] (p. 97) argues that groups limited to suicide survivors seem more likely to cohere quickly and to 'avoid a replication of the empathic failure that too often occurs for survivors in their larger social networks'. Such groups should focus on areas such as facilitating integration of the loss by understanding why and how the suicide occurred, exploring the meaning of the loss for the survivor, and providing space for the expression of all types of feelings both positive and negative.[51] Effective support groups for suicide survivors should also include a psychoeducational component, which has been found to reduce survivor anxiety and bolster coping strategies.[51] Psychoeducational resources and materials should also be designed to support and educate those in the survivor's support network so as to reduce their negatively held stereotypes about this group of mourners. A third objective of the treatment team should be to encourage the family to engage in a grieving ritual for the survivor. Some cultures restrict the use of traditional grieving rituals which can leave the survivor with no closure.[51] Developing their own unique ritual can be a liberating experience for the family. Finally, survivors are at risk for increased suicidality of their own, although possibly less so when it is a terminally ill patient that takes his or her own life. Nevertheless, the treatment team should proactively assess the family member's risk, and make an appropriate referral if warranted.

Key learning points

- Suicide is a tragic but often preventable response to terminal physical illness.

- Existing data on the frequency of suicidal ideation in the terminally ill may be misleading, in that patients often disclose these thoughts only after a stable, ongoing physician–patient relationship has been established.

- Patients suffering from terminal illnesses, such as cancer and AIDS, are at increased risk of suicide relative to the general population, particularly in the terminal stage of illness.

- Psychiatric disorders (such as major depression, delirium, and adjustment disorders) are frequently present in hospitalized patients who are suicidal. Depression is a factor in 50 percent of all suicides.

- Physically ill patients commit suicide most frequently in the advanced stages of disease.

- Loss of control and a sense of helplessness in the face of illness are important factors in suicide vulnerability.

- The prevalence of organic mental disorders, such as delirium, among seriously medically ill patients has been found to range from 25 percent to 85 percent during the terminal stages of illness. Clinical experience has found these confusional states to be a major contributing factor in impulsive suicide attempts, especially in the hospital setting.

- Assessment of suicide risk and appropriate intervention is critical. Early and comprehensive psychiatric involvement with high risk individuals can often avert suicide in the medical setting.

- The clinician's ability to establish rapport and elicit a patient's thoughts is essential. Allowing the patient to discuss suicidal thoughts often decreases the risk of suicide. The myth that asking about suicidal thoughts 'puts the idea in their head,' is false and should be dispelled.

- Analgesics, neuroleptics, or antidepressant drugs should be used when appropriate to treat any agitation, psychosis, major depression, or pain that are contributing to the patient's suicidal ideation.

- Novel psychotherapeutic interventions aimed at improving spiritual wellbeing, sense of meaning and diminishing hopelessness, demoralization, and distress are being developed which may prove effective in reducing suicidal ideation and attempts. Interventions for hopelessness, loss of meaning and purpose in the terminally ill are of particular importance when addressing the issues of desire for death and despair at the end of life.

- In cases of completed suicide, clinicians need to be sensitive to the needs of the patient's family and loved ones. These individuals may require some form of intervention to assist them in coping. Such individuals may also be at a potentially higher risk for suicide themselves.

Cancer: radiotherapy

ELIZABETH A BARNES, EDWARD CHOW

INTRODUCTION

Radiotherapy plays an important role in the multidisciplinary management of patients with cancer. It is a local treatment, and can be used with curative intent for a localized tumor, in the adjuvant setting after surgery, and with palliative intent to relieve symptoms resulting from tumor mass effect. Approximately half of all radiotherapy treatment is given with palliative as opposed to curative intent.[1] The goal of palliative radiotherapy is to use a short treatment schedule to provide effective and durable symptom relief with minimal treatment-related side effects.

Radiotherapy is used to treat cancer with ionizing radiation resulting in damage to cellular DNA (Fig. 91.1). When radiation passes through a living cell, it causes damage by direct and indirect effects. Direct effects include damage to the DNA strand (base deletions, single, and double-strand breaks). Indirect effects result from ionization of water molecules causing free radicals, which in turn damage the DNA. Repair of DNA damage is possible both in normal and malignant cells, but malignant cells often have defective DNA repair and so significant damage can accumulate. Lethally damaged cells do not show morphological evidence of radiation damage until they attempt to divide.

Radiotherapy delivery is broadly classified as external beam radiation or brachytherapy. External beam treatment involves high energy γ rays produced from a linear accelerator, or from a radioactive cobalt source housed within the head of the treatment machine. Brachytherapy involves delivering radiation over a short distance from a radiation source that is placed on or into a body surface, tissue or cavity. Another form of brachytherapy involves using
Figure 91.1 *Radiation damaging nuclear DNA resulting in cell death.*

radioactive isotopes that have affinity to specific tissues, e.g. bone or thyroid, and are injected into the blood stream and deposit radiation locally.

When a patient is seen in consultation for palliative radiotherapy, the radiation oncologist takes into consideration

tumor factors such as histology and tumor location, and patient factors such as symptom burden and life expectancy to determine whether treatment is appropriate. Repeat radiotherapy to the same site may be possible depending on the previous treatment parameters (dose and fractionation), time since previous radiotherapy, and the radiation tolerance of structures within the radiotherapy field. As radiotherapy is a local treatment, the objective is to treat the tumor while minimizing dose to surrounding normal tissue. Immobilization of the patient is first required; usually this involves having the patient lie still in the supine position. External beam treatment planning (simulation) involves localizing the tumor clinically if a superficial lesion, or using fluoroscopy or computed tomography (CT) if deep seated. After treatment field planning and radiation dose calculation, the patient then receives treatment from a linear accelerator or cobalt unit in a heavily shielded room. It is important to remember that the patient must be able to lie still, unattended, on the simulator and treatment tables (which are hard and narrow) for approximately 15 minutes at a time. This may be difficult for patients who are delirious, orthopneic, or have uncontrolled pain.

Radiotherapy services are closely linked to the level of medical care of a given country. Of the 6805 radiotherapy units worldwide, 4572 (67 percent) are in developed countries, even though they have just 21 percent of the population.[2] Moreover, 56 of the 129 developing countries (43 percent) do not have any radiotherapy facilities, with the problem being worst in Africa. The incidence of cancer is projected to rise worldwide by around 50 percent in the next 20 years, mostly in developing countries. Therefore, the lack of radiotherapy services will worsen unless there is appropriate planning and financial investment. In contrast, there is greater access to radiotherapy in resource-rich countries (such as the USA) that have both state funded and freestanding radiotherapy centers, and so patterns of practice tend to differ.

The unit of radiation dose for many years was the rad (radiation absorbed dose). This has now been replaced by the SI unit gray (Gy), (1 rad = 0.01 Gy = 1 centigray [cGy]). Typically one radiotherapy treatment (fraction) is given per day, 5 days a week (Monday through Friday). Large doses per fraction are poorly tolerated and increase the risk of late tissue toxicity. Small doses per fraction delivered over many days are used to take advantage of the observation that cancers have impaired DNA repair as compared with normal tissue. Therefore during treatment normal tissue can recover through repair and repopulation, while DNA damage in malignant cells accumulates and is fatal when the cell tries to divide. The differential toxicity between cancer and normal tissue is not complete, and normal tissues have a tolerance dose beyond which they are irreversibly damaged. This dose is lower for spinal cord and bowel than muscle and bone. The optimal dose of radiation is one that will produce the maximal probability of tumor control with minimal complications. In curative

treatment regimens a high total dose needs to be delivered (5000–8000 cGy), which is accomplished by using small daily fractions (180–200 cGy). For symptom palliation a high total dose is not required, therefore palliative fractionation schedules can be shorter and use a higher dose per fraction. This serves to minimize patient visits to the cancer center and treatment-related side effects. Commonly used palliative radiotherapy regimens include 800 cGy in a single fraction, 2000 cGy in five fractions (400 cGy per fraction) and 3000 cGy in 10 fractions (300 cGy per fraction). Treatment-related side effects are defined as acute (≤90 days after treatment start) or late (>90 days). As radiotherapy is a local treatment, apart from fatigue, side effects depend on the area treated. Acute toxicity is self-limiting and tends to resolve within 2 weeks of treatment completion. Late toxicity is usually not a problem in the palliative setting, given the low total radiotherapy doses used and the limited life expectancy of patients with advanced cancer. However, the radiation tolerance of normal tissue such as spinal cord needs to be respected, especially when retreating, as patients can live longer than expected.

BONE METASTASES

Bone metastases are common in patients with advanced cancer, and are the most common cause of cancer pain.[3] Palliation of bone metastases comprises a significant workload in a radiotherapy department, accounting for 40 percent of palliative radiotherapy courses.[1] Radiotherapy is used in the management of bone metastases for relief of bone pain, prevention of impending fractures, and promotion of healing pathological fractures. Prophylactic surgical fixation should be considered for good performance status patients with bone lesions at high risk of fracture, as prophylactic surgery is easier to perform than surgery after a pathological fracture, and is associated with better functional outcomes and increased survival.[4,5] High-risk lesions include those with >50 percent cortical destruction of a long bone; femoral lesions >25 mm in the neck, subtrochanteric, intertrochanteric, or supracondylar regions; and diffuse lytic involvement of a weight bearing bone especially if painful.[7*] Postoperative radiotherapy is routinely given and has been shown to improve functional status, decrease pain, and reduce the risk of refracture.[6*] Database analysis from a recent bone metastases trial found the risk of femoral fracture was most dependent on the amount of axial cortical involvement, and recommended prophylactic fixation for lesions >30 mm, or in nonsurgical candidates multiple fraction radiotherapy to decrease fracture occurrence.[8**]

Two recent meta-analyses have shown the overall and complete pain response rates to bone radiotherapy are 59–62 percent and 32–34 percent, respectively.[9***10***] The median time to pain relief is 3 weeks,[11**] and the median

duration of pain relief is 12–24 weeks.[9***] Acute toxicity is mild, seen in 10–17 percent of patients, and late toxicity is rare (4 percent).[12**] Toxicity is site specific, for example acute toxicity from cervical spine radiotherapy can result in dysphagia, thoracic and lumbar spine radiotherapy nausea and vomiting, and pelvic radiotherapy diarrhea. Prophylactic ondansetron can be used to reduce emesis when treating over the epigastrium, lumbothoracic spine, or a large pelvic field.[9***] Re-treatment can be considered for patients who experience initial pain relief followed by a relapse, have incomplete pain relief, or no pain relief. Re-treatment offers effective palliation, with a response rate of 63 percent.[13**] Generally a 4-week interval is given before considering re-treatment, to allow enough time to derive benefit from the first treatment. There is an ongoing international phase III randomized trial of single versus multiple fractions for reirradiation of painful bone metastases to determine the optimal dose fractionation regimen for re-treatment.[14]

Despite the frequent use of palliative bone radiotherapy, and the fact that numerous randomized trials have been conducted on dose fractionation schedules, there is still no uniform consensus on the optimal radiotherapy schedule for uncomplicated bone metastases. The most commonly employed schedules are a single 800 cGy, 2000 cGy in five daily fractions, or 3000 cGy in 10 daily fractions. Two recent meta-analyses show no significant difference in overall or complete response rates or duration of pain relief between single and multiple fractions.[9***,10***] Furthermore, no difference in quality of life, analgesic use, or acute toxicity were observed. However, the observed re-treatment rates were higher with the use of a single fraction at 20–25 percent compared with 7–12 percent following multiple fraction regimens.[9***,10***] Physician training, department policy, resource availability, and reimbursement can influence practice patterns.[15] In the USA, where radiation is reimbursed on a per fraction basis, there is a tendency to use protracted fractionation regimens. In Europe, where radiation is paid for on a global, or per episode basis and where the recent large randomized trials demonstrating equivalence were performed, single fractions are more commonly used. Practice in the USA may change with the results of RTOG 97–14, which was recently published.[12**] This compared a single 8 Gy fraction to 30 Gy in 10 fractions for good performance status breast and prostate cancer patients with painful bone metastases. No difference was found in overall response rate between the two arms, with pain improvement seen in 66 percent of patients at 3 months.

The optimal palliative radiotherapy treatment regimen is one that provides prompt and effective pain relief with minimal toxicity and patient inconvenience. A single fraction has the advantage of requiring only one visit, which is especially beneficial for patients with poor performance status and those who live at a distance from the center. For patients with longer life expectancy, receiving multiple fractions upfront may avoid the need for re-treatment, and

therefore the choice of fractionation schedule should be discussed with the patient.[16,17]

Patients with bone metastases often have diffuse bony disease, for which half-body irradiation (HBI) and systemic radionuclides can be useful treatment modalities to simultaneously target all bony lesions. HBI encompasses either the upper half (base of skull to iliac crest), or lower half (iliac crest to ankles) of the body in a single large radiotherapy field.[18**] Single fraction HBI has been shown to provide pain relief in 70–80 percent of patients.[19*,20*] The onset of pain relief is quicker than with local radiotherapy, occurring within 24–48 hours, suggesting that cells of the inflammatory response pathway may be the initial target tissue, since tumor cell activities are unlikely to be halted so quickly. The dose delivered is typically a single fraction of 6 Gy to the upper body (reduced dose due to potential for lung toxicity), and 8 Gy to the lower body. Addition of a single fraction of HBI to local radiotherapy has been shown to delay the time to disease progression and time to re-treatment.[21**] An international phase III trial looked at different fractionation regimens (15 Gy in five fractions over 5 days, 8 Gy in two fractions over 1 day, and 12 Gy in four fractions over 2 days) to determine the most effective and least burdensome treatment regimen.[18**] Results showed the 2 and 5-day regimens gave similar results (except for prostate primaries where the 2-day arm was inferior), with pain relief seen in 91 percent of patients by day 3. The 1-day regimen provided inferior pain relief and quality of life; and therefore except for prostate primaries, the 2-day regimen can be recommended for patients with widespread bony disease. Half-body irradiation is associated with acute gastrointestinal toxicity (nausea, vomiting, diarrhea), thought to be more pronounced with use of a single fraction.[22] Acute toxicity usually requires intravenous fluids and premedication with antiemetics and corticosteroids, and in some cases an overnight stay in hospital for observation. Reversible myelosuppression occurs, therefore sequential treatment of upper and lower body requires a 4–6-week interval for counts to recover.

Systemic radionuclides are deposited at the site of osteoblastic bony metastases, mirroring the uptake seen on bone scan, and emit radiation with a mean range <3 mm.[23,24] Radionuclides have been mainly studied in patients with hormone refractory prostate cancer, as these bone metastases tend to be osteoblastic rather than osteolytic. Patients with lung or breast primaries typically have mixed osteoblastic and osteolytic bone metastases, and therefore the use of radionuclides is less applicable. Strontium-89 and samarium-153 are the agents most commonly utilized in clinical practice, and can be given in a single intravenous injection on an outpatient basis. Efficacy of the various radionuclides is thought to be similar, although comparative trials have not been conducted. Contraindications for use are fracture, spinal cord compression, lesions with extraosseous component, renal failure, inadequate

hemogram, life expectancy <2 months, and chemotherapy within 1 month.[24] A randomized trial comparing strontium to local or wide field radiotherapy in patients with metastatic prostate cancer found similar response rates in all arms (65 percent), and strontium decreased the incidence of new painful sites.[25**] Strontium toxicity consists mainly of reversible myelosuppression, with a decrease in platelet and leukocyte counts of 30–40 percent at nadir, occurring at 4–8 weeks.[25**] Cancer Care Ontario Guidelines (CCOG) for patients with hormone refractory prostate cancer recommend strontium for use in patients with multiple uncontrolled painful sites of bone metastases on both sides of the diaphragm not adequately controlled with analgesics, and where the use of multiple single fields of radiotherapy is not possible.[26***] A randomized trial of strontium versus placebo as an adjunct to local radiotherapy in patients with metastatic prostate cancer found strontium improved quality of life and decreased analgesic requirement at 3 months, as well as reduction in the lifetime need for radiotherapy and rate of new painful sites.[27**] The CCOG guidelines, however, do not recommend the use of strontium in this adjuvant setting as the clinical significance of these findings is uncertain.[26***]

There is limited evidence to compare the efficacy of radionuclides with HBI.[26***] The pain relief achieved with HBI and radionuclides appears to be comparable, however the onset of pain relief is faster with HBI.[18**] Both are associated with transient myelosuppression, but with HBI acute gastrointestinal toxicity is worse, and there are concerns of late toxicity to visceral structures. Systemic radionuclides may be preferred in the setting of diffuse blastic disease, however, its use is limited by cost and resource availability. Half-body irradiation remains an effective treatment option for patients with diffuse lytic disease refractory to other therapies.

BRAIN METASTASES

Brain metastases occur in approximately 25 percent of cancer patients, and are most commonly seen in patients with lung, breast, and gastrointestinal primaries.[28,29] Brain metastases are associated with major neurological morbidity and shortened survival, with a median survival of 1–2 months with corticosteroids alone,[30] and 4–6 months with whole-brain radiotherapy (WBRT).[31] Treatment typically consists of corticosteroids to reduce peritumoral edema, followed by WBRT. The goal of radiotherapy is to provide neurological symptom relief, allow corticosteroid tapering, and possibly improve survival. The acute side effects of treatment include fatigue, alopecia, and erythema of the scalp. Long-term toxicity is limited and rarely a concern for these patients with limited life expectancy. A recent practice guidelines report found no benefit with respect to

survival or symptom control for doses higher than 2000 cGy in five fractions or 3000 cGy in 10 fractions.[32***]

A single brain metastasis is present in 30–40 percent of patients.[33] For these patients with good performance status and minimal or no evidence of extracranial disease, surgical excision followed by WBRT has been shown to improve survival over WBRT alone.[32***,34**,35**] Postoperative WBRT after surgical excision of a single metastasis can improve local control.[32***,36**] The addition of a stereotactic radiosurgery boost to WBRT for patients with good performance status has been recently shown to improve survival for patients with a single brain metastasis, and to improve functional autonomy for patients with two to three metastases.[37**]

A single institution observational study of all patients receiving WBRT for symptomatic brain metastases found at 1 month only 15–39 percent of patients benefited from treatment (depending on the criteria used), and 27 percent died at or soon after 1 month.[38*] This emphasizes the importance of appropriately selecting patients for treatment, as patients with poor performance status and rapidly progressive extracranial disease may not derive a clinical benefit from radiotherapy.[32***]

LUNG CANCER

Lung cancer is one of the most common causes of cancer death worldwide. Nonsmall cell lung cancer (NSCLC) accounts for 80 percent of lung cancers, and small cell lung cancer (SCLC) 20 percent. The latter is typically treated with chemotherapy, given the propensity for widespread dissemination at diagnosis. More than two-thirds of NSCLC patients present with incurable locally advanced or metastatic disease.[39**] The overall prognosis of patients is poor, with a median survival of less than 1 year.

The use of chemotherapy for NSCLC has been increasing over the past two decades, but radiotherapy remains an important treatment modality for patients with predominantly intrathoracic disease, who are unable to receive or decline chemotherapy, or have chemoresistant disease.[40] Thoracic symptoms can be effectively palliated with local radiotherapy, with up to 90 percent of patients obtaining relief from hemoptysis and chest pain, and up to 65 percent obtaining relief from cough and dyspnea.[39**,41**] Symptom palliation with radiotherapy has been found to last for over half of the patient's lifetime.[42**] Reirradiation using techniques to spare spinal cord can provide effective and durable symptom palliation.[43*] In locally advanced NSCLC patients with asymptomatic pulmonary disease, no advantage has been shown with respect to overall survival, quality of life or symptom control to immediate versus delayed thoracic radiotherapy.[44**] For patients with total atelectasis secondary to obstruction of the mainstem bronchus, receiving radiotherapy within 2 weeks of atelectasis

results in higher rates of complete reexpansion (71 percent vs. 23 percent after 2 weeks).[45*] Intraluminal brachytherapy with a high dose rate applicator can offer effective palliation of symptoms arising from endobronchial disease in 1–3-fraction outpatient treatments.[46*] This is also a treatment option for patients with endobronchial tumor recurrence who have received maximal doses of external beam radiotherapy.

Several studies have investigated optimal fractionation regimens for palliative thoracic radiotherapy. A systemic review published in 2003 of 12 randomized trials stated a meta-analysis could not be performed due to the large heterogeneity in radiotherapy regimens, outcome measures and patient characteristics.[47***] However, they found no strong evidence that higher doses offered better symptom palliation, but good evidence to suggest that toxicity is greater. There is a suggestion that higher doses of radiotherapy for good performance status patients with locally advanced nonmetastatic lung cancer may lead to a modest (6 percent at 1 year, 3 percent at 2 years) increase in survival.[48***] The fractionation regimens in these trials include common palliative schedules such as a single dose of 10 Gy, a total dose of 17 Gy in 2 fractions 1 week apart, 20 Gy in 5 fractions, 30 Gy in 10 fractions, and more radical doses such as 60 Gy in 30 fractions. Of note, none of these trials examined the role of chemotherapy, which is now playing an increasingly important role in patient management. Good performance status patients with locally advanced nonmetastatic disease can be considered for radical chemoradiotherapy.[49] For patients treated with palliative intent, chemotherapy has been shown to improve survival, symptom relief, and quality of life compared to best supportive care.[49] Whether combining radiotherapy with chemotherapy improves symptom relief or quality of life for selected NSCLC patients is unknown.

PELVIC DISEASE

Locally advanced and recurrent pelvic malignancies (i.e. genitourinary, gastrointestinal, and gynecological primaries) can result in many disabling symptoms. These include hemorrhage; necrotic vaginal discharge; local pelvic and neuropathic pain due to adenopathy, invasion of bone and lumbosacral plexus; lower extremity edema; fistula formation; gastrointestinal tract obstruction; and renal failure due to ureteric obstruction.

Effective symptom palliation has been seen following one to three fractions of 10 Gy given 4 weeks apart to the pelvis.[50*,51*,52*] RTOG 7905 examined combining three fractions with misonidazole (a radiosensitizer) in patients with gynecologic, bowel, and prostate cancers, and found the overall and complete response rate to treatment was 62 percent and 38 percent, respectively.[53*] A dose–response relationship has been reported, with repeat fractions giving more effective symptom palliation.[50*,53*] However, RTOG

7905 found three fractions gave a very high rate (49 percent) of late complications,[53*] while one to two fractions is associated with a late complication rate of 0–10 percent.[50,*53*] Given the high complication rate, RTOG 8502 explored using 370 cGy twice a day for 2 days, with a rest interval of 2–4 weeks, repeated three times to a total dose of 4440 cGy.[54*] This regimen was associated with a much lower risk of late toxicity (6 percent), yet gave similar symptom palliation with approximately 50 percent of patients having complete pain relief, and 90 percent complete resolution of bleeding or obstruction.[55,56*] As the incidence of late toxicity increases with time, patients with a life expectancy greater than 9 months should receive the second RTOG schedule, or other treatment schedules using lower dose per fraction, or one to two fractions of 10 Gy.

Patients with muscle invasive bladder cancer are typically smokers, older (>70 years of age), and often have numerous medical comorbidities. For patients unable to tolerate radical treatment, and for patients with locally advanced incurable disease, palliative radiotherapy with the goal of symptom relief can be given. A large randomized trial was conducted comparing the efficacy and toxicity of two palliative radiotherapy schedules (35 Gy in 10 fractions, and 21 Gy in three fractions on alternate days over 1 week).[57**] There was no difference between the two arms, with 68 percent overall improvement in bladder symptoms at 3 months, median survival of 7.5 months, and late bowel toxicity rate of <1 percent. Improvement at 3 months of individual symptoms was 88 percent for hematuria, 82 percent for frequency, 72 percent for dysuria, 64 percent for nocturia, and this was maintained in many patients for the duration of their survival. Other groups have reported using 5–6-weekly fractions of 6 Gy with effective symptom palliation,[58*,59*] late bowel (2 percent) and bladder (11 percent) toxicity was reported in one trial.[58*] Another trial reported that by using 5.75 Gy vs. 6.5 Gy in 6-weekly fractions the incidence of late bowel toxicity was reduced from 15 percent to 0 percent.[60*] Of interest, the radiotherapy treatment volume in these bladder cancer trials consisted of the bladder with a small margin (usually 100 cm³), which was smaller than the volumes treated in the RTOG trials (usually 225 cm³). This may partially explain the higher bowel complication rate seen in the RTOG trials. Using modern CT-based radiation treatment planning to treat the tumor while minimizing bowel and other structures can reduce treatment toxicity and allow for dose escalation.

Paraaortic adenopathy from pelvic primaries can result in lower back pain which can be palliated with local radiotherapy. Recurrent ovarian cancer is typically treated with chemotherapy, however radiotherapy offers very good symptom palliation with response rates >70 percent, even in patients with platinum resistant disease.[61*,62*] Patients with metastatic rectal cancer can suffer from severe pelvic pain and bowel obstruction due to their primary disease, and palliative resection or diverting colostomy is often

recommended. Palliative chemoradiotherapy with concurrent 5-fluorouracil (5-FU) has been shown to provide symptom relief in 94 percent of patients, and gives a 1-year colostomy-free survival rate of 87 percent.[63*] The study recommended radiotherapy regimens of 36 Gy/12 fraction/3 weeks, 35 Gy/14 fraction/3 weeks, or 30 Gy/6 fraction/2 weeks. A review addressing the question of the most effective dose fractionation for symptom relief in patients with pelvic recurrence from colorectal or rectal cancer included studies using doses ranging from 1500 cGy to 7000 cGy, but could not provide a definitive answer.[64***]

HEAD AND NECK CANCER

Patients with locally advanced head and neck cancer can have many devastating symptoms due to their disease. These include pain, dysphagia, hoarseness, otalgia, and respiratory distress.[65**] Tracheostomy placement may be required to maintain the airway, and patients commonly have malnutrition and may require a feeding tube. Radiotherapy with concurrent chemotherapy can be offered to patients with advanced inoperable disease with curative intent, but treatment is associated with high rates of acute toxicity, and 3-year survival rates are approximately 40 percent.[66**] Patients with incurable disease or those not able to tolerate radical treatment can be offered palliative radiotherapy. An expert panel in 1996 found there were insufficient data in the medical literature on the role of palliative radiotherapy for head and neck cancer with regards to symptomatic outcomes, toxicity, and palliative radiotherapy treatment regimes.[67***] A recent study from India reported on over 500 patients with nonmetastatic stage IV head and neck cancer treated with a short course of palliative radiotherapy (2000 cGy in five fractions).[65**] At 1 month the partial response rate was 37 percent, and >50 percent symptom relief was seen in 47–76 percent of patients. Median survival was 200 days. Patients with good performance status achieving partial response at 1 month were advised to have further radiotherapy with radical intent, and this treatment resulted in a median survival of 400 days and a disease-free rate of 10 percent.

ESOPHAGEAL CANCER

More than half of patients with esophageal cancer present with inoperable disease and require palliation of dysphagia.[68] External beam radiotherapy, intraluminal brachytherapy, photodynamic therapy, laser ablation, and stent placement are among the treatment options.[69**] Palliative external beam radiotherapy regimens that have been explored include 3000 cGy in 10 fractions with a single course of concurrent 5-FU and mitomycin C, which gave complete relief of dysphagia in 68 percent of patients at a median interval of 5 weeks, with 73 percent remaining dysphagia free until death.[70*] Another study using 4000 cGy in two daily fractions of 200 cGy over 2 weeks again found good relief of dysphagia, with a response rate of 67 percent seen at a median of 4 weeks, and a favorable toxicity profile.[71*] High dose rate brachytherapy given in one to three fractions palliates dysphagia in 50 percent of patients, although care needs to be taken with the dose delivered due to the risk of bleeding, and fistula and stricture formation.[72*] A randomized trial comparing a single fraction of brachytherapy with stent placement found dysphagia relief was faster with stent placement, although the overall response was better with brachytherapy.[73**] Higher complication rates were seen with stent placement, and quality-of-life outcomes favored the brachytherapy group. The need for reintervention was similar in both groups (40 percent), and there was no difference in median survival. Palliation of dysphagia needs to be individualized based on patient factors, local expertise, and resource availability.

SKIN CANCER

Skin cancers are classified into two main groups: melanoma and nonmelanoma (basal cell and squamous cell carcinoma).[74] Basal and squamous cell carcinomas are common in older patients, and are often seen in sun-exposed areas of the face and limbs. Neglect in older people can lead to patients presenting with large destructive lesions invading surrounding soft tissue and bone. This can result in pain, bleeding, ulceration, and secondary infection. A short course of palliative radiotherapy can reduce bleeding and allow ulcerative lesions to dry out, making dressing changes and nursing care easier. Melanoma is an aggressive disease with high rates of distant metastases. While often considered radiation resistant, palliative radiotherapy does provides effective and durable palliation. Fractional doses of ≥400 cGy are thought to be more effective than <400 cGy, with response rates of 82 percent vs. 36 percent, respectively.[75***] Examples of radiotherapy regimens using high dose per fraction are 8 Gy days 0–7–21,[76*] and four to five fractions of 6 Gy delivered twice weekly.[75***]

Key learning points

- Local radiotherapy can provide effective palliation of distressing symptoms.

- A short course of radiotherapy (one to five treatments) can be used to minimize treatment-related side effects and limit patient visits to the cancer center.

- A single 8 Gy treatment is recommended for symptomatic relief of uncomplicated bone metastasis, with an expected overall and complete response rate of 60 percent and 32 percent, respectively.

- Patients with symptomatic multiple brain metastases and reasonable performance status are recommended to receive WBRT – suggested radiotherapy schedules are 2000 cGy in five fractions or 3000 cGy in 10 fractions.

- Radiotherapy can also be used to palliate hemorrhage (hemoptysis, hematuria, vaginal bleeding, infiltrating skin lesions), cough, dyspnea, dysphagia, and pain due to tumor infiltration.

Cancer: chemotherapy

XIPENG WANG, JOHN J KAVANAGH

INTRODUCTION

In modern medicine, chemotherapy is one of the most important approaches for managing malignant disease, regardless of whether the goal of that management is cure or palliation of symptoms. However, nearly all forms of chemotherapy are associated with side effects, some of which can be serious or even life threatening, either in their own direct effects or indirectly if chemotherapy must be discontinued because of intolerable toxicity. The extent of toxicity depends both on the chemotherapeutic protocol and on the condition of the patient; poor nutritional status or cachexia, advanced age, and extent of organ involvement by primary or metastatic tumor can all affect the ability to tolerate chemotherapy.

Control of chemotherapy-related symptoms is a vital aspect of cancer therapy and an important clinical goal. Effective control of symptoms associated with chemotherapy, regardless of whether that therapy is delivered with curative or with palliative intent, can enhance the benefits to patients in terms of effectiveness, as the ability to tolerate chemotherapy increases the chances of completing planned regimens, as well as maintaining quality of life by diminishing adverse effects and protecting organ function. Hence, offering symptom-related palliation during cancer chemotherapy can help to guarantee that the chemotherapy is effective as well as enhancing the psychological and physiological state of the patients. Chemotherapy itself is increasingly being used for palliative care, the goal of which is not to prolong survival but rather to improve tumor-related symptoms, where the palliation/toxicity trade-off from treatment clearly favors symptom relief.[1]

The next section of this chapter will review some of the symptoms commonly associated with use of chemotherapeutic agents, with descriptions of efforts to address those symptoms or their underlying causes. The remainder of the chapter will describe principles for the use of chemotherapy for symptom control in advanced disease and the experience with palliative chemotherapy for lung, breast, prostate, and ovarian cancer.

SYMPTOMS RELATED TO USE OF CHEMOTHERAPY AGENTS

Fatigue

Fatigue is often cited by patients with malignancies as being a major obstacle to normal functioning and good quality of life. Between 70 percent and 80 percent of patients undergoing chemotherapy will experience fatigue.[2–5] Severe fatigue is almost universal with the use of biological response modifiers such as interferons and interleukins.[6,7] In cyclic chemotherapy, fatigue often peaks within a few days of the beginning of each cycle and declines until the next cycle is begun.[8–10] The etiology of chemotherapy-related fatigue, and factors that predispose patients to experience the more severe forms, are not well understood.

Strategies for managing fatigue should be based on educating patients about the nature of the fatigue and the available therapeutic options and anticipated outcomes, and on establishing a collaboration among patients, families, and medical professionals. For every patient receiving chemotherapy who is experiencing fatigue, we first assess the characteristics of the fatigue, such as its severity, patterns of onset, duration, and exacerbating and palliative factors. Next we evaluate possible contributing factors, including the underlying disease, the chemotherapeutic regimen and associated side effects of its component agents, sleep disturbances, and psychological factors such as depression. The third

step is to correct any existing pathophysiological disorders such as anemia, electrolyte imbalances, myelosuppression, or organ dysfunction and to provide treatment for sleep disorders or psychological problems. Both pharmacological and nonpharmacological interventions are used as appropriate.[11***,12]

TREATMENT OF UNDERLYING CAUSES: ANEMIA

Some evidence exists that links chemotherapy-induced anemia with both fatigue and interference with quality of life. Two large, prospective, nonrandomized, community oncology trials evaluated the effectiveness of epoetin alfa for treating the anemia associated with cancer chemotherapy.[13,14] In those studies, more than 4000 patients with cancer were given epoetin alfa 10 000 units three times weekly for a maximum of 16 weeks. If the hemoglobin level had not increased by at least 1.0 g/dL at 4 weeks, the dose was increased to 20 000 units three times weekly. Overall, patients experienced significant improvements in energy level, activity level, functional status, and quality of life. These improvements were independent of antitumor response and correlated significantly with hemoglobin levels.

PHARMACOLOGICAL INTERVENTIONS

A few randomized controlled trials have been done to test pharmacological therapies for cancer-related (if not strictly chemotherapy-related) fatigue.[15,16] Three classes of drug have been used for cancer-related fatigue: psychostimulants, antidepressants, and corticosteroids. Psychostimulants (e.g. methylphenidate, pemoline, or dextroamfetamine) or antidepressants (e.g. selective serotonin reuptake inhibitors, tricyclics [nortriptyline, desipramine], or bupropion) can sometimes induce increases in energy that seem disproportionate to changes in mood. Methylphenidate has been the most extensively evaluated of the central nervous system (CNS) stimulants and often is the first drug given for cancer-related fatigue. Regimens usually begin with 5–10 mg taken once or twice daily, with the dose increased as needed to control the fatigue. Most patients seem to require less than 60 mg per day. Adverse effects such as anorexia, insomnia, tremulousness, anxiety, or delirium have been rare. Corticosteroids such as dexamethasone or prednisone have been given in low doses to control fatigue in patients with advanced cancer, but no comparative trials have been done for chemotherapy-related fatigue. Empirical therapy with selective serotonin reuptake inhibitors may be useful for fatigue that does not respond to psychostimulants or corticosteroids, but no randomized trials have been conducted and little information is available regarding use of these drugs for patients who are not depressed.[17]

NONPHARMACOLOGICAL INTERVENTIONS

Nonpharmacological management strategies for chemotherapy-related fatigue can be useful, particularly if they are used in combination with education and counseling to patients and their families. Moderate exercise can be beneficial in relieving fatigue,[18,19] as can counseling on modifying activity and sleep patterns and stress management techniques.

Nausea, vomiting, and retching

The triad of nausea, vomiting, and retching (NVR) is both a common and a greatly feared side effect of antineoplastic chemotherapy that can significantly affect daily functioning, quality of life, and compliance with therapy.[20] The mechanism of chemotherapy-related NVR probably involves stimulation of the chemoreceptor trigger zone (CTZ) in the area postrema of the cerebral cortex, which is sensitive to emetic toxins in the cerebrospinal fluid and blood. Several chemotherapeutic agents in current use are quite emetogenic; carmustine, cisplatin, cyclophosphamide, cytarabine, mechlorethamine, melphalan, and streptozocin, for example, can induce NVR in up to 90 percent of patients.

Management strategies for NVR rely on identifying both the causative agent and the pattern of expression of symptoms. Dopamine, acetylcholine, histamine, serotonin (5-hydroxytryptamine [5-HT]), and, most recently, substance P and other neurokinins have been implicated in NVR, and receptor antagonists, particularly those to $5-HT_3$ and neurokinin-1, are being tested for their ability to reduce or eliminate chemotherapy-related NVR. Typical patterns of NVR have been classified as acute (occurring within 24 hours of treatment), delayed (occurring more than 24 hours after treatment), or anticipatory (occurring before, during, or after treatment). Anticipatory NVR is a conditioned response that can be linked to visual, gustatory, olfactory, and environmental factors. Attempts to manage chemotherapy-related NVR have included both pharmacological and nonpharmacological interventions.

PHARMACOLOGICAL INTERVENTIONS

$5-HT_3$ receptor antagonists
Use of $5-HT_3$ receptor antagonists has significantly improved the management of NVR, particularly when such agents are given in combination with dexamethasone.[21] Granisetron, ondansetron, and dolasetron are widely used in the USA for preventing chemotherapy-related NVR; these agents are effective for acute NVR, but most studies have failed to show a benefit for delayed NVR.[22***] The most common dosages are as follows:[23]

- dolasetron – 100 mg per oral (PO) or intravenously (IV), given once
- granisetron – 1–2 mg PO, given once, or 8 mg given IV once
- ondansetron – 16–24 mg PO given once or 8 mg PO every 12 hours for 2 doses.

Clinical experience indicates that the antiemetic efficacy of 5-HT$_3$ antagonists (given as single-agent therapy or in combination with dexamethasone) is not always maintained over multiple chemotherapy cycles. Moreover, failure to control delayed NVR from previous chemotherapy cycles can adversely affect antiemetic effectiveness during the acute phase of current cycles.[24] One randomized study showed that use of 5-HT$_3$ receptor antagonists before chemotherapy could reduce the incidence of post-treatment vomiting but had no effect on the duration of post-treatment vomiting or the incidence of anticipatory nausea or vomiting.[25]

Other antiemetic agents

Neurokinin receptor antagonists are being studied for the prevention of chemotherapy-related NVR owing to the possible involvement of substance P, which is secreted by the gastrointestinal tract and is a ligand for neurokinin receptors, in NVR. Neurokinin receptor antagonists, given in combination with dexamethasone, may be more effective than 5-HT$_3$ receptor antagonists for preventing delayed NVR after chemotherapy;[26] a neurokinin-1 receptor antagonist, aprepitant, was recently approved for use in combination with dexamethasone and 5-HT$_3$ receptor antagonists for this indication and is currently in phase III trials.[27] Metoclopramide, the prototype substituted benzamide (a selective dopamine antagonist), has also shown modest effectiveness in some but not all studies.

NONPHARMACOLOGICAL INTERVENTIONS

Acupuncture and acupressure may have some modest effects on chemotherapy-induced NVR.[28] Some types of behavioral modification skills may also be helpful.[29] Other possible interventions include modifying the patients' diet and environment so as to diminish visual, auditory, and olfactory stimuli that initiate nausea. Other treatments such as music therapy and progressive muscle relaxation may also be helpful in inducing relaxation and reducing anxiety.

Gastrointestinal effects: diarrhea and constipation

Both cancer and chemotherapy can affect bowel function and lead to diarrhea or constipation. Chemotherapeutic agents that often cause bowel hyperreactivity and diarrhea include capecitabine, cytarabine, dactinomycin, 5-azacytidine, fluorouracil, hydroxyurea, irinotecan, methotrexate, mitotane, raltitrexed, and topotecan. Chemotherapy-related diarrhea is managed pharmacologically with loperamide with a 4 mg starting dose, to be followed by 2 mg after each episode, for 12 mg or more per day.[30] Persistent diarrhea requires interventions to minimize the further complications of dehydration, electrolyte imbalance, weakness, decreased caloric intake, and weight loss. Octreotide has been successful in treating chemotherapy-related diarrhea that is refractory to other forms of therapy. Recommendations for supportive care include eating a low-residue diet of high protein

and caloric content; avoiding consumption of irritating or stimulating foods and beverages; consuming foods and liquids that are high in potassium (e.g. asparagus, bananas, Gatorade); drinking at least 3 L of noncarbonated fluid each day; eating small and frequent meals; and resuming consumption of milk products slowly after the symptoms subside.[31]

Constipation, in contrast, is associated mainly with the vinca alkaloids, and the clinical emphasis is on prevention rather than treatment. Dietary changes and use of bulk laxatives are usually insufficient, and a prophylactic bowel program is recommended.[31] Senna compounds, anthraquinone cathartics that stimulate longitudinal peristalsis in the colon, have been consistently shown to prevent or reverse opioid-induced constipation. If use of such compounds does not result in bowel movements, more aggressive therapy is indicated with rectal suppositories or osmotic laxatives with saline, sorbitol, or lactulose.

Stomatitis

Oral mucositis is another common complication of cancer chemotherapy, occurring in approximately 40 percent of patients receiving standard-dose chemotherapy. The severity varies, but severe (grade 3–4) oral or gastrointestinal mucositis increases the risk of bleeding, susceptibility to infection, and the need for hospitalization. The agents most commonly associated with mucositis are dactinomycin, daunorubicin, docetaxel, paclitaxel, doxorubicin, fluorouracil, methotrexate, raltitrexed, and high-dose busulfan, etoposide, melphalan, and thiotepa.

Principles for managing oral mucositis are to maintain the integrity of the oral mucosa, prevent secondary infection, provide pain relief, and allow adequate dietary intake to be maintained. Preventive oral care should begin in tandem with the chemotherapy so as to prevent or minimize oral complications.[32] Patients with evidence of mucositis can benefit from oral oxygen therapy, delivered every 2 hours or every hour if mucositis is severe; oral infections can be treated with topical antifungal or antiviral agents. Serious oral ulcerations can be treated with topical or systemic analgesics and topical protective agents.[33]

Anorexia

Chemotherapeutic agents can directly or indirectly lead to loss of appetite and anorexia through the induction of nausea and vomiting, stomatitis, diarrhea, or constipation.[34] Pharmacological management strategies for anorexia include the use of megestrol acetate and steroids. Megestrol acetate (given in suspension in doses of 480–840 mg/day) has led to significant improvements in appetite.[35] Steroids can also be helpful in treating anorexia. Nonpharmacological treatment strategies are to assess nutritional intake and physiological nutritional status, consider patients' likes and dislikes regarding food and fluids, encourage consumption

of small, frequent meals consisting of foods that the patients enjoy, use of nutritional supplements that are high in protein and calories, and control of symptoms, particularly nausea and vomiting.

Cutaneous reactions

Cancer chemotherapy can also lead to skin changes such as dermatitis, nail changes, hyperpigmentation, urticaria, acral erythema, and photosensitivity reactions. Most cutaneous reactions are self-limited, lasting only as long as the chemotherapy. Rashes and erythema can occur with a variety of chemotherapy drugs, including carboplatin, aminoglutethimide, carmustine, cytarabine, daunorubicin, methotrexate, and trimetrexate, among others. Palmar–plantar erythrodysesthesia, characterized by demarcated, tender erythematous plaques on the palms and soles of the feet, can range from mild to extremely painful; this syndrome is associated with use of cyclophosphamide, cytarabine, docetaxel, doxorubicin, liposomal doxorubicin, capecitabine, etoposide, fluorouracil, hydroxyurea, lomustine, mercaptopurine, methotrexate, mitotane, and paclitaxel. Management is focused on prevention and on pain relief with systemic and local therapies as needed. Extravasation of chemotherapeutic agents from vessels into the interstitium and surrounding tissue can produce local skin burning, erythema, pain, edema, induration, ulceration, and necrosis; symptoms can occur immediately or not appear for days or weeks after the chemotherapy. Extravasation of some agents, e.g. dactinomycin, daunorubicin, doxorubicin, epirubicin, idarubicin, and mitomycin, can cause long-term skin injury, whereas others such as carmustine, cisplatin, etoposide, fluorouracil, mechlorethamine, plicamycin, vinblastine, vincristine, and vinorelbine tend to cause short-lasting skin injury. Extravasation of vinca alkaloids (vinblastine, vincristine, vindesine) should be treated with hyaluronidase and local heat; extravasation or skin irritation from any of the other agents should be treated with 15–20-minute applications of ice at least four times a day during the 24–48 hours of chemotherapy.

Cardiopulmonary toxicity

The severity of pulmonary toxicity from chemotherapy varies widely, ranging from mild asymptomatic episodes to life-threatening respiratory insufficiency. The predominant clinical patterns range from interstitial pneumonitis with pulmonary fibrosis to acute hypersensitivity, noncardiogenic pulmonary edema, or acute pulmonary syndromes.[36] Common symptoms include tachypnea, dyspnea, cough, chills, and myalgia. Drugs with pulmonary toxicity include bleomycin, carmustine, mitomycin C, cyclophosphamide and other alkylating agents, vinca alkaloids, doxorubicin, methotrexate, procarbazine, cytarabine, gemcitabine, retinoic acid, and some biological agents (e.g. interleukin-2).

Acute pulmonary toxicity, which often manifests as acute shortness of breath, can result from the combination of mitomycin C and a vinca alkaloid. Onset can occur within 2 hours of receiving a vinca alkaloid with or without concomitant administration of mitomycin C. Symptoms include severe tachypnea and dyspnea, possibly with wheezing, rales, and rhonchi. Chest X-rays may show bilateral infiltrates and pleural effusions. Patients being given this combination of drugs should be monitored for the appearance of pulmonary symptoms during the first 2 hours of treatment. If symptoms appear, the chemotherapeutic agents should be discontinued immediately and supportive measures such as oxygen, bronchodilators, or corticosteroids provided. Chest-X ray, blood gases, and electrocardiogram should be obtained and psychological counseling provided if necessary. Cytarabine, cyclophosphamide, methotrexate, mitomycin are also associated with pulmonary toxicity, although this reaction is less common.[37] Docetaxel can produce fluid retention, which can result in pulmonary edema, or pleural effusion.

Cardiomyopathy is the most common form of chemotherapy-associated cardiac toxicity. Other less common cardiac reactions include myocardial ischemia, pericarditis, arrhythmias, miscellaneous electrocardiographic changes, and angina. Doxorubicin and other anthracyclines are the most likely to cause cardiomyopathy, which is both cumulative and dose related. Other chemotherapeutic agents that can lead to cardiomyopathy include cyclophosphamide, ifosfamide, fluorouracil, paclitaxel, etoposide, amsacrine, vinca alkaloids, and some biological agents (interferon alfa or gamma, interleukin-2). Doxorubicin produces intracellular free radicals that can damage the myocardial membrane. Given its cumulative toxicity, the probability of developing congestive heart failure after doxorubicin increases from about 3 percent at 400 mg/m^2 to 18 percent at 700 mg/m^2.[38] Patients with severely reduced left ventricular ejection fraction (i.e. less than 30 percent) should not be treated with anthracyclines; further, anthracyclines should be discontinued in any patient whose left ventricular ejection fraction declines by 10–15 percent during the course of treatment.[36] Management of anthracycline cardiotoxicity is based on prevention and early detection. Cardiac function should be assessed before treatment is begun and monitored during and after therapy by multigated acquisition (MUGA) scanning or echocardiography. Long-term follow-up monitoring is also recommended. Management of chemotherapy-induced cardiac dysfunction is the same as conventional therapy for heart failure.

Bladder toxicity

Contact with acrolein, the major metabolic byproduct of cyclophosphamide and ifosfamide, can cause mucosal erythema, inflammation, ulceration, necrosis, and diffuse small-vessel hemorrhagic oozing, particularly in the bladder mucosa. Standard doses of cyclophosphamide, especially

those given orally, produce bladder toxicity in less than 10 percent of cases. High-dose cyclophosphamide, on the other hand, puts patients at high risk of developing hemorrhagic cystitis,[39] the symptoms of which are hematuria and dysuria. Pharmacological treatment is with mesna, which binds acrolein and reduces its toxic effects on the bladder mucosa, as well as discontinuation of chemotherapy and hydration. Fulguration (cautery) may be necessary to stop the bleeding in some cases.

Neuropathy

Neurotoxicity is most commonly associated with vinca alkaloids, paclitaxel, cisplatin, and high-dose cyclophosphamide.[40] Central nervous system neurotoxicity can manifest as encephalopathy, seizures, cerebellar dysfunctions, ophthalmological or ototoxicity, and mental status changes; peripheral manifestations can include peripheral neuropathies with sensory or motor dysfunctions. The only effective therapy is discontinuation of the causative chemotherapy agent.

PALLIATIVE CHEMOTHERAPY

Despite its own side effects, chemotherapy can be effective in palliative as well as curative treatment, depending on the type and stage of malignancy. Palliative chemotherapy is, by definition, not intended to cure, but increasing evidence suggests that it can reduce morbidity related to the malignancy, particularly that of metastatic disease that involves or impinges on vital organs. Tumor shrinkage induced by palliative chemotherapy has shown some benefit in terms of reducing pain, dyspnea, coughing, metabolic abnormalities, and bleeding in the bowel and genital tract. These and other symptoms can be controlled to some extent by reducing tumor involving the bronchial tract or bowel, by stabilizing hypercalcemia, and by relieving pressure on vital organs. The mechanisms by which chemotherapeutic agents relieve pain are not well understood, but cytotoxic drugs that alter peripheral nerve function and can cross the blood–brain barrier could affect neurotransmitter function in both the central and peripheral and central nervous systems, which could influence pain and other symptoms independent of their effect on the tumor.

Key to the success of palliative chemotherapy for patients with advanced disease is that everyone – the patient, the family, and the physician – understand the purpose of the treatment in terms of the kinds of response that can be expected, particularly with regard to survival. In one study of patients with metastatic colon or lung cancer, those who believed that they had a significant chance of dying within 6 months were less likely to choose a possibly life-extending therapy over comfort care; specifically, if the likelihood of 6-month survival was stated to be 90 percent, 75 percent, 25 percent, or 10 percent, the corresponding proportions

of patients who would choose life-extending therapy were 51 percent, 29 percent, 31 percent, and 21 percent. Finally, patients in that study tended to overestimate their chances of surviving for 6 months relative to the estimates of their physicians.[41]

The possibility of palliative chemotherapy benefit varies among cancer types based on relative sensitivities to systemic chemotherapy. Tumors with low, moderate, and high sensitivity are listed in Table 92.1. For patients in group I, who are even in late stage, the opportunity of palliative chemotherapy should not be missed. Tumors in group II are not curable by chemotherapy once disease has disseminated. Some patients with small cell lung cancer (SCLC) and ovarian cancer might get the benefit of prolongation of comfortable life and increased quality of life. So systemic chemotherapy should be considered in this group of patients, which is dependent on patient preference and physical condition. Patients in group III have disseminated disease and tumor insensitive to chemotherapy. Palliative care is a difficult objective. Careful clinical decision making is necessary. However, in one randomized trial of chemotherapy in patients with advanced nonsmall cell lung cancer (NSCLC), the patients not only had an increased chance of prolonged survival (albeit only for a few months) but also required less hospital care and palliative radiotherapy.[42] Indeed, another similar study showed modest benefit in NSCLC.[43] Patients with group III tumors who have a good performance status should be given the opportunity to participate in clinical trials.

Another key question concerns when to consider starting palliative chemotherapy and how long that therapy should last. When curative therapy is not possible, as is the case for most metastatic malignancies, then multiple factors must be weighed in this decision. If the goal of palliative chemotherapy is to relieve or prevent tumor-induced symptoms, then it should be considered when patients are either experiencing symptoms or expected to develop symptoms shortly. Decisions in the latter case, when patients may have low-volume disease in nonvital organs or areas, can be quite difficult. The possible benefit in terms of tumor response must be weighed carefully against the toxicity of the chemotherapy. In some cases, close monitoring could allow treatment to be withheld until symptomatic progression becomes evident or imminent. For some chemosensitive tumors, chemotherapy could be the sole treatment modality for relieving symptoms, even in oncological emergencies such as superior vena cava syndrome, epidural spinal cord compression, or airway obstruction. On the other hand, chemoresistant tumors may be more appropriately managed by local treatment such as radiotherapy or surgery.[44] Stable disease can be very hard to manage; slow-growing tumors that are resistant to chemotherapy may not demonstrate apparent growth until after many months of treatment. It can be difficult to determine whether tumors are merely slow-growing or whether they are responding to the chemotherapy. If the treatment is not associated with significant side effects, it would be

Table 92.1   *Response of advanced or disseminated cancers to systemic chemotherapy*

Group I	Group II	Group III
Highly sensitive – systemic therapy must be considered	Sensitive – systemic therapy	Low sensitivity – poor response
Germ cell tumors	Prostate cancer	Esophageal cancer
Testicle	Breast cancer	Nonsmall cell lung cancer
Choriocarcinoma	Small cell lung cancer	Melanoma
Acute lymphocytic leukemia	Chronic myelogenous leukemia	Renal cell cancer
Acute myelogenous leukemia	Ovarian cancer	Pancreatic cancer
Pediatric tumors	Bladder cancer	Hepatocellular cancer
Ewing sarcoma	Endometrial cancer	
Wilm tumor	Neuroendocrine cancer	
Rhabdomyosarcoma	Kaposi sarcoma	
Lymphomas	Multiple myeloma	
Hodgkin disease	Neuroblastoma	
Non–Hodgkin lymphoma	Gastric carcinoma	
	Cervical carcinoma	
	Head and neck cancer	
	Colorectal cancer	

reasonable to discuss with the patient the possibility of discontinuing treatment until the tumor shows some progression and then resuming treatment at that time. The experience with use of palliative chemotherapy for various types of advanced disease is described briefly below.

Lung cancer

Nonsmall cell lung cancer is a cruel disease for which few treatments are effective in terms of cure and quality of life becomes quite poor as the disease progresses. Four prospective randomized trials have been conducted that compared single-agent palliative chemotherapy (with vinorelbine, gemcitabine, docetaxel, or paclitaxel) with supportive care for patients with previously treated or untreated NSCLC.[45**,46**,47**,48**] In these studies, vinorelbine or gemcitabine led to substantial improvements in quality of life and reductions in disease-related symptoms relative to supportive care. Treatment with paclitaxel or docetaxel not only led to improved quality of life but also extended overall survival time and time to disease progression. Other drugs may also be effective in palliating symptoms of NSCLC; irinotecan can reduce symptoms and prolong survival, and gefitinib (Iressa®), an epidermal growth factor receptor tyrosine kinase inhibitor, was shown in a phase I study to extend the disease-free interval and survival time as well as improving quality of life in patients with NSCLC.[49*]

Breast cancer

Palliative chemotherapy can lead to remarkable improvement in symptoms for some, but not all, women with metastatic breast cancer. Agents like docetaxel, epirubicin, capecitabine, and trastuzumab (Herceptin®) can be used for metastatic breast cancer as well as for earlier-stage disease. Perhaps not surprisingly, patients with metastatic breast cancer who responded to palliative chemotherapy are more likely to conclude that the treatment was worthwhile regardless of its toxicity. The introduction of taxanes has greatly influenced the treatment approach for breast cancer that recurs or progresses after anthracycline chemotherapy. Docetaxel in particular has been shown to extend the time to progression and overall survival time, and to alleviate malignancy-related symptoms, with improvements in quality of life comparable with those from vinblastine plus mitomycin[50**] or vinorelbine.[51**] Several approaches to palliative chemotherapy are currently being tested. In one study, the response rate and survival time were significantly higher, and pain control, mobility, and anxiety improved more, in a group given high-dose chemotherapy than in a group given lower-dose chemotherapy, despite the greater toxicity of the higher-dose regimen.[52] Other approaches involve comparing the use of single agents in sequence versus in combinations. One study showed that patients given single-agent epirubicin followed by single-agent mitomycin had similar survival time but less treatment-related toxicity and better quality of life than did patients given cyclophosphamide plus epirubicin plus cyclophosphamide followed by mitomycin plus vinblastine sulfate.[53**] Another approach, intermittent therapy, seeks to minimize treatment toxicity by discontinuing treatment after remission is achieved and beginning again when disease reappears; however, some authors have found intermittent therapy to be associated with poor physical wellbeing, mood, appetite, and quality of life.

Table 92.2 *Common paraneoplastic syndromes and associated cancers*

Paraneoplastic syndrome	Cancer type
Hypercalcemia	All types of lung cancer; breast cancer; multiple myeloma
Syndrome of inappropriate antidiuresis	Small cell lung cancer; carcinoid tumors; cancer of esophagus, pancreas, duodenum, colon, adrenal cortex, and prostate; thymomas; lymphomas
Cushing syndrome (adrenocorticotropic hormone, corticotropic hormone)	Primary adrenal tumors, pituitary adenoma, and all types of lung cancer
Hypocalcemia	Osteoblastic metastases of breast, prostate, and lung
Hypophosphatemia	Mesenchymal tumors
Hyperthyroidism	Gestational trophoblastic disease; testicular tumors
Acromegaly	Pancreatic islet cell tumors; bronchial carcinoids
Calcitoninemia	Medullary thyroid carcinoma; small cell lung cancer; carcinoid; breast cancer; colon cancer; gastric cancer
Extrapancreatic hypoglycemia	Fibrosarcomas; mesotheliomas; hepatomas; adrenal cortical carcinoma; gastrointestinal adenocarcinomas

Prostate cancer

Metastatic prostate cancer embodies some of the classic difficulties in clinical decision making regarding when (or whether) to institute palliative treatment and balancing the toxicity of treatments with the potential benefits. Metastatic prostate cancer usually occurs in older men, many of whom have other medical problems or are in otherwise poor physical condition. Some evidence exists to suggest that changes in serum prostate-specific antigen level may reflect the tumor's response to chemotherapy; in some studies, reductions of more than 50 percent correlated with improved survival and control of symptoms, but smaller declines have not been associated with clinically meaningful results. Some well-designed phase III studies have shown that palliative chemotherapy can be beneficial in hormone-refractory prostate cancer. Glucocorticoids can also be effective in some cases; in one study, mitoxantrone given with hydrocortisone or prednisone yielded modest improvements in quality of life compared with glucocorticoids alone.

Ovarian cancer

Ovarian cancer has become the fourth most common cancer in developed countries, and in most cases disease is advanced at diagnosis. During the past 20 years, use of platinum-based and taxane-based chemotherapy regimens have led to improved overall 5-year survival rates and longer disease-free intervals for women with advanced ovarian cancer. Chemotherapy can be useful for reducing the common symptoms of bloating or abdominal fullness, particularly in cases when surgery is contraindicated. In one study, palliative carboplatin was more effective in improving quality of life and relieving tumor-related symptoms than was cisplatin for patients with relapsed ovarian cancer.[54] In

endometrioid ovarian cancer, oral megestrol acetate has shown definite activity in patients with platinum-refractory disease, with only minimal toxicity and fair quality of life during treatment.[55] Deciding when to provide palliative chemotherapy versus a second challenge with platinum compounds, whether to use single agents or combinations of agents, and whether to use concomitant versus sequential therapy is particularly difficult in relapsed ovarian cancer. In one study conducted at an outpatient clinic, patients with ovarian cancer (as opposed to other types of gynecological cancer) for whom therapy was prolonged and who had little education and little social support showed the most significant impairments in quality of life and needed the most additional support and resources.[56]

Paraneoplastic syndromes

Under various conditions, patients with advanced malignancy could present diverse endocrine and metabolic disorders. Primary cancerous and metastatic sites initiate pathological effects through the excess or lack production of hormones, cytokines, and growth factors, the so called 'paraneoplastic syndromes'. Table 92.2 lists the most frequent paraneoplastic syndromes and associated cancer types.

Hypercalcemia is the most frequent metabolic disorder, and it is estimated that as many as 8–10 percent of patients with malignancy will present this disorder during their disease course. Two mechanisms contribute to the development of hypercalcemia in most patients with malignancy: osteolytic hypercalcemia (tumor invasion of bone tissues releases large amounts of calcium from destroyed areas of bone) and humoral hypercalcemia. Parathyroid hormone-related protein (PTHrP), tumor necrosis factor α, interleukin (IL)-1, prostaglandin E, and IL-6, which are produced by tumor tissue, may increase the level of calcium, in particular

PTHrP may mimic the role of parathyroid hormone in calcium metabolism.[57**,58] Renal tubular reabsorption of filtered calcium is increased in addition to the increased generalized osteoclastic activity throughout the skeleton. Although the diagnosis of hypercalcemia is not very difficult, it is often delayed. The symptoms of hypercalcemia are often vague and nonspecific. Furthermore, there is poor correlation between calcium level and degree of symptomatology. The most common symptoms include nausea, anorexia, vomiting, constipation, cramping abdominal pain, and bone pain, which are frequently thought of as symptoms of advanced malignancy and overlooked. Patients with symptomatic hypercalcemia should be managed in an emergent manner. Most patients are severely dehydrated, so immediate fluid resuscitation is indicted. Bisphosphonates are the most frequently used antiresorptive agents. These interfere with osteoclast function and inhibit calcium release from bone. If hypercalcemia does not respond adequately to the above approaches, loop diuretics can be administered for severe hypercalcemia that fails to respond. Calcitonin (6–8 IU/kg every 6–12 hours subcutaneously or intramuscularly) should be added to the regimen (see also Chapter 84). The role of palliative chemotherapy in controlling hypercalcemia is not well understood because no such clinical trials have been performed as yet. Chemotherapy could be directed at removal of the source of the hypercalcemia.

Syndrome of inappropriate antidiuretic hormone secretion (SIADH) is most commonly associated with SCLC. The abnormal production of ADH or ADH-like substances by cancer cells may result in an increase in intravascular volume, enhancing renal perfusion and decreasing proximal tubular resorption of sodium. The treatment of the underlying cancer is the most effective management of ectopic serious SIADH. Administration of systemic chemotherapy is associated with an improvement in this syndrome within 6 weeks of treatment in 80 percent of patients with SCLC.[59] Supportive management also may be undertaken while awaiting a response to the treatment of the underlying cancer.

Cancer associated with Cushing syndrome could be classified into endogenous and ectopic Cushing syndrome. The former includes excessive production of glucocorticoid by a primary adrenal neoplasm and overproduction of adrenocorticotropic hormone (ACTH) by a pituitary adenoma. Ectopic Cushing syndrome implies increased production of ACTH or corticotropic hormone (CRH) is from the tumor. There are subtle clinical differences between the two types of Cushing syndrome. The treatment of the underlying malignancy is the primary management of paraneoplastic Cushing syndrome. Symptom control in hypercortisolism can be accomplished with the use of steroid synthesis inhibitors, such as ketoconazole, mitotane, metyrapone, and aminoglutethimide.

Increasing knowledge of the pathology of cancer and the body's response to disease will improve our understanding of the mechanisms underlying paraneoplastic syndromes. Overall, the principal aim of management is to treat the underlying cancer disease and control the symptoms associated with metabolic disorders.

SUMMARY

Use of chemotherapy, whether for curative or palliative purposes, requires balancing the likelihood of the intended effect with the adverse effects of the treatment. By controlling the symptoms associated with toxicity, one can ensure that patients are able to complete the treatment – whether curative or palliative – as planned. Used effectively, palliative chemotherapy can control tumor-related symptoms and sustain good physiological and psychological functions; its ultimate objective is to maintain patients' quality of life at the highest possible level. Certainly in the past attention was focused solely on curing the disease, with the 'objective' endpoints of clinical (and pathologic) tumor response, the length of the progression-free interval, and overall survival – none of which take into account the importance of the patient's quality of life during and after the treatment process. As one author in 1996 put it, 'Palliative care is a vast wasteland in American medicine, and nowhere is it less well understood or more neglected than in the academic health science center'.[60] Thankfully, things have changed since then. Palliative care is coming to be understood as an important part of the entire range of traditional cancer management – surgery, chemotherapy, radiotherapy, or biotherapy – and palliation of symptoms has a role in therapy intended to be curative as well. Nowadays the term 'palliative chemotherapy' is no longer considered a contradiction in terms. Overall, oncologists should not overlook the possibility of palliative chemotherapy; more clinical trials should be designed with the endpoint of relieving symptoms rather than curing disease. Such trials represent substantial challenges for appropriate design and conduct, but they will ultimately allow clinicians to provide better care for patients with cancer.

> ## Key learning points
>
> - Control of chemotherapy-related symptoms is a vital aspect of cancer treatment.
> - Chemotherapy-related toxicity affects almost all the systems in the human body.
> - The goal of palliative chemotherapy is to relieve or prevent tumor-induced symptoms.
> - The relative sensitivities to systemic chemotherapy determine the possibility of palliative chemotherapy.
> - What is the most appropriate chemotherapeutic regimen for different types of cancer is not known.

Physical medicine and rehabilitation

BENEDICT KONZEN, KI SHIN

INTRODUCTION

Some may mistakenly think that the fields of palliative medicine and rehabilitation medicine have divergent goals. Yet, both fields have a common focus in the relief of suffering and the improvement of quality of life. They differ in their historical roots. Palliative medicine grew out of observations made in the care of dying patients in hospice programs. It later grew to include other serious and life-threatening illnesses of uncertain prognosis. Rehabilitation medicine had its roots in restoration of impaired physical and cognitive functioning – 'fixed deficits' often incurred as a result of trauma. As a field it later grew to include patient with progressive acute on chronic deficits, for example, patients with cancer.

The assertion has been made that rehabilitating patients with cancer or other diseases with terminal prognoses is a poor allocation of scarce medical resources. However, when economic and psychological costs are included in the equation, the argument for such treatment is strengthened. In addition to the economic argument, both moral and spiritual arguments can also be made. Every human being values the ability to make decisions; to participate actively in their home; and to have value in the eyes of their peers, family and community. These needs may become more urgent for the patient with cancer or other serious illness. Rehabilitation medicine and palliative medicine share the goals of permitting a patient the opportunity to reflect on an ongoing life; understand the implication of their disease process as it impacts themselves, their caregiver, family, and friends; and move forward both physically and mentally. Despite illness, the physiatrist's goal is to promote physical functioning; where this is impeded, the physiatrist works with caregiver and family as adjuvant supports. The palliative medicine physician, primarily, and in association the physiatrist, both attempt to reduce the pain, asthenia, fatigue, and symptoms

related to ongoing medical treatment, the final goal being living completely and fully – whether that be in a physical, cognitive, or spiritual sense. In this chapter, we will explore the role that rehabilitation medicine plays in the overall care of the palliative medicine patient.

The fields of both physical medicine and palliative care medicine arose out of specific medical care needs. Physical medicine was not formally recognized as a medical specialty until 1950. However, the historical record is long in its documentation of administering physiatric care to patients with mechanical or neurological trauma – often the result of accident or wars. The tenets of physical medicine foster the belief that despite injury, attempts at reestablishing premorbid functioning are not only desirable, but hopefully, obtainable. Palliative medicine seeks to advance all forms of medical care by treating the acute and chronic symptoms of disease. In addition, the field not only focuses on the individual, but advances the notion that care requires the additional interaction of spouse, family, acquaintances, and healthcare professionals. Both fields require a host of healthcare professionals – physicians, physician assistants, advance practice nurses, floor nursing, psychologists, and psychology nurses. Equally important are the roles played by case managers, social workers, and chaplains. The healthcare team does not exist independently. There continues to be a daily interchange between these team members. Indeed, team members must be strongly linked in purpose, but flexible enough to understand an individual's idiosyncrasies. Cultural diversity, religious belief, language, and perceptions of health, values, success, and disappointment are all unique characteristics in the patient being cared for. The field of physical medicine attempts to restore a prior level of functioning. The physiatrist is aware that family interaction is critical. Neurological injury such as a traumatic brain injury, stroke or tumor may leave a previously

accomplished, mentally adept individual dependent on others. The prior relationship of husband/wife or significant others may be inextricably altered into patient/caregiver roles.

A united team approach of health professionals establishes a support network for ongoing medical care, teaching, and training. Whether in the outpatient clinic setting or on the acute inpatient unit, both rehabilitation and palliative medicine teach patients and their families anticipated and future care needs. As a supervised team, patients and their families can practice new tasks, and troubleshoot and modify unsafe behaviors. In addition, a close-knit team network can promote diversity of ideas as well as solutions. Both fields have a role to play throughout a person's disease state and life. Activity without symptoms of pain, nausea, fatigue, or discomfort will only enhance function. Activities with family and friends help to dissipate isolation and depression. Despite the timeline of a patient's disease, the palliative medicine physician's role remains interactive. Symptom management has both physical and spiritual components. Not only are nausea, fatigue, depression, anxiety, pain, constipation, asthenia addressed; but attempts are also made to assist the patient in coming to terms with both resolved and unresolved issues – including the fear of dying, abandonment, unfulfilled dreams/expectations, and disputes. In essence, both physical medicine and palliative medicine take an integrative look at the components which define us as human: physical, mental, social, and spiritual. When disease intervenes, these two fields attempt to restore a homeostatic balance, with an eventual goal of finding peace after, hopefully, a prosperous life lived.

CANCER FROM THE REHABILITATIONIST'S PERSPECTIVE

In traditional rehabilitation, causes of disability such as stroke, amputation, brain/spinal cord injury often have a defined deficit. Patients undergo acute treatment. A return to community functioning is often anticipated. In cancer care, initial and ongoing medical treatment is not necessarily curative. The rehabilitationist addresses deficits that may be progressive over time. Traditionally, in rehabilitation medicine, therapies continue until maximal functional improvement has been obtained. However in a chronic, potentially relapsing disease state such as cancer, the therapist deals with a patient who may have had recent surgery, chemotherapy, and radiation. There may be ongoing functional loss. Despite such losses, it has been shown repeatedly that patients with cancer – even during treatment – benefit from rehabilitation.[1]

Cancer rehabilitation initially arose through the work of three physiatrists, Herbert Dietz, Harold Rusk, and AE Gunn.[2] Financial support was provided by the National Cancer Institute (NCI). Modest gains continued through the 1980s until the focus of the NCI shifted from patient rehabilitation to the cure of cancer.[2] DeLisa[3] further comments on three additional factors limiting the role of cancer rehabilitation:

- oncologist not being aware of the potential benefits of rehabilitation
- failure of physiatry residency programs to incorporate cancer rehabilitation into the curriculum
- trend toward moving rehabilitation from an inpatient service to an outpatient arena.

One of the earliest cancer rehabilitationists was Dietz.[4] In 1969, he proposed four goals for the cancer rehabilitationist:

1 Prevent disability whenever possible.
2 Where disability occurs, attempt to restore the individual to the premorbid state of functioning.
3 Institute supports in order to reduce future disability.
4 Palliate to reduce complications, maintain independence and provide comfort.

Dietz felt that the effects of cancer were wide-reaching, affecting the socioeconomic, vocational, and emotional aspects of an individual's life. Therefore a team approach initially involving physiatrist, therapists, nursing, and social work was recommended. This has since broadened in scope to also include chaplaincy, case management, speech pathology, pharmacy, medical oncology, surgery, and radiation therapy.[4]

In his initial study, Dietz interviewed 1019 patients with cancer. He devised a scale ranging from 0 to 4 with which to rate the benefit of physical therapy on patients receiving treatment; 0 represented no clinical benefit and 4 represented individuals who were fully independent with no ongoing disability. Of patients being discharged from inpatient rehabilitation, the largest percentage was rated at a 2, i.e. moderate improvement with an appropriate response to rehabilitative care (Table 93.1).[4] Dietz maintained that rehabilitation care was essential for patients with incurable and terminal disease. Since the overall goal was the maintenance of function and overall range of motion, therapies should be instituted immediately.[4]

A specific study lends further credence to the role of rehabilitation in cancer care. In 1991, O'Toole and Goden investigated functioning in 70 patients with cancer. Of these, 14 percent were ambulatory at the time of admission to inpatient rehabilitation. At discharge, 80 percent could ambulate independently. Urinary continence likewise improved from 38 percent to 87 percent. However, 3 months

Table 93.1 *Response to inpatient rehabilitation and functional improvement (N = 1019)*

Level achieved	No.
0 (no improvement)	211
1 (slight improvement)	110
2 (moderate improvement)	320
3 (marked improvement)	270
4 (fully independent)	108

Source: Dietz (1969).[4]

after discharge, 33 percent had either died or were lost to follow-up. Of the remaining 37 patients, 27 had maintained or improved functioning.[5] Of significance in this investigation, was O'Toole and Goden's correlation between the Karnofsky performance scale – a measure of functional performance used by oncologists (Box 93.1) – and the Functional Independence Measure (FIM) score – a measure of functioning used by rehabilitationists. The conclusion was that patients with scores as low as 30 (severely disabled, inpatient hospital stay indicated, death not imminent) still were candidates for rehabilitation services.[5]

Box 93.1 Karnofsky scale

- 100 – Normal. No complaints; no evidence of disease; able to work

- 90 – Able to carry on normal activity. Minor symptoms; able to work

- 80 – Normal activity with effort. Some symptoms; able to work

- 70 – Cares for self. Unable to carry on normal activity; independent; not able to work

- 60 – Disabled; dependent. Requires occasional assistance; cares for most needs

- 50 – Moderately disabled; dependent. Requires considerable assistance and frequent care.

- 40 – Severely disabled; dependent. Requires special care and assistance

- 30 – Severely disabled. Hospitalized, death not imminent

- 20 – Very sick. Active supportive treatment needed

- 10 – Moribund. Fatal processes are rapidly progressing.

FUNCTIONAL AREAS ASSESSED

Functional areas assessed by the FIM(Table 93.2) are eating, grooming, bathing, upper and lower body dressing; toileting; bladder and bowel management; transfers; and locomotion. The FIM scores also assess comprehension, expression, social interaction, problem solving and memory.

Marciniak et al. from the Rehabilitation Institute of Chicago reviewed 159 patients over a 2-year period and looked at motor function. They found that metastatic disease did not affect functional outcome. Furthermore, radiation therapy was associated with greater functional improvement than when it was not provided or completed before starting rehabilitation.[8] According to Sliwa and Marciniak[1] the most common cause of functional decline in patients with cancer is deconditioning. Prolonged bed rest along with chemotherapy and/or radiation can lead to significant functional limitations. The degree of impairment is based on the duration and degree of immobilization. In general, healthy individuals on complete bed rest exhibit a 1–1.5 percent loss in strength per day or 10 percent per week.[9] Loss of proximal lower extremity strength is often greater than that seen in the upper extremities. This impedes sitting, standing, and ambulation.[10] Urinary calcium excretion increases. Diaphragmatic and intercostal muscle activity is reduced. Maximal oxygen consumption decreases by as much as 15 percent when healthy individuals resume exercise in an upright position after 10 days of bed rest.[11] Indeed, it may take up to one month to reestablish the normal postural response.[11] Healthy young men lose 300–500 mL of plasma volume within the first week of bed rest.[12] As plasma volume declines, blood viscosity increases leading to the risk of deep venous thrombosis.[1] In addition, there may be a hypotensive response. Both stroke volume and cardiac output decline.[12] From a neurological perspective, balance and coordination decline.[13] There may even be sensory deprivation.[14] Effective bladder evacuation is inhibited by recumbency. Inactivity results in impaired colonic function and possibly constipation with anorexia.[1] Lastly, hospitalized patients are at high risk (7.7 percent) of developing a pressure ulcer as sustained pressure over bony prominences results in ischemic injury.[15]

Table 93.2   *Functional Independence Measure (FIM)*

Score range	Interpretation	Patient's effort	In everyday parlance
1	Total assistance	Less than 25%	Completely dependent
2	Maximal assistance	25–49%	Completely dependent
3	Moderate assistance	50–74%	Needs hands-on help
4	Minimal contact assist	75%+	Needs minimal hands-on
5	Supervision/set-up	75%+	Needs cues; can do task
6	Modified independent	100%	Completes task without cues but needs assistive device, independent
7	Totally independent	100%	No helper needed, task done safely without device

From: www.medfriendly.com/functionalindependencemeasure.html[7]

Neurological impairment in patients with cancer may be an increasing cause of disability. There may be both central and peripheral nerve involvement either by tumor, metastatic disease, side effect of therapy (chemotherapy/radiation) or by concurrent, related issues such as paraneoplastic syndromes, infection or vasculitis.[1] Intracranial metastases are found in approximately 25 percent of patients who die from cancer. The origins of these metastases are frequently from lung, breast, and skin.[16,17] In a study of 363 cancer patients with brain metastases, 59 percent presented with hemiparesis.[18,19] Two recent studies have investigated neurooncological patients who had completed inpatient rehabilitation. Huang *et al.*[20] noted that there was concordance in functional return and rate of discharge to the community between the brain tumor patients and stroke patients. Indeed, length of stay was shorter for the former. In a second study, O'Dell *et al.*[21] compared patients with brain tumors and traumatic injuries. With comparable age, gender, and functional admission status, both groups made similar daily functional gains and 82.5 percent of patients with brain tumors were discharged home. On evaluation of functional status after inpatient rehabilitation, Sherer *et al.*[22] found that with a mean treatment time of 2.6 months, patients maintained these gains at a mean follow-up time of 8 months.

Of great concern to the rehabilitationist is metastatic disease of the spine. Although direct spinal cord involvement by metastatic tumor is rare, most spinal cord damage is the result of epidural compression by the tumor itself or vertebral body metastases resulting in bony compression. In only a small percentage of vertebral metastatic lesions will symptoms of compression be noted.[1] Many individuals are either asymptomatic or simply present with pain. However, in a study of 211 cancer patients,[23] 74 percent of individuals with metastatic cord compression were noted to have significant weakness at presentation. Close monitoring of functional status is essential. Involvement of the cervical spine may lead to plegia. Thoracolumbar involvement may lead to paraplegia and a neurogenic bowel/bladder. Typically, in the non-cancer patient this level of injury would still allow an individual to functional independently at the wheelchair level. In the case of the oncology patient, however, the activity of the tumor, interrelated surgery/chemotherapy or radiation – and ensuing comorbidities – may alter the ultimate functional outcome of the cancer patient.[24]

REHABILITATIVE INTERVENTIONS

One of the most important tasks for the rehabilitationist and patient with cancer is the establishment of appropriate goals. Patients vary in their understanding of disease and its implications. Functionally, they will have a unique response to surgical, chemotherapeutic, or radiation treatment. Initial and final expectations of treatment may be diametrically opposed. The rehabilitationist needs to modify general principles of rehabilitation to accommodate for persistent disease and the possibility of imminent or future decline. Challenges unique to patients with cancer would include chemotherapy-induced neuropathies, progressive lymphedema, pathological fractures requiring surgical stabilization, and metastatic disease compromising neurological functioning.[24]

Compensatory strategies in the care of patients with cancer make use of assistive devices. Reachers allow paraparetic, hemiparetic/hemiplegic patients to retrieve objects. Dressing and bathing aids compensate for diminished force and coordination. Orthotics can enhance stability and safety in the patient with motor deficits by protecting and stabilizing joints which are controlled by paretic muscles (e.g. ankle foot orthoses in the treatment of a 'drop foot'). In terms of home and community accessing, mobility can be restored with the use of wheelchairs and scooters.[24]

Sensory deficits are often seen in spinal cord compression and leptomeningeal disease (53 and 50 percent, respectively).[24] Anatomically, they are associated with brachial and lumbosacral plexopathies secondary to tumor encroachment or radiation effect. Chemotherapeutic agents such as cisplatin, vincristine and taxanes have also been associated with sensory neuropathies. In addition to instruction in compensatory strategies, assistive devices, and the use of orthotic devices, therapists work on enhancing stability by broadening a patient's base of support, enhancing tactile input, and instituting safety awareness of the insensate extremity while further educating patients on the use of alternative senses such as vision.[24]

In a large series of patients with brain metastases, cognitive dysfunction was found in 58 percent.[18,19] Such deficits can increase caretaker burden, render patients unsafe and limit effective communication. Deficits arising from neurological tumors include apraxia, alexia, aphasia, and agnosia. Patients may experience inattention, difficulties with concentration and disturbance in short-term memory. Strategies are limited, but may include memory notebooks or computerized prosthetics.[24] In cases of cerebellar dysfunction where ataxia and truncal instability destabilize the patient, therapists use devices with a broad support base such as wide-based quadruped canes, standard walkers, and hemiwalkers.[24]

Discussion continues about what is the most distressing experience among cancer patients, whether it is uncontrolled pain or fatigue. Santiago-Palma and Payne[25] noted that in approximately 70 percent of patients, fatigue was chronic or was acute during chemoradiation therapy. Specifically, fatigue may be the result of cachexia, infection, anemia or other metabolic/endocrine disorders.[25] Metastatic disease to the lungs and pleural effusions may result in significant dyspnea with concurrent decline in endurance.[25] In 2001, Winningham[26] identified 'cancer-related fatigue syndrome' (CRFS) as the most distressing experience among cancer patients. Winningham looked at fatigue from a metabolic/cellular level. She proposes that fatigue is amenable to rehabilitative efforts. Indeed, treatment for

cancer-related fatigue may lie in endurance exercise training. When oxidative metabolism is maximized – as during exercise – there is improvement in muscle mass, plasma volume, pulmonary ventilation/perfusion, cardiac reserve, and a subsequent increased concentration of oxidative muscle enzymes. Interleukin-1 and other myotoxic cytokines are downregulated.[27] Finally, resistance exercise reduces steroid-induced loss of muscle mass.[26] Optimization of oxidative capacity, however, requires sound nutritional support. Even with nutritional intervention in the form of supplements, oral intake may be insufficient. The patient may have alteration to nutrient processing secondary to mechanical (surgical) intervention or cachexia.[28,29]

Pain is a prevalent finding in patients with cancer. In 70–90 percent of patients with advanced disease, significant pain is present.[25] From a symptom-control perspective, pain was controlled without excessive sedation in 85–90 percent of patients with cancer when the right combination of nonpharmacological techniques, pharmacological therapy, and radiopharmaceuticals were used.[30] Current recommendations suggest use of nonopioid agents initially for mild pain with addition of opioids for moderate or severe pain.[30] From the rehabilitationist's perspective, additional useful adjuvant therapy might include massage, and heat and cold modalities with certain restrictions. Physical therapy should educate a patient regarding proper seating dynamics, pressure relief, orthotics, assistive equipment and compensatory strategies.[25]

ROLE OF REHABILITATION IN PALLIATIVE CARE

At first glance it would appear that the two fields of rehabilitation and palliative care are divergent. Rehabilitation, in the traditional sense, focuses on the restoration of function lost either through illness, trauma or intervention. Acutely, patients may be cared for in a hospital setting and then transitioned to outpatient services. The expectation is that even with alterations in physical functioning, the patient should reestablish the premorbid level of activity. In contrast, in palliative medicine, the patient is presumed to be in a terminal phase of either an acute or chronic illness. Restoration of physical and cognitive functioning may occur, but is not the overall objective. The goal of palliation becomes assessing symptoms related to the disease state or its subsequent treatment, i.e. pain, dyspnea, asthenia, fatigue, cachexia, somnolence, delirium, depression, constipation; and instituting an appropriate intervention. As an internist, the palliative expert also attempts to maintain a homeostatic balance for the body. Unique to palliative medicine has been the arena of close, dynamic interplay with patients and their families. Whereas most physicians typically distance themselves from talking about dying, coping with illness, and the incorporation of family into this process, the palliative care physician sees this as a prerequisite in the total care of the patient. Discussion of end-of-life issues is viewed merely as a completion of this task.

The role of the cancer rehabilitationist has been modified. Without a clear understanding of the patient's prior health, disease process, prognosis, anticipated limitations based on pharmacological intervention, surgery, radiation and lastly family and economic supports, the rehabilitationist is unable to completely care for the patient. Therefore, the rehabilitationist dons – in limited fashion – the cloak of the palliative care physician. The goal, however, is maintaining function in the immediate future and preparing for possible future decline. Maintenance of the patient's autonomy in functioning, whether transferring to a chair or to the toilet, is attempted. A close collaboration between both disciplines is essential. In a study of 239 hospice patients, Yoshioka[31] demonstrated that functional improvement occurred in 27 percent of patients. In another study by Montagnini et al.[32] 18 out of 100 palliative care patients took part in a physical therapy program. In this group, 90 percent had ongoing deconditioning and pain. Montagnini found that 56 percent of those undergoing physical therapy demonstrated functional improvement.[32]

The complementary roles of physical medicine and palliative care medicine should be further investigated. Indeed, both disciplines 'enable the dying person to live until he dies, at his own maximum potential performing to the limit of his physical and mental capacity with control and independence whenever possible'.[33]

CONCLUSION

In general, researchers have yet to look at the overall dynamic of patients with cancer. When a patient presents for initial evaluation to a physician, the overall health and background of the patient is evaluated. Initial presenting complaint, general past medical health, concurrent medical comorbidities such as cardiopulmonary and endocrine disease are typically investigated. Emphasis should also be on how patients function in the home, within the family unit, at work, financially, emotionally – all of these are essential to determine what resources patients will draw upon to combat their illness. If there is no motivation or impetus to get better; if there is a poor support network, negative sense of self-worth, spiritual conflict or inability to work in trusting union with healthcare workers, the patient is at a marked disadvantage. Correlations have been shown with mood, affect, depression and the state of one's immune functioning.

Likewise, if a sound relationship of concern, compassion, and investment is not shared by the physician or conveyed in word or action to the patient, medical treatment will not be successful. In terminal disease, the idealistic goal is cure. Cure, however, may not be medically available at this time – despite the best of our scientific endeavors and research protocols. The goal, therefore, is simply and clearly explaining to the patient their disease process; options of optimal care; the true

risks and disabilities inherently possible in current treatment regimens; and the promise by healthcare providers of attempting to physically do as little harm as possible in seeking a physical cure wherever possible. When attempts at treatment are exhausted, healthcare workers need to maintain a symptom-relieving role while providing ongoing educational and emotional support to the patient and caregiver.

Key learning points

- Palliative medicine and rehabilitation medicine both aim to restore function. The patient is viewed as a complex individual.

- To understand the patient's psychologic, physical, medical, and spiritual dimensions requires an interactive team approach by physician(s), advanced practice nurses, hospital/clinical nursing, psychologist, chaplain, social work and case manager.

- Physical activity may improve immunological function, cardiorespiratory status, motor ability, and endurance. It may relieve stress and improve symptoms of asthenia, fatigue, dyspnea, anorexia, and constipation.

- Family support is essential in the patient's ongoing medical care and successful transition from hospital to home or hospice setting.

- The goal of both rehabilitation medicine and palliative medicine is restoring autonomy (informed decision making) back to the patient and allowing mental and spiritual clarity.

Integrative and alternative medicine and palliative medicine

NANCY C RUSSELL, LORENZO COHEN

DEFINITION AND TYPES OF TRADITIONAL AND COMPLEMENTARY THERAPIES

Traditional medicine is defined by the World Health Organization (WHO) as health practices, approaches, knowledge, and beliefs incorporating plant, animal and mineral based medicines, spiritual therapies, manual techniques and exercises singularly or in combination to treat, diagnose, and prevent illnesses or maintain wellbeing.[1] Complementary/alternative medicine (CAM) is defined by the US National Center for Complementary and Alternative Medicine (NCCAM) as a group of diverse medical and healthcare systems, practices, and products that are not presently considered as part of conventional medicine. *Complementary medicine*, as defined by NCCAM, combines mainstream medical therapies with CAM therapies for which there is some high-quality scientific evidence of safety and effectiveness. *Alternative medicine*, however, is typically defined as a treatment modality for which there is no scientific evidence of efficacy and it is used *in place of* conventional, mainstream medicine.[2]

To integrate complementary medicine with conventional medicine, it must be practiced with the knowledgeable awareness of the conventional healthcare professional. The complementary medicine practitioner should be aware of and knowledgeable about the conventional treatments and at the least there is an open communication between the two practitioners. When this occurs, patients receive complementary treatment modalities using an integrative medicine approach versus simply receiving two different treatment modalities (conventional and complementary).

Complementary therapies have been subdivided into five subsections:[2]

- *Alternative medical systems* that have evolved independently and sometimes earlier than conventional Western medicine, e.g. traditional Chinese medicine (herbal and acupuncture), homeopathy, and Ayurveda (Indian-based medicine).
- *Biologically based approaches* such as nutrition, herbal/plant, animal/mineral, or other products.
- *Body-manipulative systems* such as chiropractic and massage.
- *Energy-based therapies* that seek to affect proposed energy fields of individuals through electromagnetic waves or the energy of individual practitioners, e.g. yoga, tai chi, qigong, Reiki, Healing Touch.
- *Mind-body approaches* such as meditation, prayer, support groups, guided imagery, music therapy, art therapy, and other behavioral techniques.

In palliative care settings, complementary/integrative medicines (CIM) may be used for managing symptoms, increasing wellness (quality of life, reported sense of wellbeing), and improving treatment efficacy.

In this chapter we will describe the use and need for complementary therapies, assessments of their effectiveness,

quality assurance, evidence-based internet resources, standards of care, and the role of the healthcare professional in advising patients about their use. Although we will highlight some findings from previously published reviews of their effectiveness for patients with cancer, we will not provide comprehensive reviews of specific modalities. Rather, we will focus on some guidelines and evidence-based internet resources that can assist healthcare professionals in their advice to patients and families.

USE OF COMPLEMENTARY THERAPIES

The WHO estimates that up to 80 percent of people in developing countries rely on traditional medicines for their primary healthcare. People in more developed countries also seek out these medicines and practices assuming that they are effective and may be safer than allopathic medicine because they are natural.[3] A 1997 survey of US adults found CAM use (excluding self-prayer) varied from 32 percent to 54 percent among the sociodemographic groups surveyed.[4] A 2002 survey by the US Centers for Disease Control and Prevention (CDC) found that 36 percent of adults had used CAM therapies (non-prayer) during the past 12 months.[5]

An estimated 48–69 percent of US patients with cancer use CAM therapies[6,7] and percentages increase if spiritual practices are included.[7] Complementary therapies are used in 70 percent of all oncology departments engaged in palliative care in Britain[8,9] and by 28 percent of advanced cancer/palliative care patients in a Canadian community and hospital setting.[10] A survey of five clinics within a US comprehensive cancer care center found that CAM therapies were used by 68.7 percent of patients (excluding psychotherapy and spiritual practices) and were 11.6 times more likely to be used by patients with distant or unstaged disease (95 percent confidence interval [CI] 1.5 to 92.8).[7] A later survey in the breast and gynecological clinics within that same center found that CAM therapies, (defined as herbs, supplements, and mega doses of vitamins) were used by 48 percent of patients. Again, statistically significant differences existed by disease status with CAM therapies used by 38 percent of newly diagnosed patients, 49 percent of those with recurrence or relapse, and 55 percent of those in remission ($\chi^2 = 9.34$, $P = 0.009$).[6]

Whether or not patients use CAM therapies for treatment of cancer or its effects, they may use them for other chronic conditions such as arthritis. CAM therapies were currently being used by 69 percent of patients attending six university-based primary care clinics for osteoarthritis, rheumatoid arthritis, or fibromyalgia.[11]

NEED FOR COMPLEMENTARY THERAPIES

Conventional medical approaches have powerful pharmaceutical medicines for managing problems within palliative care settings. Yet all drugs have limitations and a medicine for one set of problems often has side effects that aggravate other problems. Pain and related problems, for example, can be pharmaceutically managed with opioids, corticosteroids, nonsteroidal anti-inflammatory drugs (NSAIDs), and psychotropic medications. However, this pharmaceutical management often comes at a price in terms of both financial costs and physiological side effects.[12,13] Any approach or therapy that can lower the doses needed or delay the start of these drugs would be beneficial.

EFFECTIVENESS OF COMPLEMENTARY THERAPIES

Assessing the effectiveness of complementary therapies requires the same standards of research methodology as conventional therapies. Yet, popular pressure may rush some of these therapies into full-scale phase III clinical trials before the proper preclinical research and dose-finding studies have prepared the basis for a scientifically sound well-designed trial. Conducting a phase III clinical trial with too small a dose may yield results of noneffectiveness when, in fact, other doses or regimens might have been found to be effective.[14]

Although the randomized, double blind, placebo controlled trial is considered the gold standard for clinical research, it is especially challenging for many of these therapies. Randomization may affect recruitment of subjects if those who are eligible already have strong biases in favor of either the standard or the alternative complementary therapy. Healthcare practitioners may have biases in favor of certain treatments or ideas about which groups might benefit the most. Disguising nonpharmaceutical therapies is not as simple as disguising pharmaceuticals with tablet coatings. Some herbal therapies may have associated tastes, textures, or smells that are part of their effectiveness and difficult to either disguise or duplicate. Disguising acupuncture, exercise, or mind-body approaches with sham treatments is difficult to do without adding some effects. Most complementary therapies require trained practitioners who would have difficulty providing a sham therapy while untrained practitioners might have difficulty providing a convincing sham therapy. If a sham therapy is to be provided, the information provided to the patient during the informed consent process must be honest without exposing the sham procedure. In comparisons between unconventional and standard treatments this document must again be honest without biasing the patient in favor of either procedure. Blinding of therapies to both the patient and the practitioner can be especially challenging.[15,16]

The number and variety of complementary therapies limits the extent to which any one review of the evidence can do justice to all therapies; nevertheless, several reviews have been published. Ernst reviewed nine complementary therapies used in palliative cancer care for which there were

some scientific data: acupuncture, aromatherapy, enzyme therapy, homeopathy, hypnotherapy, massage, reflexology, relaxation, and spiritual (energy) healing. He concluded that acupuncture could be effective for reducing nausea and vomiting after chemotherapy, although he called for more rigorous clinical trials.[8***] His conclusion is consistent with a US National Institutes of Health consensus statement.[17***]

For most other therapies, Ernst reported encouraging, but not compelling evidence and again stated a need for more trials with rigorous designs. He noted a few herbs with palliative care possibilities: St John's wort and kava for mood regulation, ginger for nausea, and valerian for sleep problems. However, these had not had adequate testing in patients with cancer at the time of his review.[8***] Subsequent reviews of these herbs by the collaborative review organization, Natural Standard, found each of them to be effective.[18***] However, important contraindications need to be observed when prescribing these herbs; in particular, St John's wort, as it increases metabolism of certain drugs, and kava, which has been found to have toxicities in people with previous liver problems.[18–20] Newell and colleagues[21] reviewed psychological therapies for cancer patients and concluded that interventions involving self-practice and hypnosis for managing nausea and vomiting could be recommended, but further research was suggested to examine the benefits of relaxation training and guided imagery. Further research was also warranted to examine the benefits of relaxation and guided imagery for managing general nausea, anxiety, quality of life, and overall physical symptoms.[21***] Natural Standard also concluded that guided imagery could improve quality of life and sense of comfort, but that further research was needed for firm conclusions. Meditation to relieve anxiety had some reported benefits, but better designed studies were needed. Numerous studies have showed evidence that relaxation techniques may moderately reduce anxiety and insomnia, but again studies with better designs were needed.[18***]

Wendy Weiger and colleagues reviewed CAM therapies commonly used by patients with cancer.[22***] They concluded that the direction of evidence suggested effectiveness for several types of therapies: energy-based, body manipulative, and mind-body, and specifically, acupuncture, to relieve chemotherapy-related nausea and exercise to improve physical function, psychological state, and physical symptoms in patients receiving conventional therapy. Mind-body therapies indicating effectiveness included various forms of individual and group therapy, relaxation, imagery, hypnosis, and meditation. These could alleviate emotional distress and certain physical symptoms of disease and side effects of conventional treatment including cancer-related pain.[22***]

Weiger et al. found good evidence for the use of massage to relieve anxiety, nausea (related to bone marrow transplantation), and lymphedema (manual lymph drainage).[22***] Natural Standard's review of massage, however, found the studies concerning anxiety and cancer-related pain to be

inconclusive. They did find evidence of benefit for the massage known as 'manual lymphatic drainage' when combined with elastic sleeves or bandaging for patients with arm edema after breast cancer surgery.[18***] They found no evidence that the usual practices of massage promoted cancer although, of course, it should not be done directly on tumors and care must be exercised in patients who have bony metastases, are prone to bleeding, or have just had radiation or surgery.[18] One study (not noted in that review) has identified metastasis associated with massage, but it followed deliberate attempts immediately after breast cancer surgery to enhance dye uptake into sentinel lymph nodes for diagnostic purposes.[23*,24*,25*]

The only herbal product included in the Weiger review was PC-SPES, a combination of eight herbs: *Isatis indigotica* (da qing ye), *Glycyrrhiza glabra* (licorice), *Panax pseudoginseng* (san qi), *Ganoderma lucidum* (ling zhi), *Scutellaria baicalensis* (Chinese skullcap), *Chrysanthemum morifolium* (chrysanthemum), *Rabdosia rubescens*, and *Serenoa repens* (saw palmetto). Although beneficial and adverse effects had been demonstrated in randomized controlled trials, these effects were largely attributed to contamination with estrogen. Nevertheless, reviewers noted several *in vitro* effects that could not be attributed entirely to estrogen.[22***]

QUALITY ASSURANCE

Widely reported contamination of PC-SPES and other products has highlighted the need for quality assurance within the herbal industry. The US Food and Drug Administration and the WHO, in consultation with major producers, have proposed guidelines for good manufacturing practices (GMPs). However, actual regulation of herbal processing and shipping involves complex issues since most herbs are classified as foods that cannot be regulated in the same manner as drugs. Nevertheless, GMPs are being supported by some major producers and independent nongovernmental groups such as the American Botanical Council,[26,27] and results of independent laboratory testing are available. ConsumerLab (www.consumerLab.com), for example, tests products according to recognized standards of quality, ingredients claimed on labels, purity, and biological availability. Lists of brands that have passed their tests may be accessed for free, but names of those that have failed require a subscription.[28]

To responsibly suggest or even accept the use of readily available herbal supplements, behavioral techniques, or alternative modalities such as acupuncture and massage for symptom control, clinicians must have access to routinely updated authoritative evidence-based reviews. These reviews must consider the preponderance of evidence from all known well-designed studies and meta-analyses rather than isolated individual studies. Comprehensive reviews must include information concerning safety, specific indications

for use, potential interactions, dosing, frequency, and quality of different brands. Clinicians in previous decades would have sought such information within large reference volumes in libraries. Today's clinicians may more easily access the latest comprehensive reviews through the internet, but they must also be able to quickly filter through many resources to find those that are most reliable.

EVIDENCE–BASED INTERNET REVIEWS

The rapidity with which a comprehensive review can become out of date and the ease of internet publishing have fostered the growth of comprehensive scientific review organizations that provide electronic access to their reviews. An assessment of websites with reviews of CAM therapies for patients with cancer was published in 2004 by Schmidt and Ernst.[29] They used eight popular search engines to search for the terms 'complementary' or 'alternative medicine' and 'cancer' and identified the first 50 websites that appeared on at least three engines. Their final list of 32 websites was evaluated for

- quality based upon a Sandvik score of 0–5 points as 'poor', 6–10 points as 'medium' and 11–14 points as 'excellent'
- reliability based on whether it displayed the Health on the Net (HON) code
- risk to patients based on an overall score and type of CAM discussed (curative, preventative, or palliative).

Each website was also scored based upon discouraging the use of conventional medicine or clinician's advice, and providing commercial details. Ten websites received a score of 12 or better. Seven of these top 10 websites were sponsored by either government or academic institutions and three were sponsored by individuals or private businesses.[29]

For recommendation to the health professionals reading this chapter, we evaluated 15 websites: the 10 websites recognized by Schmidt and Ernst (Quackwatch;[30] Oxford University's Bandolier;[31] the National Cancer Institute [NCI] Fact Sheets;[32] Rosenthal Center of Columbia University;[33] Holistic online;[34] International Health News – yourhealthbase;[35] Oncolink sponsored by the Abramson Cancer Center of the University of Pennsylvania;[36] University of Virginia Medical Center;[37] NCI Office of Cancer Complementary and Alternative Medicine [OCCAM] PDQ summaries;[38] and The University of Texas MD Anderson Cancer Center Complementary/Integrative Medicine Education Resources [CIMER][25]) plus five others that were not identified by Schmidt and Ernst as being in the top 32 websites: American Cancer Society,[39] Memorial Sloan–Kettering Cancer Center,[19] the Cochrane Review Organization,[40] Natural Standard,[18] and Natural Medicines Comprehensive Database.[20]

Eight of these 15 complementary/alternative websites provide generally reliable information for patients and the general public, but are not adequate for health professionals. Quackwatch[30] has a predominantly negative bias consistent with its mission to 'combat health related frauds'. NCI Fact Sheets[32] provide authoritative summaries of reviews for patients and the general public, but lack specific citations. Holistic online[34] provides generally positive information about an extensive set of herbs and other therapies (both alternative and conventional), but it does not provide professional documentation or descriptions of their review process. The Rosenthal Center at Columbia University provides the herbal database of abstracts, HerbMedPro,[33] but no systematic reviews of therapies. The University of Virginia Medical Center[37] describes opportunities for research at their center, but no reviews or study results. The University of Pennsylvania's Oncolink[36] provides brief synopses and frequently asked questions about complementary therapies. International Health News[35] provides summaries of individual articles. At the time of the Schmidt and Ernst review, the American Cancer Society[39] provided summaries of reviews, but these are no longer available.

Seven remaining websites provide valuable resources for healthcare professionals. Natural Medicines Comprehensive Database (www.naturaldatabase.com) provides the largest number of evidence-based reviews of complementary therapies (over 1000). The majority of its authors and editors are doctors of pharmacy and their reviews include scientific names, uses, safety, effectiveness, mechanisms of action, adverse reactions, interactions, dosage and administration. Full access requires an individual or institutional subscription.[20] It has received top ratings in comparative evaluations for answering questions about herbal and dietary supplements.[41–43] However, these one to two page reviews do not provide background or indepth assessments of the evidence on which their conclusions are based.

The oldest and most comprehensive of the scientific review organizations for conventional therapies is the Cochrane Review Organization (www.cochrane.org). Founded in 1993 as an international nonprofit independent organization, it now provides over 2000 systematic reviews and has recently added the complementary therapies of massage, acupuncture, and chiropractic. Its review process includes searches of multiple bibliographic databases by professional librarians. At least two blinded independent reviewers evaluate studies according to standard sets of questions with discrepancies resolved through conferences with attempts to contact authors for resolution of remaining questions. A statistician and an editorial board join with reviewers for development and summation of final conclusions. Abstracts of Cochrane reviews are free, but completed reviews require either individual or institutional subscription.[40,44]

Indepth analyses and commentaries about recent systematic reviews and meta-analyses of some complementary therapies found in searches of the *Cochrane Library* and PubMed are a feature of *Bandolier*, a monthly journal about evidence-based healthcare produced by scientists at

Oxford University (www.jr2.ox.ac.uk/bandolier).[31] Modeling itself upon the Cochrane organization, Natural Standard (www.naturalstandard.com) formed a multidisciplinary, multi-institutional initiative dedicated to the review of complementary and alternative therapies. It follows a similar process to build indepth evidence and consensus-based analysis of scientific data in addition to historical and folkloric perspectives. It now provides several hundred authoritative reviews. Access requires subscription, but some institutions with subscriptions have also purchased summaries of reviews for public access.[18]

The NCI Office of Cancer Complementary and Alternative Medicine (OCCAM) has reviewed about a dozen complementary therapies (www3.cancer.gov/occam). These 'PDQ' cancer information summaries provide extensive details and citations for health professionals including background, history of development, proposed mechanisms of action, and relevant laboratory, animal and clinical studies.[38] Memorial Sloan–Kettering Cancer Center (www.mskcc.org/mskcc/html/11571.cfm) provides over a hundred evidence-based reviews. These are written either by an oncology-trained pharmacist with expertise in botanicals or a cancer nutrition specialist with secondary reviews by at least two other editors or panel advisors.[19] The University of Texas MD Anderson Cancer Center's website for complementary/integrative medicine (www.mdanderson.org/cimer) provides over 80 reviews that include indepth assessments of the background and evidence by their own staff plus purchased summaries of some of the previously described reviews by Natural Standard and the *Cochrane Library* and access to all reviews by the NCI OCCAM and Memorial Sloan–Kettering. Their own methodology includes searches by library personnel, reviews by an epidemiologist and secondary reviews by appropriate faculty members or outside advisors.[25]

Searching these seven websites may be efficiently accomplished by physicians or delegated to appropriate clinic personnel. Patients or caregivers can then be given specific recommendations, printed summaries, or the names of these or other prescreened websites. Questions generated from this information can then be brought back for discussion with the physician or other clinic professional.

Although the NCI, the American Cancer Society and the MD Anderson Cancer Center websites also provide links to other reliable websites, patients or caregivers may wish to investigate independently. If so, they should be encouraged to look for websites that subscribe to the principles of the Health on the Net Foundation and carry its 'Honcode' seal. This nongovernmental organization is supported by the State of Geneva in Switzerland, the Swiss Institute of Bioinformatics and the University Hospitals of Geneva. It screens websites for compliance with its eight principles of authority: medically trained and qualified professionals, support of the patient/site visitor and his or her physician, confidentiality, clear references to source data, claims supported by appropriate and balanced evidence, transparency of

authorship, transparency of ownership, and honesty in advertising and editorial policy.[45] The Honcode is displayed by two of the above seven websites for healthcare professionals: the NCI and the MD Anderson Cancer Center.

STANDARDS OF CARE

As some complementary therapies have demonstrated evidence of effectiveness, they may have become accepted standards of practice in some areas. Accordingly, it is wise to keep an open mind and to consult with other professional colleagues such as physical therapists, registered dieticians, and psychologists before making quick judgments that may be recognized as inadequate by knowledgeable patients and caregivers. Certain types of massage, nutritional guidelines, and behavioral techniques for example, are now accepted standards of care for certain conditions.

ROLE OF THE PALLIATIVE CARE PROVIDER

Deciding whether to recommend a complementary therapy or warn against its use may not even be an option for the healthcare provider if patients are already using it without the physician's knowledge. The percentage of patients using complementary therapies in cancer centers without telling their physicians has varied from 38 percent to 60 percent.[6,7] For this reason, physicians, nurse practitioners and other palliative care professionals must strive to maintain an inquiring, but nonjudgmental attitude toward patients concerning complementary therapies. Their role is to assist the patient in relieving their symptoms with the best of conventional and/or complementary resources rather than dismissing their efforts. General role playing in such situations has been described in articles[46] and internet videos.[25] The ultimate goal is to understand a patient's motivations and ensure that the approach they choose is safe and potentially worth the investment when there is an associated cost with little evidence for efficacy.

Key learning points

- Important distinctions exist between *alternative* medicines with little evidence of effectiveness that may be used in place of conventional treatments for cancer and *complementary* medicines with some evidence of effectiveness that may be used in addition to conventional treatments for cancer and its side effects. To *integrate* complementary treatments with conventional treatments requires the knowledgeable awareness of the conventional practitioner based upon open dialog with the patient.

- Many patients with cancer engage in some type of CAM modality at some point in the treatment trajectory, but especially when disease is advanced.

- Some CAM treatments may be beneficial, some may cause harm on their own or due to negative interactions with conventional medicine, and others may have no benefit.

- Cancer patients are typically well-informed medical consumers, but they may gather information about CAM from both reputable and questionable sources. Accordingly, it is the responsibility of healthcare professionals to become as informed as possible in this new and expanding area.

- Today's healthcare professionals and patients have powerful new tools and professional societies that have developed for evaluating the potential of proposed complementary therapies for palliative care needs. Working together, healthcare professionals and patients can make educated decisions about what to incorporate and what to avoid at different stages of the cancer treatment trajectory.

- Appropriate discussions about CAM in the palliative care setting will increase an open dialog about this important topic, optimize patient healing and comfort, and ensure that patients are provided safe and effective care.

Human immunodeficiency virus and palliative care

ROBERT E HIRSCHTICK, JAMIE H VON ROENN

INTRODUCTION

Therapeutic advances in recent years have extended the survival of patients infected with the human immunodeficiency virus (HIV) in the developed world.[1*] In affluent countries, HIV infection has become a chronic, treatable condition, similar in many ways to congestive heart failure. However, there is still considerable morbidity and mortality associated with HIV infection.[2] Moreover, as with congestive heart failure, the trajectory of late-stage illness does not proceed steadily downward but rather follows an irregular course of sudden valleys and surprising peaks.[3,4]

Many of the issues faced by people with advanced HIV infection fall within the traditional purview of hospice and palliative care. For example, the palliative care consultation service of a large urban hospital reported the following issues in patients with acquired immune deficiency syndrome (AIDS): pain in 40 percent, psychosocial issues in 31 percent, nausea and/or vomiting in 14 percent, and interpersonal conflicts in 13 percent.[5] However, there are many unique aspects involved in the palliative care of HIV-infected individuals, and HIV/AIDS remains largely a socially unacceptable disease. Infected patients may be shunned by family or friends and suffer physical and emotional isolation as a result.[6] The young age at death of HIV-infected patients may exact a toll upon healthcare providers. The presence of a homosexual partner may exacerbate friction with family members, especially when major healthcare decisions need to be made. The patient may have a history of past or current narcotic abuse, which can challenge not only

the prescribing expertise of practitioners but also the limits of their compassion. Finally, many HIV-infected patients, owing to social, cultural, or economic considerations, may be reluctant or unable to access support services and medical resources, including hospice and palliative care programs. For example, African Americans now comprise the largest group of HIV-infected persons in the USA.[2] However, they are less likely to use hospice and palliative care services than are European Americans.[7] Moreover, physicians are less likely to have discussions about end-of-life issues with African American AIDS patients than they are with European American AIDS patients.[8]

SYMPTOM BURDEN

A significant symptom burden is associated with HIV infection throughout the trajectory of disease, although it is greatest in patients with advanced and/or refractory HIV infection.[4,5,9] The high prevalence of pain and other symptoms in patients with AIDS has been documented since the onset of the epidemic. The etiology of some of the most common symptoms has changed over the course of the epidemic, but the overall prevalence has not. Without the use of highly active antiretroviral therapy (HAART), opportunistic infections account for many symptoms: headaches with cryptococcal meningitis, wasting and abdominal pain with mycobacterium avium complex infection, and blindness from cytomegalovirus retinitis, to name but a few. The contribution of opportunistic infections to pain and other

symptoms in patients with AIDS has diminished over time as HIV therapy, where available, has become more effective and the frequency of these infections has decreased.

In the pre-HAART era, the most common symptoms in patients with AIDS included weight loss, pain, anorexia, depression, anxiety, cough, dyspnea, fatigue, and diarrhea.[4,5,9] More recent data (1996) from 3000 US patients reported the following as the 10 most common symptoms: constitutional symptoms (fever, sweats, chills) – 51 percent, diarrhea – 51 percent, nausea and anorexia – 50 percent, numbness and tingling/neuropathic pain in the hands and feet – 49 percent, headaches – 39 percent, weight loss – 37 percent, vaginal symptoms – 36 percent, sinus symptoms – 35 percent, visual disturbances – 32 percent, and cough or shortness of breath – 30 percent.[10] Currently, the median number of symptoms in patients with advanced HIV infection is 4, with a range of 0–25 in patients in a palliative care setting.[9]

PAIN

Pain frequently complicates the course of HIV infection. Often underdiagnosed and undertreated, pain is now more frequently a result of chronic HIV infection and/or medication toxicities than opportunistic infection in the developed world. One longitudinal study found that over a 2-year period, almost 90 percent of AIDS patients experienced pain and almost 70 percent experienced continuous pain.[11] Peripheral neuropathy, headache, and abdominal pain are the most common pain syndromes.[11]

Neuropathy

Peripheral polyneuropathy develops in about a third to half of patients with AIDS.[10,12,13] The predominant symptoms are pain, paresthesias, and numbness involving the feet and lower legs. The two most common causes of neuropathy are medication-induced and HIV-induced. These two conditions are indistinguishable clinically. The severity of distal sensory neuropathy induced by HIV is worse in late-stage disease.[14] The antiretroviral medications stavudine (D4T) and didanosine (DDI) are the medications most often associated with painful peripheral neuropathy. Pain may improve or stabilize after discontinuation of these medications but frequently it persists.

Management of peripheral neuropathy in the setting of HIV is similar to that of peripheral neuropathy in general. Gabapentin is the most commonly used medication. It appears to be effective in this setting but most experience is anecdotal. A daily dose of ≥600 mg is required for efficacy.[15***] In a placebo-controlled trial involving diabetics, gabapentin at 900–3600 mg per day was significantly more effective than placebo in reducing pain intensity and quality of life. Dizziness (in 20 percent of subjects) and sleepiness (in 23 percent) were the most common adverse effects.[16**]

Gabapentin is more effective in reducing pain than in reducing numbness.

Lamotrigine has been studied as a treatment for HIV-associated neuropathy. Simpson et al. found that 11 weeks of lamotrigine was more effective than placebo in reducing neuropathic pain.[17] However, there was no benefit relative to placebo in patients who were no longer taking neurotoxic antiretroviral therapy. Hence, lamotrigine may have less relevance in end-of-life care, when neurotoxic antiretroviral therapy would likely be discontinued. Rash occurred in 14 percent of lamotrigine-treated patients, which was not significantly greater than placebo.

Tricyclic antidepressants are inexpensive medications often used for neuropathic pain. However, their frequent adverse effects limit their utility. A controlled trial of amitriptyline showed no benefit and more adverse effects compared with placebo.[18**] Topical capsaicin has also been demonstrated to be ineffective for this indication.[19]

FATIGUE

Fatigue, a highly prevalent symptom in patients with HIV infection, interferes with normal function and quality of life. Leading physiological factors contributing to fatigue in patients with HIV infection include anemia, deconditioning, muscle wasting, involuntary weight loss, hypogonadism, and opportunistic infection. General considerations for the evaluation and treatment of fatigue are outlined in Box 95.1.

Box 95.1 General considerations for the evaluation and treatment of fatigue

Assessment

- Severity, duration, impact
- Muscle weakness, wasting, somnolence
- Impaired cognitive function, altered mood

Potential etiologies

- Antiretroviral medications
- Other medications
- Opportunistic infection
- Anemia
- Depression/anxiety disorder
- Cachexia/wasting
- Major organ failure
- Dehydration

- Substance abuse
- Sleep disorder
- Endocrine abnormality
- Deconditioning
- Chronic pain

Anemia is a well-documented, reversible cause of fatigue. Randomized controlled trials have demonstrated significant improvement in overall quality of life in association with an increase in hematocrit.[20–22] Although health professionals frequently wait until the hemoglobin is 8 g/dL or less to intervene, studies have demonstrated that the incremental increases in quality of life with treatment are highest when hemoglobin is in the range of 11–13 g/dL.[23] The increase in hematocrit has been associated with improvements in energy, activity, and functional level and overall quality of life.

Fatigue has frequently been associated with depression and is a hallmark of major depressive disorders. But treatment of depression, in and of itself, in patients with cancer has not been shown to reverse fatigue.[24**] No similar data are available in the setting of HIV infection. Hormonal abnormalities, such as hypothyroidism and hypogonadism, are readily reversible causes of fatigue. Hypogonadism is the most common endocrine abnormality in patients with HIV infection, with low testosterone concentrations currently identified in about 15 percent of HIV-infected men in countries where HAART is available.[25] Changes in exercise or activity pattern, particularly associated with infections or opportunistic infection-related deconditioning, results in decreased activity and performance status, and are associated with fatigue regardless of the underlying cause of the deconditioning.

The first step in treatment is the identification of reversible factors that may contribute to fatigue. Common contributing factors, in addition to those above, include pain, sleep disorders, medications, and opportunistic infection. Both pharmacological and nonpharmacological interventions have been evaluated for the treatment of fatigue. Nonpharmacological interventions include exercise programs and maintenance of optimal levels of activity; restorative therapies; sleep therapy; and psychosocial interventions, including stress management, relaxation, and support groups.

The potential utility of psychostimulants for the treatment of HIV-related fatigue is supported by the results of a limited number of trials. A randomized, double-blind, placebo-controlled trial of methylphenidate (up to 60 mg daily), pemoline (150 mg/day), or placebo in patients with AIDS-related fatigue demonstrated an improvement in fatigue with treatment.[26**] Of methylphenidate-, pemoline-, and placebo-treated patients, 41 percent, 36 percent, and 15 percent, respectively, demonstrated improvement in fatigue on self-reported rating scales. Corticosteroids are thought to provide a boost in energy for patients with advanced malignancy, though it is unclear what their role and/or adverse effects might be in patients with chronic viral infection.

GASTROINTESTINAL SYMPTOMS

Diarrhea

Diarrhea is much less common since the introduction of HAART. However, it remains a chronic problem, reported by 28 percent of HIV-infected individuals who are receiving HAART.[27] Prior to the availability of effective anti-HIV therapy, infection was the most common cause of diarrhea. Now most cases are noninfectious, usually medication related.[28,29*] In one reported cohort, infection was responsible for 53 percent of cases of chronic diarrhea prior to the availability of HAART. Two years later, after HAART became available, the prevalence of chronic diarrhea was unchanged but infection accounted for only 13 percent of case.[29] Many antiretroviral agents, particularly protease inhibitors, cause diarrhea. The most common infectious causes are cytomegalovirus (CMV), cryptosporidiosis, *Clostridium difficile*, and *Giardia*. The patient's CD4 lymphocyte count (T cell count) is useful in determining the likelihood of certain pathogens. For example, CMV colitis, *Mycobacterium avium* complex (MAC), and microsporidiosis tend to occur only in patients with CD4 lymphocyte counts lower than 100/mm^3.

The initial approach to diarrhea in a palliative care situation is to discontinue potential medication culprits (e.g. protease inhibitors) and/or initiate nonspecific anti-diarrhea therapy such as loperamide. If fever or abdominal pain is present or if initial symptomatic therapy is unsuccessful, stool studies for ova and parasites, culture and sensitivity for bacterial pathogens, cryptosporidiosis, *C. difficile*, and mycobacteria are warranted. Upper and lower endoscopy with biopsies would be the next step. An extensive workup of this nature would be expected to yield a specific etiological diagnosis in two-thirds of patients.[30,31] Such a workup may not be appropriate in a palliative situation. If the diagnostic workup fails to identify a specific etiology, antimotility agents, such as loperamide, atropine/diphenoxylate, or tincture of opium can be quite helpful. High doses may be necessary. Subcutaneous octreotide is an effective albeit expensive treatment.[32] Changing or discontinuing antiretroviral agents may also be helpful.

Nausea

Virtually every anti-HIV medication has the potential to cause nausea. Zidovudine and the protease inhibitors are the worst offenders in this regard. Switching anti-HIV medications is the preferred option. In the patient with end-stage infection, stopping anti-HIV therapy altogether is an appropriate step. We have seen many patients who perked

up considerably after HAART was discontinued, but only for a period of weeks to a few months.

Oral and esophageal symptoms

Oral candidiasis (thrush) is frequently seen in late stage infection.[33] It typically appears as white 'cottage cheese'-like plaques on buccal, pharyngeal, or lingual mucosa. Less often it manifests as patchy erythema. It may be asymptomatic but frequently is associated with oral discomfort and difficulty swallowing.[34]

Esophageal candidiasis is the most common cause of dysphagia. Concomitant oral thrush is present in approximately 80 percent of cases.[35] Empirical therapy with oral fluconazole is appropriate for dysphagia, even in the absence of oral thrush. Oral fluconazole is an effective treatment with a 90 percent response rate.[36**] Extensive use of this drug has fostered the development of resistant strains, particularly in individuals with end-stage AIDS.[37] If fluconazole proves unsuccessful, there may be value in trying oral voriconazole[38] or oral amphotericin suspension.[39] Although the unfavorable side effect profile of IV amphotericin B generally makes it unsuitable in the palliative care setting, once weekly dosing may be effective and well tolerated in the management of recalcitrant oral and esophageal candidiasis.

Odynophagia (painful swallowing) is usually caused by CMV, herpes simplex virus (HSV), or idiopathic esophageal ulcers.[40] The first two conditions are treated with anti-CMV therapy (e.g. ganciclovir or valganciclovir) and anti-HSV therapy (aciclovir or valaciclovir), respectively. The last condition responds to treatment with oral corticosteroids.

INVOLUNTARY WEIGHT LOSS AND WASTING

Involuntary weight loss, even as little as 5 percent of premorbid weight, portends a poor prognosis for persons with HIV infection.[41] Weight loss is still common even in the era of HAART.[42] In one cohort of HIV-infected subjects, the majority of them receiving HAART, 18 percent of subjects lost >10 percent of body weight and 21 percent lost greater than 5 percent of body weight. In the Multicenter AIDS Cohort (MACS), an ongoing study of 5622 homosexual and bisexual men at four US sites, the proportion of AIDS diagnoses in which wasting was present increased from 5 percent in the period between 1988 and 1990 to 18.9 percent in the time period 1996–99.[43] Whether or not lipodystrophy (a syndrome of central adiposity and peripheral lipoatrophy) is being misdiagnosed as the wasting syndrome is unclear from current data but needs additional study.

The assessment of patients with HIV-related wasting includes evaluation for opportunistic infections, degree of HIV control, gonadal function, potential adverse effects of medications, gastrointestinal function, symptoms that interfere with oral intake, and psychosocial or financial factors

that might contribute to weight loss. Many HIV medications have gastrointestinal side effects.

Endocrine disturbances, particularly gonadal dysfunction, contribute to HIV-related weight loss. Early in the epidemic, and potentially currently, in the absence of HAART, as many as 50 percent of men with AIDS were hypogonadal. With the availability of HAART, the incidence has dropped to about 15 percent.[25] Loss of lean body mass and decreased functional status are highly correlated with androgen concentrations in HIV-infected men with hypogonadism and wasting.[44***,45,46] Testosterone therapy in both hypogonadal and eugonadal men increases lean body mass.[44***] A recent meta-analysis of the use of testosterone therapy for the HIV wasting syndrome concluded that testosterone improves lean body mass and weight to a small degree, with the greatest effect seen when testosterone is delivered intramuscularly.[44***]

Anorexia is an important contributor to HIV-related weight loss and was the primary target of early interventions for wasting. Megestrol acetate, a synthetic, orally active progestational agent, has been used widely as an appetite stimulant in patients with advanced cancer.[47**,48**] In patients with AIDS-associated weight loss, treatment with 800 mg/day of megestrol acetate, as compared to placebo, leads to significant improvement in weight, overall sense of wellbeing, appetite, and caloric intake.[49**,50**] Although generally well tolerated, megestrol acetate may lead to a variety of adverse endocrinological effects. Megestrol acetate, similar to glucocorticoids, suppresses the pituitary adrenal axis and may cause reversible adrenal suppression, diabetes mellitus, and a steroid withdrawal syndrome.[51,52] In addition, across a broad range of doses, megestrol acetate reduces serum testosterone to castrate levels.[53]

Studies of megestrol acetate for the treatment of cachexia have consistently demonstrated improvement in appetite and weight gain.[47–50] The composition of this weight gain, however, as evaluated by dual energy X-ray absorptiometry, tritiated body water methodologies, or bioimpedance analysis (BIA), is primarily fat mass without a significant increase in lean tissue or edema.[48,54] Dronabinol (delta-9-tetrahydrocannabinol) was first evaluated as an orexigenic agent in patients with cancer-related anorexia and cachexia. A subsequent multicenter, randomized, double-blind, placebo-controlled study of dronabinol, as compared with placebo, demonstrated improved appetite, as measured by a visual analog scale ($P = 0.01$) and improved mood ($P = 0.005$).[55**] There was no significant increase in weight. The dronabinol dose was reduced to 2.5 mg once daily in 18 percent of patients due to central nervous system toxicity. A four-arm, randomized, pharmacokinetic study evaluated the use of single-agent dronabinol, megestrol acetate, or combination therapy. The addition of dronabinol to megestrol acetate provided no added benefit compared with megestrol acetate treatment alone.[56]

Thalidomide is an inhibitor of tumor necrosis factor (TNF) production by monocytes *in vitro*. Three placebo-controlled trials of thalidomide in patients with

HIV-associated weight loss have demonstrated weight gain with treatment.[57**,58**,59**] In the largest of these trials, thalidomide 100 mg daily for 8 weeks produced a significant weight gain (+1.7 kg vs. placebo), about half of which was lean body mass. Anabolic agents offer the potential to improve weight and body composition, ideally by replenishing lean body mass. Two oral anabolic agents, oxandrolone and oxymetholone, have been evaluated in placebo-controlled trials for treatment of HIV wasting.[60**] Oxandrolone led to a sustained increase in weight (mean +1.8 kg) over 14 weeks, while oxymetholone-treated patients gained a mean of 3 kg over 16 weeks.

Resistance training also can increase lean body mass, 1.4 to 2.1 kg, in asymptomatic HIV-infected men receiving HAART and in eugonadal men with AIDS wasting.[61,62] More dramatic improvements in lean body mass are observed from combination treatment with exercise and an anabolic agent. A randomized controlled trial of testosterone and resistance training stimulated a 4.6 kg gain in lean body mass,[63**] whereas treatment with supraphysiological doses of nandrolone and resistance training resulted in a net weight gain of 2.9 kg.[64]

Growth hormone increases protein synthesis and has anticatabolic, protein-sparing effects. A randomized placebo-controlled study of recombinant growth hormone 0.1 μg/kg per day subcutaneously in patients with AIDS-related weight loss demonstrated increased weight (+1.6 kg; $P < 0.0001$) and lean body mass (+3 kg; $P < 0.001$) and decreased body fat (−1.7 kg; $P < 0.0001$).[65**] Paton et al. evaluated the protein-sparing effects of recombinant human growth hormone in HIV-infected subjects with acute opportunistic infections compared with placebo. Improvement in weight and lean body mass was observed in the treated subjects.[66] This suggests the potential short-term use of growth hormone to prevent or attenuate opportunistic infection-associated wasting. Optimal therapeutic schedules and dosing of growth hormone are unclear, and its cost has limited its use to some degree.

Weight loss remains a clinically and prognostically significant issue for HIV-infected individuals. There is now a large body of knowledge to support the benefits of nutritional counseling, dietary supplements, appetite stimulants, anabolic agents, and an exercise prescription for the treatment of HIV-related weight loss.

DRUG INTERACTIONS

There are many potential drug interactions in the palliative care of HIV-infected individuals. In this regard, the protease inhibitors (PI) and non-nucleoside reverse transcriptase inhibitors (NNRTI) are the most problematic. For example, the PI ritonavir is a potent inhibitor of CYP3A4 enzyme of the hepatic cytochrome P450 enzyme system. As a result, ritonavir significantly slows the metabolism of several palliative medications. Ritonavir therapy increases plasma levels and prolongs the duration of activity of benzodiazepines (in particular, midazolam and triazolam), bupropion, and ergot derivatives. These medications should not be used in combination with ritonavir. Furthermore, ritonavir decreases plasma levels of methadone, fentanyl, codeine, and hydrocodone. Increased dosages of these medications may be needed when used concomitantly with ritonavir. Ritonavir is the PI most likely to interact with other medications. Among the remaining PIs, nelfinavir, fosamprenavir, and indinavir are less likely to interact with other drugs. Saquinavir is least likely.[67] Ritonavir is frequently used in a fixed dose combination capsule with another PI, lopinavir (Kaletra). The NNRTIs efavirenz and nevirapine reduce plasma levels of methadone by 35–50 percent. An increase in methadone dosage of approximately 20 percent is required to prevent narcotic withdrawal symptoms when efavirenz is added to a stable methadone regimen. The NNRTI delavirdine increases plasma levels of methadone and amfetamines (see Tables 95.1 and 95.2).

Alternative therapies are commonly used by people infected with HIV. There is an interaction between St John's

Table 95.1 *Palliative drugs that should not be used concurrently with anti-HIV drugs*

HIV medication	Drugs that should not be coadministered
Protease inhibitors	Midazolam, triazolam, ergot derivatives, bupropion
Non-nucleoside reverse transcriptase inhibitors	
Delavirdine	Alprazolam, midazolam, triazolam, phenytoin, carbamazepine

HIV, human immunodeficiency virus.

Table 95.2 *Palliative drugs that may require dosage adjustment when given concurrently with anti-HIV drugs*

HIV medication	Drugs requiring dosage adjustment
Protease inhibitors	Methadone, fentanyl, tramadol, propoxyphene, clonazepam, carbamazepine, nefazodone, SSRI antidepressants, tricyclic antidepressants, amfetamines, dronabinol, risperidone, diazepam, zolpidem, dexamethasone, phenytoin
Non-nucleoside reverse transcriptase inhibitors	
Delavirdine	Methadone, amfetamines
Efavirenz	Methadone, carbamazepine, sertraline
Nevirapine	Methadone

HIV, human immunodeficiency virus; SSRI, selective serotonin reuptake inhibitor.

wort and the PI indinavir. St John's wort induces CYP3A4 and decreases plasma levels of indinavir.[67] Similarly, St John's wort can affect the metabolism of NNRTIs. Thus, St John's wort should not be taken by patients who are taking PIs or NNRTIs.

PROGNOSIS

HIV infection and AIDS have become chronic conditions in countries where HAART is available. Without effective antiretroviral therapy, the median survival following an AIDS-defining condition is less than 2 years.[68] Now with HAART, it is hoped, and expected, that people with AIDS will live for decades.[1] Rates of HIV-associated death have fallen by 80 percent in the USA as a result of HAART.[1,2] Since even patients with advanced immunodeficiency may respond to HAART,[69, 70**] no patient, regardless of how ill they might appear, should be given a poor prognosis until they have received treatment if it is available.

These improvements have been remarkable. Yet death rates from HIV in the USA have leveled off although AIDS remains the fifth leading cause of death in people aged 24–44 years.[2] African Americans are disproportionately infected. The combination of longer life expectancy plus 40 000 new infections annually in the USA has yielded an increasing prevalence of the disease.[2]

The modes of AIDS-related death have changed for patients treated with HAART. Although opportunistic infections continue to be the primary cause of death in the developing world, they are much less frequent and are no longer the leading causes of HIV-associated death in countries where HAART is routinely prescribed. Rather, chronic liver disease is now the most common cause of death in people infected with HIV.[71] This is in large part due to coinfection with hepatitis C virus (HCV). It is estimated that 30–40 percent of HIV-infected individuals are also infected with HCV.[72] In coinfected individuals, almost half of deaths are due to liver disease. Coinfection with HIV and HCV appears to accelerate the course of both.[73***]

RECOGNITION OF END–STAGE DISEASE

Recognizing the potential for dramatic improvement in health with HAART for patients with previously untreated, advanced HIV disease, how does one recognize the patient who is no longer appropriate for life-sustaining therapy? Virological, clinical characteristics, and comorbidities provide useful information. Patients with a history of nonadherence to antiretroviral therapy regimens, inability to obtain HAART, and/or highly resistant HIV infection fare poorly. Underlying liver disease, particularly cirrhosis and/or active hepatitis interfering with the ability to deliver effective antiretroviral therapy safely, also poses a significant risk for patients' overall longevity.

Refractory malignancy, with or without adequate control of HIV infection, predicts a poor prognosis, as it does in the general population. Similarly, end-stage liver disease, generally secondary to hepatitis C virus, carries a poor prognosis. For patients whose prognosis is defined by a secondary illness or uncontrolled, refractory HIV infection, withdrawal of HIV medications should at least be considered and discussed at length with the patient. The balance between the potential benefit from HAART versus the burden of continuing to take the medications should be weighed in the context of the patient's goals and comorbidities. As is the case for all patients with chronic and/or progressive illness, constant reassessment of goals, toxicities of therapy, and definitions of quality of life need repeated evaluation and discussion.

Key learning points

- HIV-associated death rates have fallen in developed countries.
- The symptom burden of HIV-infected people remains high, averaging four symptoms per person.
- Anti-HIV medications frequently cause symptoms.
- Fatigue is common and often responds to pharmacotherapy.
- Weight loss is common and often responds to pharmacotherapy.
- Nausea and diarrhea are common and may require discontinuation of anti-HIV therapy.
- Anti-HIV medications frequently interact with palliative medications.

Neurological diseases

RACHEL BURMAN

INTRODUCTION

This chapter will focus on the palliative care of adults with the more common progressive neurodegenerative diseases and their carers, and stroke will also be considered in some detail. More detailed discussion of palliative care in children can be found in Chapter 98, and of neoplasms – radiotherapy and chemotherapy – in Chapters 91 and 92, respectively. Studies have supported the application of the principles of specialist palliative care to the care of people with neurological disorders for some time. Saunders *et al.* described the first successful inclusion of patients with a neurodegenerative disorder (amyotrophic lateral sclerosis [ALS]) in a palliative care service back in 1981.[1] O'Brien *et al.* later researched the role of specialist services for these ALS patients and their carers and confirmed its relevance.[2] Addington-Hall and McCarthy demonstrated that data from the 'Regional study of care for the dying' showed dying from cancer was not much different from dying of chronic obstructive pulmonary disease (COPD), congestive heart failure, or stroke.[3] Furthermore they were able to demonstrate that people dying from congestive cardiac failure, COPD, and stroke had unmet health and social care needs in the last year of life.[4] Epidemiological data analyzed by Higginson in 1997 showed that only a quarter of all deaths dealt with by healthcare professionals on a daily basis in the UK are due to cancer.[5]

Neurologists have also endorsed the relevance of palliative care to people with neurological conditions. The American Association of Neurology issued a statement in 1996 saying that neurologists have a duty to provide adequate palliative care to their patients.[6] There is also a palliative care research group as part of the World Federation of Neurology. More recently the Multiple Sclerosis Society of Great Britain has funded a 3-year project to look at the palliative care needs of people severely affected by multiple sclerosis; this is still ongoing. There is no room for complacency when studies in the Netherlands report 5 percent of patients with multiple sclerosis and 20 percent of patients with ALS request and die by either physician-assisted suicide or euthanasia.[7,8] The disease progression of these neurodegenerative disorders cannot be significantly altered, it is therefore all the more important that appropriate palliation of the attendant symptoms and psychological distress is given.

STROKE

Stroke is a heterogeneous collection of conditions. It may be as a result of intracerebral bleeding or infarction of an area of the brain or it can occur following a subarachnoid hemorrhage. Rarer causes include vasculitis and venous sinus thrombosis. The prevalence of stroke varies in different populations and differs also with age and ethnicity. The Framingham study in the USA estimated the annual age-adjusted incidence for women was 4.5/1000 and for men 6/1000.[9] Of these, 60 percent are atherothrombotic infarctions, 23 percent cardiac embolisms, 7 percent subarachnoid hemorrhage, 7 percent intracerebral hemorrhage. Brain infarction may be due to emboli from the heart, aorta, or major brain supplying arteries. Hemodynamic changes due to severe stenosis or occlusions may cause infarctions as can the microangiopathy of hypertension and diabetes.

The typical clinical manifestations of stroke are hemiparesis, visual loss, hypesthesia, diplopia, hemianopia, or loss of consciousness. The therapeutic options for stroke patients include admission to a specialist stroke unit for management of imbalanced hemostasis and prevention of secondary infections, etc., administration of aspirin or in selected cases, thrombolysis. Thrombolysis improves mortality and

morbidity by up to 30 percent, whereas aspirin improves these by only 1–5 percent.[10] The long-term prognosis of stroke is also poor. There are several predictors of functional recovery after stroke: age, previous stroke, consciousness at onset, urinary continence.[11] Only 25 percent of stroke patients survive without major disability; 20–50 percent of all patients experience some kind of disability with 20–25 percent of patients developing poststroke dementia and 10–30 percent dying within a year of experiencing a stroke.[11] Of these, many will die suddenly making it more difficult to predict the number or indeed which patients and families might best be helped by palliative care. A study of palliative day care in England showed that human immunodeficiency virus (HIV)/acquired immune deficiency syndrome (AIDS), ALS and stroke were the three second most important diagnoses after cancer which require palliative care.[12] Also a secondary analysis of the Regional Study of Care for the Dying undertaken in England found that 65 percent of bereaved relatives reported stroke patients as experiencing pain in the last year of life while 51 percent experienced confusion, 56 percent urinary incontinence and 56 percent depressed mood. Pain control was reported as inadequate.[4]

Palliative care challenges

SYMPTOM CONTROL – PAIN

The pain requirements of patients prior to sustaining a stroke should not be overlooked particularly when there are communication difficulties following the stroke. The direct result of the stroke may cause several pain problems. Around 30 percent of stroke patients experience poststroke headache. Up to 70 percent of such patients experience 'shoulder–hand syndrome', the upper limb has reduced movement and therefore becomes stiff, this in turn leads to hand swelling and the hand appears blue, clammy, and hot. A neuropathic central poststroke pain occurs in 8 percent of patients. It is not particularly responsive to opioids but it shows some response to amitriptyline.[13*] Another study of central pain showed lamotrigine to be effective.[14*]

PSYCHOSOCIAL CARE – DEPRESSION AND ANXIETY

Poststroke depression is reported as a common occurrence. In a Scandinavian study, minor depression was diagnosed in 14 percent of patients and 26 percent of the patients experienced major depression. The only independent predictors of poststroke depression were found to be a premorbid history of depression and dependency in daily living following stroke. Relatives caring for such patients in the community report that they would have liked more support and those stroke patients who died in hospital are reported as requiring more psychological support in one study.[4] This would suggest a role for palliative care in supporting these patients and their families.

ADVANCE PLANNING/END-OF-LIFE CARE – FEEDING

The dysphagia which necessitates artificial feeding of stroke patients is in itself a poor prognostic indicator.[15] Whether to provide artificial nutrition to patients with such a poor prognosis is an important consideration. Following a stroke, 30 percent of conscious patients have an impaired swallow on the day after the stroke, 16 percent at 1 week and 2 percent at 1 month.[16] Poor nutrition may predispose to muscle weakness and fatigue which will impair rehabilitation, it will also predispose the patient to pressure area sores. Hence, persistent dysphagia may require the insertion of a nasogastric tube or percutaneous gastrostomy. The relative risks and benefits of these two procedures were looked at in a randomized controlled trial. Greater mortality and decreased nutritional intake was demonstrated in the nasogastric group. However, the median survival rate post-insertion of a percutaneous gastrostomy was found to be only 53 days. The International Stroke Trials Collaboration FOOD Trial data have now been published and recently reported that it cannot support the early parenteral feeding of people following a stroke.[17**] The input of specialists in palliative care with their experience of end-of-life decision making may be helpful as this issue engenders strong feelings among families and friends of stroke patients.[18]

NEURODEGENERATIVE DISEASES

Multiple sclerosis

Multiple sclerosis is the most common of the demyelinating diseases which share the pathological features of focal areas of degeneration of the myelin sheath that surrounds nervous tissue. It is the most common cause of chronic disability in young adults. The process of demyelination is associated with inflammation and then gliosis. Evidence suggests this is a T-cell–mediated inflammatory process experienced by genetically susceptible people in the presence of particular environmental factors. The pathological plaques are discrete areas of scarring which are scattered throughout the central nervous system in different locations at different times. This leads to a wide range of clinical signs and symptoms.[19] It particularly affects the brain stem, optic nerves, and spinal cord. In Britain and northern Europe its prevalence is about 80–100 per 1 000 000 population. It is roughly twice as common in females as in males and the mean age of onset is around 30 years, with a range of 20–50 years. Multiple sclerosis has a variable disease trajectory. About 25 percent of people affected have relatively benign disease with mild exacerbations from which they make a complete recovery. Unfortunately, 10 percent of patients develop a rapidly progressive (primary) illness which leads to severe disability relatively quickly.[20]

In most patients the disease follows a relapsing and remitting course with variable degrees of recovery, at least initially, before a progressive (secondary) deterioration ensues; 80–90 percent of people will convert to secondary progressive multiple sclerosis within 20–25 years of diagnosis. The median survival from onset is 28 years for men and 33 years for women, with overall life expectancy being 7 years less than would be expected; death is most often as a result of infection. During this time an ever increasing burden of disability and symptoms is accrued with the inevitable impact on the person's quality of life.

There is no cure for multiple sclerosis at present. Acute relapses often respond to corticosteroids, most often administered intravenously for 3–5 days. Trials have shown immunomodulating therapies interferon-β1a, interferon-β1b and glatiramer acetate reduce both the frequency of acute attacks and the accumulations of plaques within the central nervous system .[21*]

Amyotrophic lateral sclerosis

This is the most common degenerative disorder of the motor neuron system in adults with 1.5–2/100 000 per year. Most people are diagnosed after the age of 40 with a mean age of onset around the late fifties.[22] For most the cause is unknown. There is a family history in only 5 percent of cases, of these 20 percent have a gene mutation of the superoxide dismutase (*SOD1*) gene on chromosome 21. Amyotrophic lateral sclerosis is characterized by involvement of upper and lower motor neurons. This manifests itself clinically with fasciculations and slowly progressive paresis of the voluntary muscles coupled with hyperreflexia and spasticity (see also Box 96.1).

Box 96.1 Symptoms of amyotrophic lateral sclerosis

Direct symptoms

- Atrophy ± weakness
- Spasticity
- Dyspnea
- Dysphagia
- Dysarthria

Indirect symptoms

- Sleep disturbance
- Thick secretions
- Drooling
- Constipation
- Pain

The sensory system is normal with sparing of eye movements and sphincters in the vast majority of patients. The average prognosis is 3–4 years although there is considerable variation. About 20–30 percent of patients present with bulbar symptoms of slurred speech and difficulty in swallowing.[23] Ten percent of patients live more than 10 years. Cognitive function is usually intact although dementia is present in around 2 percent of patients. There are no disease-specific drug treatments for ALS. Riluzole, an antiglutamate agent has been shown to prolong life by approximately 3 months.[24*]

Parkinson disease

Parkinson disease is a progressive neurodegenerative disorder which results from the loss of pigmented neurons from the substantia nigra. The idiopathic form is assumed when no cause of symptomatic parkinsonism is found such as the side effects of neuroleptic medication. The diagnosis is made on the symptoms of bradykinesia occurring with cogwheel rigidity with or without a resting, pill-rolling tremor[25] in the presence of positive response to levodopa or other dopaminergic therapies. The dyskinesias may respond to levodopa/dopaminergic therapies, but these in themselves cause problems in the longer term. A number of additional symptoms of Parkinson disease cannot be relieved by the drug therapies (Box 96.2).

Younger patients do better than older patients with an expectation of a prognosis of 20–30 years when their motor manifestations are controlled by drugs and neurosurgical procedures such as deep brain stimulation. In particular, older patients may, 5–10 years following diagnosis, begin to experience more and more difficulty with problems that are not only related to drug-induced on–off periods but also to neuropsychiatric problems.[26] Hallucinations and cognitive decline often herald the onset of diffuse Lewy body disease or dementia with Lewy bodies.[27] Depression is more common

Box 96.2 Parkinson disease

Bradykinesia ± tremor/rigidity

Additional features

- Bladder symptoms – hypomimia (mask-like face)
- Constipation – seborrhea
- Pain – shuffling gait
- Cognitive disturbance – freezing episodes
- Psychiatric problems – bulbar symptoms
- Postural imbalance – stooped posture

---

in older patients and complicates at least 20 percent of patients, rising with increasing age of onset.

Huntington disease

This is a genetically transmitted neurodegenerative disease which affects movement, personality and cognitive ability. It is an autosomal dominant condition which affects female and male patients equally. The prevalence of the disorder is 5–10 per 100 000 population.[28] There is a juvenile variant which may present before the age of 20 but most people present with the condition around the age of 40. Voluntary and involuntary movement deteriorates during the disease trajectory. Cognitive impairment is usually apparent at the onset of the choreoathetotic movements which occur. These predominantly affect the upper limbs and may also involve the mouth and face. The orofacial movements may interfere with mastication, speech, and swallowing. While the cognitive features appear with the movement disorder, mood disturbance often predates this. The most common mental disturbances are depression, mania, or hypomania. There may also be violent outbursts of antisocial behavior or frank psychosis. Predictive testing of risk individuals as well as prenatal screening is now possible. This is because of the discovery in 1993 of the Huntington mutation on gene IT-15 of chromosome 4.[29] Interestingly, as little as 18 percent of at-risk individuals have participated in predictive testing programs.[30]

Palliative care challenges

SYMPTOM CONTROL

Pain

Around 50 percent of people with multiple sclerosis[31] and up to 75 percent of people with ALS[2] experience pain, although there is no evidence of sensory involvement in the ALS patients.[32] Musculoskeletal pain is often overlooked in patients with neurodegenerative disorders. It may be the result of immobility in combination with muscle weakness. It is also the result of spasticity, gait disturbance, and poor sitting posture. Joint pain may be exacerbated by the loss of a protective muscle sheath or abnormal tone. Appropriate involvement of physiotherapists and occupational therapists in conjunction with nonsteroidal anti-inflammatory drugs (NSAIDs) can be beneficial. In immobile patients there may be pain secondary to 'skin pressure', continuous pressure on pressure areas. The pain caused if these areas actually break-down is very difficult to control.

Neuropathic pain is described by patients with both ALS and multiple sclerosis; it is described as being burning or shooting in nature. Patients often also describe altered sensations particularly in the lower limbs. These can be likened to insects crawling over the skin. This is as a result of nerve damage and the pain responds to neuropathic agents such as amitriptyline and newer agents such as gabapentin or pregabalin. A recent paper concluded that the combination of an opioid and gabapentin is more effective than either agent on its own.[33**] The use of nonpharmacological interventions such as transcutaneous electrical nerve stimulation has been reported to be of benefit on occasions. In multiple sclerosis the formation of plaques on sensory nerves can lead to pseudoradicular pain syndromes such as facial pain which mimics the condition *tic douloureux*. Many patients experience more than one if not all of these different pain problems and the involvement of a palliative care specialist who is experienced in taking a complete and holistic pain history can be appropriate and helpful.

Spasticity

All the neurodegenerative disorders can result in muscle cramps, spasms, and spasticity. It is however, the most typical and debilitating of MS symptoms. It reflects the degree of corticospinal tract involvement. Spasticity increases fatigue and immobility. Care must be taken in treating spasticity in a person who is still able to weight bear and therefore carry out activities such as transferring. The extensor spasm they are experiencing in their lower limbs may be the reason they can still carry out these activities as it compensates for the loss of strength. Spasticity is also associated with flexor spasm triggered by touch or movement. These can be extremely painful. Any number of preventable stressors such as cold, a full bladder, stretching, over exertion, and infection can initiate spasms and should be avoided.[34] Simple measures such as leg warmers and positioning should be tried but almost inevitably pharmacological management becomes essential.

Oral baclofen, diazepam, dantrolene and tizanidine are all agents that are equally effective at controlling muscle spasm.[35***] They all have different mechanisms of action and so can be alternated or combined and titrated against clinical effect. All these drugs can be sedating and cause weakness. Baclofen is associated more often with nausea, benzodiazepines with delirium and dantrolene with hepatitis. If only a few muscle groups are affected then local injection of botulinum toxin may be helpful but only in combination with adequate post-injection physiotherapy. Baclofen can be delivered continuously to severely affected individuals via an intrathecal pump situated subcutaneously. Palliative care is characterized by the systematic and meticulous monitoring of symptoms and their pharmacological management. This expertise could be of benefit to this group of patients.

SECRETIONS

Salivary drooling

The inability to swallow one's own saliva may be the result of a specific bulbar palsy such as occurs most commonly in ALS or it may just be the product of a generally deteriorating swallow as may occur with any of the neurodegenerative disorders. Whatever the etiology, it is a very embarrassing symptom which causes local soreness and excoriation. Drug therapy is aimed at reducing the amount of saliva produced.

Anticholinergic medication such as hyoscine hydrobromide administered either sublingually or transdermally may be of benefit. Other medications such as glycopyrronium bromide or amitriptyline can also be useful. Radiotherapy has been tried in refractory cases and botulinum B toxin injections into the salivary glands are being researched.[36]

Thick mucous secretions

This is a problem most often found in patients with ALS. They produce large amounts of viscid secretions which they are unable to cough up because of their reduced respiratory effort. This can cause distress and airway compromise if they become retained in the pharynx. It is particularly of concern if there is the possibility of the use of noninvasive positive pressure ventilation (NIPPV) as these secretions may be forced back into the lungs during this therapy and cause an increase risk of chest infection. The use of humidified air is sometimes helpful in loosening secretions. Anticholinergic drugs may reduce the amount of such secretions but in turn make them more tenacious. Mucolytic enzymes such as acetylcysteine have been tried via the nebulized or oral route. There may have to be very careful balancing between the control of salivary drooling and thick pharyngeal mucous secretions in patients with ALS.

CONSTIPATION

Bowel and bladder involvement in the late stages of neurodegenerative disorders is inevitable. It is the result of poor gut mobility. Constipation may also be exacerbated by poor dietary intake, limited mobility and decreased intake of fluid for fear of urinary incontinence. Bulking agents should be avoided, the use of stool softening aperients is important. Movicol is preferable to lactulose as it is iso-osmolar and does not cause the same degree of associated flatulence and bloating. Stimulants such as senna or sodium picosulfate may be required. Rigorous bowel management including occasional suppositories is crucial to avoid impaction. Enemata and manual evacuation become necessary otherwise and in extreme circumstances the formation of a colostomy has been necessary.

BREATHLESSNESS

See section on noninvasive positive pressure ventilation below.

PSYCHOSOCIAL CARE

Advance planning – parenteral feeding

Most patients with a neurodegenerative disorder will have a functioning gastrointestinal tract but they will also develop a degree of dysphagia. One study indicated up to 87 percent of people with ALS will have a swallowing deficit of some severity.[32] The problems with initiating or coordinating a swallow are often compounded by the presence of excessive saliva, weight loss, and a lack of interest in food. Fear of choking can also contribute to decreased oral intake. It is important that regular assessment of both oral intake and swallow function are undertaken. This should be done by a multiprofessional team involving speech and language therapists, dietetic specialists, and occupational therapists, and there is also a role for a palliative care specialist.

The goal is to maintain nutrition by the oral route for as long as possible. This period may be extended by appropriate eating aids, neck positioning, and oral food supplements. However it is important to be aware of the optimal timing for any placement of a tube to initiate parenteral feeding.[37] If a patient becomes too emaciated and weak they are less able to withstand the procedure to place a permanent feeding tube. The deterioration of respiratory function, which most commonly accompanies ALS, is also a major factor because if a person's respiratory function has deteriorated too far they will not be able to tolerate the placement of a percutaneous endoscopic gastrostomy and the necessary anesthetic. They will have to then undergo a radiologically inserted gastrostomy instead. Those patients who are too weak for either procedure will only be able to tolerate the insertion of a nasogastric tube. They may indeed be too unwell and weak for any parenteral feeding to be appropriate. There are obvious ethical dilemmas involved in this decision making .[38] The provision of nutrition to a loved one is a fundamental part of providing care for that person and the inability to do this can have a very distressing effect on the families of these patients.[39]

Whereas it may be obvious with a patient who has entered the terminal phase of their illness that to proceed with artificial hydration and nutrition is inappropriate, it is a more difficult decision in those with only a limited prognosis. A number of factors should be considered apart from the individual's ability to undergo a placement procedure. There are practical issues about the community and carer support that may or may not be available. There may be strong cultural or other beliefs of the patient and their family to consider. Of paramount importance is whether the benefits of starting feeding outweigh the anticipated burdens. These include the likelihood of any complications either of the procedure or post-procedure such as pain, hemorrhage, or an infection. The possibility that the patient is at risk of regurgitation and aspiration or indeed the probable prolongation of prognosis, which is not universally or always regarded by a patient as an advantage. Advance planning and discussion with or without the writing of a formal advance directive ensures that the wishes of the patient are known. (See Chapter 109 for further details of advance directives.) This further ensures that any decision is made in the patient's best interests as it can take into account the patient's own assessment of their quality of life, wellbeing, and spiritual or religious beliefs. A specialist in palliative care has appropriate experience to be able to helpfully facilitate this highly individual set of considerations.

Noninvasive positive pressure ventilation

Neurodegenerative disorders often lead to hypoventilation, initially experienced at night. This is a particular feature of

ALS. Symptoms of hypoventilation have been successfully treated with NIPPV. These include daytime fatigue and somnolence, depression and anxiety, morning headache, reduced appetite and weight loss, disturbed sleep, and nightmares.[40] Dyspnea is a problem for up to 85 percent of patients with ALS,[32] and NIPPV has been shown to alleviate these symptoms successfully. It has also been shown to extend a person's prognosis. This extended prognosis is, however, in the face of continuing and ongoing disability. Significantly, carer burden has also been shown to increase. Patients with predominantly bulbar ALS are less likely to benefit from NIPPV. One study showed that two-thirds of patients unable to tolerate NIPPV had bulbar symptoms and were less likely to be able to protect their airway.[41] It is important that people embarking on the use of NIPPV know that the symptoms of breathlessness can also be palliated by the use of benzodiazepines[42] and opioid drugs[43] and that NIPPV does not preclude the use of these. A discussion should take place detailing the progressive nature of the respiratory muscle weakness and also the tendency to ventilator dependence. It is best practice to refer all these patients using NIPPV to local community palliative care teams for local support as this inevitable deterioration takes place. The involvement of a palliative care healthcare professional in the whole of the discussion and decision-making process is therefore very important.

Key learning points

- It would appear there is a role for the needs-focused approach of palliative care in the management of people affected by neurodegenerative disorders.

- There is a need for symptom control, psychosocial support, and help with advance planning and end-of-life decision making.

- There are particular challenges working with people who have an unpredictable disease course of uncertain length.

- There will be learning needs for palliative care team members.

- These patients are prone to fatigue and communication difficulties, which affects their ability to participate in psychosocial support and counseling.

- Cognitive complications of neurodegenerative disorders raise issues around competency in decision making and advance planning.

- Finally, there are particular treatment options and decisions such as percutaneous endoscopic gastrostomy feeding and starting NIPPV. These require a specific multiprofessional assessment, which should usefully include specialist palliative care.

End-stage congestive heart failure

EDWARD R DUNCAN, AJAY M SHAH, MARK T KEARNEY

INTRODUCTION

Most chronic cardiac disorders result in the common end-point of left, right or biventricular dysfunction. This is true whether or not the root cause is valvular, ischemic, congenital, or metabolic. Therefore this chapter will focus on the management of end-stage heart failure.

Traditionally palliative care specialists have concentrated their efforts on patients with malignant disease. However, it is now well established that patients with end-stage cardiac disease have a similar prognosis and symptoms as those with cancer. Moreover, there is growing evidence supporting the need for increased involvement of palliative care services in the management of these patients. Despite this, only a small minority of patients who die of cardiac failure received palliative care support compared with the majority of those with neoplastic disease. Consonant with this, heart failure patients make up only 1–2 percent of total hospice admissions in the UK.[1]

The prevalence of terminal chronic heart failure is rising due to the aging population and improved survival of patients with occlusive coronary artery disease. This has helped focus the attention of physicians across specialities on the care needs of this large group of patients. Greater input from palliative medicine specialists will be necessary if these needs are to be met.

DEFINITION AND CLASSIFICATION

The term 'congestive heart failure' (CHF) describes the complex syndrome of signs and symptoms resulting from ventricular dysfunction and the ensuing reduced cardiac output. The stages of heart failure are most commonly defined using the New York Heart Association (NYHA) criteria. However, another staging model has been proposed by the American Heart Association (AHA; Table 97.1). This better reflects the underlying pathophysiology and progressive

Table 97.1 *Comparison of the models proposed by the New York Heart Association and the American Heart Association for the staging of heart failure*

New York Heart Association	NYHA class I: patients with cardiac disease but with unlimited physical activity	NYHA class II: patients with cardiac disease resulting in slight limitation of physical activity	NYHA class III: patients with cardiac disease resulting in marked limitation of physical activity. Mild activity causes symptoms	NYHA class IV: patients with cardiac disease and are unable to do any physical activity without symptoms. May be symptomatic at rest
American Heart Association	Stage A: patients at high risk of heart failure but without cardiac dysfunction	Stage B: patients with structural heart disease '*in situ*' but no symptoms	Stage C: patients with structural heart disease with previous or current symptoms	Stage D: patients with refractory symptoms that require special intervention such as hospice care or positive inotropes

nature of the disease and is analogous to models of neoplastic disease.

CLINICAL COURSE AND EPIDEMIOLOGY

Left ventricular dysfunction is often a progressive problem. An insult to the myocardium, such as an ischemic event, can result in a gradual decline toward ventricular failure irrespective of etiology. Only rarely does left ventricular function actually improve, e.g. after valve replacement surgery. In response to insults such as increased pressure load or loss of muscle mass from myocardial infarction, the ventricle undergoes 'remodeling', whereby both structural and biochemical changes occur. Activation of the sympathetic nervous system and the renin–angiotensin–aldosterone axis are initially probably adaptive, but in the long-term cause progressive worsening of cardiac function and heart failure through multiple mechanisms.[2] Medical therapies (such as angiotensin converting enzyme [ACE] inhibitors) can slow this process, but eventually worsening left ventricular function leads to the onset of symptoms. The common etiologies of cardiac failure include ischemic heart disease (~70 percent), hypertensive heart disease (~15 percent) and valvular heart disease (~5 percent).[3] Cardiomyopathies and congenital heart disease are less common but remain significant and affect a younger population. Nutritional deficiencies (e.g. beri-beri) contribute to cardiac failure in the developing world.

The prevalence of left ventricular dysfunction is increasing as improved management of myocardial infarction and ischemic heart disease prolong survival.[4] Medical therapies for cardiac failure have also improved prognosis but the underlying pathological process is usually only delayed and not reversed. In 2000, the incidence of first admission to hospital with a primary diagnosis of cardiac failure was 1–2 per 1000 population,[5] with a prevalence of up to 2 percent among a northern European population. Heart failure is also much more common in older people. In the UK, the incidence increases in an exponential fashion with age from 1.7 per 1000 population in those aged 55–64 to 16.8 per 1000 in those aged >85.[6] Older people with cardiac failure often have multiple associated comorbidities, e.g. reduced mobility, cognitive impairment, or depression. Physicians must therefore also be adept at managing these issues.

PROGNOSIS AND MODE OF DEATH

Historically, palliative medicine developed within hospices to care for those patients who were terminally ill with cancer. It is now argued that its remit be extended, as studies show that heart failure is associated with symptoms and a prognosis as poor as the majority of soft tissue tumors.[7] Indeed, 1-year mortality following a first admission to hospital with a diagnosis of heart failure remains greater than 25 percent.[8] This is despite evidence that for the first time demonstrates a fall in annual mortality rates. A large Swedish study showed a reduction in 1-year mortality of up to 10 percent between 1993 and 2000. However, this improvement was seen in young patients (age <64) who only represented 8 percent of the study cohort. Annual mortality in older patients (age >75) fell by just 3 percent. These reductions in mortality coincided with widespread introduction of ACE inhibitors in the 1990s as well as improved management of underlying disease processes. Further improvement in prognosis after 2000 would be expected due to increased use of β blockers and other interventions. However, the overall impact on heart failure deaths has been relatively small and the prognosis in chronic heart failure remains poor.

A barrier to the integration of palliative care services in the management of terminal heart failure is prognosis. Many cardiologists feel it is important to be able to recognize when a patient is entering their last months of life before thinking about referral to palliative care services. This is extremely difficult in those with heart failure. The course of this disease is erratic with long periods of chronic illness and decline interspersed with acute and severe exacerbations from which patients can make a surprising recovery (Fig. 97.1). Up to half of heart failure patients die suddenly and unexpectedly[9]
Figure 97.1   *Life trajectory of a patient with heart failure. Following an initial insult to the myocardium, patients experience a chronic decline in function with acute decompensations that require hospitalization. Death is often sudden and unexpected. Both prognosis and the rate of decline have improved with advances in heart failure management.*

and these are often those who are the least symptomatic. Most deaths are from cardiovascular causes (intractable heart failure, myocardial infarction). Only a minority (~10 percent) die from noncardiovascular causes.[10]

Multiple studies have shown factors that predict high or low mortality among groups of patients with CHF. Unfortunately they are poor predictors of death for each individual patient. These factors include low ejection fraction,[11] functional capacity (whether measured by NYHA class or 6-minute walk test),[12] elevated B-type natriuretic peptide,[13] intolerance of ACE inhibitors,[14] or worsening renal function.[12] At present it is necessary to use such indicators of prognosis in advanced heart failure, however they remain inadequate. The Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatment (SUPPORT) demonstrated the failings of guidelines for determining prognosis in CHF. Guidelines based on those supplied by the National Hospice Organization in the USA failed to identify CHF patients with a prognosis of less than 6 months. Narrowing the inclusion criteria dramatically cut sensitivity excluding many that did subsequently die.[15] The current AHA guidelines recommend hospice care to ease patient suffering as an 'end-of-life consideration' but do not advise when to implement it.[16] The European Society of Cardiology recommends palliation in persistent NYHA class IV heart failure despite optimum therapy where no long-term treatment is available.[17]

Once a strategy for determining the terminal stages of heart failure has been found, it will be easier to ensure timely palliative care input and a move away from invasive treatments. Some centers are exploring combined care, where palliative medicine expertise is combined with standard cardiology care in multidisciplinary clinics. Such a strategy does not require that a point in time be identified where the patient 'becomes palliative'.

SYMPTOMS

Heart failure and malignant conditions share many features including distressing symptoms, poor quality of life, and gradual debilitation. Palliative care physicians are experienced at treating these symptoms albeit in different circumstances. Interestingly, the level of symptoms experienced by patients is not proportional to their degree of ventricular dysfunction, and patients with extremely poor ventricular function can remain remarkably asymptomatic for a long period of time.

Characteristic symptoms of CHF include shortness of breath, fatigue, and ankle swelling, but others include depression, poor quality sleep, confusion, short-term memory loss, dizziness, and nausea.[18] As would be expected, the most commonly reported symptom is breathlessness, present in up to 90 percent of patients.[19] Breathlessness presents either on exertion or at rest, as orthopnea, or nocturnal dyspnea.

Fatigue is also prevalent (69 percent) and exaggerated by ankle edema, weight gain/loss, and depression. Depression is very common and yet underdiagnosed and undertreated in those with cardiac failure. Up to 48 percent of nonhospitalized patients with NYHA class II or worse are depressed (Beck Depression Inventory score >10) and rates of major depression correspond to those seen in patients with other chronic diseases.[20] Depression has also been linked to increased mortality, increased rates of rehospitalization and worsening quality of life in those with heart failure.[21] Despite this only 7 percent of patients receive antidepressants.[20]

Many patients also experience pain in the last 6 months of life (up to 75 percent).[19] Chest and joint pains have been reported as common, but often the cause of pain is not specified. In elderly patients pain may relate to comorbidity rather than to left ventricular failure itself. SUPPORT reported that severe pain in the last 3 days of life occurs at comparable frequencies in heart failure and a number of cancers.[22]

Cardiac cachexia is a well-recognized complication of CHF arising in approximately 10–15 percent of patients with CHF.[23,24] It is characterized by a poor prognosis and a severe wasting process that particularly affects skeletal muscle and promotes exercise intolerance with marked breathlessness and fatigue at low workloads.[25]

MEDICAL MANAGEMENT

Patients with severe and end-stage heart failure benefit from both standard medical therapy and palliative care, and both of these approaches should be integrated and continued until the terminal stages of the illness. Early discontinuation of regular medical treatments is not recommended due to difficulties in predicting death, and because these treatments are proved to reduce symptoms and increase time out of hospital.

A number of drug therapies are recommended for routine use by the AHA in most patients with left ventricular dysfunction. These include an ACE inhibitor, a β adrenergic blocker, and a diuretic.[16***] Large trials have demonstrated reduced hospitalization rates and clear prognostic benefits of ACE inhibitors,[14**] β blockers[26**] and the aldosterone antagonist spironolactone.[14,26,27**] Both ACE inhibitors and diuretics maintain euvolemia, thus improving symptoms, especially breathlessness and weight gain. β Blockers provide prognostic and symptomatic benefit.[28] This benefit is seen in older patients[29] and in all classes of heart failure.[30] There is however a lack of strong evidence to guide prescription of β blockers in end-stage heart failure. Anecdotally it has been described that they are poorly tolerated and make patients feel worse in the short term. Where patients have symptoms attributable to β blockers, tapering down the dose or stopping the drug may be appropriate. More recently angiotensin receptor blocking agents have been demonstrated to reduce hospital admissions and

improve prognosis when used both alone and in combination with ACE inhibitors.[31**]

Among patients with refractory heart failure (AHA stage D) use of diuretic infusions or continuous outpatient support with inotropes may achieve hospital discharge in those patients proving to be inotrope-dependent in hospital.[32*] Furthermore, there is evidence supporting use of intermittent inotropic support in an outpatient population for relief of refractory heart failure symptoms.[33] However, concerns have been raised that despite beneficial effects on symptoms, the outpatient use of inotropes may be associated with a shortened life expectancy.[34,35] This risk may prove to be acceptable to highly symptomatic patients with end-stage heart failure. It must also be noted that most of the evidence regarding use of outpatient inotropic support is anecdotal or gleaned from small studies and that further research is required in this area.

Cardiac surgery for ventricular dysfunction in the form of cardiac transplantation is an established treatment for end-stage heart failure but the majority of patients are not candidates due to age, other comorbidity or shortage of donor organs. An increasing number of patients with severe cardiac dysfunction and severe symptoms are now receiving electrophysiological devices in the form of implanted cardiac defibrillators, biventricular pacemakers or devices that combine both functions.

Cardiac damage results in dyssynchronous and inefficient cardiac contraction. Biventricular pacing resynchronizes the left and right ventricles thereby increasing cardiac output. Cardiac resynchronization improves exercise tolerance, quality of life and reduces hospitalization.[36**] In terminally ill patients, these devices should be treated like any simpler pacemaker implant. Defibrillator implantation improves prognosis in those with significant left ventricular impairment (ejection fraction <30 percent) after myocardial infarction.[37**] Furthermore the combination of biventricular pacing and defibrillator capability in a single device has additional prognostic benefits when compared to biventricular pacing alone in NYHA class III/IV heart failure.[38**] Concerns have however been raised over the psychological impact of defibrillator insertion, and evidence exists that suggests increased levels of anxiety and depression in this group of patients compared to the general cardiac population.[39] It is likely that the presence of a defibrillator in a patient with end-stage disease will also have a significant and detrimental psychological impact. It is therefore essential for patients to be adequately advised prior to defibrillator implantation of the indications, contraindications, and consequences of this procedure. Furthermore, situations where the device might be turned off should be discussed at this time. This will help avoid surprises near the end of life. Implantable defibrillators are becoming increasingly common and the results of recent trials suggest this trend will continue. Physicians working in the hospice setting with heart failure patients will need to be aware of these devices and their management (see Box 97.1).

Box 97.1 Implantable defibrillators: key practical points

- The use of implantable defibrillators is increasing

- Those touching a patient with an implantable defibrillator at the time of a shock will not receive a shock

- Defibrillators can be activated or deactivated at the bedside using a programming device. As defibrillators become increasingly common, more hospitals outside major centers will become equipped to program them. Alternatively, representatives of the manufacturer can be contacted. Defibrillators must be deactivated before removal

- Patients with implantable defibrillators require psychological support before and after insertion. The device can be misperceived as life saving and acts as a focus of attention for patients with end-stage disease and their relatives

- There is little published evidence regarding management of defibrillator devices in those patients entering terminal stages of their illness where defibrillation may be unacceptable

- The situations when deactivation of a device would be appropriate must be discussed clearly with the patient when the device is implanted

---

PALLIATIVE CARE IN TERMINAL CARDIAC FAILURE

A consensus conference convened in the USA in 2003 to define the then current state of 'palliative and supportive care in advanced heart failure' acknowledged that symptom palliation in advanced heart failure had simply not been studied.[40***] There is a dearth of data supporting the use of treatments that are extremely well established in palliative care in other disease states.

This is emphasized in the management of breathlessness in cardiac failure. Despite opioids being of irrefutable value in the treatment of acute left ventricular failure and malignancy, there is only anecdotal evidence supporting their use in chronic heart failure. There are no large trial data to reinforce this.[40,41] Further beneficial effects of opioids could include relief of anxiety and pain. There is also no clear role for domiciliary oxygen therapy in end-stage heart failure, as no conclusive evidence exists showing oxygen therapy relieves the sensation of breathlessness, despite reducing hypoxia.[42***]

The experience of palliative care physicians in other disease states must therefore be applied in cardiac failure to

manage the many familiar symptoms until the necessary research has been completed. Patients with cardiac failure are poorly informed about the course of their illness and the purpose of their medications. They often mistake symptoms of their underlying heart failure for side effects of their medication.[18] This occurs because of poor education of patients at and following diagnosis, compounded by barriers to good communication such as fatigue, hypoxia, and confusion. Patients need and want to be better informed regarding their condition and management.[43] The evolution of specialist multidisciplinary heart failure services, in particular the arrival of specialist heart failure nurses, should start to address this, and may help to integrate specialist cardiology and palliative services.

Patients with severe heart failure report having to rely heavily on family and friends for help performing activities of daily living. This provokes feelings of 'being a burden'. Poor mobility and an inability to leave the house promote isolation. Qualitative studies suggest the majority of patients with severe heart failure have thought about death and find it difficult to discuss with those close to them.[43] Access to psychological support, counseling and social services therefore could be of great benefit.

'Best practice' in the terminal stages of heart failure remains unclear. The SUPPORT study gives insight into current practice and highlights how palliative care input is needed. Patients with CHF are more likely to die in hospital than those with a malignancy,[22] with only 3 percent dying in a hospice despite almost 50 percent preferring comfort care rather than life-extending care. Heart failure patients also experienced higher incidence of invasive life-sustaining treatments (including cardiopulmonary resuscitation, ventilation, and nasogastric feeding) during their last 3 days than those patients with lung or colon cancer.[44] Furthermore, those who received 'do not resuscitate' orders take longer to do so than those with cancer and often continue to receive invasive treatments.

Among patients with CHF admitted to hospital in NYHA Class IV it is reported that only 25 percent discussed their resuscitation preference with a physician[45] despite the majority being conscious and able to communicate during their last days. Around 25 percent did not want to be resuscitated in the event of a cardiac arrest. The SUPPORT study emphasizes the need for palliation in CHF patients, that the patients themselves are aware of their poor prognosis and that a large number would welcome care aimed specifically at maintaining comfort. The problem of predicting death in CHF remains.

CONCLUSIONS

Patients with severe cardiac failure represent a highly symptomatic population with a poor overall prognosis who would benefit from palliative care support. Further research is needed to validate existing palliative treatments for use in cardiac disease, but this should not stop these patients receiving appropriate care. Greater communication is required between the specialities involved to ensure adequate and timely integration of palliative care services into the management of these patients.

Key learning points

- The incidence of congestive cardiac failure is increasing. It is predominantly a disease of older people.

- The symptoms and prognosis of patients with cardiac failure are similar to those of patients with terminal malignant disease.

- There is a lack of research into symptom alleviation in terminal cardiac disease. The experience of palliative care specialists in other disease states must be used at present.

- Breathlessness, fatigue, and pain are the most commonly reported symptoms. Depression is also common.

- Routine medical therapy (including ACE inhibitors, β blockers and diuretics) has a role in reducing symptoms and hospital admissions.

- The incidence of implantable defibrillators is increasing.

- Congestive cardiac failure patients need to be better informed regarding their disease and their prognosis, and thus be more capable of making end-of-life decisions.

Palliative care for children

FINELLA CRAIG, ANN GOLDMAN

INTRODUCTION

The death of a child is one of the biggest tragedies that can happen to a family. In the developed world, the plans and expectations of a parent barely acknowledge the possibility that their child might die. Society has become unfamiliar and uncomfortable with death in childhood, leaving many, including professionals, ill equipped, both emotionally and by a lack of experience, to provide support during the child's illness and after death. Consequently, many families will feel alone and unsupported while experiencing a grief and distress that is intense and longlasting.

Children and families need experienced professionals to support and guide them through their child's illness and death and through the bereavement process. In the UK, care is often shared between the primary care team, based in the local community (which includes the family doctor, children's community nurses, and the local hospital) and disease-specific specialist teams (e.g. oncology, neurology teams) based at a tertiary hospital. Although the management of symptoms can be similar in adults and children, the palliative journey and the difficulties encountered are often very different.

In this chapter we have drawn on our experience to emphasize some of the specific issues of pediatric palliative care that are relevant to children in any area of the world. We hope professionals will find this a useful tool when working with children and families.

CHILDREN NEEDING PALLIATIVE CARE

Children with life-limiting illness can be considered in four broad groups, each with different palliative care needs:[1]

- Life-threatening conditions where curative treatment may be possible but can fail. Palliative care is needed in times of prognostic uncertainty or when cure becomes impossible. Cancer is an example.
- Conditions where premature death is inevitable but where life can be prolonged by periods of intensive treatment. Cystic fibrosis and acquired immune deficiency syndrome (AIDS) fit this pattern.
- Progressive conditions where treatment is entirely palliative and may extend over many years. Neurodegenerative diseases and many inborn errors of metabolism are examples.
- Irreversible but nonprogressive conditions causing severe disability, such as severe cerebral palsy. These can lead to a susceptibility to health complications and the likelihood of premature death.

The range of life-limiting conditions that affect children is wide, with many conditions rare, specific to the pediatric population and with a protracted course. The number of children requiring palliative care is relatively small. In the UK, the annual mortality for children and adolescents (0–19 years) with life-limiting conditions is 1.5–1.9 per 10 000 and the prevalence of children requiring palliative care is 12–17 per 10 000.[1] In a health district with a child population of 50 000, in any 1 year there will be 60–85 children known to have a life-limiting condition, of whom 8 are likely to die: 3 from cancer, 2 from heart disease, and 3 from other conditions.[1] With such relatively small numbers, pediatric palliative care is unlikely to be a priority when there are limited resources available, yet it can be difficult for any one professional to develop adequate experience and expertise.

PROVIDING SERVICES FOR THE FAMILY

An essential requirement of palliative care is that children receive good care for their underlying condition as well as expert palliative care support, wherever they choose to be. Most children and families prefer to spend as much time as possible at home and it is essential that the primary healthcare team be actively involved in care provision. Most primary healthcare teams, however, will have limited experience of caring for children with life-limiting illness and are unlikely to have any specialist knowledge of the underlying condition. In contrast, many families will become experts in the disease and its management.

Most children with palliative care needs have a number of different teams and professionals involved in their care. For example, a child with cerebral palsy may see a neurologist, a gastroenterologist, the local pediatrician, and family doctor, in addition to attending a child development clinic and having input from education and respite and social services. With each professional doing his or her own bit, there is a risk that care is poorly coordinated with no one person addressing the overall needs of the child and family. For some children care may focus around inpatient or outpatient hospital management. Families may build close relationships with hospital staff, placing considerable trust in a few professionals with experience in their child's particular disorder and questioning the advice of others. It is easy for the primary healthcare team to feel superfluous and marginalized, making it difficult to define their role. For other disorders, frequent hospital contact is unnecessary and there is no clearly identified specialist team. This can lead to the contrasting situation of a child with long-term illness being cared for at home by the family, with very little or no hospital input. Here the primary healthcare team may at times be overwhelmed and feel abandoned and unsupported by hospital services.

It is essential that for every child with a life-limiting diagnosis, one person from the group of professionals involved be identified to act as a key worker for the child and family, facilitating good communication and coordinating professional care. This ensures that all the family's needs are being met, without overlap or gaps developing, and minimizes the chance of any part of the team becoming marginalized. In most situations the professional who fulfills this role most effectively is a nurse.

ORGANIZATION OF SERVICES

Pediatric palliative care is an evolving specialty and still defining and researching the clinical care children need and the best way to provide services. Globally, there has been a steady increase in the number of specialist pediatric palliative care medical and nursing posts and in the number of children's hospices and community-based teams providing pediatric palliative care. However, no one model of care will fit all countries and all localities and care continues to be provided by a variety of professionals with different backgrounds and experiences. To ensure that children and families receive appropriate support it is essential that their needs be considered individually, in the context of the illness and of what is available locally.

One established model of pediatric palliative care is for children with cancer. Here the child's care is likely to be shared between a children's cancer center some distance from where they live, their local pediatric department, and care at home. Pediatric oncology outreach nurse specialists are usually hospital based but go out into the community. They offer expertise and experience in symptom management, as well as psychosocial support. When the child is at home they liaise closely with the local pediatric community nurses and primary healthcare teams, who in turn provide most of the ongoing medical and nursing care for the child. Second, children with other life-limiting diseases, especially those with a prolonged course where care is mainly home based, have traditionally had less well-structured provisions for care. However in the UK, an increasing number of districts have now developed multidisciplinary teams of local professionals (e.g. community pediatrician, nurse, social worker, and psychologist) who devote part of their time to providing palliative care support for these children.

A third model of care is that provided by the increasing number of children's hospices.[2,3] Here, care is provided by a multidisciplinary team of professionals with experience and expertise in pediatric palliative care, often working closely with local community and hospital based services. Unlike adult palliative care, relatively few children die in hospices, so a major role is in the provision of respite care, particularly for children with prolonged illnesses and considerable nursing needs. Children with cancer tend to be referred to hospices less frequently than those with non-malignant disease, perhaps because the need for respite care is not as great. In addition to providing respite care many children's hospices have developed considerable experience and expertise in palliative symptom management. Some have particular expertise in rare disorders, such as Batten disease and muscular dystrophy. A fourth model for palliative care is the specialist palliative care team based in a tertiary pediatric center. These teams see sufficient numbers of patients to develop considerable palliative care expertise and liaise closely with the primary healthcare team and local pediatric services providing most of the ongoing care.

As there is no single model of service provision, the service available to children and families remains, to some extent, dependent on geographical location and the underlying condition. Some children may not have access to any of the service models discussed above, whereas others may access a children's hospice, locally based palliative care services, and palliative care services coordinated from a tertiary center. It is essential that whatever the local set-up, the allocation of a key worker with a specific remit for palliative

care should ensure that families are neither neglected nor the focus of inappropriate or uncoordinated help. The key worker needs know what services are available locally, be able to access existing services and be able to identify and find ways to supplement gaps in service provision.

PALLIATIVE CARE NEEDS

For children dying from cancer the point at which treatment becomes symptom directed rather than curative is often clear – usually when all realistic attempts at curative treatment have been exhausted. For many other children with life-limiting diseases, however, there is no clear transition point. One of the big challenges of pediatric palliative care is to balance aggressive disease-specific management aiming to prolong life with symptom-directed management and quality of life. It is essential that palliative care is provided alongside good care of the underlying disease. Parents and professionals need to recognize which takes priority at different times, as this will influence their choices, for example in where they choose to be and how the symptoms should be managed.

Choosing the location of care

Ideally, families and children should be given a choice as to where they will be cared for, although limited resources may prohibit this. Many families will choose different places at different times, so it is important that they are given some flexibility to move between home, hospital, and hospice as they choose, without their care being compromised. If there is a possibility that their child may benefit from medical interventions, such as intravenous antibiotics, many families will choose to be in hospital. When death seems inevitable most families will choose to be at home.[4] Families need to be given a realistic idea of the support that is available and what to expect with regard to the needs of their child as they deteriorate, to enable them to make informed choices regarding where they want to be. Those who are at home must have access to advice and support 24 hours a day.

Parents bear a heavy responsibility for nursing and personal care of their child, especially when they are at home, and most take on the burdens willingly. However, while viewing parents as part of the caring team, it is important to acknowledge their need for support themselves, as well as the needs of siblings. The needs of the professionals caring for the child on a day-to-day should also be considered, as they may need access to specialist palliative care advice and support, especially if they have limited experience themselves.

Empowering children and families

The greatest fear for most parents is that their child will suffer distressing symptoms which neither they nor the professionals supporting them will be able to relieve. It is essential to provide families with detailed and honest information about their child's current symptoms and any others that may be anticipated, especially if there are concerns about the possibility of sudden distressing symptoms, such as convulsions, acute agitation, or bleeding. As death approaches parents will need and value further information, including what signs might suggest that death is imminent and the possible modes of death. Although professionals can sometimes be reluctant to undertake such frank discussion, families who know what to expect and have a clear plan of what to do are likely to feel more in control, and more confident and less anxious.

Advanced planning is a vital component of good palliative care. As well as discussing anticipated symptoms, an appropriate management plan should be drawn up for each possible scenario. Both the parents and the sick child need to take an active part in planning a practical and acceptable regimen of care. The team should ensure that appropriate drugs are prescribed and available, with suitable doses via accessible routes being calculated ahead of time so that medication can be given as soon as it is needed. If the child is at home, the medication doses and the route of administration should be such that the parents will be able to give the drugs themselves, although there should always be a professional available whom they can contact for additional support.

SYMPTOM MANAGEMENT

The symptoms experienced, the principles of symptom management and the drugs used in palliative care are often similar in pediatric and adult practice. The main differences lie in the disorders encountered, the assessment of symptoms, the routes of administration, and the doses used.

Many of the symptoms encountered in pediatric palliative care are common to a variety of illnesses. However when a child has a rare disorder it may be difficult to anticipate which particular problems will develop as the disease progresses. It is always worth seeking advice from professionals with disease-specific expertise as well as contacting parent help groups for rare illnesses as these may offer additional information and practical advice.

Patterns of symptoms

As in adult palliative care, the pattern of symptoms experienced is dependent on the underlying condition. Some children, such as those with cancer, usually have a relatively short final illness lasting only weeks or months, with pain from tumor invasion as a predominant symptom. Others, such as those with neurodegenerative disease, will have a more protracted illness, with progressive impairment of intellect, communication, and mobility over a number of years and with seizures, excessive secretions, and recurrent pneumonia as predominant features.

Assessment of symptoms

As in adults, thorough assessment of any symptom is essential before developing a plan of management. Since the experience of pain and other symptoms is subjective, ideally the children should provide this information themselves. However, their ability to do so will vary in relation to their level of understanding, experience, and communication skills. In preverbal children and those with severe developmental delay this can be particularly challenging.[5]

A variety of approaches are usually necessary to build up a more complete picture of a child's symptoms. Much can be gained from observing a child's behavior and comparing it to a time when symptoms were absent or different. Parents are particularly adept at this and their opinions should be sought and respected. When it comes to listening to the child, a range of assessment tools for different ages and developmental levels are available, but these were developed more specifically for acute pain. They include body charts, pictures of faces and visual analog scales.[6] Play specialists can also help to uncover a child's symptoms with the use of toys, puppets, art, and music. The team should remember that psychological and social factors affecting the child and family are often significant and are an important part of the assessment (Box 98.1).

A holistic approach

A holistic approach to symptom management is essential. Unresolved social, psychological, or spiritual concerns are likely to have a detrimental impact on the symptom experience. Children, like adults, have hopes and expectations for the future and mourn these losses. Many are aware of what they will not achieve in this life and need to explore a continued identity in the future, perhaps the reassurance that they will not be forgotten by their parents or the possibility of a spiritual continuity. Like adults, they may have tasks they want to achieve before death and business affairs to deal with, such as who will have their possessions and who will look after their pets.

For both parents and children, a fear of what the symptom means may lead to underreporting of symptoms, or unnecessary anxiety about relatively small problems. They must be given an opportunity to discuss what the symptom means to them, as this may highlight specific anxieties or misunderstandings that need to be addressed. Explaining the reason for the symptom and discussing a logical stepwise approach to management can also be helpful, reassuring the child and family that the situation is not out of control.

Basic principles

Simple measures for symptom management should always be considered, either on their own or alongside drug therapy. The value of maintaining a calm environment and care

---

Box 98.1 Assessing a child's pain

Watch the child:

Nonspecific, but often enlightening

Behavioral changes

- Crying, screaming, irritable, aggressive, head banging
- Clinging, quiet, withdrawn, frightened look, reluctant to move

Physiological changes

- Increased heart rate/respiratory rate/blood pressure
- Decreased saturations, change in color, sweating

Ask the child:

Difficult, dependent on age/developmental level/ contributory factors

Use play, puppets, drawings, music (play specialists)

Specific assessment tools:

- Over 3 years – FACES scales (e.g. Bieri, Wong, Baker, Oucher)[7,8]
- School age – Visual analog scale (straight line, ± numbers); color body chart (different colors for different pains)
- Older child – Any of the above; numerical rating scales; direct questioning

Ask the parents:

They know their child best, but they may lack confidence in their own assessment

Consider contributory factors:

Coping skills of the child and family

Past experience of the child and family

Anxiety and emotional distress levels in the child and family

Meaning of the pain and underlying disease to the child and family

---

over positioning should not be underestimated, as well as distraction, imagery and relaxation techniques, play, art and music therapy.

Where medication is necessary, the preferences of the child and family need to be taken into account. Many find that taking a lot of medication is difficult, so complex regimens may not be possible. It is important to find the

most acceptable route for the child and to be flexible to changing situations. The key issues in deciding on routes of administration are as follows:

- The oral route is often preferable.
- Long-acting preparations are more convenient and less intrusive.
- The child should be allowed to choose between liquids and whole or crushed tablets.
- As a child's condition deteriorates the treatment plan often has to be simplified, routes of administration altered and priority given to those drugs that contribute most to the child's comfort.
- Although rectal drugs are not popular in some countries, they can have a role. Some children prefer these to using any needles and they may be helpful in the final hours when the child's level of consciousness has deteriorated.
- If parenteral drugs are needed they are usually given by continuous subcutaneous infusion, not as bolus doses. Alternatively, an intravenous line can be used if it is already in place.
- Intramuscular drugs are painful and not necessary.

Many of the drugs used in palliative care have not been recommended formally for use in children but a body of clinical experience has developed in the absence of many trials or extensive pharmacokinetic data.[9] Doses of drugs for children are usually calculated according to their weight. In general neonates tend to need reduced doses relative to their size, whereas infants and young children may need comparatively higher doses and at shorter intervals than adults. Our recommendation is that drug dose is determined using a standard pediatric formulary. In the UK this includes *Medicines for Children* produced by the Royal College of Paediatrics and Child Health[10] or the *BNF for Children* (*BNF* is the *British National Formulary*).

Pain

After thorough assessment of pain a treatment regimen can be planned. This should consider the likely cause of the pain and whether this can be relieved by specific measures (e.g. radiotherapy for an isolated bony metastasis, antibiotics for a urinary tract infection). Symptomatic relief can be addressed by combining pharmacological, psychological, and practical approaches. Although analgesics often form the backbone to a plan, this combined approach is more likely to be successful.

The World Health Organization ladder of analgesia is widely adopted for children, although recent evidence has shed some doubt on the routine use of codeine. Up to 10 percent of the UK population may be poor metabolizers of the drug (to morphine) rendering it of little or no benefit to them, and there may be very low efficacy in infants due to their immature enzyme systems.[11]

STRONG OPIOIDS

These are used extensively in managing pain in pediatric palliative care (see also Chapter 50). When prescribing strong opioids for children, the following points should be borne in mind:

- Long-acting morphine preparations are effective and particularly convenient.
- Families should also have a short-acting preparation for breakthrough pain.
- Where oral administration is difficult or impossible transdermal patches such as fentanyl or buprenorphine should be considered.[12*]
- If oral or transdermal routes are not appropriate, morphine or diamorphine can be given via subcutaneous or intravenous infusion.
- Some children may have sudden onset of severe pain, needing breakthrough analgesia with a faster onset of action than oral morphine. Fentanyl lozenges can fulfill this role, although it may not be possible to use them in very young children or those with severe neurological impairment.[13*]
- Studies of the pharmacokinetics of oral opioids and their metabolites suggest that in young children metabolism is more rapid than in adults and they may require relatively higher doses for analgesia. Neonates and children under 6 months old, however, require a lower starting dose of opioids because of their reduced metabolism and increased sensitivity.[10]

Side effects of opioids

Many doctors lack experience of using strong opioids in children and exercise undue caution, prescribing doses that are too low or too infrequent. Respiratory depression with strong opioids is not usually a problem in children with severe pain and the side effects from opioids tend to be less marked than in adults. Nausea and vomiting, for example, are rare and routine antiemetics are not needed. Constipation is probably the most common side effect of opioids and regular laxatives should always be prescribed. For some children relatively mild laxatives such as lactulose may be sufficient, but the majority will require a stimulant in addition to a softener.

Some children are initially quite sleepy on starting opioids and parents should be warned about this or they may fear that the child's disease has suddenly progressed and that death is imminent. The drowsiness usually resolves within a few days. Itching with morphine may occur and may respond to antihistamines. If either the somnolence or the pruritus remain troublesome, switching to fentanyl or hydromorphone (or a combination of the two) is usually effective.[14*]

Parental concerns over opioids

Parents may be reluctant for their child to have strong opioids. It is important to establish exactly what their concerns are, particularly as children may be aware of their parents'

reluctance and may consequently underreport their pain. Parents may be anxious about the side effects, in which case it will be helpful to reassure them that these too can be treated. They may also be worried that if opioids are started 'too early' there will be nothing left for later. It is important to explain to parents and children that there is no upper dose limit to strong opioids and that gaining good pain control early is the best way of optimizing the long-term management of pain.

Another difficulty for parents is the feeling that by agreeing to start opioids they are acknowledging that their child is really going to die. They may even be concerned that this step represents them giving up hope – something they would find unacceptable. This clearly requires sensitive discussion and support. It may be helpful to explain that death is unlikely to be imminent, and to gently encourage them to focus again on the immediate needs of the child. With this, in the vast majority of cases, their perception will change such that their child can again receive the analgesia that he or she requires.

MUSCULOSKELETAL PAIN

Nonsteroidal anti-inflammatory drugs are often helpful for musculoskeletal pains, especially in children with nonmalignant disease. However, some caution is needed in children with cancer who have bone marrow infiltration because of the increased risk of bleeding. Bisphosphonates may also be used for bony pain in a variety of diseases, such as malignant disease and osteogenesis imperfecta. Oral chemotherapy should also be considered in children with malignant disease.

HEADACHES

Headaches from central nervous system leukemia respond well to intrathecal methotrexate. Headaches from raised intracranial pressure, associated with progressive brain tumors, are best managed with gradually increasing analgesics. Although steroids may seem helpful initially, the symptoms will inevitably recur as the tumor increases in size and a spiral of increasing steroid doses will then develop. The side effects of steroids in children almost always outweigh the benefits.[15] There is an increase in appetite (at a time when feeding may be difficult), dramatically changed appearance and often marked mood swings. Both parents and the children find these distressing.

OTHER FORMS OF PAIN

Neuropathic pain can often be helped by antiepileptic and antidepressant drugs. As with adults, there may be a role for methadone or ketamine. For severe pain unresponsive to these drugs, epidurals and nerve blocks should be considered. Painful dystonia or muscle spasms may improve with diazepam, baclofen, or trihexyphenidyl.

Gastroesophageal reflux should always be considered in children having episodes of pain associated with abnormal posturing, as reflux can mimic dystonia and often occurs alongside neurodevelopmental abnormalities. Physiotherapists and occupational therapists may also be able to help with pain management using exercises, positioning, and physical aids.

Feeding

The neurological impairment in children with neurodegenerative diseases and brain tumors often leads to difficulty with chewing and swallowing, to the extent that they are unable to tolerate an oral diet. Others, such as those with cancers, respiratory and cardiac disease, lose their appetite as the disease progresses. This can be one of the most difficult symptoms for parents to cope with as the inability to feed and to nourish their child often makes them feel they are failing in a basic parental role.

Assisted feeding, via a nasogastric tube or gastrostomy, is often appropriate for children with slowly progressive diseases. However, it is unlikely to be appropriate for children in the end stages of a rapidly progressive illness. In this situation nutritional goals aimed at restoring health should become secondary to comfort and enjoyment. It is often helpful to explain to parents that their child's deteriorating appetite is part of the dying process and that giving sufficient volumes of feed to achieve nutritional goals will not only be difficult, but may make their child feel more unwell and could precipitate vomiting. As long as the risk of aspiration is small, parents should be encouraged to allow their child to eat small amounts of foods they enjoy whenever they feel like it. They should be dissuaded from putting large plates of food in front of their child with the expectation that they should try to eat it, as this is likely to result in failure and disappointment for both the child and the parents.

Nausea and vomiting

Nausea and vomiting are frequent problems in a variety of diseases. Children with conditions that compromise oxygenation of the gastrointestinal tract, such as cardiac and respiratory diseases, can be very sensitive to the volume of feed given. Overfeeding can also be a precipitating factor, as parents often want to give extra nutrition to a child who is unwell or underweight. For some children, therefore, reducing the volume of feed given at any one time can cause significant improvement.

Gastrointestinal reflux should also be considered as a cause of vomiting, particularly in children with neurological impairment. A trial of antireflux medication may be appropriate. As in adults, antiemetics should be selected according to their site of action and the presumed cause of vomiting. Hyoscine patches and rectal medications are probably used more frequently in pediatrics than in adult

palliative care, to avoid the need for subcutaneous or intravenous administration in children who cannot tolerate drugs enterally, especially those with a relatively long disease course.

Seizures

Watching a child have a seizure is extremely frightening for parents and they should always be warned and advised about management if there is any possibility that this may happen. Children with neurodegenerative diseases often develop seizures as part of their ongoing disease and will already be taking long-term anticonvulsants. These can be adjusted when the pattern of seizures changes.

Sudden acute onset of seizures can be treated with rectal diazepam or, if the child or parents prefer, buccal midazolam. This has now been extensively studied in children and found to be at least as effective as rectal diazepam, well tolerated and highly acceptable to families.[16*] If the buccal preparation is not available, the intravenous preparation can be used buccally. Repeated severe or continuous seizures in a terminally ill child can be treated at home with a continuous subcutaneous infusion of midazolam, adding phenobarbital if necessary.

Agitation and anxiety

As with adults, agitation and anxiety may occur as a consequence of unresolved fears and distress. Children, especially, are often given limited information and excluded from conversations and discussions about their illness. Rather than protecting them, this can increase anxiety as limited or conflicting information makes it harder for them to make sense of what is happening. In addition, they will need to use their imagination to fill in the gaps and this can be so much more frightening than reality. Children must be given opportunities to seek information, clarify misconceptions and receive support. Medications, such as benzodiazepines, haloperidol, and levomepromazine should only be used as an adjunct to this.

Respiratory symptoms

Dyspnea, cough, and excess secretions can all cause distress to children and anxiety for their parents. If the underlying cause of the symptom can be relieved, even temporarily, this may be appropriate. Palliative radiotherapy, for example, can bring good symptomatic relief to some children with malignant disease in the chest.

Where treatment of the underlying cause is unlikely to be beneficial, symptom relief can be addressed by combining drugs with practical and supportive approaches. Fear is often an important element in dyspnea, so reassurance and management of anxiety may help to relieve symptoms. Simple practical measures such as finding the optimum position, using a fan and relaxation exercises may all help. The sensation of breathlessness can be relieved with opioid drugs and small doses of sedatives, such as diazepam or midazolam, are often helpful in relieving the associated anxiety.

Children with chronic chest diseases causing gradually increasing hypoxemia may suffer from headaches, nausea, daytime drowsiness, and poor-quality sleep. Intermittent oxygen may help relieve these symptoms and can be given relatively easily at home. Children with dyspnea in the later stages of malignant disease do not usually find oxygen helpful. Excess secretions are often a problem for children with chronic neurodegenerative diseases as they become less able to cough and swallow. This may also occur in other terminally ill children as they approach death. Oral glycopyrronium bromide, or hyoscine hydrobromide (given transdermally or subcutaneously) can help to reduce the secretions. Altering the child's position often provides temporary relief, but suction equipment is not usually helpful in the long term.

Anemia and bleeding

The treatment of anemia in the late stages of a child's life should be directed toward relief of symptoms rather than the level of hemoglobin. Transfusions are only helpful if they make the child feel better and it should be explained to the child and family that there is likely to come a point in the illness where they will stop finding transfusions beneficial. Blood counts are not routinely indicated but are sometimes helpful to support a clinical decision to transfuse.

Florid bleeding (e.g. severe hemoptysis or hematemesis) is extremely frightening for a child, distressing for the carers and may leave the family with unforgettable painful memories. If this is a serious risk, such as in liver disease, emergency drugs should be readily available and include an appropriate analgesic and sedative, such as diamorphine and midazolam. Correct dosage should be calculated ahead of time and the drugs and syringes immediately accessible. In an emergency parents can give these drugs by the buccal route, but must be shown in advance how to administer them.

Many children with malignant diseases have widespread bone marrow infiltration and low platelet counts. Although petechiae and minor gum bleeding are common, serious bleeding is unusual. Minor gum/nose bleeding can be managed with tranexamic acid, either orally or by direct application to the bleeding point. Platelet transfusions are usually confined to bleeding that is severe or interferes with the quality of life. They are rarely justified solely on the basis of a low platelet count. A child with an established history of bleeding throughout the illness, however, may appropriately be treated with regular platelet transfusions.

SUPPORT FOR THE CHILD AND FAMILY

Support for the child and family begins at the time of diagnosis and continues as the illness progresses, through the

Box 98.2 Predicting how well a family will cope

Positive

- Cohesive family
- Supportive family
- Flexible approach
- Open communication in family
- Open communication with staff
- Good record with past stress

Negative

- Over-involved family
- Unconnected family
- Rigid approach
- Closed communication in family
- Closed communication with staff
- Poor record with past stress
- Previous parental psychopathology
- Concurrent stresses (e.g. single parent, parental strife, financial problems)

child's death and into bereavement. All the family – the sick child, the parents, siblings, and the wider family – will be affected by the illness and need support, both as a family unit and as individuals. A flexible approach, with time to listen and build up relationships, is important.

Although all families will suffer emotional distress the majority possess considerable strength and resilience and do find ways to continue to function effectively from day to day. A number of factors have been identified which can help predict a family's capacity to cope, and this knowledge can be helpful in identifying families who may be at extra risk and need particular support (Box 98.2). It is important to be aware of families and family members who have language difficulties or a different cultural approach to illness and death.

At diagnosis

The time of diagnosis of a life-threatening illness is one of great turmoil for the family. This is when their bereavement begins. The way in which the diagnosis is given has a powerful impact and forms the foundation for communication in the future. The family's expectations and pattern of life are disrupted and, especially if frequent hospital admissions are involved, many practical difficulties arise in day-to-day living. It can be easy for the parents and other

children to feel overwhelmed, helpless, and out of control. Parents have a great need for information at this time and may value written information, contact with other parents in similar situations and links with self-help groups. The sick children face the trauma of being in hospital and the experience of unpleasant and frightening investigations and treatment. They may be particularly confused as explanations of what is happening may be delayed while parents themselves are just learning about the illness. Some parents may be reluctant to discuss the diagnosis with their children and need encouragement and help to do so.

As the disease progresses

As the illness progresses the family have to live with the underlying conflict of maintaining some hope and semblance of day-to-day life despite persistent uncertainty. The parents may develop depression, anxiety, and sleep disturbance although they are often reluctant to speak of these problems unless asked specifically. Marital discord and loss of libido are also common. Parents may find it difficult to maintain discipline and boundaries for the sick child and to balance their time and emotions between the sick child and well siblings.[17] If frequent hospital admissions are involved there are practical difficulties of travel, separation, and finance. If the child has heavy nursing needs, with physical disability and/or developmental delay, the burdens of care can be considerable. Parents may have little time to themselves or to devote to well brothers and sisters, so the opportunity for some respite care for the sick child, either at home or away from home, becomes essential.[1,18] Trying to encourage as normal a life as possible – maintaining friendships, education, and outside activities – within the confines of the illness is a continual but important struggle. Children usually want to attend school as much as possible, so as the illness progresses extra support, special facilities and home education may need to be introduced.

Most families use some avoidance and denial as part of their coping strategy, including avoiding discussion and reminders of the illness. This is normal behavior that helps protect them from extremes of emotion. It allows them to live with the illness and function day-to-day, while coming to understand and recognize the situation gradually. This needs to be recognized and respected, as frequent discussions about the disease at this time may prove burdensome rather than supportive. In addition to this, parents often want health professionals to maintain some hope as long as their child is alive. This has to be expressed in the context of honest information about the progression of the disease and it can prove challenging to get the balance right for each individual family.[19]

The final stages

Eventually it becomes clearer that not only is death inevitable but that the time of death is becoming quite

close. This may be apparent from gradual deterioration in a long progressive illness or occur more abruptly such as after a relapse in cancer. The emotional impact at this time can be dramatic for parents, particularly for those who have held a very positive and 'fighting' approach throughout treatment. For others it is just a confirmation of what they have dreaded and known was inevitable all along. Sometimes there is a sense of relief that the uncertainty and suffering will soon be over, alongside the distress and sadness. The sense of relief can be very confusing for parents as they can interpret this as wishing their child dead, which, of course, is not what they want.

In addition to being given information and the opportunity to discuss their child's care, parents need an opportunity to explore their own feelings and express their emotions. They may be able to talk to each other openly and offer each other support, but more often they will cope in different ways and find the whole experience so physically and emotionally exhausting that they have little strength left to offer support either to each other or to their other children. Both the parents and well siblings can find it helpful to talk to someone outside the immediate family during this time.[19,20]

Many parents have never seen anyone die and will value the opportunity of talking about what may happen at the moment of death. They also appreciate information about the practical details of what to do after their child has died. Most will have been anticipating the funeral in their mind and are relieved to be able to acknowledge this and make some plans before the child has died.

An important issue for parents at this time is what to discuss with the child who is sick and with their other children. A natural reaction is to protect their children from the fear of death and many parents feel they can only do this by not allowing the child to know that they are going to die. However, it is clear that children understand and learn about their illness and its implications whether the parents and the professionals encourage it or not.[21] It is important to provide opportunities for the sick child to seek the information they want in order to make sense of what is happening and to discuss what is actually on his or her mind. Parents (and health professionals) can be surprised by the nature of the child's fears: rather than being scared of death *per se* it is more common that they are scared of situations that they can be genuinely reassured about. Even when parents are very open with their children, it is not unusual for the *children* to 'protect' their *parents* by keeping their worries to themselves, so a trusted professional may be the most appropriate person with whom a child can talk freely. Open discussion with children, particularly when death is a real possibility, can be a daunting prospect and very difficult to establish in practice.

Communicating with children must take into consideration their level of understanding about illness and the concept of death.[21,22] It also will be influenced by the child's previous experiences, the family's style of communication, and their own personal defenses. Some approaches to helping families toward a more open and honest pattern of communication include:

- shifting the emphasis from 'telling' to 'listening'
- helping them identify the child's indirect cues as well as obvious questions
- discovering the child's fears and fantasies
- maintaining the child's trust through honesty
- building up the whole picture gradually
- explaining that communication need not rely on talking – drawings, stories, and play are often more effective and easier for children.[23,24]

It can be equally difficult for the parents to discuss the seriousness of the situation with their other children. Siblings may feel isolated and left out by their parents and, noticing the differential treatment they are receiving, can come to resent their sick brother or sister. They may feel less worthy and develop low self-esteem as a result. This is less likely if they have opportunities to talk about their feelings and are given honest answers to their questions about what is happening. They also benefit from being involved in the day to day care of their brother or sister, by having a role in planning and attending the funeral and by being allowed to keep some of their sibling's possessions.[25,26]

The bereaved family

The grief suffered after the loss of a child has been described as the most painful, enduring and difficult to survive and is associated with a high risk of pathological grief. Parents lose not only the child they have loved, but their hopes for the future and their confidence in themselves as parents. It puts an additional stress on their own relationship and alters the whole family structure. The brothers and sisters who are grieving may continue to feel isolated and neglected as their parents can spare little time or emotion for them.

Ideally the professionals who know the family well and have been involved throughout the sick child's life should continue to be available through the bereavement. Grief is likely to continue over many years and its depth and persistence is often underestimated. Parents value continuing contact with professionals who have known their child and the opportunity to talk about the child and their grief when others in the community expect them to 'have come to terms with it'.[19] This support, initially more frequent and gradually decreasing, helps facilitate the normal tasks of mourning. Help can be offered for brothers and sisters and information provided about appropriate literature, telephone helplines, and support organizations. Most families will not need formal counseling but it is important to be able to recognize when there are signs of abnormal grief that may require referral for specialist help.

CONCLUSIONS

Helping to care for a child and family with a life-threatening illness is rarely easy. It presents many challenges both in terms of the professional tasks that may be required and to our own emotional resources. Families greatly value professionals who stay alongside them throughout their journey, offering practical help and support in an almost intolerable situation. Parents will have a lasting memory of their child's death and as professionals we have the opportunity to help make these memories as good as they can be.

Key learning points

- The numbers of children receiving palliative care are small compared with the adult population and many of the diseases encountered are rare.

- Parents are usually the main carers and a family-oriented approach is essential.

- Professionals providing day-to-day care may have limited experience of the underlying disease, yet it is essential that palliative care is delivered alongside good disease-specific management.

- A key worker must be allocated to coordinate the care, which is often provided by professionals from a number of different organizations.

- When talking to children it is essential to be sensitive to their level of understanding, previous experience, and communication ability.

- The principles of symptom management are similar in adults and children, but the assessment of symptoms, the doses of medication, and the routes by which medication is given are often different.

- The death of a child raises specific issues in bereavement and appropriate support for families and professionals must be provided.

Chronic obstructive pulmonary disease

J RANDALL CURTIS, GRAEME ROCKER

INTRODUCTION

Chronic obstructive pulmonary disease (COPD), or chronic obstructive airways disease, is a leading cause of morbidity and mortality worldwide and age-adjusted mortality continues to increase whereas mortality from other leading causes of death, including cardiovascular disease and cancer, has decreased.[1,2] Among patients with life-limiting illnesses such as COPD, there are documented shortcomings in our current provision of end-of-life care.[3] There has been growing recognition of the importance of improving the quality of palliative care for patients with COPD, as evidenced by the appearance of sections on palliative care in the recent American Thoracic Society/European Respiratory Society (ATS/ERS; www.thoracic.org/copd) and Canadian Thoracic Society COPD guidelines released in 2004.[4] This chapter will examine the important aspects of providing high quality palliative care for patients with COPD.

The focus of the chapter is on the specific issues of providing high quality 'end-of-life' care to patients with COPD as well as high quality palliative care. Since end-of-life care for patients with COPD often occurs in the setting of an acute exacerbation of their chronic disease, good quality end-of-life care requires communication with patients *prior* to the acute exacerbation to be sure they receive the care they want. Therefore, the first section to follow will review the problems with current end-of-life care for patients with COPD; and the second section will review issues concerning prognostication for patients with COPD. The third section explores issues around communication about end-of-life care that are unique or particularly important for patients with COPD. Since palliative care can also be viewed more broadly to refer to the care intended to palliate symptoms

and maximize quality of life, much of the care provided to patients with severe COPD is in fact palliative care focused on symptom management and improving or maintaining quality of life. Therefore, the fourth section will cover some of the issues regarding symptom management and quality of life unique to the patient with severe COPD.

IDENTIFYING THE PROBLEM WITH END–OF–LIFE CARE FOR PATIENTS WITH COPD

The landmark study called SUPPORT (the Study to Understand Prognosis and Preferences for Outcomes and Treatments) enrolled seriously ill, hospitalized patients with one of six life-limiting illnesses that included COPD. The SUPPORT study found that compared with patients with lung cancer, patients with COPD were much more likely to die in the intensive care unit, on mechanical ventilation, and with dyspnea.[5*] These differences in the kind of care occurred despite the fact that most patients with COPD preferred a course of care that focused on comfort, rather than prolonging life. In fact, the SUPPORT investigators found that patients with lung cancer and patients with COPD were equally likely to prefer not to be intubated and not to receive cardiopulmonary resuscitation (CPR).[5] In addition, a study in Britain also found that patients with COPD were much more less likely to die at home and much less likely to receive palliative care services than patients with lung cancer.[6*] These differences seem likely to be due in part to the difficulty physicians have in prognosticating for patients with COPD and especially for identifying with confidence those patients who are likely to die within 6 months. This fact was demonstrated using the SUPPORT prognostic model

showing that 5 days prior to death, the prognostic model predicted that a patient with lung cancer had a less than 10 percent chance of surviving 6 months, whereas for patients with COPD the model predicted a more than 50 percent chance of surviving 6 months.[5] Nonetheless, despite these difficulties in prognostication, it remains the responsibility of physicians caring for patients with severe COPD to address issues of end-of-life care to provide the best possible care for these patients at the end of their lives.

Although reasons that patients with COPD receive less palliative care than those with lung cancer are not entirely clear, prior studies show that only a small proportion of patients with moderate to severe COPD have discussed treatment preferences and end-of-life care issues with their physicians and the vast majority of these patients believe their physicians do not understand their preferences for end-of-life care.[7,8*] A recent study suggested that only a third of patients with oxygen-dependent COPD had discussed end-of-life care with their physicians and there were important aspects of end-of-life care that less than 10 percent of physicians discussed with their patients.[9*] Patients with COPD are more likely than patients with cancer or AIDS to express concern about the lack of education that they receive about their disease, treatment, prognosis, and advance care planning.[10*] It is likely that at least part of the reason that patients with COPD may receive less palliative care is that patient–physician communication about end-of-life care occurs less often, is more difficult to conduct for patients with a less certain prognosis, or some combination of both. It is also possible that since patients with cancer and patients with COPD are often cared for by different specialists, there may be differences in attitudes, skill, or experience among these different specialists.

PROGNOSTICATION FOR PATIENTS WITH COPD

Since one of the barriers to providing high quality palliative care to patients with COPD is the difficulty in making an accurate prognosis for these patients, it is important for those providing palliative care to these patients to be familiar with the data that do exist. Table 99.1 outlines the prognostic factors for patients with COPD during acute exacerbations and when they are stable and the studies identifying these factors are discussed below.

Acute exacerbations of COPD requiring hospitalization

The SUPPORT study published outcomes of 1016 patients admitted to five US hospitals with hypercapnia complicating acute exacerbations of COPD (AECOPD).[3*] The average age of patients was 70 years, 51.5 percent were male, and 78.1 percent had >2 significant comorbid illnesses.

Table 99.1 *Independent predictors of increased mortality in the SUPPORT (at 6 months) and BTS (at 3 months) trials*

	SUPPORT	BTS
Acute physiology score (APACHE)	✓	NR
Impaired performance status	✓	✓
Low BMI	✓	NR
Increased age	✓	✓
Increased heart rate	✓	NR
Poor oxygenation	✓ (low Pao_2/Fio_2)	✓ (low Sao_2)
Low albumin	✓	NR
Low pH	✓	✓
Leg edema	✓ (reduces mortality)	✓ (increases mortality)
Assisted ventilation	NR	✓

NR, not reported; BMI, body mass index; APACHE, Acute Physiology, Age, and Chronic Health Evaluation.

The mortality for the index admission was 11 percent rising to 20 percent at 60 days, 33 percent at 180 days, and 43 percent at 1 year. The median survival for these patients was approximately 2 years. Six-month mortality was higher for those patients readmitted two or more times (36 percent) than for patients not readmitted (21 percent). The SUPPORT study data were collated between 1989 and 1994 from only five US centers before widespread use of non-invasive mechanical ventilation (NIV) for AECOPD complicated by hypercapnia,[11] which may limit generalizability of these findings. Another study to look at outcomes of AECOPD comes from the UK using a British Thoracic Society (BTS) clinical audit.[12*] The BTS study reported on data collated from 1400 admissions between 1997 and 2001 of whom only 13 percent of eligible patients received some form of ventilatory support. The predictors of 3-month mortality included age, comorbidities, and the severity of the exacerbation.[12]

Other recent studies of more than 100 patients with AECOPD reported index hospital admission mortality rates of 11–24 percent.[13–16*] Higher mortality rates have been reported in patients using long-term oxygen (50 percent index admission mortality in a Spanish study)[17*] and patients who could not be weaned after 3 weeks of mechanical ventilation (68 percent 2-year mortality).[18*]

Age is one of the most consistent predictors of death for patients admitted with AECOPD. Relative to patients in the BTS study <65 years old, the odds (95 percent confidence intervals [CI]) of death at 3 months for patients aged 75–79 years and >80 years were 2.2 (1.3 to 1.7) and 3.0 (1.8 to 4.9), respectively.[12*] In other follow-up studies of 270 and 362 patients, age and presence of comorbidities were consistent predictors of death beyond successful discharge.[16,19*] Other factors that predict survival in some but not all studies include the severity of the initial respiratory acidosis.

The BTS study showed that a presenting pH < 7.26 increased the relative risk of mortality at 3 months (relative to pH > 7.35) to 3.8 (95 percent CI 2.7 to 5.4), but this was not found in SUPPORT. For a patient bed bound before admission, one study found that the risk of death increased by a factor of 20.[12*] Finally, in the BTS study, a presenting Sa_{O_2} <86 percent increased the mortality risk by a factor of 2.3 (95 percent CI 1.6 to 3.2) relative to an Sa_{O_2} >92 percent.[12] Most recently, in recognition that single indicators of disease severity are not in themselves sufficiently powerful as predictors of death in COPD, Celli and colleagues have described a multidimensional tool (the BODE index) that integrates measures of the body mass index (B), the degree of airflow obstruction (O), dyspnea scores (D), and exercise capacity (E).[20*] As a multidimensional score it proved more accurate in mortality predictions in a validation cohort of 625 patients than the forced expiratory volume in 1 second (FEV_1) alone, both for deaths from all causes and for deaths related to respiratory disease.[20] Whether the BODE index will prove useful in clinical practice and for both men and women with COPD is not yet determined.

Predictors of survival in stable COPD

Initial FEV_1 and age were the most important predictors of survival among 985 COPD patients followed for 3 years.[21*] In a retrospective study of 400 patients with COPD in Holland, low body mass index (BMI), age and low Pa_{O_2} were significant independent predictors of increased mortality.[21] Weight gain through nutritional therapy with or without anabolic steroids had a positive impact on survival in a prospective study of 203 patients.[22*] A low BMI was also associated with an increased mortality risk (relative risk 7.11, 95 percent CI 2.97 to 17.05) in the Copenhagen City Heart Study that enrolled 2132 subjects with airflow obstruction and followed them for 17 years[23*] and in a recent UK prospective cohort study of 137 elderly patients with COPD.[24*]

Readmission rates

In SUPPORT 900 patients survived to index discharge, of whom 446 or 50 percent were readmitted 754 times over the next 6 months: 28 percent of patients were readmitted once, 13 percent twice, and 9 percent three times or more. Of the 416 patients who died with COPD, 15–25 percent of their last 6 months was spent in hospital.[25*] Canadian data also demonstrate that the majority of patients with COPD die in hospital.[26*] Of the 1400 BTS study patients, 34 percent were readmitted within 3 months of the index hospitalization.[12*] The following factors were the major independent predictors of hospital readmission: previous admission (odds ratio [OR] 2.5, 95 percent CI 2.0 to 3.2); lower percent-predicted FEV_1 (1.8, 1.4 to 2.3) and more than five medications at the time of readmission (2.7, 2.0 to 3.7).[12]

In summary, despite the increasing amount of prognostic data to help clinicians identify patients with severe COPD at high risk of death, these data do not provide clinicians with an easy way to identify with certainty those patients with a prognosis of less than 6 months. Since the hospice benefit in the USA is based on a prediction of a prognosis of less than 6 months, clinicians will need to use their clinical judgment to identify patients likely to benefit from hospice care and they will, in our opinion, need to be willing to accept a higher degree of uncertainty in this prognosis than is often seen for patients with metastatic cancer.

COMMUNICATION ABOUT END–OF–LIFE CARE WITH PATIENTS WITH COPD

Communication about end-of-life care is a particularly important component of caring for the patient with severe COPD because these patients are at high risk for an acute exacerbation of their disease that may result in respiratory failure of rapid onset. For this reason, discussions about patient preferences in the event of acute respiratory failure and for circumstances in which they would not want life-sustaining therapies started or continued are important topics for discussion for patients, their physicians, and their families.

Prior research shows that the majority of patients with severe COPD report that their physicians have not end-of-life care with them.[7–9*] A recent study of patients with oxygen-dependent COPD suggested that there were aspects of discussing end-of-life care, such as prognosis and what dying might be like, that are rarely discussed. When these discussions occur, patients rate the quality of these discussions relatively poorly.[9*] These studies suggest physicians need to be aware of the barriers to communication about end-of-life care and should work to improve the ways they discuss this issue. Another report from this study suggests that the barriers to communication about end-of-life for patients with COPD are diverse and patient specific.[27*] Two barriers were endorsed by more than 50 percent of patients including, 'I'd rather concentrate on staying alive than talk about death' and 'I'm not sure which physician will be taking care of me if I get very sick'. The former suggests that physicians must be skilled in talking about this difficult subject with patients who would rather not talk about it. It may be helpful in these situations to acknowledge that this is a difficult topic for discussion but an important one for patients and physicians to address. The second barrier suggests that discussions of continuity may be an important aspect to encouraging these discussions.

When discussing mechanical ventilation for 'end-stage COPD', 41 percent of Canadian respirologists responding to a survey reported that the majority of these discussions take place in the intensive care unit (ICU) and only 23 percent in the clinic or office.[28*] Often these discussions occur

late in the disease trajectory. For example, 84 percent of physicians wait until dyspnea is severe and 75 percent of physicians wait until the FEV_1 is <30 percent predicted. When discussing mechanical ventilation almost all physicians spontaneously mention intubation (96.8 percent) but far fewer physicians discuss aspects of weaning, sleeping, or eating. Some discourage mechanical ventilation in a setting of alcohol abuse, severe depression, and smoking.[28] The authors wrote, 'At the very least, this observation suggests that physicians should question their beliefs and biases when making end of life recommendations'.[28] Physicians need to be aware that the way they frame discussions influences choices patients make.[29]

There has been increasing dissatisfaction with advance directives over the past two decades. A number of studies have suggested that advance directives do not influence the treatments that patients receive[30–32**] and do not change end-of-life decision making.[33–35*] However, in the setting of good communication between patients, families, and physicians, advance directives may be an important component to end-of-life care and may be especially useful among patients with COPD who have strong feelings about the situations in which they would want to forego CPR or, particularly relevant for COPD, mechanical ventilation for acute respiratory failure. This is a topic that should be discussed with all patients with severe COPD. For patients who have experienced mechanical ventilation in the past, this offers physicians an opportunity to use their prior experience as a reference point for discussing potential future episodes of acute respiratory failure and circumstance under which they would not want mechanical ventilation. Patients' prior experiences with mechanical ventilation or with relatives or friends who have required life support can be important facilitators to patient–physician communication about treatment preferences and end-of-life care.[27*]

It is important to realize that depression may modify patients' treatment preferences. Depression is common among patients with COPD[36–39*] and a recent study suggests that patients with depressive symptoms are more likely to choose to forego CPR that those without depressive symptoms.[40*] As noted below, depression can be treated in patients with COPD and if depression improves, treatment preferences should be revisited.

Based on the prognostic information described in the preceding section and on clinical experience, there is an emerging profile of patients for whom discussions about treatment preferences or end-of-life care are especially important.[41] This profile includes patients with FEV_1 <30 percent predicted, those with more than one admission in the last year, those patients who are becoming increasingly dependent on others, those with left heart failure or other comorbidities, older patients, depressed patients, or the unmarried patient with advanced COPD. Any one of these factors should trigger a clinician to consider initiating a discussion of treatment preferences for life-sustaining treatments and end-of-life care. The presence of more than one of these prognostic indicators should be clear criteria for having such a discussion with the patient.

PALLIATING SYMPTOMS AND MAXIMIZING QUALITY OF LIFE

The majority of treatments available for patients with COPD are palliative in the sense that the majority of these treatments are focused exclusively on palliating symptoms and maximizing quality of life. The few exceptions include long-term oxygen therapy,[42,43**] lung transplantation,[44*] and, perhaps in highly selected patients, lung volume reduction surgery.[45**] Otherwise, most treatments are provided with the goal of palliative care. As a consequence, these therapies should generally be started with the understanding that the patient and clinician will reassess whether they are serving the goal of palliating symptoms or improving or maintaining quality of life without causing adverse effects. This review will not attempt to summarize all aspects of management of COPD, but will attempt to cover some of the unique features of managing symptoms, particularly dyspnea, for patients with severe COPD. In addition, this review will cover some of the treatments shown to improve health-related quality of life among patients with severe COPD. Health-related quality of life is an important outcome measure for the provision of high quality palliative care and there have been considerable advances in the measurement and reporting of health-related quality of life as an outcome measure for patients with chronic lung diseases.[46]

Bronchodilators

Inhaled bronchodilator therapy is a mainstay of treatment for dyspnea among patients with COPD. There is some evidence that for most patients, the combination of a β agonist and quaternary anticholinergic agent such as ipratropium provides a better degree of bronchodilatation and reduction in acute exacerbations than either agent alone.[47*] There is also recent evidence that patients with severe COPD may benefit with a long-acting quaternary anticholinergic such as tiotropium.[48**] The data for use of long-acting β agonist therapy in the stable COPD population are less clear, although there may be some benefit of these agents.[48]

Systemic therapies targeting bronchodilation are less successful. Theophylline is used much less commonly today than 20 years ago because it has relatively weak bronchodilatory effects and can have significant systemic side effects. Nonetheless, there may be some patients with severe COPD who have received maximal inhaled bronchodilator therapy and remain symptomatic. A study by Kirsten and colleagues suggests that patients with severe COPD on theophylline have worsening dyspnea and exercise tolerance when the drug is stopped.[49**] In addition, a trial by Mahler and colleagues suggests patients with severe COPD may have

decreased symptoms of dyspnea even without any improvement in exercise tolerance.[50**] Therefore, patients who remain symptomatic after maximal inhaled bronchodilator therapy may benefit from a trial of theophylline.

Corticosteroids

There are precious few data that systemic corticosteroids are beneficial long term in the setting of chronic, stable COPD. The recent GOLD statements on COPD recommend that systemic steroids not be used in this setting due to the significant side effects and lack of compelling data suggesting significant benefit.[1] Inhaled corticosteroids certainly have much less adverse effects, but the data that they benefit patients with chronic stable severe COPD are also limited. A randomized trial by Burges and colleagues (the 'ISOLDE trial') did suggest that patients with moderate or severe COPD have a very small but statistically significant benefit in health-related quality of life with a slightly slower decline over several years than patients randomized to placebo.[51**] The patients receiving inhaled corticosteroids also had a small reduction in the number of exacerbations compared to those receiving placebo suggesting that the number of patients one needed to treat to eliminate 1 exacerbation per year was only 3. Therefore, inhaled corticosteroids are a reasonable adjunct treatment for patients with severe COPD especially if they have frequent exacerbations.

Oxygen

Oxygen therapy is an important component of treatment for patients who meet criteria used in two large randomized controlled trials of oxygen. These trials used the following criteria in determining eligibility for enrollment in the study:

- $Pa_{O_2} \leqslant 55$ or oxygen saturation <88 percent or
- Pa_{O_2} 56–60 or oxygen saturation of 88 percent

  and one of the following criteria as evidence of end organ damage from chronic hypoxia:

  – hematocrit >45 percent
  – evidence of right heart strain by electrocardiogram (EKG)
  – peripheral edema.

These studies, in combination, showed that oxygen therapy improves survival and quality of life for patients who met eligibility criteria and also suggest that the closer patients come to 24 hour a day use, the more benefit they obtain.[42,43**] However, it is important for clinicians to realize that patients who are terminally ill, but do not meet the strict oxygenation criteria above still qualify for oxygen therapy on the basis of their terminal illness and many of these patients may benefit from oxygen therapy.

Noninvasive positive pressure ventilation

Noninvasive positive pressure ventilation has been evaluated for the management of chronic respiratory failure (generally defined as an increased Pa_{CO_2}) in patients with severe COPD. There have been several small randomized trials that have suggested that in highly select patients with COPD, noninvasive positive pressure ventilation during the night can improve symptoms and health-related quality of life.[52–55**] However, clinical experience suggests that most patients with severe COPD and chronic respiratory failure will not tolerate NIV at home. A consensus conference suggests considering a trial of noninvasive positive pressure ventilation for patients with COPD and chronic respiratory failure if patients meet the following criteria:

- documented obstructive lung disease optimally treated
- persistent daytime symptoms
- chronic respiratory failure defined as:
  – $Pa_{CO_2} \geqslant 55$
  or
  – P_{CO_2} 50–54 and nocturnal desaturation ($\leqslant 88$ percent for 5 consecutive minutes on 2 L/min O_2)
  or
  – Pa_{CO_2} 50–54 and two or more hospitalizations for COPD in 12 months.[56]

Opiates

Opiates are an important part of the armamentarium for the treatment of dyspnea in the patient with severe COPD maximally treated with bronchodilators and other therapies; however, it is important to acknowledge that the benefit achieved with these agents is relatively modest. There have been a number of randomized trials and a recent meta-analysis that suggest that oral opiates reduce the sensation of dyspnea although are associated with some side effects.[57***] For example, a recent randomized trial of sustained release morphine for 4 days showed reduced dyspnea scores but increased constipation despite laxative treatment.[58] The meta-analysis also suggests that while oral and parental opiates can reduce the sensation of dyspnea, there are inadequate data to conclude that nebulized opiates are effective. Opioids are an important therapeutic option for patients with dyspnea that persists despite maximal bronchodilator therapy. They should be considered not only in end-of-life situations, but also in stable patients whenever breathlessness is severe in COPD and continues despite maximal bronchodilator therapy. However, clinicians should assess the benefit of this therapy and the burden of side effects for each individual patient.

Other pharmacologic agents for dyspnea

A number of small studies have examined the role of other oral agents including benzodiazepines, phenothiazines,

and buspirone. These studies, recently reviewed in two reviews of treatment of dyspnea in severe COPD, were either negative or inconclusive, suggesting that these agents should not be routinely used for dyspnea in patients with COPD.[59,60**]

Although antidepressants are not routinely used for the treatment of dypnea in patients with COPD, it is important to note that depression is very common among patients with COPD.[36–39*] Antidepressants can significantly improve mood in patients with COPD and depression and, in addition, in these patients with depression, antidepressants can also improve physical symptoms including dyspnea.[61**]

Nonpharmacological treatments

There are a number of nonpharmacological approaches that can have an important effect on dyspnea and other symptoms as well as quality of life. An example of such approaches includes pulmonary rehabilitation. Although different pulmonary rehabilitation programs include different components, randomized trials have clearly shown that pulmonary rehabilitation can improve dyspnea, exercise tolerance, and health-related quality of life.[62–64**] Important components of this nonpharmacological therapy include teaching patients breathing techniques and teaching nonpharmacological methods such as the use of fans and relaxation techniques that may help reduce sensations of anxiety and increase the perception of control when patients feel dyspneic.

Another important treatment option for patients with severe COPD is referral to hospice. Hospice programs may be able to offer patients with COPD tremendous amounts of psychologic, emotional, and spiritual support in their final months as well as intensive symptom assessment and management above what a hospital or office-based physician can offer. Hospice is underutilized by patients with COPD in part because of the difficulty prognosticating for these patients.[6] However, there are many patients with severe COPD for whom a physician may have reasonable confidence that the patient is likely to die within 6 months. If patients improve, they can be taken off the hospice benefit without penalty and still be eligible to return to hospice if they deteriorate again.

Caregiver burden

Few studies have reported measures of caregiver burden for the families of patients with COPD. One randomized, controlled, multicenter trial involved 1966 patients in the USA and included patients with COPD. Compared with usual care, a team-managed, home-based primary care model significantly reduced caregiver burden and improved caregiver health-related quality of life .[65**] In a Canadian multicenter study of patients with COPD, patients reported that reducing burdens on their loved ones was the aspect of care that they considered needed most attention.[66*]

In summary, palliative care is an important and large component of the treatment of patients with severe COPD. Physicians caring for such patients must be familiar with the treatments that can palliate patients' symptoms and improve or slow the decline in their quality of life. In addition, communication about end-of-life care is an important aspect of care for all these patients.

Key learning points

- Patients with COPD were much more likely to die in the intensive care unit, on mechanical ventilation, and with dyspnea and are less likely to receive palliative care than patients with lung cancer despite the fact that most patients with COPD prefer a course of care that focused on comfort, rather than prolonging life.

- Only a third of patients with oxygen-dependent COPD have discussed end-of-life care with their physicians and there were important aspects of end-of-life care that less than 10 percent of physicians discussed with their patients. Furthermore, patients with COPD are more likely than other patients to express concern about the lack of education that they receive about their disease, treatment, prognosis, and advance care planning.

- Despite increasing amount of prognostic data to help clinicians identify patients with severe COPD at high risk of death, these data do not provide clinicians with an easy way to identify with certainty those patients with a prognosis of less than 6 months. Clinicians will need to use their clinical judgment to identify patients likely to benefit from hospice care and they will, in our opinion, need to be willing to accept a higher degree of uncertainty in this prognosis than is often seen for patients with metastatic cancer.

- There is an emerging profile of patients for whom discussions about treatment preferences or end-of-life care are especially important and this profile includes patients with FEV_1 <30 percent predicted, those with more than one hospital admission in the last year, those patients who are becoming increasingly dependent on others, those with left heart failure or other comorbidities, the elderly, the depressed, or the unmarried patient with advanced COPD. Any one of these factors should trigger a clinician to consider initiating a discussion of treatment preferences for life-sustaining treatments and end-of-life care and the presence of more than one of these prognostic indicators should be clear criteria for having such a discussion with the patient.

> ● The foundation of treatment of dyspnea in severe COPD includes bronchodilators and oxygen. Opiates are also useful, although benefits may be limited by side effects for some patients. Corticosteroids and other pharmacological agents are of less certain benefit for stable patients. Nonpharmacological therapies are important adjuncts for treatment in this population and pulmonary rehabilitation programs are one option for providing these therapies to patients.

Other infectious diseases: malaria, rabies, tuberculosis

SUE MARSDEN

INTRODUCTION

Malaria, rabies, and tuberculosis are diseases from which people die in the developing world.[1–8] These are diseases associated with poverty, and therefore are not usually seen as diseases creating palliative care issues for the developed world. Hence they have received little attention in this regard. Nonetheless, each year some 3 million people die worldwide from tuberculosis, 2 million from malaria, and about 40 000–100 000 die from rabies;[1–8] these are conservative estimates. These three infectious diseases, and others, are all preventable or treatable and clearly public health interventions are critically important in this respect. However, while deaths are occurring with unrelieved symptoms and distress as happens daily, management of patients dying with these diseases demands the application of palliative care principles.

MALARIA

Malaria is a life-threatening parasitic disease caused by the genus *Plasmodium*, transmitted by female mosquitoes of the genus *Anopheles*.[1,2,9] Although malaria has been essentially eliminated from many countries with temperate climates, 40 percent of the world's population, mostly those living in the developing countries, remain at risk. Today, in tropical and subtropical countries malaria causes acute illnesses in 300–500 million people and is responsible for approximately 2 million deaths each year.[1,2,10] Most of these deaths are in young children with 90 percent of deaths due to malaria

occurring in sub-Saharan Africa.[2] It is estimated that an African child dies from malaria every 30 seconds.[2]

Etiology and pathogenesis

Malaria in humans is caused by one of four species of *Plasmodium*: *P. falciparum*, *P. vivax*, *P. ovale*, and *P. malariae*.[1,2] *P. falciparum* causes the highest mortality and is the most common causative organism in sub-Saharan Africa.[1,2,9] *P. vivax* is more widely distributed and causes mild recurrent disease if the first episode is not treated adequately. *P. ovale* is rare and can also cause recurrent disease.[2] *P. malariae* has scattered distribution, mainly in Africa and can live in asymptomatic hosts for decades or cause acute illness.[2] It has been associated with membrano-proliferative glomerulonephritis and nephrotic syndrome in children.[2,11]

LIFE CYCLE OF THE MALARIAL PARASITE[1,2]

Plasmodium sporozoites are transmitted to humans from the salivary gland of the female *Anopheles* mosquito by injection under the skin. The life cycle in the human host, summarized in Box 100.1, results in some merozoites differentiating into gametocytes. These can then be transferred from an infected human to a biting mosquito. The parasite completes its sexual cycle within the mosquito forming new sporozoites, which are then available to infect another human. *P. vivax* and *P. ovale* can remain dormant in liver parenchyma for months or years and are responsible for recurrent malaria if treatment has not intervened.

Box 100.1   Life cycle of *Plasmodium* in humans[1,2]

Exo-erythrocytic and asymptomatic phase of infection

1 Sporozoites reach the blood stream and travel to the liver

2 Hepatocytes are infected and the asexual sporozoites multiply to a form called schizont containing thousands of merozoites

3 After 6–16 days merozoites are liberated into the bloodstream

Erythrocytic phase

4 The merozoites invade the red blood cells

5 In the red blood cells they turn into ring forms, trophozoites, and degrade hemoglobin

6 Once more, this time within red blood cells, the parasite forms squizonts, which multiply and lyse the red blood cells

7 Thousands of merozoites are liberated into the blood stream infecting new red blood cells

8 This process continues with repetitive cycles of red blood cells invasion and lysis resulting in hemolytic anemia

9 Some merozoites differentiate into gametocytes, the form acquired by female mosquitoes after biting an infected human

PATHOGENESIS

P. falciparum infection is more severe with a higher mortality and thus most likely to be implicated when a patient requires palliative care. It is the only *Plasmodium* causing microvascular disease.[12] As the parasites mature the infected red blood cells adhere to the endothelial cells in capillaries and post-capillary venules of, significantly, the brain and kidneys but also other organs.[1,13–15] This sequestration leads to a functional microvascular obstruction.[16,17] Cytokines, e.g. tumor necrosis factor α (TNFα), contribute to the process.[1,18,19]

In addition, there is consumption of glucose and production of lactate by the parasite as well as the hypoglycemic effects of TNFα.[1] These contribute to glucose deprivation, lactate excess, and acidemia at a tissue level. There is lysis of red blood cells leading to acute anemia, as the schizont stage parasites mature. Chronic anemia occurs from lysis and the effect of TNFα.[1,20]

In contrast, *P. vivax* and *P. ovale* do not cause sequestration and hence do not cause the microvascular complications in brain, kidneys, and lungs. However, sickle hemoglobin, which can provide some protection against severe *P. falciparum* does not protect against those parasites that do not sequester.[1,21]

Prevention

Cooperative public health initiatives aimed at controlling mosquito populations and reducing transmission are critical in preventing malaria, e.g. the World Health Organization (WHO) Roll Back Malaria global partnership.[9]

Clinical manifestations

The incubation period after an infectious bite is 8–14 days except for *P. malariae,* which may be 18–42 days.[9] The presentation of uncomplicated malaria is variable and mimics many other infectious diseases.[2] Fever is common and may initially be persistent rather than tertian.[3] Most commonly there may be general malaise, headache, backache, chills, episodic sweating, and sometimes vomiting and abdominal pain.[22] In young children there may be nonspecific irritability, refusal to eat, and vomiting. Anemia, jaundice, hepatomegaly, and splenomegaly may follow.

As malaria can mimic a number of other acute illnesses, it is crucial to have a high index of suspicion.[2,3] It should always be considered in the differential diagnosis of acute febrile illness in endemic areas or in people traveling to these areas. Unless *P. falciparum* infection is diagnosed and treated promptly, deterioration can occur at an alarming rate, especially in children.[3] Severe malaria may develop with its attendant morbidity and mortality.[3,23,24] Severe malaria may present with:[2,3]

- CNS dysfunction – clinical manifestations may vary from confusion, delirium, obtundation to seizures and deep coma. Unrousable coma, not attributable to any other cause in a patient with falciparum malaria is defined by the WHO as cerebral malaria
- Hypoglycemia
- Acidosis
- Acute renal failure
- Abnormal bleeding
- Pulmonary edema
- Hyperparasitemia – this occurs where more than 5 percent of red blood cells are infected

Diagnosis

Microscopic examination of thick and thin blood smears for the parasites is highly sensitive, specific, and economical.[2,3] The thin smear allows identification of the *Plasmodium* species. Rapid diagnostic tests are available, which detect antigens by immunochromatography. They are easy to perform and quick but their sensitivity varies.

Due to the rapid evolution and high mortality of severe malaria it is crucial to make a rapid diagnosis. Treatment may need to be initiated before laboratory tests are available. For practical purposes and in the environment where severe malaria occurs this is justified and often necessary.[2]

Treatment

Severe malaria should, if at all possible, be treated aggressively with appropriate antimalarial medications together with general supportive measures and management of organ failures in an intensive care unit.[3] Antimalarial medications include quinine (WHO recommended drug of choice), quinidine, artesunate, artemether, artemisinin and chloroquine, although the last is of limited use due to drug resistance.[3,24–28]

Even with prompt treatment with an effective antimalarial drug, cerebral malaria has an estimated fatality rate for hospital admissions of 20–50 percent.[2] Sadly, patients often present late and are misdiagnosed. Also, in the environments where severe malaria usually occurs intensive medical support measures and/or appropriate medications are not available.

Symptom management

As part of the management of malaria, meticulous attention must be paid to all symptoms and emotional support of the patient and family. When it is recognized that treatment aimed at aggressive disease is not possible or is futile, palliative care principles clearly must continue and assume the primary focus of care.[2]

CENTRAL NERVOUS SYSTEM SYMPTOMS[2*]

Delirium
In the earlier stages of the disease trajectory attempts must be made to treat any potentially reversible causes of delirium, e.g. dehydration, hypoglycemia, urinary retention, fever. Otherwise the following are important:

- *Environment.* General comfort support measures as always include attention to the physical environment, noise level, presence of family, and quiet music if possible.
- *Medications.* Antipsychotics, e.g. haloperidol 2–5 mg every 6 hours and 2–5 mg every 1 hour prn. Rapid titration may be necessary with initial doses given more frequently. Alternative medications are chlorpromazine and levomepromazine.
- *Sedation.* As well as antipsychotics, the patient may require sedation. Diazepam, lorazepam, and midazolam if available should be considered.

Convulsions
Seizure activity requires the use of anticonvulsants, e.g. diazepam 10–20 mg intravenously (IV), rectally (PR) or intramuscularly (IM); midazolam 5–10 mg IM/IV/SC or phenobarbital 200 mg SC/IM.

Coma
It is essential to pay careful attention to physical care to maintain skin integrity and maintain hygiene.

PAIN

Severe pain may be the result of increased muscle tone and spasm. Baclofen 5–10 mg SC/IM or diazepam 5–10 mg IM/IV may be given. Opioids may also be required.

FEVER

Fever may be alleviated with oral acetaminophen (paracetamol) in the early stages and may be given rectally if necessary.

OTHER ASPECTS

In addition to good symptom management and personal care of the patient, provision of emotional and spiritual support to the patient and family are important. This can be particularly poignant as the disease presenting earlier is curable and as many of the patients are so young. Both the patient and the family also require clear explanation as to the nature of the disease, prognosis, and symptoms that are being experienced and their management.

RABIES

Rabies is a fatal acute encephalomyelitis and remains one of the most common viral causes of death in developing countries.[4,5,29] It has 100 percent mortality in previously unvaccinated patients who, without palliation have agonizing deaths.[4,5]

Reliable data on the incidence of rabies in humans are scarce. Estimates of the incidence, worldwide, range from 40 000 to 100 000 annually, the vast majority in developing countries.[4–6,30] It is estimated that some 10 million people receive postexposure treatments annually, following bites from animals suspected to have rabies. Unfortunately most are treated with vaccines carrying a high risk of neurological complications. The incidence of human rabies in developed countries is very low, e.g. one to two cases annually in the 1990s in the USA. Some island nations are reported to be rabies free. Most cases in developed countries are from bites from rabid wild animals, e.g. bats, foxes, and raccoons. In developing countries bites from domestic and feral animals, usually dogs, are responsible.[5,6,30] Transmission between humans has only been documented as a result of corneal transplant.[4–6,29]

Etiology and pathogenesis[4–6]

Rabies is caused by a *Lyssavirus*, a bullet-shaped, negative-stranded RNA virus, a member of the *Rhabdoviridae* family. It is transmitted via the saliva of infected animals, being introduced by bites, scratches, licks on broken skin, and contact with mucous membranes. After entry through a breach in the skin or mucous membrane the virus replicates in muscle cells, and infects the muscle spindle and

subsequently the nerve innervating the spindle. Further replication occurs within these neurons and virus rapidly spreads centrally toward the central nervous system. Virus is present within dorsal root ganglia within 72 hours of inoculation.

Rabies infection appears to require local viral replication, perhaps to reach a critical load, before nervous system infection occurs.[4,5] Thus, if anti-rabies immunoglobulin and active immunization are given in time, virus may be prevented from spread to the nervous system and disease prevented. Once virus has entered the peripheral nerve, however, disease is inevitable. After spreading to the spinal cord, the virus spreads throughout the central nervous system and then centrifugally out to the rest of the body via peripheral nerves. High concentration of virus in saliva results from shedding from sensory nerve endings in the oral mucosa as well as replication in salivary glands. The brain in rabies shows an encephalic picture and the spinal cord shows severe inflammation and necrosis.

Prevention[5,6]

The control of animal rabies is central to the prevention of human disease. Unfortunately, few countries have been able to achieve this. Prophylaxis for domestic animals and humans at high risk together with postexposure treatment for exposed humans is the basis of control. Dramatic decreases in human cases have been reported recently in China, Thailand, Sri Lanka, and Latin America, This follows the implementation of programs for improved postexposure treatment of humans and the vaccination of dogs, with also encouraging trends in the Philippines.[31] However, in many developing countries the cost of these programs and the cost of controlling feral dog populations remain obstacles and may not achieve political priority.

PREEXPOSURE PROPHYLAXIS[5,6,31]

Preexposure prophylaxis (PEP) is usually confined to people at high risk of rabies exposure, e.g. veterinarians and laboratory workers. Those caring for patients with rabies should ideally be vaccinated, but in the underresourced settings that rabies usually occurs this is prohibitively expensive and vaccination is unlikely to occur. Transmission to healthcare workers has *not* been reported and remains a theoretical risk when normal universal infection control measures are observed. This may, of course be difficult if a patient has uncontrolled aggressive and violent delirium.

The recommended PEP involves a series of three intramuscular or intradermal injections given on days 0, 7, and 21 or 28 with a booster every 2–3 years.

Postexposure treatment[6,31,32]

- *First aid*. The most effective mechanism to protect against rabies following a suspicious bite is to vigorously wash and flush the wound with soap and water. Ethanol, iodine or povidone-iodine solution should be applied.
- *Anti-rabies immunoglobulin*. This should ideally be applied on the day of the bite (day 0) but can be applied up to day 7. Human immunoglobulin, if available should be used or alternatively equine, following a skin test. The immunoglobulin is infiltrated in and around the wound.
- *Vaccination*. This is recommended following a bite from an animal in which rabies is a possibility but may be discontinued if the animal remains healthy for 10 days or is proved at autopsy to be negative for rabies. Purified vero-cell vaccine (PVCV) or purified duck embryo (PDEV) vaccines are used. There are various vaccination schedules. Reduced intradermal regimens have been found to be effective and less expensive.

Obstacles to treatment

Although postexposure treatment is available there remain real and heart-rending obstacles to obtaining this. Many patients do not seek treatment through ignorance, fear, folk beliefs, and overwhelming poverty. Education programs are making inroads in some places. An example of this is the national program of the Department of Health in the Philippines encouraging pet owners to have dogs vaccinated and to seek vaccination following a suspicious bite.[5] However, overwhelming poverty and political motivation remain worldwide issues in the eradication of rabies as with many global health problems.

Clinical manifestations (Table 100.1)[4,5,29]

The incubation period for rabies may be from a few days to several years. The average incubation period is 20–90 days. The time of onset of symptoms depends on:

- the severity of the wound, i.e. the depth, size, or multiplicity
- clothing protection at the site of bite
- the site of wound in relation to the brain, i.e. patients with facial bites develop symptoms earlier.

The early clinical features are nonspecific influenzalike symptoms and localized paresthesia, pain, and pruritus at the bite site. The later clinical presentation evolves into two forms: the encephalitic (furious) form (in about 80 percent of patients) or the paralytic (dumb) form.

'FURIOUS' RABIES

The features of encephalitic rabies are typically described as hydrophobia – representing an exaggerated irritant reflex of the respiratory tract with laryngeal spasm – episodic hyperactivity, seizures, aerophobia, hyperventilation, and

Table 100.1 *Clinical stages and symptoms of rabies[5]*

Stage	Time period	Symptoms
Incubation period	<30 days (25%) 30–90 days (50%) 90 days–1year (20%) >1 year (5%)	
Prodromal symptoms	2–10 days	At bite site: paresthesia, pain and pruritus General: fever, malaise nausea, vomiting
Acute disease		

Furious (80%)	2–7 days	Hydrophobia
		Aerophobia
		Dysphagia
		Delirium with:
		  aggression
		  disorientation
		  hallucinations
		  terror
		  hyperexcitement
		  hypervigilance
		  confusion
		Autonomic dysfunction with:
		  hypersalivation
		  sweating
		  priapism
		Seizures

Dumb (20%)	2–7 days	Ascending flaccid paralysis

autonomic dysfunction with papillary dilatation, increased salivation, sweating, and occasionally priapism. However, the feature of rabies that is often most distressing for patients, families and carers is delirium. The features that predominate are aggression, disorientation, hallucinations, overwhelming terror, hyperexcitability, hypervigilance, and confusion.

'DUMB' RABIES

Paralytic rabies is characterized by ascending paralysis resembling Guillain–Barré syndrome.

Outcome

Whatever the initial symptom complex, cardiac arrhythmias and coma intervene and death is inevitable within a few days. Most patients die within 72 hours of the onset of clinical symptoms.

Symptom management

DELIRIUM[5,33,34*]

As in any palliative care situation the first priority is good symptom management. This in turn allows personal care of the patient and psychosocial and spiritual issues for the patient and family to be addressed. There are few other situations where this is as true as in need for control of the delirium associated with rabies. Rabies patients without appropriate medication often die alone in a locked and barred room, physically restrained, agitated, terrified, paranoid, and with classic hydrophobia and aerophobia. The delirium can be managed with:

- Haloperidol 5 mg given hourly subcutaneously (SC) or IM titrated to the desired effect (with a minimum of three doses), followed by regular four hourly injections.
- Levomepromazine 25–100 mg every 4–6 hours SC or chlorpromazine 50–100 mg every 4–6 hours IM may be considered as alternatives.
- It may be necessary to add sedation with a benzodiazepine, e.g. diazepam or midazolam.

HYDROPHOBIA AND AEROPHOBIA

These do not respond to haloperidol as shown in a recent unpublished study (Starfish Palliative Care Program, San Lazaro Hospital, Manila, Republic of Philippines, personal communication, November 2004, March 2005, July 2005). Hydrophobia describes, in fact the exaggerated reflex of the respiratory tract with laryngeal spasm[4] and is not a 'phobic' symptom as such. It is more likely to respond to antispasmodics such as diazepam (Starfish Palliative Care Program, personal communication, November 2004, March 2005, July 2005).

SECRETIONS

These have been successfully controlled with diphenhydramine 50–100 mg every 4–6 hours.[5,33,34*] Alternatives that may be considered, if available, are glycopyrrolate or hyoscine butylbromide. Hyoscine hydrobromide should not be used as it may aggravate agitation.

SEIZURE ACTIVITY

This will require the use of anticonvulsants, e.g. benzodiazepines, such as diazepam or midazolam, or phenobarbital.

NAUSEA AND VOMITING

Antidopaminergic antipsychotics such as haloperidol and levomepromazine are effective antiemetics. If these are not being used to control delirium then other antiemetics such as metoclopramide may be considered.

FEVER

This is usually a more significant symptom in the prodromal phase and can be managed with paracetamol.

Physical environment

The room in which the patient is cared for should be clean, pleasant, as quiet as possible, and free of draughts. Seating should be available for family.

Family support and communication ([5,33,34] and Starfish Palliative Care Program, personal communication, November 2004, March 2005, July 2005)

When symptom control is achieved patient and family can communicate, say their goodbyes, and deal with as much unfinished business as possible in the short remaining time. Staff have an important role in supporting and facilitating this. To support the family the following are important:

- Space should be provided close to the patient for the family to rest, talk, and receive support and information.
- Honest gentle communication concerning the imminence of death should be provided. Emotional support is necessary for the family who are experiencing a sudden loss, often of the family breadwinner. Any practical advice concerning social support services available is important. Most often the family is from a very poor socioeconomic background.
- Discussion and education concerning transmission of disease and indications for postexposure vaccination. Families need information that the disease is spread by saliva introduced into a wound or mucous membrane. It is not transmitted through touching intact skin. Thus families need reassurance that it is safe to sit with their dying loved one and that careful contact will not transmit the disease. Postexposure vaccination is recommended for:
  – sexual partners, due to the possibility of transmission through saliva
  – others considered at risk, e.g. a contact who has been bitten by the patient or exposed to the saliva of the patient.
- When a rabies patient's symptoms are well controlled the family may decide to take their loved one home (reference 5 and Starfish Palliative Care Program, personal communication, November 2004, March 2005, July 2005). This may be for purely important economic reasons. It is cheaper to transport a live person than a dead body. It also has obvious emotional and social benefits for patient and family. Families need careful counseling and practical support for this to occur.

Carer education and support[5]

All healthcare professionals and other carers involved in caring for rabies patients need education regarding:

- The facts concerning rabies transmission. In most developing countries PEP is prohibitively expensive. However, as mentioned above, transmission to healthcare workers has *not* been reported and remains theoretical and unlikely if normal care and universal infection control rules are followed. Staff attending to patients' personal care should ideally wear protective gown, gloves, and goggles. If good symptom control is achieved the risk of being bitten or spat at by a patient is minimized.
- The principles of palliative care, emphasizing the pivotal role of good symptom control with *appropriate*, *adequate*, *regular* medication.

TUBERCULOSIS

Tuberculosis is an infectious disease caused by mycobacteria. The histology characteristically consists of granulomas.[7] Infection usually occurs following inhalation of infectious particles into the lungs.[7,8] It then spreads via blood stream, lymphatics, airways, or direct extension. Pulmonary tuberculosis is the most common form of the disease constituting 80 percent of tuberculosis infections in developing countries. However, any organ or part of the body can be affected.

Mycobacterium tuberculosis infects nearly 2 billion people worldwide and causes 3 million deaths a year.[7] These occur mostly in developing countries and mainly in the age group of 15–49 years.[8] Tuberculosis is associated with overcrowding, poverty, malnutrition, alcohol abuse, and an increase in the rate of human immunodeficiency virus (HIV)/acquired immune deficiency syndrome (AIDS) infection.[7,8] In developed countries tuberculosis had been steadily decreasing until the mid-1980s. With the AIDS epidemic this decrement has ceased or reversed and is again concentrated in underprivileged and low socioeconomic communities in these countries.[7,35,36]

Pathogenesis and transmission[7,8]

The usual causative organism is *M. tuberculosis*, an aerobic, nonspore-forming acid-fast bacillus, but occasionally *M. bovine* can also be the cause. Microorganisms are expelled into the air in tiny droplets from an infected patient with pulmonary tuberculosis. These dry rapidly, becoming droplet nuclei that harbor the microorganisms and may remain suspended in air for several hours. *M. tuberculosis* can remain alive for up to several hours, and even up to 3 years in a closed environment. A close contact may inhale the droplet nuclei, following which bacterial multiplication begins in the terminal airspaces. Initially the focus is subpleural – in the mid-lung zone. Macrophages ingest the bacteria and an

initial pulmonary Ghon focus is formed. Macrophages may be carried by the lymphatics to regional lymph nodes, where they form the primary complex, and sometimes to distant lymph nodes. However, in an immunocompromised host they are not retained in the lymph nodes and may spread through the blood stream to other organs. The primary complex itself may progress causing bronchial collapse, erosion of the bronchus and further distal spread, pneumonia and cavitation or lympho-hematogenous dissemination, resulting in miliary tuberculosis.

Development of tuberculosis is usually arrested at the primary stage by the host's immune system. Hence healthy well-nourished individuals with an intact immune system do not usually develop the disease, whereas those with a compromised immune system, e.g. due to malnutrition or HIV infection, are very likely to develop tuberculosis following mycobacterium exposure. Determinants of infection occurring are: closeness of contact and infectiousness of the source. Patients with positive smears, i.e. direct microscopy positive, are highly infectious. Those with positive findings only on culture, i.e. direct microscopy negative, are less infectious.

Tuberculosis morbidity in a given population, however, is determined by two factors, the risk of infection (e.g. as in overcrowding) and the risk of developing active disease once infected (e.g. as where immune deficiency exists).

Clinical presentation and diagnosis[7,8,37]

In the presence of nonspecific symptoms tuberculosis should always be suspected if occurring in the environment previously described. This is especially so where there are associated sputum-positive family or contacts.

PULMONARY TUBERCULOSIS

The respiratory symptoms of pulmonary tuberculosis may be cough, sputum, which may be bloodstained, dysnea, and chest wall and pleuritic pain.[7,8] Generalized symptoms include weight loss, anorexia, fatigue cachexia, night sweats, and fever.[7,8] Diagnosis is made by direct microscopy of sputum smears using Ziehl–Neelsen stain (wherever possible three specimens are collected), sputum culture, and radiography.[7,8]

COMPLICATIONS[8]

Complications of pulmonary tuberculosis include hemoptysis, acute respiratory distress (due to pleural effusion, lung collapse, pneumothorax or cardiopulmonary insufficiency due to cor pulmonale), and bronchiectasis and/or pulmonary fibrosis.

EXTRAPULMONARY TUBERCULOSIS

Tuberculosis lymphadenitis and pleuritis are the two most common.[7,8] Others are: meningitis, pericarditis, peritonitis,

and urogenital and skeletal tuberculosis.[7,8] The specific symptoms will depend on the organ involved, e.g. chest pain in pleuritis and lymphadenitis, bone pain in skeletal tuberculosis and delirium, and seizure activity, headache, vomiting, meningism, focal signs, and coma in tuberculosis meningitis.

TUBERCULIN SKIN TESTS

These reflect exposure to *M. tuberculosis* and have little value in diagnosing clinical disease where tuberculosis is common. Especially in adults, a positive test is infrequently followed by disease and a negative test does not exclude disease. It may be useful in young children who have been in contact with infectious persons recently. The tine test is usually used for screening and contact tracing in children while the Mantoux test is preferred for diagnosis. The diagnosis of tuberculosis in children may be difficult and the WHO has developed clear criteria in this respect.[8]

Tuberculosis treatment[7,8]

The cornerstone of treatment of tuberculosis is appropriate chemotherapy. The usual antituberculosis drugs used are isoniazid, rifampicin, pyrazinamide, ethambutol, and streptomycin. For successful treatment it is essential that the medications are taken:

- in appropriate combination
- in the correct dosage
- regularly
- for a sufficient period to prevent relapse, i.e. for at least 6 months.

Unfortunately these criteria are often not met in environments of poverty and overcrowding,[35,38] and patient ignorance of the importance of continued treatment. Inadequately treated tuberculosis can be worse than not treating at all due to the emergence of drug-resistant organisms.[8] Therefore education and counseling of patients, their families and communities and public health measures are critical in the management of tuberculosis.

The implementation of the highly cost effective Directly Observed Treatment Short Course (DOTS)[8*] in 1991 has resulted in cure rates of 95 percent even in some of the poorest countries. The DOTS strategy uses four different drugs given over 6–8 months, with medications taken under direct observation of healthcare workers who continually monitor patients during the course.

Unfortunately in recent years there has been an alarming emergence of multidrug-resistant (MDR) tuberculosis organisms in some populations. These can develop when incorrect medications or wrong combinations are given or drugs are not taken for long enough.[8] It is estimated that some 50 million people worldwide are already infected with MDR tuberculosis. The WHO and its international partners have formed the DOTS-plus working group in an attempt to address this problem.[8,39–48]

Tuberculosis prevention[8,49–51]

Bacille Calmette Guérin (BCG) vaccination, using live attenuated vaccine from a strain of *M. bovis*, is used for prevention of tuberculosis throughout much of the world. Although evidence is conflicting it is suggested that BCG vaccination of children will result in 60–80 percent decrease in the incidence of tuberculosis in a population.

Chemoprophylaxis is used to treat those at risk of developing tuberculosis, usually using isoniazid.[8,37] It is used for contacts of smear-positive patients and those with depressed immunity in a population where tuberculosis is prevalent.[8]

Palliative care

Tuberculosis is treatable and every effort should be made to treat and cure the disease even in extremely sick patients.[8] However, when this is no longer achievable, applying palliative care principles is paramount. The focus must include attention to physical, emotional, spiritual, social, and educational needs of the patient and family.

Symptom management

Most patients dying from tuberculosis have respiratory and nonspecific symptoms (Box 100.2).[8]

Box 100.2 Symptoms in dying patients with pulmonary tuberculosis

Respiratory symptoms
- Dyspnea
- Cough
- Hemoptysis
- Thoracic pain
- Terminal secretions

General symptoms
- Fatigue
- Cachexia
- Night sweats
- Fever

RESPIRATORY SYMPTOMS

Dyspnea
- Treat any reversible aspect
  - Pleural effusion: drain if feasible.
  - Associated obstructive airways disease: optimal use of bronchodilators and steroids.

- General symptomatic measures
  - Supplemental oxygen in the presence of hypoxia.
  - Air flow using fans or simply open window.
  - Opioids: these reduce the subjective sensation of breathlessness.[52*] If the patient is opioid naïve a starting dose of oral morphine 5–10 mg every 4 hours or 2.5–5 mg SC every 4 hours with additional as needed doses available for exacerbations. Patients will still have tachypnea and this needs to be explained to families with reassurance that this in itself is not distressing.[52]
  - Benzodiazepines: where there are significant anxiety episodes benzodiazepines could be considered, e.g. lorazepam 1 mg prn or diazepam 5–10 mg prn.

Cough
A dry cough is always present in these patients. As the disease progresses it may become purulent and blood stained. Opioids may be useful, e.g. morphine 5–10 mg every 4 hours prn. Inhaled cromoglicate may be useful.

Hemoptysis
Hemoptysis can be a very distressing symptom for both patient and family especially when massive, when it can be the terminal event. The following should be considered:

- In the earlier stages tranexamic acid 500 mg three times daily, if available, should be considered.
- Dark linen and towels, if available, can reduce the visual impact.
- If massive bleeding and associated choking are possibilities, a short-acting benzodiazepine such as midazolam or lorazepam should be available. In the home situation a preloaded syringe, e.g. of midazolam 5–10 mg, should be made available.

Respiratory secretions
As the patient becomes more unresponsive and secretions accumulate it is important to counsel the family that the noisy breathing is not distressing for the patient and represents pooling of secretions. It does not indicate that the patient is choking.[52] Medications that may be used to reduce secretions are glycopyrrolate 0.4 mg SC every 4 hours or hyoscine butylbromide 10–20 mg SC every 4–6 hours. Hyoscine hydrobromide should be used with caution as it may cause or aggravate agitation.

NONSPECIFIC SYMPTOMS

Fatigue and cachexia
Fatigue and cachexia are among the most common and severe symptoms in tuberculosis. Pain and clinical depression may contribute to fatigue and should be appropriately managed. Antidepressants and psychostimulants, e.g. methylphenidate should be considered.

Patients with anemia may benefit from blood transfusion. Food intake *per se* is unlikely to resolve the severe weight loss

related to tuberculosis as cachexia is a syndrome resulting from metabolic abnormalities. However, it may be that cachexia syndrome has been confused with malnutrition in the environment where these patients are dying. Encouraging and extraordinary results have been seen where patients have merely been fed adequately (Starfish Palliative Care Program, personal communication, November 2004, March 2005, July 2005). However, in the presence of true cachexia syndrome the social value of meals remains important even where the patient is able to take very little. Families need counseling that cachexia is a metabolic consequence of advanced disease.

Night sweats and fever

These are common and unpleasant. Hydration needs to be maintained. Fever can be managed with acetaminophen or nonsteroidal anti-inflammatory medications.

PAIN

Pain is often underreported and under-treated due to reluctance to use analgesics in the presence of dyspnea. Thoracic and skeletal pain is managed with the usual principles of initially using regular nonopioids, e.g. acetaminophen and a nonsteroidal anti-inflammatory, moving to opioids as necessary.

OTHER SYMPTOMS

Less common extrapulmonary tuberculosis presentations require symptom management depending on the site. For example tuberculosis meningitis may result in delirium, seizure activity, and coma requiring appropriate attention to these symptoms.

Physical care[8]

Dying tuberculosis patients are inevitably wasted, dependent and often bed bound. They require meticulous attention to skin care and bodily functions to prevent pressure areas and skin excoriation, and tears.

Emotional, spiritual, and social needs

The very diagnosis of tuberculosis without the knowledge that it is incurable and the patient is now dying will have evoked many emotional issues including fear, grief, anger, and despair. Patients are often in the most productive part of their lives and may be parents and breadwinners. As well as fears for themselves they may have fears for future support of their families, a sense of uselessness as well as the stigma attached to the diagnosis.

Patients may see their disease and fate as punishment and this may be inextricably intertwined with spiritual and religious beliefs. Emotional and spiritual counseling and support for both patient and family are thus important. Patients and families may become socially isolated as a result of the diagnosis. The diagnosis has important personal and financial implications. The despair resulting may be compounded by the impoverished, underresourced environments in which patients die from tuberculosis, where the above mentioned suggestions made for symptom management of the dying patient are unavailable and/or unaffordable.

These factors, and the public health issue of ensuring that families and contacts are treated and monitored, emphasizes the inextricable interconnection between public health medicine and palliative care in the management of tuberculosis in developing countries.

Key learning points

- Malaria, rabies, and tuberculosis are treatable or preventable diseases that together result in millions of deaths with uncontrolled symptoms in the developing world.

- When it is clear that no disease-orientated treatment is available or no longer possible, palliation of symptoms is paramount. This must not be seen as an excuse to reduce attempts to aggressively treat tuberculosis and malaria if at all possible.

- Patients dying of these diseases are often young and in their most productive years. The families' despair and grief needs emotional and social support.

- Public health and palliative care are inextricably linked in the management of these patients, their families, and communities.

Practical aspects of palliative care delivery in the developing world

ROBERTO WENK, LILIANA DE LIMA

INTRODUCTION

The *World Health Report*, published by the World Health Organization (WHO), indicates that almost 57 million deaths occurred worldwide in 2001. The vast majority of these deaths occurred in developing countries, where over three-fourths of the people in the world live. Infectious diseases such as human immunodeficiency virus (HIV) infection, malaria, tuberculosis, and respiratory infections caused over half of the cumulative deaths in developing countries.[1]

With the exception of the USA, developed countries registered a decline or no change in population during the last decade, and 99 percent of population growth took place in the developing countries. If this trend continues, by 2050, industrialized nations will record a population increase of only 4 percent, whereas the population in developing countries will expand by 55 percent. For example, countries in western Asia are expected to gain about 186 million people by 2050.[1] Overall, the world population will reach approximately 9 billion by mid century. Developing countries will face the burden of this population growth, which will result in greater demand for healthcare services. With limited funding, inadequate infrastructure, and limited access to preventive and curative measures, more individuals will require palliative care services.

The developing world varies greatly from country to country and region to region. A limited number of excellent facilities are available in developing countries, with the latest technology and medications and capable of delivering care similar to that of the developed countries, but the majority of the population does not have access to these institutions and are cared for in facilities with limited resources.

Healthcare initiatives in the developing world must deal with poverty, inadequate infrastructure, poor administrative systems, limited access to medications, bureaucratic and inefficient processes related to the production, importation and distribution of medications, restrictive laws and regulations related to the prescribing of opioids, insufficient support from national health authorities, low level of political will to establish palliative care programs,[2–4] and limited education for healthcare providers.[5] An additional barrier to the implementation of palliative care programs in developing countries is that the majority of healthcare spending, both public and private, goes toward curative efforts.

Patients in resource-poor settings pose challenges which need to be taken into account when developing palliative care programs and strategies. Many palliative care initiatives in these countries have developed as islands of excellence but they are not well integrated into the national health systems and have limited impact. Palliative care is still not included in the mainstream of care and tends to be delegated to a secondary role. This has resulted in the development and implementation of different models of care. Care is provided by local programs and teams with structural and operational differences shaped by the needs and limitations of each setting rather than by following a set of consistent guidelines. Programs are adapted to their environment and most survive using resources in unique ways.[6] Sadly, there is evidence that the quality of care during the dying process is poor and that many patients suffer unnecessary pain and symptoms.[7]

To adapt to these limitations and the needs of the population, it is imperative that palliative care workers adopt

practical measures to provide cost-effective and efficient care to the patients. These include strategies to build and improve capacity, adopting low-cost treatment measures, developing data management procedures to establish mechanisms for quality control, and identifying sources of funding to cover the costs of the palliative care services. This chapter describes these strategies and provides some examples of settings where they have been successful in improving the delivery of palliative care.

CAPACITY–BUILDING STRATEGIES

Capacity strengthening is crucial for effective palliative care programs with the ability to reach the majority of the population in need. Many initiatives have been successful largely as a result of the capacity-building strategies adopted by program leaders, which have positively influenced the willingness of policy makers to incorporate palliative care in the healthcare agendas. Some of the programs implemented in developed countries that have shown significant results may be applicable to and adapted by developing countries. Initiatives such as the Programa de Cuidados Paliativos del Servicio Extremeño de Salud in Spain, have been successful by adopting a basic structure that relies on full regional coverage through mobile teams consisting of a doctor, a nurse, and a psychologist, who visit patients either at home or in any of the public hospitals of the region. The program requires centralized coordination as a way to monitor progress and activities and to measure outcomes.[8]

As a result of these capacity-building strategies, several important governmental as well as nongovernmental palliative care initiatives have emerged in recent years in developing countries. But even with these improvements, there are still enormous gaps to be bridged to bring palliative care to those in need of it.

Community health approach in home care

Given the extent of the problem in developing countries where healthcare resources are severely limited, a community health approach that relies extensively on home-based care and community involvement in the provision of care and support is the most cost-effective approach. The community health approach requires development of teams and networking with actions and tasks carried out by community members; a high level of population coverage; and periodic evaluations to improve the quality and performance of programs providing palliative care in patients' homes. In some countries, for diseases such as HIV/acquired immune deficiency syndrome (AIDS) and cancer these palliative care activities are integrated with the ongoing activities of other healthcare providers.

In Kerala, India, neighborhood network palliative care programs have shown exceptionally good success rates.

More than 50 percent coverage for all severely ill patients seems to have been achieved within 2 years of initiation of the project and the district where it was first launched now has an estimated coverage of more than 70 percent. Involving the local community in all stages, from planning to monitoring, has ensured sustainability of the project. Neighborhood groups find the resources to deliver care locally: 80 percent of the funds for programs are raised locally. The groups' advocacy role also results in generating support from local government.[9]

In Africa, several model programs are demonstrating the beneficial integration of hospice-, community-, and home-based care for people with cancer and HIV/AIDS.[10,11] For example, the South Coast Hospice in KwaZulu-Natal, South Africa, developed an integrated care program in which patients with HIV/AIDS are referred to teams of nurses and trained community caregivers who care for them in their own homes.[12] The program has halved average patient stays at the local hospital, and extended care provided at home costs less than a 2-day stay in the hospital.[13] Hospice Uganda has been successful in implementing a hospice model which has become part of Uganda's national healthcare policy. Hospice Uganda has been particularly successful in improving access to morphine by establishing a cost-effective distribution system of inexpensive morphine sulfate preparations.[14]

Volunteers

In settings where human resources are limited, the use of volunteers for home-based care programs has proved to be useful and practical. Volunteers play an essential role in palliative care, and more so in developing countries where limited funds hinder the capacity to hire human resources for end-of-life care.[15,16] Patients in developing countries who are diagnosed with terminal diseases are usually sent home to die with little or no treatment recommendations. By carrying out many of the tasks of the palliative care providers, volunteers from the community become an important and crucial source of support for such patients and their families and when available, to the palliative care team.[17] In this process family members are empowered to the highest possible degree to ensure continuity of treatment.

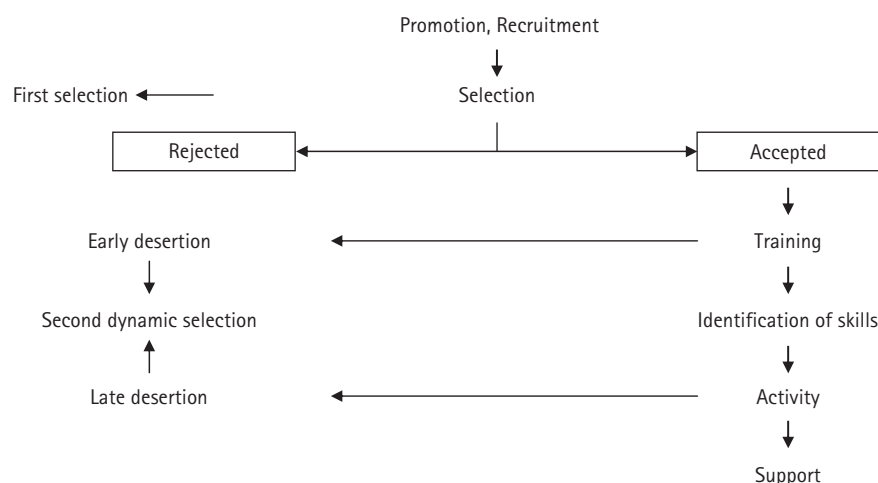
Volunteers in palliative care have proved to be efficient in two main areas: direct patient care (feeding, hygiene, administration of medication, patient evaluation, helping in domestic chores such as shopping for food, cleaning house, cooking, etc.) and providing administrative support to the program (administrative and secretarial tasks). Individuals who are interested in undertaking volunteer work in palliative care need to be carefully selected, trained, and taught about the chores and tasks that they will be helping with. Some of the practical aspects in volunteer programs which have proved to be effective in the


Figure 101.1 *Process to initiate and maintain a volunteer program in palliative care.*

Programa Argentino de Medicina Paliativa – Fundacion FEMEBA (PAMPFF) include:

- *Selection.* Careful selection guidelines are aimed to match the required personal skills[18,19] with the needs of the patient, the family, and the program.
- *Dropouts.* The program found that 10 percent of volunteers who fulfilled the selection criteria dropped out during the training. Fifteen percent of volunteers who completed the training dropped out after starting the work. A strategy was designed to solve this problem and early and late dropouts were significantly reduced after including a description of the volunteer tasks, and stories of other volunteers' experiences, and an initial interview with a psychologist before training.
- *Training:* A comprehensive training program for volunteers is a practical way to maximize their role and to prevent dropout. PAMPFF's training program is based on other successful initiatives, and includes bedside training and spending time with the palliative care team before being sent out into the community.[20] Figure 101.1 shows the steps to initiate and maintain a volunteer program in palliative care designed by the PAMPFF group.[21]

Volunteers need to feel that they have the support of the program, the patient, and the family. Much of the work done by volunteers is based on mutual trust, and in order for volunteers to feel comfortable in their role and perform their tasks they need to know that their work is crucial and needed.

Distant care

An additional barrier to the implementation of palliative care programs in developing countries is that a majority of healthcare spending, both public and private, goes toward curative efforts; hospitals in urban areas often account for more than 80 percent of total healthcare costs. However, the majority of the population in the developing world continues to live in rural areas.[22] This means that inexpensive and effective healthcare strategies need to be put in place to improve the access and delivery of care to the rural populations. One of these strategies is 'distant care'. In settings where the provision of care in distant areas is not possible, distant care programs, through a main care provider, have proved to be a useful and practical approach.

Most palliative care teams or units in developing countries are based in large and medium urban areas[23] and terminally ill patients living in small cities and rural areas need to travel long distances to receive palliative care. This becomes even more difficult when patients are frail and unable to travel for follow-up visits. Additional difficulties patients may face when having to travel to cities to see a doctor include not having access to a car, having to travel slowly and uncomfortably by bus, living in areas with no access to public transportation, or inability to afford the transportation fees.[24]

As in other regions of the world, some teams have solved this problem with the help of trained volunteers who do home visits, during which they perform basic care tasks and provide practical support to the main caregiver.[25] However, this is not always possible as not all volunteers are willing to travel to rural areas or have access to the required resources to perform such visits. To improve the care for such patient groups, some teams in developing countries have implemented the practical strategy of 'distant care', which is carried out through a main caregiver and without an initial clinical evaluation of the patient.[26]

The PAMPFF implements distant care as follows:

1 When a patient is unable to attend an initial doctor evaluation, a relative seeks help by contacting the palliative care group or care provider.
2 The relative is then informed about 'distant care' and its limitations, including the risks involved.
3 If acceptable to them, the relative is asked to identify the main caregiver in the family.
4 The main caregiver then provides information about the patient, his/her clinical situation using an assessment form which combines elements of the Edmonton Symptom Assessment Scale (ESAS)[27,28**] and the Memorial Symptom Assessment System (MSAS).[29**] Figure 101.2

shows the assessment form used by the PAMPFF which includes items from these scales, and has proved to be useful in the palliative care program.

5   Based on existing information about frequent syndromes in palliative care and using the information provided by the main caregiver, a presumptive diagnosis of the patient's condition is made.

6   If needed, medications are prescribed for pain and symptom control, following the WHO[30***] guidelines and other recommendations in the literature.

7   The main caregiver receives verbal and written instructions on the administration of medications, symptom evaluation, diet and hydration, hygiene and other important tasks.

8   The main caregiver is given a phone number that they can call to consult the team at any time and they are asked to report the patient's situation once a week.

9   Patients may be hospitalized in public institutions for severe or refractory symptoms or if the main caregiver is unable to continue providing the necessary care.

A pilot study measured the effectiveness of the distant care model[26*] and indicated that it is significantly correct and helpful. The data showed that the presumptive diagnosis was incorrect in 10 percent of the cases, and the majority of the main caregivers reported being very satisfied with the level of care provided.

Diagnosing and treating a patient without clinical assessment entails a risk but the benefits of providing comfort and relief of suffering greatly surpass this risk. Distant care fulfills both the medical responsibility of caring for people with the available resources and the therapeutic obligation of providing treatment with a favorable benefit/burden ratio.[31]

COST–EFFECTIVE TREATMENT STRATEGIES

The WHO and several professional and scientific organizations have promoted public health policies and made recommendation to national governments to implement pain relief and palliative care as components of cancer and AIDS care.[6,30***,32***,33] A large body of knowledge has emerged on the assessment and management of the physical and psychosocial problems that occur in patients who develop cancer and other progressive incurable illnesses. However, the overwhelming majority of the available written material refers to the delivery of palliative care using resources mostly available in developed countries which may not be available in developing countries or may not be applicable to the conditions and diseases that occur in the patient population. In addition, there are socioeconomic and cultural issues that pose particular challenges for the healthcare team. By motivating and empowering health care providers to develop their own treatment protocols and by enabling the implementation of appropriate knowledge in the field of palliative care, both the quality of life and the quality of death of terminally ill people can be improved significantly.[25]

Some treatment strategies and inexpensive technologies have been successfully adopted and implemented in the developing world. A few of these include:

●   *Proctoclysis*. This is a simple and inexpensive alternative method of hydration, which may be helpful when resources are limited. A small nasogastric tube is inserted in the rectum for hydration, daily or every other day. It uses the colon's intrinsic ability to absorb normal saline or tap water. Assessments of comfort showed that this technique is well tolerated and that family members can successfully administer proctoclysis at home.[34*] This method may be especially helpful in situations in which technical difficulties make intravenous or subcutaneous infusion difficult or expensive. Such settings may include developing countries, a rural setting, or when nursing care is limited.

●   *Edmonton injector*. The Edmonton injector is a simple, nondisposable, low-cost device, which was originally designed in Argentina. It permits patients to self-administer injections of opioids, metoclopramide, or other drugs intermittently into a subcutaneously inserted needle. A bag containing 50–100 mL of medication allows pharmacists to prepare the medication from powder at a minimal cost. A simple mechanical movement safely allows patients to inject medication. The device does not need batteries and requires little training for use by patients and families. The cost of this treatment is less than US$1.00 per day and the device is not patented, thus enabling groups in developing countries to manufacture their own devices.[35*] Unfortunately, in some countries this injector is not available or has not been approved by the local healthcare authorities, mostly due to its extremely low cost which makes it unattractive to manufacturers.

●   *Methadone*. A synthetic opioid and *N*-methyl-D-aspartate (NMDA) antagonist, methadone is a potent analgesic for treating cancer pain. Its characteristics include excellent absorption, high lipid solubility, high potency, long half-life, lack of known metabolites, decreased opioid cross-tolerance, and low cost which makes it suitable for developing countries.[36***,37**]

●   *Thalidomide*. This drug has been available for approximately 50 years but its beneficial effect in large research studies has not been established. In some pilot studies it has been found to be effective in reducing anorexia, chronic nausea, fatigue, and insomnia in patients with advanced cancer.[38*] It has also been found to have analgesic effects in patients with neuropathic pain related to leprosy reactions and aphthous ulcers related to HIV. The drug is not patent protected and therefore it could be readily available at a minimal cost to developing countries. Unfortunately, there has been no major research on this agent and further studies need to be conducted to determine the potential beneficial uses in cachexia, fatigue, and other symptoms related to advanced cancer.

AVAILABILITY AND ACCESS TO OPIOID ANALGESICS

Pain relief is the cornerstone of palliative care and adequate access to and availability of opioid analgesics to all patients in need are crucial.[39,40] Many countries have reported an improvement in the availability of different weak and strong opioid analgesics but the high prices relative to the monthly salary constitutes a barrier to access.[41*] A recent study among developing and developed nations demonstrated that the median cost of opioid medication was twice as high in developing countries as it is in developed countries. In US dollars, a 30-day prescription was US$112 in developing countries compared with US $53 in developed countries. Cost as percent of gross national product (GNP) per capita per month was 10-fold higher in developing countries where patients have to spend more than a third of their salary to cover pain therapy. Median cost was 31 percent of GNP per capita per month in the developing countries compared with 3 percent of GNP per capita per month in the developed countries. Half of opioid preparations cost more than 33 percent of monthly GNP per capita in developing countries compared with only 4 percent in developed countries. And there are fewer programs to offset medication costs in developing countries. Only one of the five developing nations (20 percent) in the study had a subsidization program or socialized medicine compared with four of seven (57 percent) of the developed nations.[42*] Probable reasons for the high prices are relative small markets, red tape, bureaucratic procedures, and tax burdens. Thus, large overheads are needed to cover the costs of production, distribution, and sales. Government-imposed caps on the prices of opioids is not a good solution as this could risk the availability of medications, especially in countries with small markets where the operating costs for the pharmaceutical industry are not compensated for the limited sales. In some countries the only solution is for the healthcare system to subsidize the opioid analgesics.

Unfortunately the problem of accessibility does not seem to be a priority for international institutions working to improve pain relief. It is crucial that these organizations initiate claims and requests to governments, the pharmaceutical industry, and healthcare providers, to help address and solve this problem. Several hospice and palliative care programs have adopted cost-effective strategies to produce and distribute inexpensive morphine. These include establishing links with local pharmaceutical companies willing to produce the opioid as immediate-release tablets and compound preparations (made by a pharmacist according to the national pharmacopoeia as per a patient's needs), or generic preparations of the following:

- For oral use: aqueous solutions of morphine (6 mg/mL), oxycodone (3 mg/mL) or methadone (10 mg/mL).
- For subcutaneous use: micropore cold sterilized aqueous solutions of morphine or oxycodone (10 mg/mL) The same can be done with dexamethasone, metoclopramide, hyoscine, haloperidol.

INFORMATION DISSEMINATION AND DATA MANAGEMENT

Data collection and analysis are critical in palliative care for understanding the current levels of quality and ways to measure improvement in care. Also, information facilitates the caring process, especially when several disciplines and different services participate.[43***] Unfortunately, only limited information regarding end-of-life care is available in developing countries, and to our knowledge, no national government systematically collects information on quality end-of-life care of its patients.

In countries with financial limitations it is difficult to secure the support of professional data managers to develop and maintain a system designed to meet the needs of the program. This can lead to the quite opposite situations of either collecting large amounts of useless data or nothing at all. To establish a cost-effective program, it is important to identify the crucial information that needs to be collected and then develop a data management system based on the needs and existing resources.[44,45] Several palliative care programs have adopted data collection systems with successful results.[46] One such initiative was developed by the PAMPFF which includes data collection forms and a database based on the Minimum Data Set from the National Council for Palliative Care in the UK.[47] The information is collected in two categories:

- *General information.* This includes basic demographic indicators, religious affiliation, health insurance, main caregiver information, diagnosis, prescribed medications and treatments, addictions, other diseases, other medications currently in use, anatomical diagram for registration of pain and the Edmonton Labeled Visual Information System (ELVIS).[48**]
- *Process of care.* This includes information on sources of referral, evolution and prognosis of clinical disorders including assessments using tools such as ESAS,[28**] Edmonton Comfort Assessment Form (ECAF), Confusion Assessment Method (CAM)[49*] or Mini-Mental State Examination (MMSE),[50*] and other conditions such as hydration, bowel movements, hospitalization between consultations, opioid routes and doses, adjuvant drugs, diagnostic and therapeutic practices.

The database was created using the Microsoft Access 2000® software, which has proved to be flexible, safe, and comprehensive. The information is retrieved easily and can be exported to other software applications. Figure 101.2 shows the basic form which has been used in the PAMPFF and may be used for data collection. The form can be completed by volunteers or professionals, and the information may be provided by the patient or the main caregiver. Figure 101.3 shows the steps followed to load data and retrieve information.

FUNDING STRATEGIES

With a few exceptions, palliative care in developing countries is neither recognized as a discipline nor is it incorporated within health systems. As a result there is no budgetary allocation through public funds[51] and palliative care programs are unable to receive reimbursement for services rendered through health insurance programs. Palliative care workers in developing countries are forced to work *pro bono* or in other areas and dedicate the remaining hours to palliative care. Programs are forced to look for funding through private pay, donations, and charity from the community in order to cover the cost of operations and the provision of services. Long-term financing of palliative care is a big challenge and the mechanisms to finance and sustain the services vary depending on the structure of the team or program.

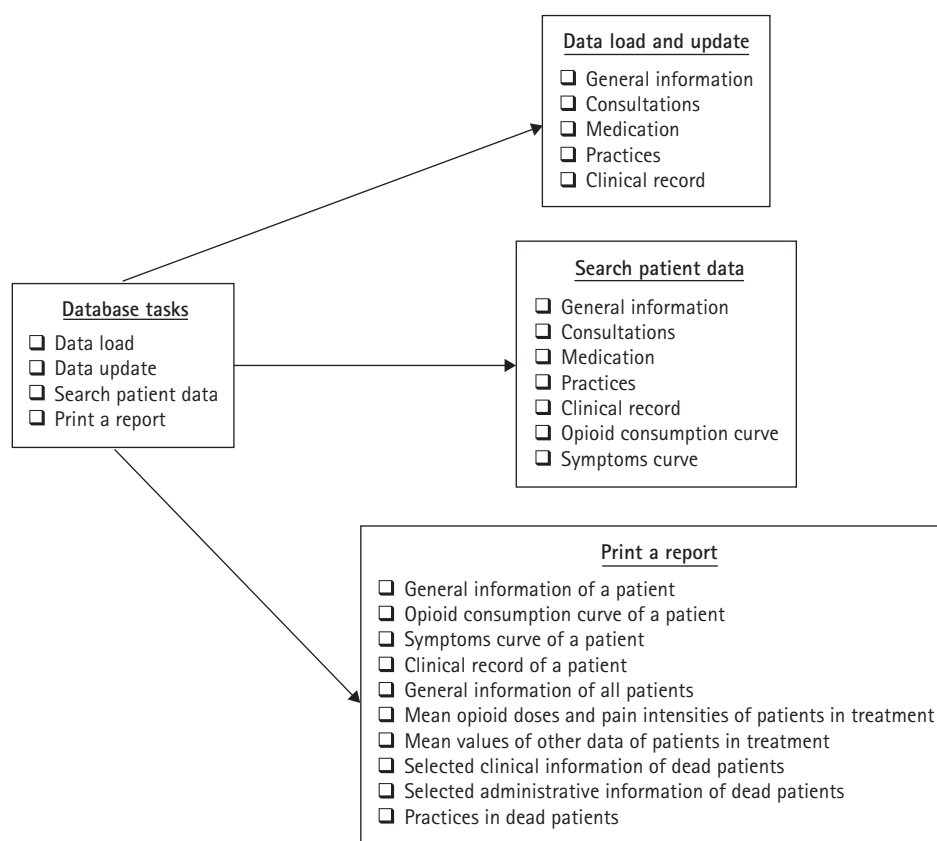
Thus, palliative care programs in developing countries usually develop with community support; are based in donated houses, churches or community institutions; provide


Figure 101.3   *Database working scheme.*

services through volunteer work; and raise funds for non-volunteer professional fees, medication, and supplies from local charity, religious orders, neighborhood groups, donations, and sometimes from contracts with local purchasers. These funding mechanisms have proved to be effective in sustaining palliative care services in small towns and where there is a relatively small population base.[52] As patients share similar needs, and the amount of resources needed to run the services is small, it can be offered by locals who establish partnerships with other individuals and institutions which have the capacity to raise and/or provide money. Hospital-based programs delivering care through multidisciplinary teams face tougher challenges to fund their activities. They are more complex, require a larger infrastructure, and more staff members.

Some countries have adopted funding mechanisms which combine efforts from the program and the institution. This joint funding collaboration has worked well in the PAMPFF and it has provided additional benefits to the program, such as full responsibility over budgetary allocation and the identification of funding sources outside the healthcare system. Both strategies have proved to be practical and safeguard the programs from the pressures and limitations of the healthcare system. Palliative care programs and initiatives in developing countries need to identify sources and activities capable of generating funds to support the operational

costs of the program. PAMPFF had implemented teaching and educational activities, which require registration fees and generate additional revenue. These have proved to be a substantial source of funding for the program.

Many other alternatives exist and programs in each country need to evaluate the resources in the community and their needs to develop and implement successful resource-generating strategies. Long-term survival depends on the ability to confront critical economic and human resource situations which interfere with the smooth development of the activity. Economic autonomy requires dedication and labor, but guarantees sustainability.

CONCLUSION

Developing countries face two socioeconomic challenges that may delay the development of palliative care initiatives. First, the need to constantly adapt to legal, political, economic, and social changes reduces the demand for modifications in the healthcare system.[40*] Second, most of the economic growth registered by developing nations is still not enough to satisfy the social needs of the population. These factors pose financial, organizational, and

educational barriers to the development of palliative care. However, the drive to reduce these barriers and generate feasible programs will result in the development of practical strategies such as the ones described in this chapter. The provision of palliative care is far from homogeneous and many developing nations have designed and implemented effective and successful strategies which have proved to help patients and families live a better quality of life until the end.

Many of these strategies are not acceptable under the standards of care in developed nations, but a flexible approach is needed to be able to help those in need. Home-based care may be the only feasible option for adequate access to palliative care in areas with limited resources. Effective palliative care for patients and families should rely on the development of home-based palliative care integrated within the existing healthcare system. Countries should plan to bridge the current gaps by building on their existing strengths and optimizing available resources. Low-cost and high-coverage approaches and national policies to promote accessibility and drug availability are key components. An understanding of the palliative care needs of a community will help establish broad support from the local people and the health authorities in each country. The support that palliative care workers in developed nations may provide to their colleagues in developing countries includes the empowerment to generate their own models of care, strengthen their capacity to reach patients and provide care, development of inexpensive medications, and design and application of research to evaluate the effectiveness of their treatment protocols.

Key learning points

- During the last decade 99 percent of population growth took place in developing countries. If this trend continues, by 2050 the population in developing countries will expand by 55 percent. This will result in greater demand for healthcare services. With limited funding, inadequate infrastructure and limited access to preventive and curative measures, more individuals will require palliative care services.

- Developing countries face several limitations which challenge the development of palliative care. To adapt to these limitations and the needs of the population, it is imperative that palliative care workers adopt practical measures to provide cost effective and efficient palliative care to the patients. These include strategies to build and improve capacity, low-cost treatment measures, data management procedures to establish mechanisms for quality control, and identifying sources of funding to cover the costs of the palliative care services.

- Volunteers play an essential role in palliative care, and more so in developing countries where limited funding hinders the capacity to hire human resource for end-of-life care. By carrying out many of the tasks of the palliative care providers, volunteers from the community become an important and crucial source of support for the patient and the family, and when available, to the palliative care team. In this process family members are empowered to their highest degree possible to ensure continuity of treatment.

- In some developing countries where it is not possible to treat patients in distant rural areas, some teams have implemented a practical strategy called 'distant care' which is carried out through a main caregiver and without initial clinical evaluation of the patient. Data show that the distant care model is significantly accurate and helpful, and the majority of the main caregivers have reported being very satisfied with the level of care provided.

- The overwhelming majority of published material refers to the delivery of palliative care using resources mostly available in developed countries which may not be available in developing countries or may not be applicable to the conditions and diseases that occur in that patient population. There are alternative treatment strategies and inexpensive technologies that have been successfully adopted and implemented in the developing world, such as proctoclysis, Edmonton injector, methadone, and thalidomide.

- Many countries report an improvement in the availability of different weak and strong opioid analgesics but their high prices relative to the monthly salaries constitute a barrier to access. The problem of limited access to opioids needs to be addressed by international organizations working to improve pain relief. In the mean time, the provision of opioids needs to be subsidized by governments or through preparation of low-cost opioids.

- Data collection and analysis are critical in palliative care to understand the current levels of quality and ways to measure improvement in care. The amount of information available in developing countries in end-of-life care is limited and to the authors' knowledge none of the national governments systematically collect information on quality end-of-life care of their palliative population.

- With a few exceptions, palliative care in developing countries is neither recognized as a discipline nor is it incorporated within the health system. This results in no budgetary allocation through public funds and the inability to receive reimbursement for services rendered through health insurance programs. Palliative care workers in developing countries are forced to work *pro bono* or in other areas and dedicate the remaining hours to palliative care. Programs are forced to look for funding through private pay, donations, and charity from the community to cover the cost of operations and the provision of services.

- Palliative care programs and initiatives in developing countries need to identify sources and activities capable of generating funds to support the operational costs of the program. Long-term survival is dependent on the ability to confront critical economic and human resource situations which interfere with the smooth development of the activity. Economic autonomy requires dedication and labor but guarantees sustainability.

Prognostic indicators of survival

MARCO MALTONI, AUGUSTO T CARACENI, CATERINA MODONESI

INTRODUCTION

Experts in the field of palliative care may argue that it is such a valid therapeutic option at any stage of chronic, debilitating diseases, that it should be recommended and administered in any situation. From this perspective, survival prognosis predictions would not have any impact on clinical practice, but promote palliative medicine purely as 'end-of-life' care. On the other hand, although a 'palliative approach' is clearly desirable along the entire course of chronic-degenerative diseases, it is also reasonable to consider life expectation as being one of the useful parameters for defining the most adequate proposal in terms of choices relating to therapeutic and support programs. Box 102.1 shows the reasons why survival prognosis prediction could be useful.

Box 102.1 Reasons for making a prognosis prediction

To help:

- oncological specialists understand when chemotherapeutic treatment is inappropriate and becomes futile[1*,2]

- other specialist doctors or general practitioners understand the most timely moment to direct a patient to a palliative care programme[3*]

- palliative care doctors choose the most suitable palliative treatment intensity

- palliative care doctors understand whether the patient's condition is such that he or she is eligible

---

for state reimbursement, when this is linked to determined life-expectancy conditions[4]

- researchers in identifying a precise population in which the results of therapeutic action can be assessed and compared with those obtained in other populations

- clinicians in communicating with both patients and their families

- both patients and their families take part in clinical choices

- both patients and their families deal with practical issues which depend on life-expectancy

- patients deal with the existential and spiritual issues of life

---

Prognostic information, however, is probabilistic, and individual variations are such that the therapeutic choice for each individual patient should only be made after taking many other physical, psychologic, and spiritual variables into consideration.

GENERAL PROGNOSIS

The proportion of patients with cancer assisted in palliative care programs exceeds 80 percent in all major case studies.[5*] This is due to the fact that, in its advanced stage, the course of neoplastic disease is foreseeable and, therefore, appropriate assistance can be planned. General prognosis in cancer is related to diagnosis, stage of the disease,
Figure 102.1 *Different trajectories of functional decline approaching death in three clinical situations. Modified from Lunney et al.[7]*

and – partially – to the impact of therapies. During the early stages of solid and hematological malignant diseases, the outcome doctors aim for is cure. In disseminated advanced solid cancers, the only possible objective outcome is to prolong survival, and there is heterogeneity with respect to prognosis, revealed by strongly differing survival medians among different tumors.[6]

In noncancer diseases, prognostic assessment and the patient's subsequent introduction to hospice programs are more problematic, as the disease trajectories are more difficult to forecast, and there is greater variability in individual prognosis (Fig. 102.1).

PROGNOSIS IN PATIENTS WITH ADVANCED CANCER

In addition to the early and the metastatic stages of cancer disease, is it possible to identify a third situation ('far advanced cancer disease' or 'terminal cancer phase') for which survival prognosis indicators could be defined? And, if this phase does exist, is it formed by a homogeneous population or does it incorporate various types of patient?

A weak point in all studies carried out on prognostic indicators in advanced stages of cancer is the investigated population, or, better, the 'inception cohort'. Its definition would allow homogeneous recruitment at a fixed and uniform point in time along the natural history of the disease. Some authors have included all patients who entered hospices or palliative care programs in their studies on prognostic indicators;[8*,9*,10*,11*] other have attempted to standardize and code the population's 'terminality' criteria;[12*,13*,14*] whereas still others have elaborated specific criteria to define when patients with different cancers could be considered in a terminal phase.[15*]

The problematic issues in the methodology of studies on prognostic indicators are shown in Box 102.2.

Clinically, 90 days can be considered as the most relevant period of time used to define the terminal phase, even though the median survival of patients in most hospice programs is approximately 30–45 days.[16]

Box 102.2 Weak points in the methodology of studies on prognostic indicators

- Identification of the inception cohort

- Retrospective cohorts

- Heterogeneous population sampling and setting

- Limited use of multivariate statistical analyses

- Brief description of the statistical method and insufficient information about the recruitment method and sampling procedures

- Extremely limited use of the training and testing sample method

- Inadequate ratio between the number of variables studied and number of patients enrolled

- Lack of a systematic procedure, heterogeneity, and selection of the variables studied

- Little attention paid to variables which are currently becoming more important, such as comorbidity

---

PROGNOSTIC INDICATORS IN PATIENTS WITH TERMINAL CANCER

Prognostic indicators in oncology patients referred to palliative care programs have generally been studied using a set of observations on prognostic variables in series of patients, then assessing the outcome for each patient. After this, researchers generally use statistical models to evaluate the link between predictors and outcomes. Information about the prognostic predictivity of different indicators can be gathered from both original studies and systematic reviews of literature. Although such revisions were merely qualitative in the past,[17] they have recently

been conducted according to evidence-based medicine directives[18***,19***,20***,21***] (Table 102.1).

Prognostic indicators

CLINICAL PREDICTION OF SURVIVAL

The Clinical Prediction of Survival (CPS), or the carer's clinical judgment of the possible course of the patient's illness, was the first indicator whose prognostic predictivity was assessed.[22*] It proved able to maintain its prognostic importance in a multivariate analysis.[13*]

One often emphasized fact is that CPS is inaccurate, and that the CPS exceeds actual survival (AS) by a factor ranging from 1.08 to 5.3. Error percentages range from 30 percent to 78 percent, with the rate of optimistic errors out of total errors from 12 percent to 88 percent[19***] generally equal to or higher than 60 percent. A recently published, systematic review confirmed the over-optimism of CPS: median CPS 42 days, median AS 29 days on eight evaluable studies with 1563 patients. Although agreement between CPS and AS was considered poor (weighted κ 0.369), the two were highly significantly associated after log transformation (Spearman rank correlation 0.60, $P < 0.001$).[20***] To define CPS as being accurate, much depends on the definition of accuracy which, in turn, depends on how the clinical estimate is expressed and the error defined. Both definitions are heterogeneous in published studies. In most studies, CPS is calculated temporally, that is, it is expressed numerically in terms of the time each individual patient can be expected to live, and then compared with the same patient's AS.[10*,22*,23*,24*]

Other methods have also been used to express prediction. For example a method gives a minimum and maximum estimate of predicted survival,[25*,26*] another estimates that the patient will still be alive after a given period of time from the prediction,[27*] another includes the patient in a range of lengths of estimated survival,[14*,28*] yet another provides the smallest range that would include 90 percent of deaths of similar patients.[29*]

The error definition used in the studies has been very inconsistent: 100 percent error for overestimation and underestimation (CPS = 2 AS or AS = 2 CPS),[12*,22*,24*,29*] 33 percent deviation from CPS and AS,[30*] AS over or under the maximum or minimum CPS limit,[25*] CPS correlations with various periods of AS.[10*,27*] Two issues need to be considered related to this heterogeneity. First, the modifications in accuracy due to either variations in the measuring units in defining the error or variability in the survey methods are apparent rather than real. Second, the percentage deviations between CPS and AS that are statistically significant and recorded as errors may actually be clinically irrelevant.

When making individual prognosis, however, clinicians should consider a range of factors which limit the CPS. It has been suggested that CPS is affected by the 'horizon effect', implying that the closer the moment of death, the more accurate the prediction.[9*,28*] Other authors do not confirm this hypothesis,[10*,25*] however, and others still stress there is greater accuracy in the long or short compared to the medium term.[14*] It appears that repeated predictions improve their predictive ability.[9*,22*,25*] The continuous involvement of the physician along the course of disease of the patient appears to lower CPS reliability.[30*]

As far as the prediction variability is concerned, Maltoni *et al.* demonstrated that the correlation coefficient between CPS and AS is 0.78 ($P < 0.01$) for oncologists with experience in palliative care and 0.45 ($P = 0.01$) for less experienced oncologists.[24] Christakis and Lamont reported that nononcologist specialists are three times more pessimistic than general physicians, and that more experienced physicians are more accurate.[30*] Llobera *et al.* indicate a higher accuracy among oncologists rather than among general physicians.[31*] Other studies have failed to demonstrate any significant differences among the various disciplines[16,22*,23*] or professional roles.[27*] A small study revealed high accuracy in nurse auxiliaries during the last days of the patients' lives.[9*] The accuracy achieved by specialist palliative care professionals appears to have improved over the years whereas that of referrers to palliative care services has apparently remained the same.[16]

Other features of CPS deserve further investigation, including whether two prognosticators are better than one,[32] and whether patients' characteristics are relevant. One study showed less over-optimism for cancer than for noncancer patients.[30*] CPS is best used if integrated with other, more objective and reproducible prognostic indicators, also resulting from multivariate analyses.[13*,33*,34*]

PERFORMANCE STATUS

Performance status (PS) has been studied in great depth, and undoubtedly proved to be an independent prognostic parameter.[18***] It has been assessed using different scales and according to various survey approaches, such as the Karnofsky Performance Status (KPS),[12*,24*,25*,35*,36*] Activities of Daily Living (ADL),[37*] Eastern Cooperative Oncology Group (ECOG) PS,[38*,39*] and a tailored version of KPS for palliative settings, namely the Palliative Performance Scale (PPS).[40*]

The KPS is the most widely used scale in palliative care studies. Low KPS values are tightly linked to short survival rates, although high values do not necessarily indicate longer survival, since values may drop extremely quickly at any time due to a patient's rapid, unexpected, deterioration. Although initial studies of KPS showed good interrater reliability, later studies registered some controversial data.

PHYSICAL SIGNS AND SYMPTOMS, AND PSYCHOLOGICAL FACTORS

Several signs and symptoms have been integrated with both CPS and PS to increase their prognostic capability. In 1988, after having identified PS as significant prognostic indicator

Table 102.1 *Comparison of systematic reviews on prognostic indicator studies*

Author, year	No. of studies/No. of patients	Criteria selection of studies/PFs examined
Viganò *et al.*, 2000,[18]	22/7089	Examined 18 clinical–biologic possible predictors evaluated in at least three studies (of the 136 assessed)
Chow *et al.*, 2001,[19]	CPS: 12/2920 PFs: 18/6158	Biochemical and molecular markers were not studied
Glare *et al.*, 2003,[20]	8/1591	CPS only
Maltoni *et al.*, 2004,[21]	Four systematic reviews CPS: 16/3079 Signs and symptoms: 21/7621 Biological factors: 9/2919 Prognostic scores: 8/1954	Only studies with a median population survival of ⩽ 90 days

*, strength of recommendation.
CPS, Clinical Prediction of Survival; PFs, prognostic factors.

in their series of 1592 hospice patients, Reuben *et al.* found that 5 out of 14 evaluated symptoms retained their prognostic value which was independent at the multivariate analysis.[36*] The symptoms linked to survival included shortness of breath, dry mouth, eating problems or anorexia, trouble swallowing, and weight loss. Four out of these five symptoms were related to the nutritional state of the patient, so a 'terminal cancer syndrome' hypothesis was formulated (characterized by a reduction in the functional state of the patient, and symptoms of the cancer anorexia-cachexia syndrome [CACS]), independent of both the original location and metastatic spread of the disease.

In a vast majority of the studies in which the signs and symptoms of CACS were tested, they appeared significant for a correlation with worse prognosis, in univariate or multivariate analyses.[12*,36*,37*,41*,42*] A negative prognostic

Results	Level of study evidence and/or strength of recommendation shown	Formal meta-analysis	Comment

Prognostic factors categorized according to their relationship with prognosis:
    probably non-associated
    possibly associated
    definitely associated
The latter were:
    low performance status; CPS
    cognitive impairment; anorexia
    dyspnea; xerostomia;
    weight loss; dysphagia
	No	No	Clinical prediction should be considered as one of the criteria, and used together with other factors

CPS used alone: D* Use of aggregates of PFs including CPS: B* PFs: performance status; anorexia; weight loss; dysphagia; cognitive failure; CPS	Yes	No	The study used evidence criteria which were more sound for clinical trials than prognostic studies
Agreement between CPS and AS poor (κ 0.36), but the two were highly significantly associated after log transformation (Spearman rank correlation 0.60, $P < 0.001$)	Yes	No	Median CPS 42 (28–84) days Median AS 29 (13–62) days Clinicians overestimate survival, but predictions are correlated with survival; predictions have discriminatory ability, even if they are miscalibrated
Recommendations on PFs: Use of CPS indicated, but together with other PFs (A*) Performance status (B*) Some cancer anorexia-cachexia symptoms (weight loss, anorexia, dysphagia, xerostomia)(B*) Cognitive failure (B*) Dyspnea (B*) Leukocytosis (B*) Lymphocytopenia (B*) C-Reactive protein (B*) Prognostic score (A*)	Yes	No	Specific assessment methods of the quality for prognostic studies were chosen

correlation has also been reported for asthenia.[15*,31*] Other symptoms for which a correlation with negative prognosis has definitely been shown are cognitive failure[10*,41*,43*] and dyspnea.[12*,36*,44*]

A series of other psychosocial factors or factors linked to the original disease have only sporadically shown prognostic predictivity. For example, these (age, sex, race, marital status, education and income, socioeconomic factors and possibility of psychosocial support; type, histology and stage of cancer) were included in univariate analysis, but not confirmed in multivariate analysis, or studied in populations with illnesses at a less advanced stage.[45*,46*]

Some authors have drawn attention to a link between quality of life and survival in palliative care populations,[31*,42*] whereas others consider the quality of life less important than organic and physical factors.[27*] Some recent

data suggest that the prognostic value of quality of life multidimensional evaluation tools should be ascribed to subscales referring to physical symptoms.[45*,46*] A recent study of two independent cohorts of 248 and 756 patients showed that physical health-related quality of life indicators should be focused to gather prognostic evidence.[47*]

BIOLOGICAL FACTORS

The prognostic value of some biological factors, particularly if linked to the patient's nutritional state, has been demonstrated in population settings, which cannot always be extrapolated to those included in palliative care programs. These include albumin and prealbumin levels, Nutritional Index (NI), Prognostic Nutritional Index (PNI), and Prognostic Inflammatory and Nutritional Index (PINI).[48] Among those factors which are directly or indirectly linked to a patient's nutritional state, lymphocytopenia has proven to be important in populations included in palliative care programmes.[13*,49*] A poor prognostic correlation has also been demonstrated for leukocytosis,[13*,49*] and high levels of C-reactive protein.[50*,51*] Less convincing evidence is there for increased levels of bilirubin[38*] and vitamin B_{12},[50*] and low pseudocholinesterase levels.[49*]

Some studies of heterogeneous populations of patients have given prognostic importance to hemoglobin, levels of sodium and calcium, some enzymes, and proteinuria.

Strengthening of prognostic accuracy achieved by the combined use of CPS and other prognostic factors

Some studies have aimed to verify the increase in prognostic accuracy from the combined use of CPS and other prognostic factors. Morita et al.[8*] reported that the prognostic accuracy of physicians before and after the combined use of clinical judgment and an instrument comprising more objective parameters improved as follows:

- Number of cases with a difference between AS and CPS of 28 days or longer – from 42 percent to 23 percent, $P < 0.01$.
- Number of patients with an AS either twice as long or half as long as CPS – from 49 percent to 37 percent, $P = 0.05$.
- Number of cases with serious errors of prognostication, i.e. patients who represented both the previous situations – from 27 percent to 16 percent, $P = 0.028$.

Furthermore, in the previously mentioned review by Glare et al.,[20***] it emerged that for all the KPS categories identified (<40, 40–50, >50), R^2 values obtained in 981 patients for CPS alone, other prognostic factors alone, and CPS plus other prognostic factors, were as follows, respectively: KPS < 40: 0.46, 0.25, 0.50; KPS 40–50: 0.35, 0.15, 0.38; and KPS > 50: 0.24, 0.08, 0.27.

Finally, even when used in a slightly different population consisting of seriously ill hospitalized adults, the combination of the Study to Understand Prognosis and Preferences for Outcomes and Treatments (SUPPORT) model with physicians' estimates improved both predictive accuracy (receiver operating characteristic [ROC] curve area = 0.82) and the capacity to identify patients with a higher probability of survival or death.[33*]

Prognostic indicators combined in prognostic models

PROGNOSTIC SCORES

The prognostic scores studied in only those populations included in palliative care programs have been reported here. A systematic review[21***] identified eight works on the development of prognostic scores in cancer patient populations in palliative care programs, with a median survival inferior than or equal to 90 days. In four of these works, the prognostic score was built: Poor Prognostic Indicator,[10*] Palliative Prognostic Score,[13*] Palliative Prognostic Index,[41*] and Terminal Cancer Prognostic Score.[52*] Validation on an independent population was supplied for the Palliative Prognostic (PaP) Score in three works,[11*,34*,43*] whereas Morita et al. validated the Palliative Prognostic Index (PPI) in the original work.[41*] Another score was recently developed, following the period examined by the quoted review: the Prognostic Scale.[53*]

The PaP Score is based on factors identified in an Italian prospective multicenter study of 540 patients with advanced cancer, with a median survival of 32 days (1–355).[13*] The final model obtained by means of a backward selection procedure is shown in Table 102.2. Three risk groups were formed, and patients were fairly well distributed between the three groups. The survival curves are shown in Figure 102.2. The PaP Score was also tested on a population of noncancer patients, where it retained its predictive ability.[54*] The peculiarity of the PaP Score is that it can be used 'together with' rather than 'instead of' the clinical judgment of the physician, since it includes the CPS.

The PPI comprises the Palliative Performance Scale, oral intake, edema, dyspnea at rest, and delirium.[41*] It has been shown that PPI improves the predictive ability of physicians with experience in palliative care.[8*] The Prognostic Scale was also validated, and demonstrated that, like different PS values, differing degrees of severity of the symptoms impacted survival differently too.[53*]

PROGNOSIS IN NONCANCER PATIENTS

Chronic degenerative diseases are more common among older people, and the average age is increasing at a considerable rate in more developed Western countries. Changes

in disease patterns including a chronic course, multiorgan insufficiency and polymorbidity are linked to the general aging pattern of the population. The subjective problems older people have are similar to those of patients with

Table 102.2 *Palliative Prognostic Score (PaP Score)*

Prognostic factor		Partial score
Dyspnea	Absent	0
	Present	1
Anorexia	Absent	0
	Present	1.5
Karnofsky Performance	≥50	0
Status (KPS)	30–40	0
	10–20	2.5
Clinical Prediction of	>12	0
Survival (CPS) (weeks)	11–12	2.0
	9–10	2.5
	7–8	2.5
	5–6	4.5
	3–4	6.0
	1–2	8.5
Total white blood cell	Normal (4800–8500)	0
(WBC) count (cell/mm^3)	High (8501–11000)	0.5
	Very high (>11000)	1.5
Lymphocyte percentage (%)	Normal (20.0–40.0)	0
	Low (12.0–19.9)	1.0
	Very low (0–11.9)	2.5

PaP Score = Dyspnea score + anorexia score + KPS score + CPS score + Total WBC count score + lymphocyte percentage score.

Risk groups	Total score
A: 30-day survival probability >70%	0–5.5
B: 30-day survival probability 30–70%	5.6–11.0
C: 30-day survival probability <30%	11.1–17.5

advanced cancer. A series of problems specific to noncancer diseases hinders prognostic assessment. Since the progressive functional decline can regress repeatedly, it is more difficult to define this as a prognostic indicator for noncancer patients. The 'typical' terminal phase in some noncancer diseases is difficult to identify, and sometimes even does not exist.[7*]

Patients' access to hospices can be limited by the fact that, in some countries, reimbursements are only granted if the said patients can produce certification specifying 'a life expectancy of 6 months or less, should the disease take its usual course'. The National Hospice Organization (NHO) prognostic guidelines may be useful in predicting prognosis in noncancer patients.[4] Excessively restrictive eligibility criteria may lead to a risk that sensitivity decreases, thus preventing many patients who would be entitled to hospice programs from accessing them. Considering the peculiar course of noncancer diseases, it is advisable that the judgment regarding prognosis be periodically reviewed, and modified if necessary.

Similar to what has happened with terminal cancer patients, specific studies of selected populations of noncancer patients in hospice programs may help to better identify targeted features and prognostic indicators, although this issue is still controversial.[55*] However, some indicators, that is, the 'general prognostic indicators' and the 'specific prognostic indicators', can be found in these patients, too.

General prognostic indicators in noncancer diseases

IMPAIRED FUNCTIONAL STATUS

A recent reduction in functional status has been shown to have prognostic value, when evaluated as KPS or ADL,
Figure 102.2 *Survival curves of patients in palliative care programs in an Italian multicenter study. Groups identified according to the Palliative Prognostic (PaP) Score value. Modified from Pirovano et al.[13]*

log rank (df = 2) = 294.8, P < 0.001

No. of patients							
A	178	148	95	56	35	28	21
B	205	107	39	10	9	6	2
C	136	13	2	1	0	0	0

in several studies of older people, and various diseases, including heart disease, lung disease, dementia, coma, and stroke.[4,55*,56]

ALTERATIONS IN NUTRITIONAL STATUS

Alterations in nutritional status have also proved to have prognostic value for heart disease, pulmonary disease, dementia, human immunodeficiency virus (HIV) disease, liver disease, renal disease, stroke and coma, and end stage amyotrophic lateral sclerosis in patients with swallowing difficulties without gastrostomy feeding.[4,55*,56]

Specific prognostic indicators in noncancer diseases

HEART DISEASE

In the absence of a precipitating factor which can be treated, survival usually ranges from 6 months to 4 years. Functional status described according to the New York Heart Association Classification (NYHA) is the most important prognostic factor: class IV, namely, symptoms of congestive heart failure at rest, despite optimal treatment with diuretics and vasodilators, is correlated with the worst prognosis.

Factors which contribute to poorer prognoses include a left ventricular ejection fraction of 20 percent or less, aging, intractability of underlying heart disease, dilated cardiomyopathy, uncontrolled arrhythmia, contractility changes over time, high cardiothoracic ratio measured on a standard chest radiograph, and oxygen consumption.[4,55*,56,57*,58*]

LUNG DISEASE

Making a prognostic prediction for lung diseases at an advanced stage is extremely difficult. The 5-year survival was shown to be 45 percent in a study on hospitalized patients with chronic obstructive pulmonary disease.[59*] Negative prognostic indicators have been identified: low forced expiratory volume at one second (FEV_1) (less than 30 percent), repeated episodes of respiratory failure, presence of cor pulmonale, hypoxemia, dyspnea at rest unresponsive to therapies, and low functional status.[4,55*,56]

DEMENTIA

The mean survival rate of patients with dementia ranges from 5 to 8 years, and the 'advanced' stage of the disease may last 2 years. Difficulty in formulating a prognosis is one of the obstacles for those hospices who accept patients with dementia.[60*] In hospice programs, such patients have a significantly higher survival rate than patients with other diseases (35 percent >6 months).[5*] The prognostic indicators that are considered are functional status measured with Functional Assessment Staging (FAST). Stage 7 FAST patients presented a mean survival of 6.9 months and a median survival of 4 months.[61*] Other factors include type

of dementia (vascular dementia appears to lead to death more rapidly than Alzheimer disease), age, gender, severity of dementing illness (inability to walk without assistance), presence of medical complications.[56*]

HIV DISEASE

Mortality due to acquired immune deficiency syndrome (AIDS) dropped considerably from the early 1990s to 1997, when it leveled off. The median survival rate increased from 11 months in 1984 to 46 months in 1995.[62*] The advent of Highly Active AntiRetroviral Therapy (HAART), together with the treatment of opportunistic infections and symptom palliation, altered the prognostic of a disease which invariably led to death in a few months to a more a prolonged one.

Late-stage HIV disease definition could, however, be applied to patients with long standing, symptomatic HIV disease, with severe immunosuppression, cumulative morbidity, and failure or inability to tolerate antiretroviral therapy.[63] Consequently, the importance of some of the traditional prognostic indicators used (CD4 cell count, viral load, certain opportunistic infections) may lessen.[7*,64*] These factors should thus be integrated with more recent ones, such as a noncompliance or nonreaction to HAART, functional deficits (impaired ability to conduct routine activities, cognitive impairment) and/or the existence of other life-threatening conditions predictive of short-term mortality: weight loss and neurological abnormalities.[63]

AMYOTROPHIC LATERAL SCLEROSIS

Palliative care in amyotrophic lateral sclerosis (ALS) begins with how the patient is informed of the diagnosis, and continues to prevent both the 'choking to death' and the 'locked-in syndrome' in an intensive care unit after intubation and artificial ventilation'.[65] The NHO criteria enable clinicians to predict a survival of ≤6 months for ALS hospice patients. They include critically impaired breathing or rapid progression and life-threatening complications, or rapid progression and critical nutritional impairment.[4] These criteria were present in only 5 of the 97 ALS patients enrolled on a hospice program, of which 91 percent had a survival of less than 6 months. The same work force aimed to update the criteria, and suggested adding forced vital capacity (FVC) of less than 30 percent, or an FVC < 60 percent with a steady decline over past 2–3 months, and either two other respiratory indicators or one respiratory and one nutritional indicator.[66*]

LIVER DISEASE

Prognostic indicators that are additively negative in end-stage cirrhosis are laboratory indicators of severely altered liver functionality, and clinical indicators of end-stage liver disease (ascites refractory to therapies, spontaneous bacterial peritonitis, hepatorenal syndrome, hepatic encephalopathy

refractory to therapies, recurrent variceal bleeding).[55*]Other factors have also been reported, including malnutrition, muscle wasting, active alcoholism, hepatocellular carcinoma, HBsAg positivity.[4]

RENAL DISEASE

The Core Curriculum in Nephrology Palliative Care[67] has reported that end-stage renal disease (ESRD) patients in dialysis survive a quarter the time of age-matched patients without renal disease, with an annual mortality rate of 23 percent. The NHO examines different situations, such as ESRD, acute and chronic renal failure, with chronic ambulatory peritoneal dialysis (CAPD).[4] Laboratory criteria for renal failure, clinical signs and symptoms associated with renal failure, and comorbid complications that predict early mortality in hospital and patients with acute renal failure are given.

STROKE AND COMA

Predictors of early mortality during the acute phase immediately following the acute episode have been identified:

- coma beyond 3 days' duration (associated with any four of the following: abnormal brain stem response, absent verbal response, absent withdrawal response to pain, high serum creatinine level, age >70)
- severe dysphagia
- certain computed tomography (CT) or magnetic resonance imaging (MRI) findings.

Some clinical factors are correlated with poor survival once the patient has entered the chronic stage: age, poor functional and nutritional status, post-stroke dementia, medical complications.[4]

CONCLUSIONS

Awareness of prognostic indicators may help physicians who do not feel particularly confident about making a prognosis, find it difficult and stressful to make predictions, and believe that patients' expectations of the prognostic ability of their carers are excessive.[68*]As far as communication of the prognostic in the frame of the physician–patient relationship is concerned, ethical, cultural, religious and psychological issues should be considered by doctors, to avoid causing a severely ill patient even more suffering: although there is a patient's right to be informed there is no patient's duty to be informed.

Therefore, appropriate use of life-expectancy prognostication, to improve and personalize the treatment of patients in the advanced and terminal stages of the disease, can only be achieved if it forms part of a multidisciplinary palliative care program, which still considers the individual value of the patient's remaining lifetime invaluable.

Key learning points

- Awareness of the prognostic survival indicators helps clinicians in the difficult decision-making process, and may lead to better communication with both patients and their families. Prognostication has only a probabilistic value, which should be carefully considered when examining the possible course of each individual patient's illness.

- Trajectories of noncancer chronic disease make prognosis prediction for these diseases more complex compared with the palliative phase of cancer.

- Prognostic indicators in palliative care patients differ from those for the early and advanced stages.

- Clinical Prediction of Survival is an independent prognostic indicator in palliative care cancer patients. However, as its accuracy is conditioned by a number of restrictions, and it should only be used in conjunction with other, more objective, prognostic indicators.

- The following indicators have definitely shown independent prognostic ability: Performance Status, signs and symptoms of CACS, delirium, dyspnea.

- Clinical Prediction of Survival and other prognostic indicators may be included in simple models or prognostic scores. The prognostic ability of the score increases when it is used 'together with' rather than 'instead of' clinical judgment.

- Prognostic indicators can also be found in noncancer diseases. Some of them are common to more than one disease (functional status and nutritional status), whereas others are specific to individual diseases.

- The main aim of prognostication is to personalize the treatment of patients when dealing with the severest stage of their disease, while simultaneously continuing to fully consider the individual value of the patient's remaining lifetime.

Palliative sedation

NATHAN I CHERNY

INTRODUCTION

Sedation in the context of palliative medicine is the monitored use of medications intended to induce varying degrees of unconsciousness to induce a state of decreased or absent awareness (unconsciousness) in order to relieve the burden of otherwise intractable suffering. The intent is to provide adequate relief of distress.[1]

Sedation is controversial insofar as it diminishes capacity: capacity to interact, to function, and, in some cases to live. In the context of a field of endeavor committed to helping the ill and suffering to live better, there is a potential contradiction of purpose. Sedation for the relief of suffering touches at the most basic conflict of palliative medicine: are we doing 'enough' or are we doing 'too much'. This issue exemplifies the tensions in achieving the dual goals of palliative care: first, to relieve suffering and, second to do so in such a manner so as to preserve the moral sensibilities of the patient, the professional carers, and concerned family and friends.

Sedation is used in palliative care in several settings:

- transient controlled sedation
- sedation in the management of refractory symptoms at the end of life
- emergency sedation
- respite sedation
- sedation for psychological or existential suffering.

Each of these will be discussed, describing the context of application, and practical and ethical considerations.

TRANSIENT CONTROLLED SEDATION

Transient controlled sedation is routinely and uncontroversially used to manage the severe pain and anxiety associated with noxious procedures. Sedation enables patients to endure interventions that would otherwise be intolerable. The depth of sedation required is influenced by the nature of the noxious stimulus, the level of relief achieved by other concurrent approaches, and individual patient factors. When these techniques are well applied, reports of pain and suffering are infrequent. Since these patients are expected to recover, careful attention is paid to maintaining adequate ventilation, hydration, and nutrition.

Occasionally transient sedation will be needed for a self-limiting severe exacerbation of pain.[2] In the full anticipation that this will be a reversible intervention of last resort, close monitoring of respiratory and homodynamic stability is essential. In one case report this was achieved with midazolam administered by a patient controlled analgesia device.[2]

SEDATION IN THE MANAGEMENT OF REFRACTORY SYMPTOMS AT THE END OF LIFE (PALLIATIVE SEDATION)

At the end of life the goals of care may shift and the relief of suffering may predominate over other considerations relating to functional capacity. In this setting, the designation of a symptom as 'refractory' may justify the use of induced sedation, particularly since this is the only option that is

capable of providing the necessary relief with certainty and speed. Various names have been applied to the issue of sedation in this setting: terminal sedation, palliative sedation. Though no single term has achieved universal support, of these options, palliative sedation is generally preferred.[3–6]

Symptoms at the end of life

Among patients with advanced cancer, clinical experience suggests that optimal palliative care can effectively manage the symptoms of most cancer patients during most of the course of the disease. Physical and psychological symptoms cannot be eliminated, but are usually relieved enough to adequately temper the suffering of the patient and family.[7–12] This phase may be referred to as the ambulatory phase of advanced cancer.

As the disease progresses and the end of life approaches, patients commonly suffer more physical and psychological symptoms (including pain) and it often becomes more difficult to achieve adequate relief.[13–16] For some patients, the degree of suffering related to these symptoms may be intolerable. Despite intensified efforts to manage such problems, some patients do not achieve adequate relief and they continue to suffer from inadequately controlled symptoms that may be termed 'refractory'.

Refractory symptoms at the end of life

The term 'refractory' can be applied to symptoms that cannot be adequately controlled despite aggressive efforts to identify a tolerable therapy that does not compromise consciousness. The diagnostic criteria for the designation of a refractory symptom include that the clinician must perceive that further invasive and noninvasive interventions are either (i) incapable of providing adequate relief, (ii) associated with excessive and intolerable acute or chronic morbidity, or (iii) unlikely to provide relief within a tolerable time-frame. The implication of this designation is that the pain will not be adequately relieved with routine measures and that sedation may be needed to attain adequate relief.

EPIDEMIOLOGY OF REFRACTORY SYMPTOMS AT THE END OF LIFE

The prevalence of refractory pain at the end of life remains somewhat controversial.[17–20] The use of sedation in the management of refractory symptoms has been evaluated in several studies over the past 10 years[19,21–24] (Table 103.1).

In a study of homecare patients treated by the palliative care service of the Italian National Cancer Institute, Ventafridda et al. found that 63 of 120 terminally ill patients developed otherwise unendurable symptoms which required deep sedation for adequate relief.[19] In almost half of these cases the underlying problem was severe pain. In a retrospective survey of 100 patients who died in an inpatient palliative care ward, Fainsinger et al.[21] found that 16 patients required sedation for adequate symptom control prior to death, 6 for pain; an additional 2 patients who may have benefited from sedation died with severe uncontrolled pain. Stone et al.[23] compared two palliative care services in London, England and retrospectively looked at 115 patients. They found that 30 patients (26 percent) were prescribed sedatives. The commoner reasons were agitated delirium, mental anguish, pain, and dyspnea.

Survey data show that 5–35 percent of patients in hospice programs describe their pain as 'severe' in the last week of life and that 25 percent describe their shortness of breath as 'unbearable'.[28]

Sedation at the end of life as a clinical dilemma

Persistent severe pain at the end of life challenges the clinician clinically, emotionally and morally and contributes to the onerous nature of clinical decision making in this setting. It is useful to recognize both the clinical and the ethical dimensions of this dilemma. From a moral perspective, there is a major dilemma related to nonmalfeasance. Clinicians want neither to subject severely distressed patients to therapies that provide inadequate relief or excessive morbidity, nor to sacrifice conscious function when viable alternatives remain unexplored.

Table 103.1   *Surveys of the use of sedation in the management of refractory symptoms*

Authors(s)	Year	N	Place	Percentage sedated for refractory symptoms
Ventafridda et al.[19]	1990	120	Home	52
Fainsinger et al.[21]	1991	100	Hospital	16
Morita et al.[22]	1996	143	Hospice	43
Stone et al.[23]	1997	115	IP and home	26
Fainsinger et al.[24]	1998	76	IP hospice	30
Chiu et al.[25]	2001	251	IP palliative care	28
Muller-Busch et al.[26]	2002	548	IP palliative care	14
Morita[27]	2004		Multicenter	<10–50

The clinical corollary of this moral dilemma is the need to distinguished a 'refractory' pain state from 'the difficult situation', which could potentially respond within a tolerable time-frame to noninvasive or invasive interventions and yield adequate relief and preserved consciousness without excessive adverse effects. The challenge inherent in this decision making requires that patients with unrelieved symptoms undergo repeated evaluation prior to progressive application of routine therapies.

Case conference approach to decision making

Since individual clinician bias can influence decision making,[29,30] a case conference approach is prudent when assessing a challenging case. This conference may involve oncologists, palliative care physicians, specialists from other fields relevant to the prevailing symptom control problem, nurses, social workers, and others. The discussion attempts to clarify the remaining therapeutic options and the goals of care.

Clearly, it is critical that clinicians who are expert in symptom control be involved in the patient evaluation. When local expertise is limited, telephone consultation with physicians who are expert in palliative medicine is strongly encouraged.

CLINICAL PRACTICE

Preconditions and guidelines

In a thoughtful review, Wein[31] described a set of nine clinical preconditions for the consideration of sedation in the management of refractory symptoms:

- The illness must be irreversible and advance to death imminent.
- The symptoms need be determined to be untreatable and refractory by other means.
- The goals of care must be clear.
- Informed consent from the patient (direct, living will, advanced directives), or by proxy, must be obtained.
- Corroborative consultation should be sought.
- Staff should be involved and informed as appropriate.
- The family should be involved as guided by the patient's wishes and clinical condition.
- Full documentation of clinical condition and medication.
- Agreement must be undertaken that cardiopulmonary resuscitation (CPR) will not be initiated.

A clinical practice guideline has been published in Canada.[32] The purpose of the guide is to establish ethically acceptable criteria and guidelines for the use of palliative sedation as a form of treatment for intractable pain and symptoms associated with acute or chronic morbidity in the palliative care setting. The guideline defines palliative sedation and refractory symptoms, states the rational for the use of sedation, and sets criteria for its application. In this guideline the basic criteria for considering the use of palliative sedation include the following: (i) a terminal disease exists, (ii) the patient/client suffers from a refractory symptom/s, (iii) in all but the most unusual circumstances, death must be imminent (within days), and (iv) a 'do not resuscitate' order must be in effect. If the criteria are met, then a 5-step process is set in progress:

1 The attending physician shall ensure the patient is assessed by a physician expert in symptom management.
2 The attending physician, based on the recommendation and advice from a physician expert in symptom management, shall consult directly with the patient and family and as appropriate with the other care providers regarding the option of palliative sedation.
3 If the option of palliative sedation is selected by the patient or 'agent' as identified within the Personal Directives Act, the attending physician or physician expert shall ensure the discussion by which the appropriate consent was obtained is documented on the health record.
4 Once consent is obtained for palliative sedation, the physician expert in symptom management will arrange for palliative sedation and appropriate monitoring of the patient.
5 The existing criteria and rationale used to determine the patient is a candidate for palliative sedation and the consultation process between the attending physician, palliative care consultants, patient and family will be documented on the health record.

It is important to note that this guideline explicitly indicates that expertise in the area of pain or symptom management is required by the healthcare disciplines implementing palliative sedation.

Discussing sedation with the patient and their family members

If the clinician perceives that there is no treatment capable of providing adequate relief of intolerable symptoms without compromising interactional function, or that the patient would be unable to tolerate specific therapeutic interventions, refractoriness to standard approaches should be acknowledged. In this situation, the clinician should explain that, by virtue of the severity of the problem and the limitations of the available techniques, the goal of providing the needed relief without the use of drugs that may impair conscious state is probably not possible.

The offer of sedation as an available therapeutic option is often received as an empathic acknowledgment of the severity of the degree of patient suffering. The enhanced patient trust in the commitment of the clinician to the relief of

suffering may, in itself, influence decision making, particularly if there are other tasks or life issues that need to be completed before a state of diminished function develops. Indeed, patients can, and often do, decline sedation, acknowledging that symptoms will be unrelieved but secure in the knowledge that if the situation becomes intolerable this decision can be rescinded. Alternatively, the patient can assert comfort as the paramount consideration and accept the initiation of sedation.

With the hope and knowledge that it may be possible to achieve adequate relief without compromising interactional function, the patient who equally prioritizes comfort and function may elect to pursue only those approaches with modest morbidity, despite a relatively low or indeterminate likelihood of success. As the goals of prolonging survival and optimizing function become increasingly unachievable, priorities often shift. When comfort is the overriding goal of care, and the principal intent of any further intervention is to achieve lasting relief, there may be no tolerable time-frame for exploring other therapeutic options. In this situation, interventions of low or indeterminate likelihood of success are often rejected in favor of more certain approaches, even if they may involve impairment of cognitive function, or possibly foreshortened duration of survival.

This situation becomes more complicated when the clinician is less certain that the available approaches will fail. Therapeutic decision making is strongly influenced by the patient's readiness to accept the risk of morbidity and enduring discomfort until adequate relief is achieved. As always, patient evaluation of therapeutic options requires a candid disclosure of the therapeutic options, including information regarding the likelihood of benefit, the procedural morbidity, the risks of side effects, and the likely time to achieve relief. If these are acceptable to the patient, then further trials of standard therapies should be pursued. If the patient requires relief and either the procedural morbidity, the risks of adverse effects or the likely time to achieve relief are unacceptable, then refractoriness should be acknowledged and sedation should be offered.

These decisions are usually made by consensus between the clinicians, the patient and the patient's family. The process of this decision making is predicated on an understanding of the goals of care for the individual patient. These goals can generally be grouped into three broad categories: (i) prolonging survival, (ii) optimizing comfort (physical, psychological, and existential), and (iii) optimizing function. The processes of goal prioritization and informed decision making require candid discussion that clarifies the prevailing clinical predicament and presents the alternative therapeutic options. Other relevant considerations, including existential, ethical, religious, and familial concerns, may benefit from the participation of a religious counselor, social worker or clinical ethics specialist.

With the patient's consent, it is prudent to involve the family in these discussions. They suffer with the patient and will survive with the memories, pain and the potential for guilt at not having been effective advocates for their loved one: either because the patient died in unrelieved pain or remorseful that the patient may have been sedated when other options were not given a fair chance. If it is agreed that sedation is the most humane and appropriate way to control symptoms, it is advisable to ask the patient and family members if they have any specific goals that need to be met prior to starting sedation or if they would appreciate a chaplain/spiritual support prior to starting sedation.

Discussing sedation with the ancillary staff members

Involvement of ancillary staff such as social workers, primary care nurse, psychologist and other health professionals is a point that cannot be adequately emphasized. Just as cancer is a family illness, so is its management a team effort. Information about who the patient is comes from many sources; the patient and family will find support and connect with different personalities; team involvement allows support for its members, prevents burn-out and helps monitor counter-transference issues.[31]

Consent and 'do not resuscitate' status

Consent to the use of sedation acknowledges the primacy of comfort as the dominant goal of care. The initiation of CPR at the time of death is almost always futile in this situation,[33–35] and furthermore, is inconsistent with the agreed goals of care.[33,35] Sedating pharmacotherapy for refractory symptoms at the end of life should not be initiated until a discussion about CPR has taken place with the patient, or, if appropriate, with the patient's proxy, and there is agreement that CPR will not be initiated.

Drug selection

The published literature describing the use of sedation in the management of refractory symptoms at the end of life is anecdotal and refers to the use of opioids, neuroleptics, benzodiazepines, barbiturates, and propofol.

OPIOIDS

In the management of pain, an attempt is usually made to first escalate the opioid dose. Although some patients will benefit from this intervention, inadequate sedation, or the development of neuroexcitatory side effects, such as myoclonus or agitated delirium, often necessitate the addition of a second agent.[36–38]

MIDAZOLAM

In general midazolam is the most commonly used agent.[22,24,39–45] This benzodiazepine has a relatively short

half-life and therefore, for the purposes of palliative sedation, generally needs to be administered by continuous infusion. The short half-life also allows for rapid dose titration. A subcutaneous or intravenous line can be used. A starting dose of midazolam 1 mg/h by continuous infusion is suggested. This dose may need to be titrated rapidly to effect. In most cases, doses of between 1 mg/h and 7 mg/h are required. Some suggest using a higher dose of sedative initially to obtain sedation as soon as possible. Once deep sedation is induced, the dose should be lowered until the lowest effective dose to maintain sedation has been found. Reassessment of the patient is required on a regular basis. Rarely, benzodiazepine drugs can cause a paradoxical agitation, and an alternative strategy is required.

BARBITURATES

Greene[46] reported experience in the management of refractory physical symptoms using barbiturates alone among 17 imminently dying terminally ill patients suffering from persistent physical symptoms. Amobarbital (9 cases) or thiopental (8 cases) were used and adequate symptom relief was achieved in all cases. The median survival of these patients after initiation of the infusion was 23 hours (range 2 hours to 4 days). Although most of the patients maintained interactional function for a time, all patients died in their sleep. This approach has been endorsed by Truog et al.,[47] who also described the potential utility of barbiturates for terminal agitation or terminal anguish.

METHOTRIMEPRAZINE

Methotrimeprazine is an antipsychotic phenothiazine which can be administered orally or parenterally (intravenously [IV], subcutaneously [SC], or intramuscularly [IM]). Parenterally, it is often used to provide sedation in the management of refractory symptoms at the end of life.[48,49] In addition to its sedative properties, it is also moderately analgesic. Parenteral dosing is conventionally started at 6.25 mg every 8 hours and every 1 hour prn for breakthrough agitation. If necessary, the dose may be increased to 12.5 mg or 25 mg every 8 hours and every 1 hour prn for breakthrough agitation. Orthostatic hypotension is a common adverse effect and this medication is best avoided for ambulatory patients.

CHLORPROMAZINE

Chlorpromazine is an antipsychotic phenothiazine which can be administered orally, parenterally (IV or IM), and rectally. It has been used to provide sedation in the setting of agitated delirium and refractory dyspnea at the end of life.[50] In this published experience, the median rectal dose was 25 mg every 4–12 hours and the median IV dose was 12.5 mg every 4–12 hours.[50] It is a relatively cost effective option that can be easily used in the home.[51]

PROPOFOL

The published experience in the use of propofol for sedation in this setting is anecdotal.[42,52–55] In the rare event that other agents have been unable to provide adequate relief its anesthetic properties may be particularly useful to provide sedation. Propofol is very similar to the short-acting barbiturates but it has a short duration of action and a rapid onset. These characteristics make it relatively easy to titrate.[53] In one report the patient was started on a loading dose of 20 mg, followed by an infusion of 50–70 mg/h.[54]

Drug administration

The management of sedating pharmacotherapy for refractory symptoms in patients with advanced cancer demands a high level of clinical vigilance. Irrespective of the agent selected, administration initially requires dose titration to achieve adequate relief, followed subsequently by provision of ongoing therapy to ensure maintenance of effect. The depth of sedation that is required to achieve adequate relief is highly variable. In some situations, patients may require only light sedation to achieve adequate relief, in other situations, particularly at the end of life, deep sedation may be required.

Regular, 'around the clock' administration can be maintained by continuous infusion or intermittent bolus. The route of administration can be IV, SC, or rectal. In some situations drugs can be administered via a stoma or gastrostomy. In all cases, provision for emergency bolus therapy to manage breakthrough symptoms is recommended.

Patient monitoring

Once adequate relief is achieved the parameters for patient monitoring and the role of further dose titration is determined by the goal of care:

- *When the goal of care is to ensure comfort until death for an imminently dying patient.* In this setting the only salient parameters for ongoing observation are those pertaining to comfort. Symptoms should be assessed until death; observations of pulse, blood pressure, and temperature do not contribute to the goals of care and can be discontinued. Respiratory rate is monitored primarily to ensure the absence of respiratory distress and tachypnea. Since downward titration of drug doses places the patient at risk for recurrent distress, in most instances it is not recommended even as the patient approaches death.
- *If the patient wishes to be less sedated and dying is not imminent.* In this context comfort, the level of sedation and routine physiological parameters such as heart rate blood pressure and oxygen saturation are monitored. In these cases, the drug should be administered by the lowest effective dose that provides adequate comfort. The depth of sedation necessary to control symptoms varies greatly. For some patients, a state of 'conscious sedation', in which

they retain the ability to respond to verbal stimuli, may provide adequate relief without total loss of interactive function.[22,41,45,46] Some authors have suggested that doses can be titrated down to reestablish lucidity after an agreed interval or for preplanned family interactions.[22,46,47] This, of course, is a potentially unstable situation, and the possibility that lucidity may not be promptly restored or that death may ensue as doses are again escalated should be explained to both the patient and family.

Nutrition and hydration when patients are sedated

Contrary to the assertions of Quill *et al.*[56,57] and Orentlicher *et al.*[58] the discontinuation of hydration and nutrition are *not* essential elements to the administration of sedation in the management of refractory symptoms at the end of life. While there is wide consensus that invasive forms of enteral or parenteral nutrition are not essential aspects of care for patients who lose the ability to eat and drink at the end of life,[59] no consensus exists regarding the withholding of hydration. Available data do not support the assertion that it is 'typical'[58] or essential to the approach of 'terminal sedation'.[56,60]

Opinions and practices vary. This variability reflects the heterogeneity of attitudes of the involved clinicians, ethicists, the patient, family and local norms of good clinical and ethical practice.[39] Individual patients, family members and clinicians may regard the continuation of hydration as a non-burdensome humane supportive intervention that represents (and may actually constitute) one means of reducing suffering.[60,61] Alternatively, hydration may be viewed as a superfluous impediment to inevitable death that does not contribute to patient comfort or the prevailing goals of care and that can be appropriately withdrawn.[62] Often, the patient will request relief of suffering and give no direction regarding supportive measures. In this circumstance the family and healthcare providers must reach consensus as to what constitutes a morally and personally acceptable approach based on the ethical principles of beneficence, nonmalfeasance, and respect for personhood.

In cases where there are religious or culturally based reservations regarding the discontinuation of nutritional support, it should be maintained unless there is evidence of direct patient harm by the intervention.

EMERGENCY SEDATION

The context

In some cases, patients who are in an immediately preterminal stage will present with overwhelming symptoms as they are dying. In these situations emergency decisions will need to be made without recourse to a case conference or even cross consultation. This may occur in the setting of a

dying patient with sudden onset severe dyspnea,[63] agitated delirium,[64] massive bleeding, or pain. Care planning that anticipates potential emergencies and plans responses can help reduce the stress of emergency decision making in situations such as these.

Planning

Contingency plans for the management of catastrophic situations should be discussed with the patient and with family members. If the patient is at home, sedating medications should be prepared and a clear plan for emergency administration should be discussed. In situations in which family members or other carers at home feel that they would be unable to administer emergency medications, consideration should be given to inpatient care.

Administration

As in the previous scenario, midazolam is recommended as the drug of choice. Initial sedation can be achieved with a bolus of 2.5 mg SC/IV which can be repeated after 5 minutes if adequate sedation is not achieved. Once the patient is calm an SC or IV infusion can be used. In the patient who is in an immediately preterminal stage the only salient parameters for ongoing observation are those pertaining to comfort. Symptoms should be assessed until death; observations of pulse blood pressure and temperature are superfluous. Respiratory rate is monitored primarily to ensure the absence of respiratory distress and tachypnea.

RESPITE SEDATION

The context

In many instances, the notion of refractoriness is relative. Among patients who are not imminently dying, severe emotional and physical fatigue influence the patient's perception of the intolerability of symptoms or of further attempts to alleviate them. Since this may be a reversible phenomenon, sedation is often presented initially as a respite option to provide relief and rest, with a planned restoration of lucidity after an agreed interval. After such respite, some patients will be sufficiently rested to consider further trials of symptomatic therapy.[22]

Administration

There are critical differences in the monitoring of sedation in this setting. In addition to the level of sedation it is essential to monitor routine physiological parameters such as heart rate blood pressure and oxygen saturation. In these cases, the sedating agent should be administered by the lowest effective

dose that provides adequate comfort. Despite all of these pre-cautions, sedation of this sort is a potentially unstable situation, and the possibility that lucidity may not be promptly restored or that death is among the risks involved, should be explained to both the patient and family.

SEDATION FOR PSYCHOLOGICAL OR EXISTENTIAL SUFFERING

The context

Patients approaching the end of life often suffer from existential issues including hopelessness, futility, meaninglessness, disappointment, remorse, death anxiety, and disruption of personal identity.[65–69] If life is perceived to offer, at best, comfort in the setting of fading potency or, at worst, ongoing physical and emotional distress as days pass slowly until death, anticipation of the future may be associated with feelings of hopelessness, futility, or meaninglessness such that the patient sees no value in continuing to live.[67,69–74] Death anxiety is common among cancer patients; surveys have shown that 50–80 percent of terminally ill patients have concerns or troubling thoughts about death, and that only a minority achieve an untroubled acceptance of death.[70,75,76] Together, these symptoms have been labeled a 'demoralization syndrome'.[77] In a Japanese report, 1 of 240 patients received sedation for the relief of severe existential distress alone, but a further 19 patients who received sedation for other symptoms described their lives as meaningless.[78]

Specific consideration in this situation

Sedation in the management of refractory psychological symptoms and existential diastases is different. By the nature of the symptoms being addressed it is much more difficult to establish that they are truly refractory: the severity of distress of some of these symptoms may be very dynamic and idiosyncratic, the standard treatments have low intrinsic morbidity and for some, like existential distress, there are no well established strategies. Additionally, the presence of these symptoms does not necessarily indicate a far advanced state of physiological deterioration. This factor, compounded with the observations that psychological distress and the desire for death may be very variable[74] and that psychological adaptation and coping is common,[79] cast doubt over the issue of proportionality.

The dilemma

These situations present a major dilemma insofar as it is neither desirable to subject patients with refractory psychological or existential suffering to protracted trials of therapies that provide inadequate relief, nor to sedate patients when viable alternatives remain unexplored. In this setting,

as with physical symptoms, refractory psychological or existential distress must be distinguished from 'difficult' problems which have been resistant to relief thus far but which could potentially respond within a tolerable time-frame.

Published guidelines

Guidelines to assist in this situation have been published:[80–82]

- This approach should be reserved for patients in the advanced stages of a terminal illness with a documented 'do not resuscitate' order.
- The designation of such symptoms as refractory should only be done following a period of repeated assessment by clinicians skilled in psychological care who have established a relationship with the patient and his or her family along with trials of routine approaches for anxiety,[79] depression,[79] and existential distress[83–87].
- The evaluation should be made in the context of a case conference since individual clinician bias or burnout can influence decision making.[1,88,89]
- In the rare situations that this strategy is indeed appropriate and proportionate to the situation, it should be initiated on a respite basis with planned downward titration after a pre-agreed interval. It has been reported that respite sedation can break a cycle of anxiety, distress, and catastrophizing that precipitates requests of this kind. Only after repeated trials of respite sedation with intensive intermittent therapy should continuous sedation be considered.

ETHICAL CONSIDERATIONS

Sedation to relieve otherwise intolerable suffering for patients who are dying as normative practice

There is no distinct ethical problem in the use of sedation to relieve otherwise intolerable suffering for patients who are dying. Rather, the decision making and application of this therapeutic option represents a continuum of good clinical practice. Good clinical practice is predicated on careful patient evaluation (as previously described) which incorporates assessment of current goals of care. Since all medical treatments involve risks and benefits, each potential option must be evaluated for its potential to achieve the goals of care. Where risks of treatment are involved, the risks must be proportionate to the gravity of the clinical indication. In these deliberations, clinician considerations are guided by an understanding of the goals of care and must be within accepted medical guidelines of beneficence and nonmalfeasance. Finally, the penultimate decision to act on these considerations depends on informed consent

or advanced directive of the patient. In this clinical context, the decision to offer the use of sedation to relieve intolerable suffering to terminally ill patients presents no new ethical problem.[88,90]

As with any other high risk clinical practice, potential for nonbeneficent abuse exists. Wein has described prerequisites to ensuring that sedation of imminently dying remains on an ethically sound footing:[31] appropriate patient selection; candor and consent; cross-consolation; documentation; knowledge of medications and illness; and a commitment to titrate and monitor. Despite the potential for shortening life, this approach has been endorsed as acceptable normative practice by legal precedent.[91] In the 1957 English case of *R v Adams,* Justice Devlin wrote in his judgment:

> If the first purpose of medicine, the restoration of health, can no longer be achieved, there is still much for a doctor to do, and he is entitled to do all that is proper and necessary to relieve pain and suffering, even if the measures he takes may incidentally shorten life.

He justified this approach rejecting the notion that this is a special defense, but rather by endorsing the clinical pragmatist approach that[92]

> The cause of death is the illness or the injury, and the proper medical treatment that is administered and that has an incidental effect on determining the exact moment of death is not the cause in any sensible use of the term.

This approach was lent further support by the recent decision of the Supreme Court of the United States that rejected a constitutional right that encompasses assisted suicide but endorsed the use of sedation as an extreme form of palliative care in the management of refractory symptoms at the end of life.[93]

Potential for abuse

Undoubtedly the use of sedation in the relief of symptoms at the end of life is potentially open to abuse. Indeed, some physicians administer doses of medication, ostensibly to relieve symptoms but with a covert intention of hastening the patient's death. Data from the Netherlands indicated that administration of sedating medication, ostensibly to relieve distress but with manifest intent of hastening death, is commonplace.[94,95] In a recent survey of Dutch physicians who had used sedation at the end of life, hastening of death was partly the intention of the physician in 47 percent (95% CI, 41 percent to 54 percent) of cases and the explicit intention in 17 percent (95% CI, 13 percent to 22 percent) of cases.[96] Research in Australia[97,98] and the USA[99,100] indicates that this practice is not uncommon. An Australian survey of 683 general surgeons found that 36 percent had given drugs in doses that they perceived to be greater than those required to relieve symptoms with the intention of hastening death.[101] Similar practices, albeit much less

common, were reported in a survey of end-of-life care practices in six European countries.[102]

These duplicitous practices represent an unacceptable deviation from normative ethical clinical practice. Infrastructural guidelines are necessary to avoid deceitful practices of this kind.

Distinction from 'slow euthanasia'

Some authors argue that although sedation in the relief of uncontrolled symptoms may be justifiable, the concurrent discontinuation of nutrition and hydration does not contribute to patient comfort and almost certainly hastens death by starvation and dehydration. Consequently, they argue, sedation for the management of refractory symptoms is practically the same as 'slow euthanasia'.[61,103–105] This proposition is argued both by opponents to euthanasia, who are concerned about harmful aspects of the practice of forgoing nutrition and hydration,[61,103–106] and also by proponents of elective death who argue that if these acts are morally equivalent, then the more rapid mode of elective death, such as euthanasia or assisted suicide, is more humane and dignified.[56,57]

Another concern is that since sedation may hasten the death of the patient, the plea of no moral responsibility for foreseen, inevitable untoward outcomes is at best, spurious, or at worst dishonest.[107] This relates to the so called 'doctrine of double effect' which will be discussed in the subsequent section. While we absolutely reject the appropriateness of the term 'slow euthanasia' we feel that it important to address this charge.

With regard to the first concern, it is important to reassert that, contrary to the assertions of Quill[56,57] and Orentlicher,[58] the discontinuation of hydration and nutrition is *not* an essential element to the administration of sedation in the management of refractory symptoms (see Ethical issues regarding nutrition and hydration below). Furthermore, there are no data to support the assertion that it is 'typical'.[108] We hold that sedation in the management of refractory symptoms is distinct from euthanasia insofar as:

- the intent of the intervention is to provide symptom relief not to end the life of the suffering patient
- the intervention is proportionate to the prevailing symptom, its severity and the prevailing goals of care
- finally, and most importantly, unlike euthanasia or assisted suicide, the death of the patient is not a criterion for the success of the treatment.

Distinction from euthanasia

Euthanasia refers to the deliberate termination of the life of a patient by active intervention, at the request of the patient in the setting of otherwise uncontrolled suffering. This is distinct from physician-assisted suicide, where the physician provides the means of suicide and instruction to

a patient to facilitate successful suicide. The use of sedation to relieve otherwise unendurable symptoms at the end of life falls under the rubric of 'the provision of a potentially lethal medication for a patient with a narrow therapeutic index'. Clearly this situation may result in the inadvertent foreshortening of the patient's life either by direct action of the drug or as an adverse effect (such as aspiration). The use of sedation in this setting is critically distinct from euthanasia for three fundamental reasons: first, the intent of the intervention is to provide symptom relief, secondly the intervention is proportionate to the prevailing symptom, its severity and the prevailing goals of care and, finally, and most importantly, the death of the patient is not a criterion for the success of the treatment.

The doctrine of double effect

In cases where a contemplated action has both good effects and bad effects the doctrine provides an approach to answer the question: Do the means justify the end? According to 'double effect ethics', an action is permissible if it is not wrong in itself and it does not require that one directly intends the bad result. Double effect ethics assumes the integrity of the physician and unambiguous intent and motive. Classically five criteria have been described to evaluate the validity of a double effect claim:[109]

- The action is either morally good or is morally neutral.
- The undesired yet foreseen untoward result is not directly intended.
- The good effect is not a direct result of the foreseen untoward effect.
- The good effect is 'proportionate to' the untoward effect.
- There is no other way to achieve the desired ends without the untoward effect.

The 'doctrine of double effect' is problematic insofar as it does not always apply to the use of sedation in the management of refractory symptoms. When sedation is used to relieve otherwise refractory pain and suffering at the end of life, the intention is to relieve otherwise unendurable suffering. The untoward consequences that are foreseen include the possibility of foreshortened survival and the definite loss of interactional function. Since the death of the patient at the end of a long and difficult illness is not always perceived as untoward, there is a significant problem with the application of the double-effect justification. Indeed, in Jewish tradition, there is a blessing for a 'timely' death, *Baruch Dayan Ha Emet* (Blessed is the Supreme Judge). Thus, to call the potential for foreshortened survival a 'bad outcome' may, in some cases, be inaccurate (at best) or dishonest (at worst).

Since the moral justification of sedation by double effect requires that clinicians make unequivocal claims regarding the undesirability of the possibility of the patient's death, it is often inappropriate.[107] Indeed, it undermines the essential element of clinician credibility. This view regarding the 'double effect' justification for the use of sedation is supported by other critics who have claimed that, at worst it has become a meaningless mantra recited by cynical surreptitious practitioners of euthanasia cloaked as palliative care clinicians.[105]

It is prudent and appropriate to emphasize that there is no clear evidence that the use of sedation in the relief of refractory symptoms at the end of life foreshortens survival. Three studies have addressed this issue in the setting of hospice care.[23,25,110] Three other studies have addressed this issue on the management of patients with terminal dyspnea after withdrawal of mechanical ventilation.[111–113] In the latter setting, the studies found no correlation between level of sedation, dose of sedatives, and duration of survival until death.

Ethical issues regarding nutrition and hydration when patients are sedated

Although sedation is clearly beneficent in terms of providing relief of otherwise intolerable suffering, the beneficence of withdrawal of nutrition and hydration in the already sedated and comfortable patient is not self-evident, and indeed it may be perceived as harmful. This debate has both medical and ethical dimensions.

Medically, there are few data to support the clinical benefit of hydration or artificial nutrition in the imminently dying, or to suggest that it prolongs life or contributes to comfort.[114–116] Ethically, the withdrawal of potentially death deferring treatments (such as hydration) among dying patients is, for some, controversial.[60,61] For reasons of clarity, the issue of sedation must be distinguished from the distinct and separate issue of hydration.

Opinions and practices vary. This variability reflects the heterogeneity of attitudes of the involved clinicians, ethicists, the patient, family and local norms of good clinical and ethical practice.[39] Individual patient's, family members, and clinicians may regard the continuation of hydration as a non-burdensome humane supportive intervention that represents (and may actually constitute) one means of reducing suffering.[60,61] Alternatively, hydration may be viewed as a superfluous impediment to inevitable death, that does not contribute to patient comfort or the prevailing goals of care and that can be appropriately withdrawn.[62] Often, the patient will request relief of suffering and give no direction regarding supportive measures. In this circumstance the family and healthcare providers must reach consensus as to what constitutes a morally and personally acceptable approach based on the ethical principles of beneficence, nonmalfeasance, and respect for personhood.

In cases where there are religious or culturally based reservations regarding the discontinuation of nutritional support, it should be maintained unless there is evidence of direct patient harm by the intervention.

CONCLUSIONS

Sedation is a critically important therapeutic tool of last resort. It enables the clinician to provide relief from intolerable distress when other options are not adequately effective. Because sedation undermines the capacity to interact, it must be used judiciously. Clear indications and guidelines for use are necessary to prevent abuse of this approach to facilitate the deliberate killing of patients, which while benevolently intended, may have untoward sociological and ethical consequences for palliative care clinicians and the image of palliative medicine as a profession.

Key learning points

- At the end of life, all patients have the right to the adequate relief of physical symptoms.

- There is need to ensure that appropriate infrastructural measures are addressed to enhance the likelihood that this right will be fulfilled.

- Symptoms at the end of life must be assessed.

- The adequacy of symptom relief is determined by the patient.

- Inadequately received symptoms in dying patients must be relieved to the patient's satisfaction.

- Symptoms that are difficult to control must be evaluated by clinicians expert in symptom control at the end of life.

- When a symptom is refractory to normal palliative approaches, and only sedation can provide the needed relief, this should be available to patients (with appropriate infrastructural guidelines to prevent the inappropriate application of this approach).

Physical and occupational therapy in palliative care

PAMELA R MASSEY, EILEEN S DONOVAN

Against our confidence in mastery and control, we need to remember that old age and dying are not problems to be solved but human experiences that must be faced. In the years ahead, we will be judged as a people by our willingness to stand by one another, not only in the rare event of natural disaster but also in the everyday care of those who gave us life and to whom we owe so much.

We [must] emphasize . . . the singular importance of seeking to serve the life the patient still has. . .

Leon R Kass (2005)[1]

INTRODUCTION

With the current overall survival rate at 50 percent, cancer is now a chronic disease and joins the ranks of the other major chronic conditions (cardiovascular disease, lung disease, and dementia) that account for end of life.[2] According to the President's Council on Bioethics report, 'the most common trajectory toward death (in the United States) . . . is a lengthy period of debility, frailty and dementia lasting not months but years.'[3] Treatment for any of these life-threatening diseases, especially in those who are elderly, results in a variety of medical problems, complex functional changes, and significantly compromised quality of life.[4–6] People with cancer and other serious illnesses need comprehensive care designed to relieve symptoms of pain, fatigue, and weakness during all phases of their disease including pretreatment, treatment, post treatment, recurrence, and end-of-life phases.[7] To provide that level of

comprehensive care requires a team of health professionals who can address both curative care and palliative care issues regardless of where the patient is on the life–death continuum. However, the World Health Organization (WHO) has recognized that it is unrealistic to expect that the emerging needs for palliative care can be met by just expending the workforce of specialists in palliative care. WHO suggests that expanding the knowledge and skills of health professionals in general is the answer to addressing the increasing healthcare needs as individuals live longer.[8] The key to increasing the numbers of health professionals who can improve function and quality of life for seriously ill people and their families is to enhance the awareness and skills of physical therapists and occupational therapists so they feel confident in working with palliative patients and their families.

The roles that physical and occupational therapy play in comprehensive healthcare fit naturally into a palliative care model. Both physical and occupational therapy are professions that are dedicated to the maximization of a person's functional abilities to allow that person to perform tasks and roles that are important to them. Although both professions have somewhat different approaches to the achievement of their mission, there is considerable overlap and collaboration between the two disciplines is common. As defined by the World Federation of Occupational Therapists (WFOT), 'the primary role of occupational therapy is to enable people to participate in the activities of everyday life and occupational therapists do so by enabling people to do things that will enhance their ability to participate or by modifying the environment to better support participation.'[9] The World Confederation for Physical Therapy

(WCPT) has identified a number of roles for physical therapists including:

- preventing disability and deformity
- educating/training disabled people to move around
- promoting self-care
- education, training, and transferring skills to other local staff and families
- acting as an expert resource.[10]

While physical therapy and occupational therapy are traditionally viewed as rehabilitation interventions, providing rehabilitation services for terminally ill patients is not a new concept. In 1969, Dietz described categories of rehabilitation services of benefit to persons with cancer as restorative, supportive, and palliative. Dietz defined the palliative setting as one in which there is increasing disability to be expected from progressing disease with an associated decrease in functional capacity, but where appropriate provision of treatment would eliminate some of the anticipated complications (i.e. bedsores, contracture, problems in personal hygiene, and emotional deterioration secondary to inactivity and depression).[11] The benefits of physiotherapy in palliative care were recognized in the UK in 1978. Shank described the physiotherapist's role in *relief of discomfort and pain* through the use of massage, exercise, supportive positioning, splinting, and chest physiotherapy and *in maintenance/improvement in function* with assistive devices, exercise, and retraining. She concluded that the retention of an element of independence could provide the patient with valuable hope

and reduced anxiety.[12] Physical therapists in the USA had historically provided terminally ill patients with therapeutic measures such as massage, heat and hydrotherapy. However, with the inception of the hospice movement, physical therapists took on the additional roles of educator to patient, family and other health professionals, as well as becoming a functioning member of the patient treatment team.[13] About the same time occupational therapists advocated that good end-of-life care included not only the management of symptoms but also the assistance to make the best of every day. In 1983, Tigges and Sherman described the role of occupational therapists in fostering hospice patients' independence in occupational roles of self-care, work and leisure as important interventions in coping with feelings of isolation and loss of independence (Box 104.1).[14]

WHEN TO MAKE REFERRALS

It is well recognized in developed nations that people are living longer and the types of disease they are dying from are chronic diseases that are often associated with musculoskeletal disorders and disabilities. Heart disease, stroke, pulmonary failure, and cancer are recognized as the main causes of death, but comorbid conditions such as arthritis, dementia, and osteoporosis are also contributing to increased disability and the need for additional care.[15] In a study published in the *Journal of the American Medical Association* clinicians examined the patterns of functional decline at end of life for four types of illness trajectories (cancer death, organ failure death, sudden death, and frailty) and concluded that; 'End of life care must also serve those who become increasingly frail even without a life threatening illness'.[16]* Additionally, research from WHO indicates that palliative care interventions such as good pain relief, communication, information, and coordinated care from skilled professionals are effective in reducing symptoms and suffering, and that these experiences do not differ widely by disease or across countries.[15] The decision of when to begin physical and occupational therapy for the palliative care patient is often based upon the need to manage symptoms early in the course of the disease, reduce the burden on caregivers, or improve the quality of life of the patient.

Early referrals for symptom management

The use of palliative care interventions is applicable early in the course of an illness (not just at the end-of-life stage) to manage distressing clinical complications. Physicians may not consider the benefit of physical and occupational therapy early in the course of cancer, cardiovascular or respiratory diseases; but preventive interventions offered by these rehabilitation specialists may prevent pain and functional loss during the end-of-life phase of these diseases. Gerber

---

Box 104.1 Role of physical/occupational therapy in palliative care

- Help patient/caregivers determine which activities and roles they can realistically perform

- Enable the patient to take an active part in establishing goals and treatment priorities

- Apply physical/occupational therapy interventions to minimize symptoms and optimize functional abilities

- Assist the patient to find meaning with their available range of activity and occupation considering the interplay between physical, psychological, social, and vocational domains of function

- Instruct patient and caregivers regarding methods to maximize function within limits of energy, safety, and capabilities

- Enhance quality of life at the end of life for the patient and their family

noted that referrals to rehabilitation professionals for cancer patients usually target either specific impairments at anatomical level (i.e. loss of range of motion or lymphedema) or problems with mobility. However, she recommends earlier referrals to prevent predictable problems associated with medical treatment, such as skin care and exercise to manage connective tissue side effects from radiation.[7]

Multiple studies have demonstrated that the benefits of exercise include improvement in mood, sleep patterns, fitness, lipid profile, strength, functional activity, fatigue and pain levels.[7] Exercise can prevent loss of strength and functional abilities often associated with lack of activity or disuse in the cancer population.[17***] In a study of 155 androgen-deprived patients with prostate cancer, resistive exercise was effective in reducing fatigue and improving fitness and health-related quality of life.[18**] Even in the bone marrow transplant populations, Demeo has shown that exercises can be done safely immediately following high-dose chemotherapy and can effectively reduce fatigue, maintain physical performance and improve hemoglobin levels.[19*,20**,21*]

Reduce burden of caregivers

The delivery of rehabilitation services by physical and occupational therapists within a palliative care framework is appropriate in all healthcare settings including hospitals, outpatient, community, home and special palliative units.[22] Lynn observed 'Living with serious illness through to death can be an extraordinarily important phase of life for patient and loved ones, but only if the dying person is comfortable, assured of the resources needed for daily living, and respected.'[23] However, as noted in the Rand White Paper 'Living well at the end of life', the current US model, including hospice, does not serve the seriously ill populations well; addressing the healthcare delivery systems is critical to meeting the needs of these individuals and their families.[2] The number of therapists involved in palliative care in the USA is growing but is still not sufficient to meet the increased demand. Likewise, the WHO acknowledges that some developed countries conduct rehabilitation programs in nursing homes (the Netherlands and USA), but in most countries the provision of quality end-of-life care is hampered by shortages of staff with palliative care skills.[15]

In most countries, older people live at home despite their gradual functional decline. With aging populations and an associated decline in numbers of younger people to function as caregivers, the strain on older caregivers (i.e. family members) is increased. Although palliative care is often preferred to 'medical care' by patients at end of life, healthcare systems often do not provide palliative or comfort care and funding for end-of-life care is usually limited. This places further burdens on families.

An analysis of relevant studies by WHO indicates that most people (75 percent) would prefer to die at home and would prefer home care at the end of life.[15] In a study of 340 seriously ill patients, items that were consistently rated as very important at end of life by more than 70 percent of the patients included the desire not to be a burden to family and to society.[24*] However, maintaining the individual in the home setting can place extraordinary burdens on the caregiver who is usually a family member. Care at home, which can include carrying out activities of daily living such a bathing, dressing, and toileting, involves a level of intimacy and degree of physical effort often not anticipated by family members. 'Long term care for seriously ill relatives is unpaid and unsupported work that may damage the health, wellbeing and financial security of caregivers themselves'.[15] Physical and occupational therapists can teach caregivers how to provide this intimate care, how to move and assist the patient in a safe manner, and how to modify the home environment to minimize these burdens.

Improve quality of life for the person

Quality of life has different meanings for different persons. For the measurement of quality of life to be considered valid, the definition of quality of life must be determined by what the individual identifies it to be at a given point in time.[25] Calman proposed a model for assessment of quality of life in which it is defined as the difference (at a particular period in time) between the hopes and expectations of the individual and their present experience.[26] The gap between hopes and realities may be narrowed by improving patients' function through treatment or by reducing their expectations through better understanding of the limitations imposed by their disease. Using this model, improving quality of life for the palliative care patient is a dynamic process that must continually address the ongoing changes in the gap of hope and reality as their disease progresses. Physical therapists and occupational therapists, by the nature of their therapeutic and educational interventions, can and often do assist the seriously ill patient to manage the gap between hope and reality.

Nolen and Mock noted that, in addition to the importance of having control over traditional activities of daily living (bathing, dressing, and eating), having functional control over healthcare decision making and fulfillment or role expectations are equally important to patients at the end of life.[27] Occupational therapists can tailor treatments and goals to allow patients to continue to carry out meaningful activities and fulfill self-identified important life roles. Yoshioka demonstrated the importance of patient control over healthcare decisions in his study of 301 cancer patients who received rehabilitation therapy during their last 6 months of life.[28*] Although mobility and self-care scores improved with therapy for all participants, the patients and families who received the greatest benefit were those who more actively participated in their rehabilitation and helped to direct their care.

Improvement in quality of life with physical and occupational therapy interventions has been shown to be beneficial

even in the last days of life (Box 104.2). In a study of 56 cancer patients in Switzerland, the benefits of physical therapy were noted up right up to the last 24 hours before death;[29] 79 percent of the patients received beneficial respiratory management techniques during the 24 hours preceding death and 55 percent received beneficial interventions aimed at improving self care during the 8 days that preceded their death.

Box 104.2 When physical or occupational therapy is appropriate for palliative patients

- Any patient with a serious illness can benefit from therapy services

- Physical/occupational therapy can provide specialized treatment of pain, discomfort, and functional loss at any stage of illness

- Referral is encouraged early in the patient's care to prevent predicable morbidities but can be received at any time, including during and after curative treatment

- Therapy services can be provided in hospitals, nursing homes, community settings, the patient's home and the hospice/palliative care unit

---

GUIDE FOR PHYSICAL/OCCUPATIONAL THERAPY IN PALLIATIVE CARE

Therapeutic goals

The goals of rehabilitation interventions in supportive care, chronic relapsing disease, and end-of-life care are similar:

- maintain the patient's optimal function within the limits of their ability and the time frame available
- address symptoms of pain, limited cardiopulmonary capacity, strength, and range of motion as they interfere with patient comfort and function
- reduce caregiver burden via education and training
- increase caregiver competence/confidence in physical management of the patient.

Goals should be realistic and take into consideration many interrelated factors such as age, stage/type of disease, social/economic factors and cognitive abilities. The process of setting the appropriate goals is as important as the goals themselves. Although any type of patient should collaborate in the development of rehabilitation goals, it is especially helpful for patients in the palliative setting as the process provides a therapeutic outcome of allowing the patient continued control in directing his or her care. Therapists in the palliative care setting can encourage patients to explore what is truly important to them at that point in their life. Collaborative goal setting also provides an ideal opportunity for assisting patients in reframing unrealistic goals to match their current medical condition, if necessary.

Therapists' specialized skills

Physical and occupational therapists involved in the care of patients with progressive, debilitating illness or age associated decline must demonstrate not only well-developed clinical skills, but also the ability to communicate effectively, facilitate team interactions, and innovate extemporaneously. They must be sensitive to the emotional needs of the patient and family, as well as the needs of their fellow team members. In more ways than in any other rehabilitation treatment situation, the wants and needs of this patient population drive the treatment plan. The palliative care therapist must be able to establish a treatment plan focused on comfort and quality of life rather than on recovery of normal function.

In the healthcare culture where there is often a general discomfort around the topic of death, physical and occupational therapists traditionally focus on rehabilitation for living. However, in the palliative care setting, therapists must be able to manage their own fears and feelings about serious illness and death to effectively support the patients and their families who are facing those issues.[30] Trump advises that to be effective in the palliative care setting, therapists may need to address and sometimes share in patients' and families' intense emotions.[31] Furthermore, when death does occur the therapist must have appropriate methods for bringing about professional and personal closure to prevent emotional burnout. Foles *et al.* outlines a series of professional and personal activities that promote emotional wellbeing for the therapist, including attending a wake, funeral, or memorial service that allows the therapist to say goodbye to the patient and family.[32] Professional reflection on the outcomes of the therapy provided and reliance on one's own personal/spiritual beliefs and values are essential skills for therapists working in palliative care (Box 104.3).

Box 104.3 Special skills required for therapists working in palliative care

- Effective communication skills: active listening, empathy, and intuition

- Problem-solving skills and creative approaches to individual needs

- Ability to form compassionate bonds with emotional detachment

- Ability to accept death as a reality but never take away hope

---

Potential benefits – therapeutic interventions to optimize function

Physical and occupational therapists specialize in addressing physical function. Though functional decline may be inevitable in terminal illness and some chronic disease, there are many interventions that can assist in prolonging functional abilities. 'Optimizing levels of function in meaningful activities, occupational roles and in functional mobility for as long as possible is one of the benefits that therapy offers the patient. . . .'[33]

An objective assessment of function, routinely done on all patients, allows implementation of rehabilitation measures to slow, prevent or remediate performance problems. Physicians and nurses typically evaluate function, in persons with cancer, using the Karnovsky, Eastern Cooperative Oncology Group (ECOG) or similar rating scales. These scales are not always true indicators of a person's actual physical abilities as the ratings are usually based on cursory observation of the patient in an artificial environment (a clinic visit) in which they are 'stimulated . . . by the environment, anxiety and expectations.'[34] In a small study of patients with nonsmall cell lung cancer at the Jewish General Hospital in Montreal, Dalzell *et al.* compared ECOG performance status ratings (PS) with a global functional score composed of three objective measures of performance. They found that 'PS evaluation persistently underestimated the degree of functional disability as measured by the objective measures.'[35*] Cashy and Cella compared the results of PS assessment of lung cancer patients performed by the physician versus the patient's self assessment of their function and found that physicians, in general, rated the patients as performing better than the patients rated themselves.[36*]

A better indicator of the patient's actual functional abilities are objective tests of observed performance in which time or distance is measured. Functional performance tests such as 6-minute walk, 50-foot fastest speed, timed sit to stand and others have been compared between groups (i.e. cancer, HIV, AIDS and low back pain). Although all groups show overall decreased performance from normal, the cancer patient group was the lowest performing group.[37*] Lee *et al.* evaluated the self-reported fatigue measures and objective functional performance of individuals with lymphoma and recommended that physical performance measures be used in addition to self-reported measures when evaluating outcomes of rehabilitation.[38*] The 6-minute walk has also been used in studies of heart failure and shows promise as an easier to perform alternative to a multistaged exercise test.[39]

MAINTAINING FUNCTIONAL MOBILITY

Decline in functional mobility may be due to any number(s) of impairments. Often an individual impairment is not sufficient to interfere with function, but the additive effect of multiple mild impairments overcomes the patient's ability to compensate and results in functional loss. An example might be a cancer patient with mild dyspnea and marginal hemoglobin who must now alter his gait pattern to reduce pain of one limb during the stance phase. The energy cost of his abnormal gait pattern is higher than that of normal gait. This patient might be able to compensate for one or even two of his impairments, but is unable to overcome the combination of the three. Reducing the pain of weight bearing on a limb through use of gait training with an appropriate assistive device and teaching pursed lip breathing might restore this patient's independent ambulation.

Ambulatory aids vary in their ease of use and utility for given gait requirements. Crutches, canes, and walkers come in many different weights, designs and with multiple accessories such as wheels, brakes, seats, and platform attachments. Selection of the appropriate device is based on the type of assistance needed (weight relief, balance deficits, etc.), the recommended gait pattern, the overall physical and cognitive abilities of the patient and the setting in which the device will be used (out of doors, over carpet, smooth surfaces, etc.). The energy cost of using different devices differs. The amount of energy required to walk with a standard walker is significantly higher than with a rolling walker, and may require excessive cardiac work for any patient with serious illness.[18**,19*,20**,21*,39,40***] But the rolling walker may not provide the required stability for safe ambulation for an individual patient. Certain gait patterns are more energy costly than others. For instance nonweight-bearing gait is significantly more energy costly than touch down gait and requires significantly higher cardiac work.[41] Improperly adjusted ambulatory aids can be dangerous at worst and inefficient at best. Among the problems that can be seen with poorly fitted devices are:

- an inability to effectively transmit weight through the device
- dangerous or painful alterations in posture to accommodate the height of the device.

Prescription for and training in the use of a gait device should be done by a physical therapist.[42]

At some point in the course of chronic debilitating illness, the individual may need greater assistance to maintain their functional mobility. Like ambulatory devices, wheelchairs also come in many sizes, weights, and configurations and with many options. One size does not fit all. Poorly fitted wheelchairs can cause pain, contribute to skin breakdown, increase the work of sit-to-stand transfers, decrease rolling stability etc. Width and depth of the seat, height from the floor, height of the back, position of the axle, types of armrests and footrests, material of frame, and seating surface must all be taken into consideration. Patients may desire powered mobility but have not given thought to how they will get the device into and out of their home or transport it in their vehicle. For other patients, powered mobility may make the difference between dependence and modified independence in the home and between community integration and isolation. Therapists prescribe specific

wheelchairs based on the size and needs of each individual patient and how it will improve their functional ability as well as their quality of life.

MAINTAINING MEANINGFUL ACTIVITIES AND OCCUPATIONAL ROLES

'The quality of life and control over one's life to the end of that life are essential to the maintenance of dignity and self-respect.'[43] Occupational therapists assist the patient and family in maintaining quality of life in the areas of self-care, work, and leisure by:

- enabling patients to select and continue meaningful occupation within their physical ability
- prescribing and training in assistive devices or equipment to reduce the time or effort to perform activities of daily living (ADLs) or leisure activities
- teaching energy conservation techniques to counteract fatigue
- modifying the environment to facilitate continued participation in meaningful social and occupational activities
- preventing isolation by helping patients continue their social role.

Picard and Magno advocate that occupational therapists can address the patient's need for meaning in life even if that life is measured in days. Occupational therapists can help the terminally ill patient answer the painful question: What do I do tomorrow while I am waiting to die?[44] Approaching the patient from both a biomedical and biosocial model, occupational therapists encourage the patient to determine what is important to them and enable the patient to continue to exert control of their life as much as possible.[14]

Working with the patient and the family in the home setting, occupational therapists make recommendations for home modifications, which will allow continued independence in self-care, work, and play. For example, installing a ramp to allow wheelchair access to the outdoor might encourage a gardener to return to a meaningful occupation or modifying the kitchen table might encourage the home-maker to maintain her supervision of meal preparations. Additionally, the therapist can introduce any number of assistive devices and/or adapted techniques that facilitate the performance of basic and instrumental activities of daily living. Long handled bathing sponges, tub/shower benches and hand held showers can reduce the energy cost and increase the safety of bathing. Dressing sticks, reachers, button hooks, sock aids, etc. can facilitate dressing. There are many other devices to increase ability and/or reduce energy cost of activities. Occupational therapists are familiar with these devices and where to obtain them.

In institutional settings, the use of therapeutic groups can be beneficial in assisting the patient to make major life transitions. Modifying old occupational roles and transitioning to new roles is part of the therapeutic process as function declines. Dawson described the use of occupational therapy groups in a hospice setting that created a safe and supportive environment designed to assist patients in adjusting and adapting to their changing roles.[45]

In summary, rehabilitation interventions by physical and occupational therapists may not restore a palliative patient to a previous functional level but may rather provide a reasonable degree of independence and quality of life during their final days.

Potential benefits – therapeutic interventions for symptom management

During rehabilitation of terminally ill patients, there is a delicate balance between maintaining optimal function and providing comfort relief. At some point, the focus on function will diminish and the efforts on comfort will increase until death.[46] Some impairments that are consistently encountered in patients with chronic or end-of-life disease are pain, dyspnea, skin breakdown, edema, weakness, loss of coordination, loss of soft tissue or joint mobility and impaired cognition. Any or all of these impairments can have a negative impact on patient function, but they may also cause discomfort and distress in and of themselves.[4]

PAIN MANAGEMENT

Pain is a frequently cited and much feared symptom of cancer and other chronic illnesses. Although pharmacological therapies are used effectively in many cases, nonpharmacological interventions can be important adjuncts, depending on the etiology of the pain. The inadequacy of training regarding the comprehensive management of cancer pain was the focus of a study (the Network Project) which determined that existing educational programs for health professionals put little emphasis on integrating psychosocial and rehabilitation issues in managing cancer pain.[47*] Too often pain is assessed while the patient is at rest. Determining the patient's incident pain levels during their basic or desired activities is important. Patients who fear movement-associated pain will limit their movement and eventually limit their ability to move. In evaluating patient pain, the therapists must also take into consideration cultural bias, diminished capacity to report pain, special needs of older patients and the complexity of some pain syndromes.[48]

Patients with advanced cancer may have painful bone metastases. Other causes of musculoskeletal pain may be related to soft tissue tightness, postural changes and arthritis or other comorbid conditions. Interventions such as orthotics, weight relief strategies, ambulatory aids, assistive devices, instruction in specific movement patterns, and correction of faulty posture or abnormal gait may afford relief.

Neuropathic pain can be severe and interfere with function. This type of pain may due to amputation of limb or breast, nerve impingement, chemotherapy or diabetic

induced neuropathy, or other nerve disruptions. Interventions such as thermal modalities, electrical stimulation, photostimulation, and massage can be useful components of a management plan for neuropathic pain. Finally, training in relaxation techniques such as guided imagery or progressive relaxation exercise assist the patient in managing pain.

RESPIRATORY MANAGEMENT

Dyspnea is a common symptom in advanced cancer as well as in heart failure, chronic obstructive pulmonary disease (COPD) and other chronic illnesses. The causes of dyspnea are myriad and in most cases, more than one mechanism is involved.[49] The reader is referred to Chapter 69 for indepth discussion of dyspnea. Positioning, respiratory muscle training, aerobic/strength training, stretching, airway clearance techniques, and education in breathing techniques (e.g. pursed lip breathing, etc.) are all methods which rehabilitation professionals are trained to perform on patients with pulmonary impairments.

When dyspnea is due to mechanical restriction of the thorax (e.g. postural changes, shortening of intercostal muscles etc.), specific manual techniques to improve thoracic mobility may improve the patient's ability to effectively ventilate. Dyspnea can also be due to respiratory muscle weakness or fatigue. 'Clear evidence reveals that specific respiratory muscle training improves inspiratory and expiratory strength and decreases symptomatic reports of ventilatory load perception – how difficult it seems to breathe.'[50] Weiner et al. demonstrated a decrease in dyspnea and an increase in exercise capacity in patients with congestive heart failure who participated in specific inspiratory muscle training exercises.[51*] Sanchez Riera et al. described similar results in patients with severe COPD.[52**] Cahalin described decreased dyspnea and improvement in maximum inspiratory and expiratory pressure following inspiratory muscle training in patients with advanced heart failure awaiting transplantation.[39] Bredin et al. studied breathlessness in patients with lung cancer.[53**] Their intervention group received advice and support on managing breathlessness, training in breathing control techniques, relaxation and distraction as well as other information and support. Their control group received standard management and treatment. They found that although overall survival was not significantly different between groups, the intervention group reported significant improvement in breathlessness at best as well as improvement in activity levels. No objective functional performance measures were included in the study. For patients who can tolerate cardiovascular endurance training, Carrieri Kohlman et al. noted a decrease in dyspnea, associated anxiety and distress, along with an improvement in exercise performance in those patients who performed 12 treadmill walking sessions followed by an unsupervised walking program.[54**]

Therapists can also use breathing retraining to reduce dyspnea. Education regarding effective use of accessory muscles, positioning to optimize muscle length tension, pursed lip breathing, prolonged exhalation, timing breaths with activities, and other techniques have been widely used in lung disease populations. Cahalin states 'body position is an important principle to include in the treatment of people with heart failure.'[39] The position of the patient can alter the work of breathing. Respiratory airflow resistance and breathlessness increased when a group of patients with left ventricular failure were placed in supine position.[55*] In patients with inspiratory muscle weakness, positioning in Fowlers can reduce resistance to diaphragmatic excursion by maximizing the assistance of gravity.[50] Positioning patients in sidelying with the diseased lung superior improved oxygenation in some studies.[56] Positioning also can help prevent the accumulation of secretions or assist in the mobilization of secretions. Patients often have difficulty clearing secretions due to pain or weakness. Positioning, postural drainage, assisted cough and alternative cough techniques (e.g. huffing), or the use of airway clearance devices such as the Flutter® or Acapella™ may be of benefit.[57*] Patients with severe weakness of abdominal musculature (e.g. spinal cord compression) may benefit from application of an abdominal binder.

SKIN MANAGEMENT

Skin breakdown can be a significant problem for many patients and the potential for skin compromise increases as the patient becomes increasingly ill or less mobile. Loss of skin integrity (due to trauma, pressure, shear force injuries) as well as impaired skin health (due to edema, nutritional deficiencies, and impaired circulation) can contribute to the skin breakdown. Physical and occupational therapists can use several methods to address causes of skin breakdown. Positioning to reduce pressure, selection of appropriate seating/bed surfaces, teaching of weight shifts, and prescription of properly fitted wheelchairs all contribute to effective skin management. For patients who are confined to bed, it is important to avoid extended periods of time with both the head and knees in an elevated position as that increases the risk of sacral decubitus. Therapists can instruct the patient and caregivers on safe alternative positions and an effective schedule for turning to prevent skin breakdown, functional training in bathing and hygiene, improving the patient's skills in bed mobility, transfers and, if possible, gait can also have a positive effect.[58] Proper transfer training is important to prevent shearing forces which produce skin burns or tears.

EDEMA MANAGEMENT

Edema can be caused by a number of conditions (venous or lymphatic obstruction, renal failure, right heart failure, hypoalbuminemia, and others). The reader is referred to Chapter 83 for an in-depth discussion of lymphedema. Regardless of the cause, swelling may be painful, can interfere with functional mobility and contribute to skin

compromise. Management of edema depends in part on the etiology of the swelling.

For patients with lymphedema complex decongestive therapy may be beneficial. Complex decongestive therapy includes manual lymphatic drainage (a very specific form of massage), lymphatic exercises, and bandaging with short stretch bandages. This form of therapy has long been used in Europe and Australia but is gaining increased acceptance in the USA as the number of trained clinicians increases and research has supported its efficacy. In a review of treatment approaches for arm edema in breast cancer patients, Erickson *et al.* concluded that a program of complex decongestive therapy consisting of manual lymphatic massage, exercise, and compression wrapping was effective in treating lymphedema related to breast cancer.[59***] In 2005 a Cochrane review of studies of physical therapy for managing lymphedema identified 195 studies out of which only 10 were randomized clinical trials.[60***] Of those 10, data were included from only three studies as the other seven were unavailable or otherwise ineligible for inclusion. None of the three studies included evaluated the same interventions nor had any of the three studies been replicated. The Cochrane group concluded that there was weak evidence to support the use of compression bandaging with compression hosiery over compression hosiery alone. In their discussion the authors commented that although it is evident that improvement can be obtained it is unclear which treatments are most effective and yield sustained improvement. Both reviews identified the need for well-designed clinical research to identify the best approach to manage lymphedema.

In addition, many references on management of lymphedema caution against the use of massage and other manual techniques in the presence of active disease.[61] The therapist must determine the relative risks of intervention versus the benefits of treatment. In a patient with painful swelling due to lymphatic obstruction from advanced disease, for whom cure is no longer a possibility, lymphatic drainage and bandaging may provide comfort relief and be entirely justified. The use of off-the-shelf compression garments, bicycle shorts or low stretch bandaging may help alleviate the discomfort of edema. Scrotal edema is a frequently encountered problem and may occur with or without extremity edema. It is painful and often interferes with sitting, transfers, and gait. Commercially available scrotal supports are usually too small to accommodate a very swollen scrotum but, with a sewing machine, can be modified to provide the compression necessary to alleviate pain. Due to costs, rapid changes in limb dimensions, and length of time required for ordering, fabrication, and delivery, custom garments are usually not indicated.

MANAGEMENT OF WEAKNESS/FATIGUE

Many patients complain of weakness and attribute to it their declining functional performance. Patients may use the term 'weakness' to describe lack of stamina, specific motor weakness, or asthenia. Physical evaluation can help differentiate between generalized muscle weakness, cardiopulmonary impairment, specific muscle weakness, steroid myopathy, cancer-related fatigue or other contributing issues. Exercise prescription will depend on the evaluation finding and will be specific to the problem. There are multiple studies to support the use of exercise as an intervention in cancer, lung disease and other diseases.[62***,63**,64*,65**,66**] Even assisted exercise for the extremely weak can be beneficial in optimizing a person's functional abilities. In the case of specific muscle weakness, braces or splints to assist with function and/or protect joint or muscle integrity may be recommended. Additionally, training patients in the use of energy conservation techniques can assist in management of fatigue.

MANAGEMENT OF SKELETAL COMPLICATIONS

Bone lesions are often seen in patients with advanced cancer, especially lung, breast, kidney, or prostate disease. Persons with multiple myeloma, osteoporosis, or those patients who have been on steroids are also subject to fracture. Management of pathologic fractures is difficult and requires a multidisciplinary approach to control pain and preserve functional mobility. Prevention of fractures should be a focus of management of any patients at risk. Many of these patients are at risk for spinal cord or root compression with resultant functional loss. Early identification of lesions at risk for fracture might allow prophylactic surgical fixation, protective bracing or weight relief to prevent an actual break. Strengthening exercises, gait training, and orthotics are all effective measures to reduce the risk of falls (Box 104.4).

Box 104.4 Types of orthoses and benefits

Ankle foot orthosis

- Assist in clearing the toes in swing phase of gait

- Maintains stability of the ankle in stance (avoid inversion or eversion injuries)

Knee orthosis

- Unload a painful arthritic knee joint

- Prevent hyperextension of the knee when hamstrings are weak or joint capsule is lax

- Assist in stabilizing knee if quadriceps are weak

Spinal orthosis

- Limits movement of spinal segments

- Relieves pressure on nerve roots

- Facilitates patient mobility

In summary, physical and occupational interventions for the palliative care patient are varied, multifaceted, and designed to address both the maintenance of function and the reduction of symptoms. As noted in the manual from the National Institute of Clinical Excellence on supportive and palliative care in cancer (UK), there is a growing body of evidence that supports the effectiveness of many combinations of rehabilitation intervention but more detailed studies are needed to understand the relative effectiveness of these interventions (Boxes 104.5 and 104.6). [67***]

Box 104.5 Physical therapy interventions in palliative care

- Functional mobility training

- Therapeutic exercises

- Dyspnea management

- Positioning for skin care, comfort, and function

- Lymphedema control

- Orthotics

- Therapeutic modalities (heat, cold, massage, electrical)

- Caregiver instruction and training

Box 104.6 Occupational therapy interventions in palliative care

- Engagement in meaningful activities that reflect valued roles

- ADL training/adapted techniques

- Energy conservation techniques/fatigue management

- Assessment/training in use of assistive devices and modification of environment

- Group activities (emotional and social benefits)

- Orthotics

- Positioning for skin care, comfort, and function

- Caregiver instruction and training

CONCLUSIONS/FUTURE ISSUES

Disability is defined by cultures – disability does not define people but how disability is viewed is determined by the society in which one lives. What might be considered a disability in one society or culture may not be viewed as such in another. Likewise, the definition of *independence* may vary depending on the stakeholder. Governments may see independence as increasing self-reliance and reducing the burden on the state whereas healthcare professionals focus on the individual's ability to carry out self-care activities independently. For disabled people, independence may be viewed in terms of personal autonomy and the ability to take control of one's life.[9]

For the person who is at the end of life, independence or lack of disability may be defined as the ability to continue to live one's life with dignity, exerting control over one's care and maintaining functional independence in self care activities as far as reasonably possible. Physical and occupational therapy can facilitate the patient's function at a minimum level of dependence regardless of life expectancy and improve the quality of survival at the end of life, so the patient's life can be as comfortable and productive as possible. Research is still needed to understand which interventions will achieve the best outcomes and what is the optimal time for interventions over the continuum of the life–death cycle. However, there is little doubt that quality of life and the quality of the death experience are enhanced when physical and occupational therapists are part of a team of health professions supporting the palliative care patient and their family.

Key learning points

- Rehabilitation interventions should be an integral part of palliative care.

- Physical and occupational therapy enhance function and quality of life for seriously ill people and their families, and address their psychological and spiritual needs through meaningful activities.

- Improved care results in meaningful and hopeful end of life.

- Referrals should be made early in the disease to provide symptom management, reduce the caregiver's burden and improve the patient's quality of life.

- Goals of physical and occupational therapy for palliative patients are based upon what is most important to them at the time of evaluation and are continually revised as their priorities change over the trajectory of their disease.

- Therapists use specialized skills to enhance communication, form compassionate bonds, and set goals which are realistic but do not take away hope.

- The measurement of function should be performance based and use objective measures.

- Therapists can provide a wide range of interventions to improve/maintain function and reduce symptoms such pain, edema, dyspnea, weakness, fatigue, skin breakdown, and other musculoskeletal complications.

Staff stress and burnout in palliative care

MARY L S VACHON

INTRODUCTION

Working in palliative care can be both challenging and stressful. What happens when clinicians become stressed and/or burnout? This chapter will provide an overview of stress and burnout in palliative care, discuss the extent of the problem, identify the factors associated with stress and burnout, and review some approaches to avoiding and dealing with these issues in palliative care.

DEFINITION OF TERMS

Stress

The concept of stress has been used to cover a number of divergent dimensions ranging from stimuli or stressors that lead to changes in the organism, to the outcome of such stimuli, and the emotional state or experience accompanying a changing social or personal situation.[1] Much of the current interest in the subject can be dated to the research of Hans Selye, who in 1936[2] articulated his biological concept of stress as the 'General Adaptation Syndrome', a set of non-specific physiological reactions to various noxious environmental agents.[3]

Antonovsky[4] sees stress as evolving from exposure to stressors. He distinguishes between stressors and routine stimuli. A routine stimulus is seen as being one to which the person can respond more or less automatically. A stressor is a demand made by the internal or external environment of

an organism that upsets its homeostasis, restoration of which depends on a nonautomatic and not readily available energy-expending action. A routine stimulus can become a stressor under certain circumstances. Whether a stimulus is a stressor depends on the meaning of the stimulus to the person at that point in time and on the repertoire of coping mechanisms readily available. In Antonovsky's model, 'stress' refers to the strain that remains 'in response to the failure to manage tensions well and to overcome stressors'.[4 (p. 10)]

Stress can be observed at the physiological, psychological, and behavioral levels of analysis.[5–7] It is an ongoing process affected by individual personality factors and environmental variables. The individual is constantly responding to and interacting with the environment and whether the stress is a benefit or a harm to the individual depends greatly on the individual's cognitive appraisal of the stress and subsequent coping process. More recently, the European Agency for Safety and Health at Work,[8] has stated that:

> There is increasing consensus around defining work-related stress in terms of the 'interactions' between employee and (exposure to hazards in) their work environment. Within this model stress can be said to be experienced when the demands from the work environment exceed the employee's ability to cope with (or control) them.

Burnout

The term burnout is generally credited to Freudenberger.[9,10] Burnout has been characterized as 'the progressive loss of idealism, energy and purpose experienced by people in the

helping professions as a result of the conditions of their work'.[11] (p. 14) 'The root cause of burnout lies in people's need to believe that their life is meaningful, and that the things they do – and consequently they themselves – are important and significant'.[12] (p. 633)

Christina Maslach, who developed the Maslach Burnout Inventory,[13] the most commonly used instrument to measure burnout, has reviewed research in the field of burnout over the past 25 years.[14] (p. 398)

> What has emerged from all this research is a conceptualization of job burnout as a psychological syndrome in response to chronic interpersonal stressors on the job. The three key dimensions of this response are an overwhelming exhaustion, feelings of cynicism and detachment from the job, and a sense of ineffectiveness and lack of accomplishment. The exhaustion component represents the basic individual stress dimension of burnout. It refers to feelings of being over-extended and depleted of one's emotional and physical resources. The cynicism (or depersonalization) component represents the interpersonal context dimension of burnout. It refers to a negative, callous, or excessively detached response to various aspects of the job. The component of reduced efficacy or accomplishment represents the self-evaluation dimension of burnout. It refers to feelings of incompetence and a lack of achievement and productivity at work.

A MODEL OF BURNOUT AND OCCUPATIONAL STRESS

In reviewing the research, Maslach *et al.*[14] note previous research in occupational stress focused on the person–environment fit model.[15] More recent research focuses on the degree of match or mismatch between the person and six domains of the job environment. The greater the gap or mismatch between the person and the environment, the greater the likelihood of burnout. The greater the match or fit, the greater the likelihood of engagement with work. Mismatches arise when the process of establishing a psychological contract leaves critical issues unresolved, or when the working relationship changes to something that the person finds unacceptable. Six areas of work life come together in a framework that encompasses the major organizational antecedents of burnout: workload, control, reward, community, fairness, and values.

Burnout arises from chronic mismatches between people and their work settings in some or all of these areas. Preliminary evidence suggests that the area of values may play a central mediating role for the other areas. Alternatively, people may vary in the extent to which each of the six areas is important to them. Some people may place a higher weight on rewards than on values, or people may be prepared to tolerate a mismatch regarding workload if they receive praise, good pay, and have good relationships with colleagues. The palliative care literature will be reviewed using this framework.

STRESS AND BURNOUT IN PALLIATIVE CARE VERSUS OTHER SPECIALTIES

A review of the literature of stress in palliative care over the past quarter century[16] found many studies reported that staff working in palliative care had either less burnout and stress than other professionals or that they experienced no more stress than other healthcare professionals working with seriously ill and/or dying persons.

That stress in palliative care may be less than in other specialties does not negate the stress that does occur. The use of drugs, alcohol, and suicidal ideation of hospice medical directors and matrons was identified.[17] Hospice nurses were more anxious, with associated psychosomatic complaints than hospital nurses, although the latter were more dissatisfied with their jobs. High levels of mental ill health were predicted by a lack of social support and involvement in work and high workload.[18] Hospice nurses were found to be higher on the death and dying dimension of the Nursing Stress Scale and were slightly more depressed than medical/surgical or intensive care unit nurses.[19]

More recent studies confirm that palliative care specialists in the UK experience less stress and burnout than their oncology colleagues.[20] In a questionnaire sent to all consultant nonsurgical oncologists in the UK, the stress and stressors of medical oncologists, clinical oncologists, and palliative care specialists were assessed. Clinical oncologists were more likely to experience burnout. Palliative care specialists generally reported the lowest mean percentage of items rated as contributing 'quite a bit' or 'a lot' to overall job stress. The estimated prevalence of psychiatric disorder was 28 percent, similar to that of British junior house officers. The percentage of clinicians reporting high levels of exhaustion on the Maslach Burnout Inventory was similar to that of the normative sample (31 percent vs. 33 percent).[21] One-third of cancer clinicians and the normative sample reported low personal accomplishment. Significantly fewer of the UK cancer clinicians reported high levels of depersonalization compared to the US sample (23 percent vs. 33 percent, $P < 0.0001$). British palliative care nurses[22] also experienced lower burnout than expected.

Compared with oncology staff in Canada[23] and the USA,[24] the stress of the UK palliative care staff stands in marked contrast. European samples tend to have lower levels of exhaustion and cynicism compared with similar North American samples,[14] perhaps because of cultural values or it may be that American jobs are more stressful. A more recent study of senior house officers in UK hospices[25] found median stress score as measured on a visual analog scale was 55 mm (range 0–98 mm). Five respondents (22 percent) scored for identifiable psychological distress

on the General Health Questionnaire (GHQ).[26] More senior British physicians also report stress,[27] which appeared to be equal to or greater than that of the oncologists and palliative care specialists. Up to a third of consultants and nearly half of general practitioners (GPs) showed symptoms of stress that was serious enough to affect their health and impair their ability to provide high-quality care to patients. Much of this stress was due to excessive workload and lack of control over their workload and work environment. Other factors include inadequate resources for the job and sharing the emotional distress and suffering of patients.

A large study of 11 000 employees from 19 National Health Service (NHS) trusts found that 26.8 percent of health service workers reported significant levels of minor psychiatric disorders. This compared with 17.8 percent of the general population.[28] In a Canadian study of staff employed by Cancer Care Ontario,[23] physician exhaustion was much higher (53.3 percent) than reported in the UK study; 48.8 percent of physicians reported low feelings of personal accomplishment. The feelings of depersonalization in the Canadian group were similar to the UK sample (22.1 percent) of physicians. These figures are comparable to a study in which 46 percent of physicians surveyed by the Canadian Medical Association said they were burned out and emotionally exhausted. They attributed their burnout to the bureaucratic health system and fewer physicians to handle patients with complex problems.[29]

VARIABLES ASSOCIATED WITH STRESS AND BURNOUT

Demographic variables

Younger caregivers report more stressors, more manifestations of stress, and fewer coping strategies.[5] Burnout is associated with being under the age of 55 years;[20] being of age 55 years or less is an independent risk factor for burnout.[30] Increased job satisfaction is associated with older age.[31,32]

Female physicians experience more role strain than males[33] and are more likely to report suicidal ideation.[34] However, female physicians report greater job satisfaction and greater wellbeing than matched controls.[35] The latter finding was replicated in the Physician Work Life Study (N = 5704).[36] Women were more likely to report satisfaction with their specialty and with patient and colleague relationships, but less likely to be satisfied with autonomy, relationships with community, pay, and resources. There is some evidence that female physicians may be more at risk of mental health problems.[37] In the Physician Work Life Study,[36] women were 1.6 times more likely to report burnout than men. The odds increased by 12–15 percent for each additional 5 hours worked per week over 40 hours. Lack of workplace control predicted burnout in women but not in men. Women with young children who received support for balancing their lives from their partner, significant other, and colleagues were 40 percent less likely to report burnout.

In a large study of almost 2000 British family practitioners,[35] male physicians had higher anxiety scores than the norms and had less job satisfaction and drank more alcohol than their female counterparts. Dealing with death and dying was not a major source of stress; however it was associated with excess alcohol use, especially for female physicians.[38] Being single was an independent risk factor for burnout in the study of consultants in the UK.[30]

Job–home interaction

A model of burnout was tested in a study comparing burnout in two large samples of physicians in the USA (N = 1824) and the Netherlands (N = 1435).[39] Half the burnout was explained for both samples. Older physicians in the USA felt they had more control than did younger physicians. The study found an adverse impact of academic practice on work control and work–home interference in the USA. American male physicians described significantly more work control than female physicians, a sex difference not seen in the Netherlands. For both countries, work control was correlated with job stress and satisfaction, whereas work–home interference was associated with work hours, children, stress, (dis)satisfaction, and burnout. The UK study[20] also found job characteristics associated with burnout included 'being overloaded and its effect on home life'.

Occupational variables

WORKLOAD

When palliative care specialists were compared with clinical and radiation oncologists, problems with 'feeling overloaded and its effects on home life' were found to be significantly greater for the medical and clinical oncologists than for the palliative care specialists. Depersonalization and high GHQ scores were also associated with being overloaded.[20] Senior house officers in UK hospices[25] described their posts as stressful. A palliative care physician acknowledged that workload may be self-induced. He said, 'Lots of us feeling overloaded and overworked create it ourselves. We start dancing to a tune that you're called to play by yourself.'[5]

Hospice staff initially prided themselves on having the time to spend with patients that was conducive to the best patient care. Current issues with managed care, the nursing shortage, and fiscal restraint has changed this in many settings.[40] Direct patient care activities have an impact on stress through a heavy workload of complex care, a shortage of staff, and a lack of competence.[41] Nurses working with critically ill and dying children in Hong Kong and Greece felt unable to provide quality care because of the shortage in nursing personnel. This added to their stress.[42]

However, in a study of hospice nurses in the UK, Payne[22] found that despite workload being a frequently reported stressor it was not related to burnout.

CONTROL

Research suggests that restructuring high-demand, low-control jobs may enhance productivity and reduce disability costs.[43] Physicians' studies report low levels of satisfaction from not having adequate resources to perform their role.[20] In a study comparing general internists with internal medicine subspecialists and family practitioners, higher satisfaction for general internists was associated with less time pressure during office visits, fewer work hours, and fewer patients with complex psychosocial problems.[32] Seale and Cartwright[44] found 43 percent of GP respondents needed more time to give to dying patients, around one third had trouble coping with their own emotional responses to dying patients and these GPs seemed most likely to have difficulty communicating with patients who were dying and their relatives.

Recent practices in hospice led by fiscal constraints have raised increasing concern. Nurses are sometimes expected to perform procedures in the community without adequate supervision and training. When people are expected to assume responsibility with inadequate training, they have difficulty functioning.[45,40]

Nurses report being in situations both in the hospital and in the community where they feel responsible for alleviating the pain of a palliative care patient, yet do not have a physician willing to order the medication they feel will be sufficient to control pain. In addition, with earlier discharge of sicker patients, nurses with limited experience may be expected to care for seriously ill palliative care patients in their home, without access to physicians skilled in effective palliative care and symptom management.[45] Dr Neil MacDonald[46] testified before a Senate subcommittee on end-of-life care in Canada that in a study of Quebec oncologists and palliative care physicians, their opinion was that the big problem in managing cancer pain was the reluctance on the part of physicians to use opioids and the misunderstanding of patients about the use of pain medications. A nurse said that when she reported that a dying patient was in severe pain and she felt that he needed to have his medication increased, the physician asked who he was treating – the patient or the nurse?[47]

Problems of control may also involve issues of personal safety. Nurses working in a hospice in South Africa were uncomfortable going into some settings, particularly at night. As a group they explored with administration the option of refusing to go into some areas. The hospice provided them with cell phones. Brainstorming together, the nurses suggested working with the police to alert the police when the nurses were going into a potentially dangerous situation. The nurses asked the police to accompany them if they were really uncomfortable visiting certain areas but felt they should visit for the sake of the patient.[40]

REWARD

Issues related to funding have been a problem for many programs.[38] Participants in an Australian study[48] reported that economic pressures resulted in less staff support, competition between services for funding, inadequate funding to provide services in areas of need, lack of support for psychosocial needs including bereavement care, and experienced staff leaving palliative care. Nurses in a Canadian study[49] reported difficulty with resource allocation issues, but the majority of their concerns were related to their inability to provide quality care because of financial constraints and staffing cutbacks.[47]

COMMUNITY

Team communication problems have been a significant part of hospice palliative care since the early days of the specialty[16] and continue to the present time.[25,41] In the European Union, the recognition that there were communication problems between palliative care mobile teams (PCMTs) and hospital staff, led to a program of intervention, discussed below.[50]

Team issues have been documented in numerous studies and across many cultures.[5,16,41,42] In a group of 33 nurses from three midwestern cities[51] predictors of free-floating anxiety in hospice nurses included the degree of staff support and staff participation in decision making, as well as the final relationship between the patient and the nurse. Since the early days of hospices, caregivers have reported problems with timely referrals[5] and these issues continue with the development of the specialty of palliative care. Field[52] surveyed GPs in the UK working with dying patients and found that while relationships between the GPs and the district nurses with whom they worked were good, the relationships with hospitals were generally satisfactory, but rarely more than that, and there were negative comments about the provision of information from hospitals to both patients and GPs. An issue of contemporary relevance was the tension over the role of hospice and specialist terminal care services. General practitioners appreciate calling on specialist care but do not want to surrender care to the 'experts' as the GPs feel they have the best social knowledge of the patient and family. They resented hospices that were not willing to involve the GP and team as partners but wanted to deliver care on their terms. The GPs also expressed concern that the involvement of specialist providers of palliative care can have detrimental consequences for the generalist expertise of GPs (and community nurses) by deskilling them. Conflict also exists between the district nurses and the Macmillan nurses.[53]

A more recent study[54] in Wales showed significant enthusiasm among consultant physicians, 94 percent of whom would consider referring patients with nonmalignant disease to a specialist palliative care service. The physicians thought that a system of shared care and responsibility would be a means of addressing concerns regarding the lack of disease-specific expertise within the palliative care team. In Spain problems with the system also exist.[55] Half of physicians and

60 percent of nurses surveyed reported that caring for terminally ill patients at home made them feel frustrated. The 'system' was the main cause of frustration; frequently mentioned issues were bureaucracy (particularly with regard to access to narcotic analgesics) and the isolation of primary healthcare professionals, especially in rural areas. Women, younger caregivers, and those who had attended fewer patients in the past year were more likely to report feelings of frustration.

In the USA, the problem continues with timely referral.[56] Given the documented deficiencies in end-of life care,[57] it is to be hoped that the philosophy of palliative care could be incorporated into end-of-life care for increasing numbers of people. However, Byock[58] writes of the tensions between the 'loyalists' who have generally been associated with the hospice movement and the 'progressives' who 'tend to be caring, committed clinicians and administrators, often based in hospitals, nursing homes, or home health, who have awakened to the need to improve care for the dying in their own systems and are earnestly trying to do just that'.[53 (pp. 155–6)] Payne[22] found that dealing with death and dying, inadequate preparation, and workload were slightly more of a problem than were conflicts with doctors, conflicts with other nurses, lack of support, and uncertainty concerning treatment. However, conflict with staff contributed to both the emotional exhaustion and depersonalization subscales of the Maslach Burnout Inventory. Palliative care workers in rural Australia spoke of the difficulty involved in being expected to work beyond normal working hours and of the lack of anonymity in a small rural community.[47,59]

FAIRNESS

The issue of rivalries between hospice and other settings of care and between hospice programs has long been an issue.[5,40] Rivalries are encountered as programs try to determine with which agencies, if any, they will have preferred partner arrangements. Other settings have developed palliative care programs in an apparent move to avoid referral to hospices, and to gain access to funding that might be made available for dying persons.[40] In addition there are financial barriers that include reimbursement systems that provide only for the options of cure or certain death.[60,61]

> Patients without a care provider; unwilling to forego beneficial palliative chemotherapy, radiation, or surgery; or with a prognosis that was not absolutely certain to be six months or less, were caught in the middle. This part of the path felt treacherous; we had no trail markers, no compass, and darkness was about to fall.[61 (p. 27)]

VALUES

In *Crossing Over: Narratives of Palliative Care*, describing the experience of palliative care in two settings in the USA and Canada, Barnard *et al.*[62] state:

> palliative care is whole-person care not only in the sense that the whole person of the patient (body, mind, spirit) is

the object of care, but also in that the whole person of the caregiver is involved. Palliative care is, par excellence, care that is given through the medium of a human relationship.[62 (p. 5)]

A study of nurses in a European academic palliative care setting (N = 14)[63] was undertaken to gain insight into the fact that many nurses were leaving feeling frustrated by the far-reaching medical orientation on the ward and feeling unable to provide the care they wanted to give. This study challenges whether or not the assumptions of Barnard are completely generalizable at this point in time. The majority of nurses in this study had a model described as *striving to adopt a well-organized and purposeful approach* (N = 12) compared with the small group of nurses who were described as *striving to increase the wellbeing of patients* (N = 2). The pattern of the first group involved: adopting an academic attitude; developing a professional attitude; striving to remain objective; being task oriented; avoiding emotional stress; and embracing a practitioner-focused perspective. In contrast, the second group was described as: adopting a humble attitude; giving attention to patients and their experiences; being available; valuing a caring attitude; remaining attentive and thoughtful and trying to accept and cope with emotional strain. The authors quote James and Field[64] who said that by marginalizing the originating ethics of palliative care, the heart and soul of care are endangered. 'Expert' values based on medical technologies and psychosocial skills replace the compassionate help by which death is no longer a truth to confront but a process that has to be managed as efficiently as possible. The nurses were encouraged to acquire knowledge and skills, while developing moral qualities necessary to care for those who are dying were not addressed. They responded less to problems because their moral values were endangered, but mainly because they conflicted with their professional norms and established rules. In contrast Webster and Kristjanson's[48] Australian study of caregivers in palliative care found the work allowed caregivers to bring personal values to the workplace and encouraged personal growth.

ISSUES OF DEATH AND DYING

While the literature has been somewhat divided as to whether or not the care of the dying is a major stressor in hospice palliative care,[5,16] recent research in the burnout area has focused explicitly on emotion–work variables (e.g. requirement to display or suppress emotions on the job, requirements to be emotionally empathic) and has found these emotional factors do account for additional variance in burnout scores over and above job stressors.[14] Factors associated with burnout in Ramirez *et al.*'s study[20] included 'dealing with patients' suffering'. Depersonalization was associated 'dealing with patients' suffering' as well as low levels of satisfaction from 'dealing well with patients and relatives'. Low personal accomplishment was associated with stress from 'being involved with treatment toxicity and errors' and low levels of satisfaction from 'dealing well with

patients and relatives' and from 'having professional status and esteem'.[20 (p. 1268)] The most problematic stressor reported by UK hospice nurses was 'death and dying',[22] although in a North American study these were of much less concern.[51]

COPING

When close to 600 caregivers of the critically ill, dying, and bereaved were interviewed and asked what enabled them to continue working in the field, the top five coping mechanisms identified were: a sense of competence, control or pleasure in one's work (13 percent); team philosophy, building and support (11 percent); control over aspects of practice (10 percent); lifestyle management (9 percent); and a personal philosophy of illness, death, and one's role in life (9 percent).[5] Other studies have looked at sources of satisfaction in the work of palliative care staff. These include: dealing well with patients and relatives,[20] having professional status and esteem, deriving intellectual satisfaction, having adequate resources to perform one's role,[20] helping patients and families find meaning in suffering,[62,65] and having good relationships with colleagues.[66*] Palliative care has been described as a way of living. Vitality – the capacity to live and develop which is associated with energy, life, animation, and importance – is the core meaning of palliative care. The way of living involves unity with self, being touched to the heart, and personal meaning.[48]

Job engagement is conceptualized as being the opposite of burnout. It involves energy, involvement, and efficacy. Engagement involves the individual's relationship with work. It involves a sustainable workload, feelings of choice and control, appropriate recognition and reward, a supportive work community, fairness and justice, and meaningful and valued work. Engagement is also characterized by high levels of activation and pleasure.[14] Engagement is defined as a persistent, positive-affective-motivational state of fulfillment in employees that is characterized by vigor, dedication, and absorption.[14] Clearly many caregivers are engaged in their work in palliative care.

It is also important, however, to have time for one's self and family. In the study comparing physicians in the Netherlands and the USA[39] there were remarkable benefits of home support on stress reduction in the latter country.

STUDIES OF INTERVENTION

Despite a variety of articles describing intervention with palliative care staff, there have been few studies documenting the efficacy of intervention in this or other groups. A recent meta-analysis of 48 occupational stress-reducing interventions (N = 3736 participants)[67***] categorized the studies as: cognitive–behavioral interventions, relaxation techniques, multimodal programs (emphasizing both active and passive coping skills), and organization-focused

interventions. A small but significant overall effect was found. Cognitive–behavioral and multimodal interventions had a moderate effect, a small effect was found for relaxation and the effect size for organization-focused intervention was nonsignificant. Cognitive–behavioral interventions appeared to be effective in improving perceived quality of work life, enhancing psychological resources and responses, and reducing complaints. Multimodal programs showed similar effects; however, they appeared to be ineffective in increasing psychological resources and responses. The authors note that there is a marginally significant effect of job status on treatment outcome – those who appeared to have more job control had a better response to the interventions. The authors urge caution here because job status was inferred. They suggest the relatively large effect of cognitive–behavioral interventions in those with higher job control may be because employees profit most when they are provided with individual coping skills in a job that allows them to use these skills. The lack of effect of organization-focused interventions was attributed to a variety of factors.

van Staa et al.[41*] describe an intervention in a new palliative care unit in the Netherlands which may shed some light on the above findings. A carefully designed training program and staff support activities were meant to enhance personal growth, to give emotional support, and to deal with death and bereavement issues. The interventions did not involve mutual collaboration, practical problems, managerial and communication skills, and the skills needed to deliver complex palliative care. There was a cultural difference between the external consultants who embraced a relational therapeutic worldview and the hospice staff who came from a rational technical hospital environment. The former approach involves complete trust and openness in order to work. Not all staff members were convinced of the value of the nondirective approach. In addition a therapeutic group is fundamentally different from a group that has to work together after the session. The authors suggest that future leaders should focus on content as well as process issues. They also suggest that adequate resources, a supportive management structure, an extensive educational training program, and attention to individual needs should accompany support groups. These issues have been identified earlier[5,16] so it is worth noting that they still exist.[53]

Fallowfield et al.[68**] recently showed improvement in the communication skills of oncologists, which the authors hypothesized as leading to personally and professionally more rewarding consultations; the consultation can have a significant impact on clinical care and patients' and physicians' wellbeing.

STUDIES IN PROCESS

Medland et al.[66*] describe an intervention with 150 members of the multidisciplinary team in the oncology department

at Northwestern Memorial Hospital. The program aims to decrease absenteeism and enhance community to create a meaningful and rewarding work environment. The program targets both individual and organizational issues. Research has not yet been conducted but staff retention has improved. Plans are underway to measure the effectiveness of the program through 'increased overall patient satisfaction, psychosocial patient satisfaction, and spiritual patient satisfaction scores'. The level of staff psychosocial wellness, as evidenced by follow-up human services surveys, is planned for the future. Most importantly, staff will be monitored for changes in behavior reflecting use of positive coping strategies and constructive self-care behaviors.

EDUCATIONAL INTERVENTIONS

Another model for shifting established patterns is being conducted in the European Union with a goal of improving the interaction between PCMTs and the hospital staff with whom they interact.[50*] In this model, recognizing the full range of convictions held by individuals in a hospital setting, the concept of palliative care/terminal care has been bolstered by the concept of *continuous care*. Continuous care tends to *articulate* curative and palliative procedures focusing on the holistic care of patients and their family. 'Promoting the integration of continuous care in the hospital' intends to identify the challenges in integrating continuous care through an inventory and analysis of the activity of PCMTs in several countries of Europe. Competencies for PCMTs have been derived, and based on these, a pilot three phase educational programme with PCMTs undertaken and evaluated.[p.4]

Meier *et al.*[69] recently proposed an approach to physician awareness which involves identifying and working with emotions that may affect patient care. This involves looking at physician, situational, and patient risk factors that can lead to physician feelings and thus influence patient care. The steps include:

- Identify the factors that predispose to emotions that might affect patient care
- Monitor for signs (behavioral) and symptoms (feelings) of emotions
- Name and accept the emotion
- Identify possible sources of the emotion
- Respond constructively to the emotion
  - Step back from the situation to gain perspective
  - Identify behaviors resulting from the feeling
  - Consider implications and consequences of behaviors
  - Think through alternative outcomes for patients according to different behaviors
  - Consult a trusted professional colleague.

CONCLUSIONS

Palliative care is both stressful and rewarding. Although previous studies have shown that work in palliative care is not more stressful, and may be less stressful than other specialties, the increase in workload in recent years may well serve to increase the stress experienced by staff. Current work on coping holds exciting promise to change the culture of the field and to decrease team stress – which has been identified since the early days of the movement.

Key learning points

- Stress and burnout are generally less of a problem in palliative care than in other areas of healthcare, but nonetheless there are stressors and issues of concern.

- Burnout is associated with the degree of match or mismatch between the person and six domains of the job environment. The greater the gap or mismatch between the person and the environment, the greater the likelihood of burnout. The greater the match or fit the greater the likelihood of engagement with work.

- Workload, control, reward, community, fairness, and values and emotion-work variables are the primary domains of work associated with burnout. Individuals vary with respect to which are most important,

- Burnout levels are often higher in North America than in other countries for a variety of cultural reasons, however, there is some indication that burnout levels are increasing in many other countries. Palliative care staff may be experiencing increasing burnout as a result of work variables.

- Job engagement is the opposite of burnout. There is much in the literature to show that palliative care staff are engaged in their work.

- The research on the effectiveness of intervention in palliative care is still limited. A recent meta-analysis of occupational stress-reducing interventions showed that cognitive–behavioral and multimodal interventions had a moderate effect, and the effect size for organization-focused interventions was nonsignificant. Communication skills programs and educational interventions hold some promise but much research is yet to be done.

Communication in palliative care

JOSEPHINE M CLAYTON, MARTIN H N TATTERSALL

INTRODUCTION

When physicians communicate effectively they are more likely to understand and address the issues that are important for the individual patient, and patients are more likely to understand their medical problems and treatment options.[1] Moreover effective communication can reduce patient anxiety and distress[2] and improve satisfaction with the consultation.[3] Good communication in a palliative care setting is paramount. While communication in palliative care shares many of the general features of physician–patient communication in other settings, the fear and uncertainty associated with a life-limiting illness adds a greater emotional element to the interaction and thus communication may assume an even greater significance. Indeed optimal communication has been identified by patients and their families as one of the more important aspects of medical care at the end of life.[4–7]

This chapter reviews research findings relevant to communication in palliative medicine. The main focus is on physician–patient and physician–carer communication, with particular emphasis on meeting the information needs of palliative care patients and their carers.

COMPONENTS OF GOOD PHYSICIAN–PATIENT COMMUNICATION

Several components of good quality communication between physicians and patients with advanced progressive illnesses have been discussed in the literature. A good physician–patient relationship is the cornerstone to effective communication in this setting.[8,9] Attributes of a good physician–patient relationship include mutual trust, care, respect, honesty, empathy, support, and partnership, as well as the patients' confidence in their physicians' professional competence.[10,11] In general it is recommended that a physician should create an atmosphere where the patient is treated as a 'whole person' and feels that the physician is interested in and sensitive to their problems and feelings.[1] Even brief expressions of empathy may reduce patient anxiety.[12**]

Facilitation of information exchange

Prior to imparting information, it is recommended that physicians actively listen to the patient and elicit their full list of concerns.[1,13,14] The extent to which patients' concerns have been disclosed and resolved has been found to be associated with the likelihood of subsequent depression and anxiety.[15] When physicians elicit 'patients' perceptions of the problems and reactions, and the impact on their daily lives, patients feel more satisfied and comply better with offered advice and medication'.[16] Physicians cannot assume that patients will volunteer all of their concerns. Studies in palliative care and oncology settings show that a substantial number of patients' concerns remain undisclosed in practice.[17,18] For example, Heaven and Maguire[17] found that hospice patients had on average seven concerns, but only three of these were disclosed to hospice nurses. The patients in this study 'showed a strong bias towards disclosing physical concerns' and 'concerns about the future, appearance and loss of independence were withheld more than 80 percent of the time'. Patients may be reluctant to disclose their psychosocial and other more sensitive concerns and believe these are an

inevitable part of their illness, for which nothing can be done.[14] Furthermore, patients may perceive their concerns to be embarrassing or abnormal and/or be concerned about burdening their health professionals, whom they see as busy people. Therefore physicians and nurses need to encourage patients to disclose their psychosocial and other sensitive concerns. They also need to acknowledge and respond empathically when such concerns are raised.[19] However, health professionals may feel ill-equipped to elicit and deal with patients' psychosocial problems.[20]

INFORMATION NEEDS OF PALLIATIVE CARE PATIENTS

Patients use information for various purposes:

- to understand their illness and treatment options[21,22]
- gain realistic expectations[23]
- make plans and priorities for the future[22]
- care for themselves[21]
- participate in treatment decisions[22]
- provide a sense of autonomy and control[21]
- as a way of coping with a serious illness.[24]

In developed countries numerous studies have documented that the majority of English-speaking patients with serious illnesses prefer to be fully informed about a variety of topics including diagnosis, prognosis, and treatment options.[25–27] However, not all patients want extensive information about their illness or prognosis.[28,29] Furthermore, patients' information needs may be strongly influenced by their countries' culture and also by the different cultures within countries. Patients from some cultures may prefer nondisclosure, especially when life expectancy is short.[30,31] However, the evidence for this is conflicting with other studies suggesting that the majority of people from certain non-Western countries still want to be fully informed about their diagnosis and prognosis.[32–34] Other factors may influence patients' preferences for information. Higher levels of information tend to be desired by patients who are younger,[25,35,36] female,[25] come from a higher socioeconomic background,[37,38] and are better educated.[35] Patients may also desire less detailed information over time as their illness progresses.[26,39]

Little is known about the specific information needs of patients referred to a specialist palliative care service or of terminally ill patients in general. Kutner et al.[27] examined the information needs and concerns of patients who met the criteria for outpatient hospice enrollment in the USA. Qualitative interviews with 22 participants identified seven key issues including: 'change in functional status or activity level; role change; symptoms, especially pain; stress of the illness on family members; loss of control; financial burden; and conflict between wanting to know what is going on and fearing bad news.'

These data were used to develop a questionnaire which was then administered to a second population of 56 patients. More than 80 percent of participants in the survey wanted

Table 106.1 *Kutner* et al.'s [27] *findings regarding preferences of terminally ill patients for information (N = 56)*

CPR, cardiopulmonary resuscitation.

their physicians to be honest (100 percent) but they also wanted their physicians to be optimistic (91 percent). Participants' preferences for some specific types of information are shown in Table 106.1. The expressed information needs and concerns were not associated with any identifiable patient characteristics. The authors conclude that physicians and other health professionals

> should be aware of the diversity of needs and concerns of the terminally ill and should routinely identify, negotiate and address specific individual needs and expectations.

Further research is needed to explore the specific information needs of palliative care patients from different cultural backgrounds.

Incurable cancer and palliative care patients' preferences for information about prognosis and dying

Physicians are challenged to deliver information relevant to prognosis and dying. Yet having a physician who is willing to talk about dying and who is sensitive to when to discuss this issue has been identified by patients and their families as one of the more important needs at the end of life.[5,6] There may be reticence to discuss dying for fear that this

could be contrary to the patients' wishes or best interests. Finding a balance between honesty and hope can be difficult to achieve. Nevertheless open conversation about death and dying can bring considerable relief to patients and their families. Furthermore, feedback from Western patients suggests that open and supportive communication, rather than nondisclosure, may be most hope giving to patients.[40]

Surveys of Western patients with advanced cancer[41] and other far progressive life-limiting illnesses[9] suggest that most patients want prognostic and end-of-life information but prefer to negotiate the level of detail and timing of this information.[41] Qualitative studies of dying patients and their families, from Western countries, have identified various important elements in health professionals' communication about prognosis and end-of-life issues, including: the need for honesty,[6,39] clear straightforward language,[6,39] showing empathy and compassion,[6,39] willingness to discuss dying but being sensitive to when the patient is ready to hear this information,[6,39] pacing information so it can be assimilated,[39] encouraging questions,[6] and assuring patients that they will not be abandoned as their illness progresses.[39]

Little is known about patients from non-Western countries preferences for style of prognostic and end-of-life communication. Further research is needed in this area.

Specific information needs of carers of palliative care patients

The support of families, both before and after the death of a patient, is an integral component of palliative care.[42] Families need information to enable them to care for their dying relative[39,43–45] and prepare for their own future after a patient's death.[5] Family members need information about a patient's illness to be mentally prepared, organize their daily life, and to be a source of information to others.[46]

Research findings suggest that caregivers of palliative care patients may have distinct information needs from the patient,[39,44,47] particularly regarding prognosis and end-of-life issues. The caregiver may need more detailed information than the patient about the dying process in order to provide care.[47] The importance of open discussion and consistent information being given to patients and caregivers has been highlighted, particularly in studies conducted in Western countries.[39,47] However, it may not be possible to meet the information needs of both the patient and their family without having individual discussions. This allows the health professional to explore individual concerns and information needs without the barrier of patient/carer protectiveness.

Patients' preferences for family members to be informed and/or influence the information they receive

The issue of confidentiality and sensitively obtaining the patient's permission prior to talking with the caregiver has

been emphasized in literature from Western countries.[39,47] It cannot be assumed that patients are close to their families or want them to be fully informed.[39,48] On the other hand patients from some cultural backgrounds may prefer disclosure negotiated through the family, when the prognosis is poor.[31,32]

Importance of establishing individual patients' and carers' information needs

Together the above findings stress the importance of establishing individual patients' information needs and patients' preferences regarding how much and how information should be shared within the family. Moreover the information needs of a patient's carer(s) may differ from the patient. Furthermore needs may change over time. An essential component of good communication is to ensure that patients and their families receive information at the level of detail that they desire, and to provide opportunities for them to discuss their fears and concerns about the future.

CURRENT PRACTICE IN INFORMATION PROVISION IN PALLIATIVE CARE AND ONCOLOGY

Physicians' information disclosure to patients

Patients with far advanced progressive illnesses may not be adequately informed of their situation or treatment options by their physicians in general medical and oncology settings in Western countries.[49–52] For example, an Australian study[49] in patients with advanced cancer found that while most of the 118 participating patients were informed about the aim of anticancer treatment (85 percent), 25 percent of patients were not told that their cancer was incurable. Only 44 percent of patients were told about alternatives to anticancer treatment such as supportive care and 36 percent of patients were informed about how such treatments would affect their quality of life. Greater levels of information disclosure were not associated with increased anxiety. Actual communication about other topics such as health-related quality of life issues, pain, and other symptoms may be less than ideal[53–55] and physicians may not recognize or respond to patients' subtle hints or cues for information.[56,57] Moreover, in general medical settings end-of-life conversations often do not occur or are conducted poorly.[51**,58*]

Little is known about what is actually discussed during palliative medicine physician consultations. We have audiotaped consultations between 18 different palliative medicine physicians and 270 different patients/carers and we will be coding these audiotapes specifically with regard to prognostic and end-of-life communication. The analysis of these data is in progress.

Although studies of actual communication are limited, some survey data are available. A study by Lamont and Christakis[59] reveals that physicians may not provide their best estimate of survival even when asked by terminally ill patients. One reason for this may be that physicians' survival estimates in terminally ill patients are often wrong and are usually overoptimistic.[60***] However, physicians may also lack confidence in communicating survival predictions or may fear that such information will cause the patient to lose hope.

There is evidence of cultural differences among health professionals in their attitudes towards truth disclosure to patients with life-limiting illnesses, with a tendency towards nondisclosure in certain non-Western cultures.[61–63] For example, Bruera et al.[64] surveyed 182 palliative care physicians from different regions and found that only 26 percent of European physicians and 18 percent of South American physicians, compared with 93 percent of Canadian physicians, thought that the majority of their patients would want to know about their terminal prognosis, ($P < 0.001$).

Patients' misunderstanding of information and the consequences of this

Several studies have shown that patients with cancer and other life-limiting conditions frequently have misunderstandings about their illness, prognosis, and goals of treatment.[51**,52,65–67] For example, Gattellari et al.[66] found that 17 percent of 244 cancer patients with metastatic disease believed their cancer was localized and incorrectly believed their treatment was given with curative intent.

When patients are not adequately informed of their prognosis they are more likely to choose aggressive treatments, which will probably not extend their life and may compromise its quality.[52] The et al.[68] showed that patients may subsequently regret such decisions. Chochinov et al.[69] found that depression was almost three times greater in 200 patients with advanced cancer who did not acknowledge their prognosis, compared with those who had partial or complete understanding ($P = 0.029$).

Summary of limitations in current practice with regards to information provision to palliative care and oncology patients and their carers

Overall these findings suggest that there are significant gaps in providing information and addressing the concerns of patients with life-limiting illnesses and their families. Interventions are needed to help patients express their concerns and have their information needs met. While less is known about the current practice in information provision specifically in palliative care consultations, such interventions may also be useful in a palliative care setting.

INTERVENTIONS TO HELP MEET PATIENTS' INFORMATION NEEDS AND PROMOTE INVOLVEMENT IN THE CONSULTATION

Interventions targeted at both health professionals and patients have been developed with the aim of (i) helping patients meet their information needs and (ii) encouraging patient participation during medical consultations. Interventions directed at health professionals primarily involve communication skills training. In addition a number of practical aids have been suggested to improve communication and/or help patients to assimilate information and achieve their information preferences.

Communication skills training for health professionals

Health professional communication skills do not reliably improve with experience alone. A randomized controlled trial of a 3-day residential communication skills course for oncologists found that course participants used more focused and open questions, greater expressions of empathy, more appropriate responses to patients cues and less leading questions at immediate[70**] and 12 months[71**] follow-up. Provision of written feedback alone to participants had little effect on objective communication outcomes.[70**]

Communication skills training modules specific to a palliative care setting, with greater emphasis on discussing prognosis and end-of-life issues, are needed.

Provision of audiotapes or written summaries of consultations

One simple intervention that has been investigated is the provision of audiotape recordings or written summaries of the consultation. A systematic review in the oncology setting was conducted by Scott et al.[72***] Trials consistently found that most people who received the audiotapes or written summaries of their consultations valued them. Improved recall of the consultation in those patients provided with an audiotape or letter was found in five out of nine studies. Patients who received an audiotape or letter were more satisfied with the information received in four out of seven studies. The only study[73**] to compare the impact of audiotapes versus summary letters found that patients preferred audiotapes to letters.

McHugh et al.[74**] found that patients who were informed of a poor prognosis at their initial oncology consultation and received an audiotape of the consultation had less improvement in psychological distress at 6 months follow-up than those who did not receive the tape. Therefore, Scott et al.[72***] advised caution in the use of interventions 'to reinforce bad news when alternative interventions such

as counselling may be more appropriate'. This may be a concern for palliative care settings where nearly all patients have a poor prognosis. However, this result was found in only one study at the point of initial diagnosis.

Only one study[75**] was conducted in the setting of a 'pain and symptom clinic' for patients with advanced cancer. In this small study (60 patients) from the USA, patients who received the tape were significantly more satisfied with the consultation and recalled significantly more information given during the consultation. Patients who received the audiotape rated it highly and it was also valued by family and friends. The authors point out that most patients in this study[75**] were receiving advice about control of physical symptoms rather than bad news. Further research is needed to assess the value of audiotape provision to palliative care patients and their families and the potential for adverse psychological effects if the audiotape includes discussion of end-of-life issues or other sensitive information.

Provision of information in written, audiovisual, or electronic format

Information leaflets about individual palliative care services and palliative care topics, such as bereavement, are commonly provided.[76] Patient education materials designed to teach patients about management of pain and other symptoms have also been developed. There are few research data regarding the effectiveness of providing information in written formats to patients in a palliative care setting. However, a survey in the UK found that '64 percent of leaflets could be understood by only an estimated 40 percent of the population'.[77]

Question prompt lists

Studies of cancer and palliative care patients' views have emphasized the importance for patients of having the opportunity to ask questions of their clinicians.[6,78] Other studies have found improved health outcomes when patients are encouraged to ask questions during general medical consultations.[79***,80**] Some health professionals encourage patients to write down their questions and bring them to medical appointments, but patients may not know what questions to ask or how to articulate their concerns.[81]

Butow et al.[82**] explored the use of a question prompt list given to cancer patients before their initial consultation with oncologists. A question prompt list is a structured list containing examples of questions for the patient to ask their physician if they wish. It is designed to encourage patient participation during a medical consultation and to assist patients in acquiring information that is suited to their needs and at their own pace. This simple and inexpensive intervention has been found to promote question asking about prognosis in three separate studies[82**,83**,84**] in the oncology setting. In the most recent of these studies,[84**]

provided the oncologist specifically addressed questions in the question prompt list during the consultation, those patients who received the prompt list were significantly less anxious immediately after the consultation and had better recall and significantly shorter consultations.

We have developed and piloted a question prompt list for patients being referred to a palliative care team.[85*] In order to identify suitable questions for inclusion in the question prompt list we conducted a series of focus groups and individual interviews with palliative care patients, their carers, and palliative care health professionals. A wide range of issues emerged for inclusion in the question prompt list including questions about: the palliative care service, physical symptoms and treatment, lifestyle and quality of life, the illness and what to expect in the future, support, if you are concerned about your professional care, for carers, and end-of-life issues. All participants felt the question prompt list, in booklet form, could be a useful tool. Of 23 patients in the pilot study, 22 agreed the question prompt list was helpful, contained useful questions, was easy to understand and would be useful in the future. State anxiety decreased after receiving the booklet and seeing the physician in 16 out of 19 patients. Participants in the pilot study endorsed the inclusion of end-of-life issues in the question prompt list, despite some reservations expressed about this by health professionals in the individual interviews. We have recently completed recruitment for a randomized controlled trial of the question prompt list in 174 patients seeing one of 15 palliative care clinicians in 10 different palliative care centers. Analysis of the results of this study is in progress. The question prompt list for palliative care patients and their families, including 112 sample questions in a booklet form, can be downloaded from www.psych.usyd.edu.au/mpru/communication_tools.html

SUMMARY

Communication is an essential component of the care of palliative care patients and their families. Most patients and their families have high needs for information, but not all patients want detailed information about their condition at all stages of their illness. There is evidence of significant gaps in information provision and addressing concerns of patients. Less is known about the specific information needs of palliative care patients and their carers and whether or not these needs are met. Discussing prognosis and end-of-life issues is particularly important but challenging in palliative care. Little research evidence is available about what information palliative care patients and their carers want and how they feel this information should be portrayed. Most relevant research regarding physician–patient communication in this setting has been conducted in Western countries. Further research is needed to evaluate the needs of patients and their families from different cultural backgrounds.

Interventions may be needed to facilitate discussion of prognosis and end-of-life issues plus help palliative care patients and their carers meet their general needs for information. Communication skills training for physicians has been found to improve communication. Some tools such as question prompt lists and audiotaping the consultation are helpful in promoting question asking, and/or patient satisfaction and recall of information. Question prompt lists seem to particularly promote question asking about prognosis and may be useful in facilitating discussion about other sensitive topics such as end-of-life issues. Further research is needed in order to optimize communication with palliative care patients and their carers.

Key learning points

- Communication has been identified by patients and their families as one of the most important aspects of medical care at the end of life.

- Most patients and their families, at least in Western countries, have high needs for information, but not all patients want detailed information about their condition at all stages of their illness.

- There is evidence of significant gaps in information provision and addressing concerns of patients with far-advanced progressive illnesses in general medical and oncology settings. Less is known about the specific information needs of palliative care patients and their carers and whether or not these needs are met.

- Communication skills training for physicians has been found to improve communication.

- Other practical tools such as question prompt lists and audiotaping the consultation are helpful in promoting question asking, and/or patient satisfaction and recall of information. Question prompt lists seem to particularly promote question asking about prognosis and may be useful in facilitating discussion about other sensitive topics such as end-of-life issues.

Spiritual care

SUSAN STRANG, PETER STRANG

THE INTERSECTION BETWEEN RELIGION AND MEDICINE

People in all phases of their lives have to struggle with existential and spiritual issues, but these come to a head when a person is afflicted with a severe illness.[1–3] When a cure is no longer an alternative, the focus of care-related efforts must move from curative to palliative care. Within palliative care, emphasis is not only on physical, mental and social factors, but also on the importance of the existential/spiritual dimension,[4–6] since spirituality intersects with medicine at the juncture of suffering.[7] When facing death, existential anxiety is activated: 'Why me and why now?', 'What was the meaning of my life and is there any meaning or purpose left to live for?', 'What will happen to me and my family?', 'Is there an existence beyond death?', 'Has God abandoned me?'. For the physician and the staff, knowledge about their patients' beliefs is essential, as some patients may explicitly base decisions about life-sustaining interventions on their spiritual or religious beliefs.[8] Other patients may not bring up spiritual concerns but still are troubled by them, and in that way spiritual issues will affect the overall wellbeing.

The division into four dimensions – physical–mental–social and spiritual – is useful to understand all dimensions of palliative care. Still, it is a didactic oversimplification, as few, if any, experiences are unidimensional. For example, body pain is primarily a physical problem, but it has definite mental, social, and spiritual impact in the form of mood disturbances[9] and impaired social functioning,[10] and pain might also trigger existential suffering.[11] The 'empty nest syndrome' is definitely a social issue, an important event in

life when the last child leaves home. Still, it is also a psychological challenge and not at least an existential boundary situation: it is a turning point in life, reminding us of the shortness of life. In such ways the dimensions are intertwined. The reverse is also true: existential suffering, e.g. death anxiety or existential guilt, may manifest itself in physical pain without obvious underlying pathology,[11] anxiety, or social withdrawal (Case 107.1).[9]

Case 107.1

'A young man recently diagnosed with cancer of the testes (with suspected metastasis to the retro peritoneal glands). Severe back pain, requiring spinal administration of analgesics. Great anxiety over living and dying. Once the man spoke to understanding personnel about the excellent prognosis, and learned that he could have his sperm frozen and become a father despite the treatment, the pain disappeared and the spinal catheter could be removed.' Source: reference 11.

In this case, existential anxiety reinforced an existing physical pain, and once the patient was supported in his existential crisis he experienced a substantial pain reduction.

It is sometimes difficult to distinguish between the emotional and existential/spiritual dimensions and, in fact, sometimes they overlap. The external manifestation might be similar, but the underlying cause is different and, therefore,

the treatment and support should be tailored considering the nature of the problem. As an example, anxiety that manifests itself in the form of restlessness and sleep difficulties should be handled differently, depending on the cause, which could be physical (unrelieved pain or dyspnea), mental, social (e.g. economic problems, divorce) or spiritual (religious guilt). Still, the division into four dimensions is useful for the sake of clarity.

SPIRITUAL NEEDS

There are no exact definitions with regard to spiritual needs, as different people emphasize different facets or interpretations of this construct.[4,12–15] In healthcare contexts, spiritual care normally includes religion and general spirituality, but less often existential issues as defined within existentialism. These aspects, though, are central to life for all people, even atheists.[16] It is impossible to draw a dividing line between the concepts. Instead, key words defining the core of each concept are more useful (Box 107.1).

Box 107.1 Key words for spirituality, religion and existentialism

Spirituality
- Meaning
- Transcendence
- Higher power/source of energy
- Relationship
- Religious dimension

Religion
- God
- Worship
- Rituals
- Social manifestations

Existentialism
- Freedom
- Isolation
- Meaning/meaninglessness
- Death

Spirituality

Today, most authors in healthcare present a holistic view of the concept of 'spirituality' that is partly distinguished from and broader than religion.[4,17–20] McCurdy stresses that spirituality deals with 'our need and capacity for relationship to whatever or whoever gives meaning, purpose, and direction to our lives'.[21] Spirituality generally comprises the following

domains, although there is great overlapping: meaning, transcendence, energy, relationships, and religious dimensions.

Religion

Religion can be, but does not have to be, an important part of a person's spirituality. In religion there is always a deity, a God. Religion joins together individuals who share the same beliefs, traditions, rituals, and worshipful acts within some kind of social institution.[22,23] In scientific terms a *substantial* definition describes what religion 'is': the Holy texts, symbols, congregation etc. whereas *functional* definitions focus on what religion 'does': e.g. offers a frame of interpretation for death, the dualism between evil and good, suffering.[24]

Existentialism

Existentialism is a philosophical movement advocated by philosophers with different backgrounds, such as Kierkegaard, Heidegger, Jaspers, Frankl, and Sartre. A clinically useful way of summarizing the existential domains has been provided by Yalom and is described below.[16]

Freedom forces us to be responsible for our lives, but by forcing us to make choices it also creates existential anxiety. Unethical choices are linked to existential guilt. Such guilt might be activated at the end of life. The person feels uneasy and is in need of 'making good'. Therefore it has clinical consequences (Case 107.2).

Case 107.2

The elderly female patient suffered from several distressing symptoms, including pelvic pain, but she refused help. Efforts to persuade her failed when the staff tried to explain the problem in medical terms. When an empathetic staff member at last came to understand that the patient considered her illness to be a punishment for a previous decision, they were able to help her: She had had an abortion when she was young, and now she felt that justice was being made, she suffered from cancer 'there' (in her genitals), consequently, she had refused help. After counseling she realized that she had been punishing herself her entire adult life. When she was allowed to put it in her own words in an accepting environment, she realized that she had been punishing herself enough through the years. This was a relief for her and she accepted now medical help for her cancer symptoms.

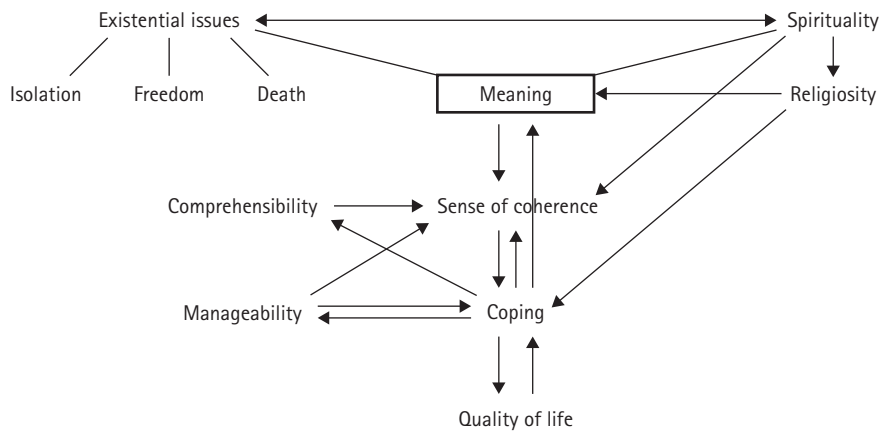
Meaninglessness versus meaning is another existentialistic dimension that is central both in existentialism and in general spirituality and religion.[25] Meaninglessness is the


Figure 107.1 *An attempt to relate different concepts where meaning issues are central.*

basic condition that forces us to search for meaning or to create meaning.[16] Some existential philosophers with a religious background such as Frankl would not agree, but emphasize that there is an inherent meaning to be found and that man can also create meaning.[26] Clinically, meaning issues have raised much attention during recent years, as meaning seems to be the strongest predictor of quality of life in palliative care settings.[27–29] Meaning is also strongly connected to concepts such as meaning-based coping[30] and sense of coherence (Fig. 107.1).[31]

Isolation refers to an unbridgeable gulf between oneself and any other being; each of us must enter existence alone and must depart from it alone. This kind of isolation may be revealed in critical transitions, e.g. when facing one's death.[32] The concept of existential isolation is therefore relevant to palliative care. It is important to realize that existential isolation cannot be resolved, but closeness and relationships make it possible to endure the burden (Case 107.3).

Case 107.3

A 50-year-old woman with breast cancer admitted to palliative care: 'I was calm, may be in shock when my doctor explained that my breast cancer had spread to my back and my lungs. However, when I left his office that day I realized that now I was facing a great loneliness, the greatest of them all. Yes, I had my family and my friends and of course they were there for me, but still I was very lonely. They would never understand what I really felt then.'

The reality of *death* creates death anxiety, which has its roots in the fear of definite separation and, in anxiety about annihilation. In the clinical setting the impending separation seems especially painful to encounter.[1] However, as claimed by existential philosophers, when death becomes a close reality, life may also become more real and intense. Heidegger describes this as a more 'authentic' mode of life.[33] People

value basic things in life such as family, relationships, and nature. The closeness of death may also make it easier to choose between important and unimportant things. However, in the terminal phase anger and demoralization may be more prominent features.[34]

RELIGIOUS PSYCHOLOGY: MODELS FOR UNDERSTANDING RELIGION

Psychology might seem superfluous for the religious believer but it can partially explain for more secularized persons which needs are satisfied by religious practice. The simplest answer would be: religious needs, an important fact, as man is religious or spiritually inclined by nature: every known culture has had a religion. An alternative way of describing it, as suggested by religion psychologists, would be: religious, cognitive, emotional, social, and political needs.[35]

Religion provides direction and meaning to a person's life and it provides him or her with tools to handle the eternal questions. In that sense, religion satisfies a *cognitive* or intellectual need. Moreover, it offers support, comfort, and security when facing suffering and death and in that way this Divine presence fulfills a deep *emotional* need. A living God who is merciful and allows close contact in prayers and rituals can be the most powerful help for the existential emptiness and meaninglessness that people may experience at times, especially in boundary situations. Furthermore, a congregation is a social institution with close interpersonal relations and within this community, a common faith creates a sense of togetherness with all believers around the world. Thus, religion provides a strong *social* structure in a fragile situation. In some societies, religion even works in concert with *political* needs and motives, e.g. in the liberation theology.

Although religion is much more than the sum of these separate facets, and a believer would probably not discuss them in these terms, this analysis may still explain why religion, in fact, fulfills many important needs. Still, the 'longing for essence in existence' is not possible to describe in analytical terms.

Religious coping

When discussing the psychology of religion, coping is an important issue. General research on coping with cancer started in the 1970s with important studies by Weisman.[36] In the 1980s Lazarus and Folkman emphasized the stress-appraisal-response model[37] and in the 1990s Folkman also emphasized that meaning-based coping was important as a complement to the above-mentioned model.[30] Inclusion of meaning in coping theories adds an existential facet to coping and brings this type of coping close to religious coping.

Specific religious coping has been studied, e.g. by Pargament who states that prayers and reading the Bible are important tools for such forms of coping.[38] Also ceremonies, symbols, rituals, meditation, religious literature, and religious mystic experiences are useful mediators of religious coping. For example, a believer may find consolation in comparing his or her life situation with the situation of biblical persons, and well-known rituals may create structure in a chaotic situation. It has also been suggested that religious belief systems are helpful to resolve grief.[39] Religious coping, at its best, may provide the suffering person with hope and a sense of control despite a chaotic situation. Other positive aspects include a sense of purpose, meaning, and acceptance. Although rituals and other forms of religious coping often have a positive effect for believers, negative outcomes are also possible, according to Pargament.

HOSPITAL CHAPLAINS

The role of the hospital chaplain has changed over time, and today hospital chaplaincy has contact with various patient groups in crisis, regardless of their faith or lack of faith.[40] The hospital chaplaincy has an important role helping people who are facing life-threatening illness. As Steinhauser showed in a comprehensive study of severely ill patients, doctors, relatives, hospital chaplains and other staff, the wishes of patients and doctors do not always coincide: 'Whereas physicians tend to focus on physical aspects, patients and families tend to view the end of life with broader psychosocial and spiritual meaning'.[41]

It is of great importance that both hospital chaplains and healthcare staff are well informed of each other's areas of competence, considering that traumatic crises and existential crises are intimately connected. Such knowledge is especially important when deciding how to offer help in acute existential crises and how to develop relevant spiritual support in healthcare. Existential support is always needed in existential crises, but sometimes medical help is also beneficial.

Although spiritual support is regarded as important,[42,43] it is not usually offered by healthcare staff due to their lack of knowledge and guidance about how to support patients

with these questions.[44,45] However, hospital and hospice chaplains possess such professional knowledge. Nevertheless, there may not be apparent routines for effective teamwork or referral, despite the fact that a majority of doctors and nurses feel that ideally a chaplain should address such issues.[44] Modern healthcare still feels lost when faced with the existential dimension because of its 'unscientific character', and chooses to focus on the medical/technical aspects[46] or clear-cut psychosocial issues. Nonetheless, people seek help and support, and questions still remain such as: 'What needs does a severely ill person have?', 'What kind of support is wanted in a partially secularized society?'. Consequently, what is the role of hospital chaplaincy?[47] It is important to bear in mind that the first questions a person who faces severe illness poses are of an existential nature: 'Why me, and why now?', 'Where is the justice?', 'Will I die?', and 'If I will not be cured, is there any meaning left?'.

What questions do patients pose to the hospital chaplains?

Recent studies show that patients do not contact the hospital chaplain primarily to discuss spiritual or religious questions. Instead the most frequently posed questions seem to be of a general existential character and are concerned with meaning-related issues, with illness, death and dying, and with their love for and care of their family.[40,48,49] These types of questions seem to be of great importance to all individuals, regardless of their religious inclination or faith.[16,50] Hospital chaplaincy is a unique resource; they are educated and have extensive training in listening, supporting and counseling others with these kind of issues.

Teamwork

Although chaplains and community-based clergy bear the primary responsibility for spiritual care, to a certain extent basic support can be provided by any member of the healthcare team.[51] The hospital chaplain's core profession is to offer deeper soul care (pastoral psychotherapy), to support the staff and to handle religious and symbolic issues.[52] However, even if staff have the privilege of using the unique competence of the hospital chaplaincy, this does not mean that the staff can deny their own situation-bound responsibility for existential or spiritual questions. Not all patients want to meet a chaplain, and hospital chaplains are not always available when acute existential crises emerge. Therefore, healthcare staff will encounter existential crises and need to handle them when they occur, since patients often have a great deal of confidence in them, and they are 'there' and available.

The central purpose of spiritual support for healthcare staff is to see and to acknowledge the patient[45,53] to listen actively to 'why-questions', questions about justice, anxiety, the vulnerability of life and, about death and dying, without

providing definite answers. In a simplified way, with reference to psychotherapeutic experiences, it could be said that the *process* of listening is more important than the actual *content*, as the patients need to find and formulate their own answers. This kind of spiritual support should, however, not be too deep or theological in nature. Instead, some of the talks might indicate the need for an additional contact with a hospital chaplain, a psychologist or with a social counselor.[52]

Many times, it is just enough to be a fellow human being, supporting the patient and his or her family through closeness, openness, friendship and engagement. This can be done by simple means, e.g. by offering a glass of water, letting the patient listen to his or her favorite music, and by just 'being there'. Existence is, to a considerable degree, about relations, to others and to the world.[54] By being there, performing everyday tasks, by validating the patient, they feel acknowledged for what they are. When a staff member does not share the same faith, there might be difficulties in offering explicit religious help. In such instances, the staff member should contact the hospital chaplaincy or ask another staff member for assistance. This is especially important in the multicultural societies of today.

RELIGIOUS STUDIES

What impact does religion have on health, survival, coping or wellbeing? How does one measure religion and is it possible to create a high scientific standard?[55] There are difficulties when measuring and operationalizing religion[56] and also a skepticism to mix-up religion with medical treatment.[57,58] Still, systematic reviews have shown that religion seems to have a positive influence on health and that it also provides tools for manageability and wellbeing during periods of illness.[59–63] Efforts have been made to summarize data. For instance, a meta-analysis has been performed on data from 42 independent studies examining the association of a measure of religious involvement and all-cause mortality. It concluded that religious involvement was significantly associated with lower mortality, indicating that people practicing or involved in religious involvement were more likely to be alive at a follow-up time than people lower in religious involvement.[64]

There is a disagreement among researchers about the definition of religion and how to measure it. Does religious membership always imply religious beliefs or religious participation? When measuring 'religiousness', do we measure the 'believers' or the 'belongers', those devoting much time to prayer or those who are merely the church participants? Several sophisticated religious scales have been devised, but still there are no commonly accepted measurement tools, probably due to the indistinct subject.[65]

The believer–belonger division of religiosity has also been conceptualized as intrinsic and extrinsic. Individuals with an intrinsic religiosity view every aspects of their lives, even illness, within the context of their religion and the religiosity is closely integrated in their daily lives. In contrast, for individuals with extreme extrinsic religiosity, religion is not an integrated part of their lives, but it may still offer security, sociability and status.[66] When facing an existential crisis the support from the congregation may still be of great help for extrinsics, whereas lack of an intrinsic belief might become a burden on a more religious level.

CULTURAL ASPECTS

In palliative care settings, spiritual care is sometimes synonymous with providing Christian soul care. In the multicultural society of today it is important to not forget other religions. Most religions offer hope in one way or another: hope for an eternal life in some form, hope for resurrection (Christianity), hope in living through the lives of one's children (Judaism), hope for rebirth and belief in karma (Eastern traditions).[67] To provide spiritual care on equal terms, healthcare needs to have good contacts with representatives of several religions, to provide holistic care for the patient. For example, in the Islamic tradition, there are five important cornerstones to the religion often unknown for Christians: the Islamic confession; the five daily prayers; the 'Ramadan' (fasting for a month each year); 'Zakat', i.e. a special form of taxes of 2.5% that one should give to poor people; and pilgrimage: when once in a lifetime a Muslim should make a pilgrimage to Mecca, if possible.[68] Certain rituals should be followed when a person is dying and there are also rituals and strict rules for taking care of the dead body. When facing death such issues may create substantial suffering if not addressed in a proper way. In a similar way there are rituals and rules for other major religions; therefore contact with representatives of respective religions is advisable.

Christianity, Judaism, and Islam have common roots and therefore may be easier for westerners to comprehend. Eastern cultures and religions are often less well-known in healthcare. As exemplified in a qualitative study of eight family caregivers, both family and caregivers may move between modern medicine, traditional/folk medicine, supernatural healing rites, religious performances, and home remedies in their search for a cure.[69]

TO PRACTICE SPIRITUAL CARE

The interest in spiritual issues has increased in recent decades.[42,63,70,71] However, the interest has seldom been translated into support and is still seldom practiced. The medical staff are often insecure in dealing with existential and spiritual care.[72,73] Once healthcare staff acknowledge the impact of spiritual care, and are willing to offer support,

when needed, how do they practice it? The guidelines described below are mainly empirically based and with few exceptions formally tested. Still, they can be used as a basis when evaluating spiritual needs and providing support in a clinical setting.

General spiritual care

Kissane advocates grief therapy in palliative care.[6] In short, the doctor or the therapist should allow the patient to talk about his or her life and all the painful losses. The therapist should not try to comfort or minimize the problems, but listen empathetically and focus on acceptance. Perhaps everything in life did not turn out right, but much in life was of great value. When a person reaches to acceptance, he feels a relief. Kissane also suggests that the therapist should focus on transcendence: when the physical situation cannot be changed any longer, one's attitude still can be modified. To transcend, i.e. to accept that one is a part of something bigger may feel comforting: to be a part of a Holy creation with a personal God (a religious form of transcendence); to be part of nature and everything living (a more secularized form of transcendence); to feel comfort in the fact that generations come and generations go and I am part of that cycle; to have a faith in a life after death and perhaps once again meet family and friends on the other side of death.

There are some other models in spiritual care that have recently developed. Rousseau stresses that physicians, together with other members of the team, are obliged to provide support in addressing spiritual concerns by listening and discussing spiritual issues, demonstrating empathy and engaging in a patient's search for meaning, thus breaking through the rigid boundaries of medical care.[74] According to Rousseau, the specific interventions that alleviate spiritual distress include: controlling physical symptoms; providing a supportive presence; encouraging life review to assist in recognizing purpose, value, and meaning; exploring issues of guilt, remorse, forgiveness, and reconciliation; abetting and facilitating religious expression; reframing goals into short-term endeavors that can be accomplished, and encouraging use of meditation, guided imagery, music, reading, poetry, and art that focuses on healing rather than cure.[74]

Greenstein and Breitbart have developed a meaning-centered group psychotherapy for patients with cancer based on the concept of the search for meaning. The goal of the intervention is to help patients focus on what has been meaningful and can still be meaningful in their lives and to encourage dying patients to find meaning in living until their death. The groups meet for eight sessions and possible sources of meaning are explored, including responsibility to others, creativity, transcendence, and ascertaining one's values and priorities.[75]

Both models focus on meaning-issues and transcendence and have great support in literature. Other similar approaches were proposed earlier, e.g. by Frankl who developed logotherapy (logos = meaning). Logotherapy focuses on finding meaning or creating meaning and Frankl distinguishes between three forms of meaning:[76]

- Creative meaning (what one accomplishes)
- Experiential meaning – what one takes from the world in terms of encounters and experiences
- Attitudinal meaning – one's stand toward suffering, toward a fate that one cannot change.

In a similar fashion, Antonovsky's concept – sense of coherence – consists of three facets: comprehensibility, manageability, and meaningfulness, but it is mainly focused on the latter aspect.[31] To focus on meaning and meaningful events is possible also for ordinary staff working with palliative care. In all stages of life, good relations, experiences and hope create meaning and this is also true for end-of-life care. Through practical measures staff can facilitate good relations, e.g. by allowing family members to stay overnight when a patient is experiencing hardship. Also dying patients enjoy positive experiences: music, flowers, beautiful environments. By focusing hope on realistic goals the staff may increase meaningfulness in fragile situations, e.g. hope for a symptom-free weekend when grandchildren come for a visit.

Another model/advise to help physicians who feel uncomfortable discussing spiritual concerns, has been offered by Lo et al.:[8]

> First, some patients may explicitly base decisions about life-sustaining interventions on their spiritual or religious beliefs. Physicians need to explore those beliefs to help patients think through their preferences regarding specific interventions.

> Second, other patients may not bring up spiritual or religious concerns but are troubled by them. Physicians should identify such concerns and listen to them empathetically, without trying to alleviate the patient's spiritual suffering or offering premature reassurance.

> Third, some patients or families may have religious reasons for insisting on life-sustaining interventions that physicians advise against. The physician should listen and try to understand the patient's viewpoint. Listening respectfully does not require the physician to agree with the patient or misrepresent his or her own views. Patients and families who feel that the physician understands them and cares about them may be more willing to consider the physician's views on prognosis and treatment. By responding to patients' spiritual and religious concerns and needs, physicians may help them find comfort and closure near the end of life.

As a help for healthcare staff, Puchalski has developed a spiritual assessment tool, FICA. It is meant to be a guide for healthcare providers regarding how to start the spiritual history and what to listen for:[55]

F – Faith and belief. Do you consider yourself spiritual or religious? (If not, what gives you meaning?).

I – Importance. What importance does your faith or belief have in your life?
C – Community. Are you a part of a spiritual or religious community?
A – Address/Action in care. What needs to be done with the information?

THE FUNCTION OF RITUALS

Spiritual needs can be met by traditional religious acts such as rituals, prayers, and worship.[77] These rituals may provide meaning to everyday life and help patients through hardships such as pain, illness and personal disasters. These needs are influenced by ethnic and cultural backgrounds.[3,78,79] Every culture in the world has some kind of rites and rituals to highlight important events in people's lives. 'Transition rites', e.g. when a child is born, weddings and funerals, are typical examples. The rituals are characterized by a predetermined form of group behavior which is internalized by the participants. Rituals, especially in association with dying and death, play a large role in the process of mourning, both on an individual and on a collective level. Besides being an official announcement of a death, funeral rituals provide an opportunity to try to find meaning through funeral oration, songs, and sacral music, all of which might appeal to inner feelings, giving them an appropriate means of expression. In that way, they help to create control in the chaos. Within healthcare it is important that the staff create space for and recognize the importance of the dimensions of rituals of dying and death, as active planning and participation in rituals might have a positive function in the mourning process.[80]

SPECIFIC SPIRITUAL/RELIGIOUS (CHRISTIAN) CARE

Soul care is facing great and varying challenges today. The task to help and support people in acute crisis is becoming more and more important as the individual person is getting more vulnerable today in existential boundary situations. To facilitate the handling of existential crises, people need room for encounter, reflection, and for the exploration of one's own life, especially when encountering suffering and death. During different times in history, different aspects of soul care have been stressed and today general counseling with a psychotherapeutic approach is not uncommon.

So in what aspects does soul care differ from psychotherapeutic counseling? In short, a psychotherapist focuses on emotional aspects, interpersonal relations and inner conflicts. The therapist approaches the patient in an objective fashion and follows a certain theory or plan of action. In Sweden, the members of the hospital chaplaincy normally have education in psychology and counseling, but in contrast with psychotherapists, chaplains are not only representing themselves, but also God and the church. They aim at integrating the patient narrative into a religious frame of interpretation and use the symbolic language of the church as well as rituals. The difference can be exemplified in the following way. A patient realizes that he has an incurable disease and asks: 'What is it like to be dying, how will it be for me?'. A psychotherapist would respond: 'Would you like to tell me more about this, what are your feelings, how are you relating to this issue yourself?' and so on, but he would never offer an explicit answer. In soul care, the chaplain may start with similar questions to comprehend the whole situation, but then also talk about the heavenly promise, God's eternal love that never abandons a person in need. In such ways a chaplain may offer spiritual comfort by offering a religious frame of interpretation.

In Sweden, Owe Wikström, a chaplain and also a prominent professor of psychology of religion has summarized four dimensions of Christian soul care in the following way:[35]

- *Care and understanding.* The first issue of soul care is not to change or cure, but to show respect, care and, understanding for a fellow being.
- *Consideration/presence of mind.* Soul care should focus on existential and spiritual aspects, the individual experiences of being a part of something beyond the physical world, and on the moral aspects of one's own life.
- *Interpretation.* Soul care is aiming at integrating private experiences and an all-embracing Christian interpretation of life. The person providing soul care uses their theological knowledge and experience. Here lies a significant difference between the (psycho)therapist and the chaplain.
- *Deepening.* The interpretation leads to a further deepening, where the chaplain tries to help a fellow being mature in their belief. This deepening comprises *experiences* of God, in contrast with intellectual opinions about religion. The deepening also leads to a longing for goodness, and for spiritual growth and spiritual sources.[35]

FUTURE ISSUES

The growing awareness of spiritual issues must have consequences for future care. The physical and the psychosocial aspects should be integrated with existential awareness, as the life-and-death issues are existential rather than psychological. Therefore, existential and spiritual aspects, e.g. the nature of existential crisis should be integrated already in basic education in order to supplement psychological theories.

Both students and staff should realize that spiritual care is not necessarily synonymous with religious support. Consequently, both staff and hospital church should be

involved and work as a team.[52] Religious issues should exclusively be handled by hospital chaplaincy, whereas both staff and hospital chaplaincy should be prepared to support in existential crisis of more general nature. Meaning is the core concept and has been proved to be a central predictor to quality of life.[29] Therefore staff should have a good theoretical basis and training in supporting in meaning-based questions in order to facilitate quality of life of the patients.

Key learning points

- When facing death, existential anxiety is activated and here spirituality and existential issues intersect with medicine at the juncture of suffering.

- In healthcare contexts, spiritual care normally includes religion and general spirituality, but also general more philosophical existential issues should be considered.

- Intrinsic religious belief might fulfill several significant needs: namely religious, cognitive, emotional, social, political ones.

- Hospital chaplaincy is a unique resource; the members have extensive training in listening, supporting and counseling others, especially in religious crises. Still, the most frequently posed questions seem to be of a general existential character.

- Basic spiritual support can to an certain extent be provided by any member of the healthcare team but presupposes a basic knowledge and training.

- Useful examples of models in spiritual care are Kissane's grief therapy, Breitbart's meaning-centered group psychotherapy, Puchalski's spiritual assessment tool.

- Rituals may provide meaning to everyday life and help patients through suffering and in the mourning process.

Family care

LINDA J KRISTJANSON

INTRODUCTION

A fundamental tenet of good palliative care is the importance of attention and support to the family.[1] This principle of care is supported by empirical evidence that demonstrates that a terminal illness in a relative has a marked effect on family members.[2–5*] Families provide practical care and hold vigil with the patient as they attempt to offer emotional support and reassurance. Family members usually feel unprepared for this caregiver role because they lack specific knowledge, skills, and understanding of about how to best provide support. They therefore look to health professionals for information, practical advice, and emotional sustenance to help them cope with the feelings of loss and helplessness.[3,6] As they witness and participate in the patient's care, they make judgments about the quality of care that the patient and they receive.[7***] They often view themselves as the patient's care advocate and may experience remorse if they believe that they did not achieve the best possible care for their loved one. Recognition of the weighty impact of the illness on the family member's psychological and physical health has led them to be branded 'hidden patients'.[7***]

This chapter synthesizes current empirical findings related to the care needs of families in palliative care. The definition of 'family' is discussed and the prime needs of family members are described with a focus on how the palliative care team might best support families to sustain their supportive role and manage the impact of the illness on their own physical and emotional health.

DEFINING THE FAMILY

The World Health Organization[1] refers to the family as the 'unit of care' and affirms the importance of family care as part of a palliative approach. In the context of the impact of a terminal illness, the definition of who constitutes the family needs to be necessarily broad and inclusive. For example, the Canadian Palliative Care Association's[8] definition of family is:

> those closest to the patient in knowledge care and affection. This includes the biological family, the family of acquisition (related by marriage/contract), and the family of choice and friends (not related biologically, by marriage/contract).

According to this definition, families may include different individuals who may or may not be related through blood or legal ties.[7***] Families may include immediate relatives, a larger network of extended family members, neighbors, and friends.

Failure to recognize the distinct characteristics or membership of families may exclude some family members who may be in need of support. This error may be more common when families do not fit a traditional definition of family (e.g. blended families, families who live geographically apart).[9***,10,11**] Therefore, supportive palliative care to families begins with a careful and open consideration of who constitutes the family. From a clinical perspective, the most practical approach to defining the family affected by the patient's illness is to permit the patient and his or her family members to define the family.

THE FAMILY'S NEEDS

The literature related to families' needs has been classified into four categories: pain management, information needs, needs for physical help with care, and assistance to manage family communication and family functioning.

Family pain management

Family members who observe poorly managed symptoms such as pain, dyspnea, and appetite problems, experience considerable distress and a type of 'vicarious suffering', especially if they feel poorly prepared to respond. In particular, pain management is consistently identified by family caregivers as their leading concern related to care of a relative with advanced disease and is a particular worry for those who provide care at home.[12*,13*,14*] Poorly managed pain may prompt fears about disease progression, and is emotionally and physically exhausting for both patient and family members who witness the distress.[14*] If family caregivers are unable to relieve the patient's suffering they may experience guilt and distress and feelings of helplessness.[15*]

Family members who are not educated in palliative care pain management practices may hold a number of attitudes and beliefs about pain medication that prevent good pain relief. For example, family members may have fears that the patient will become addicted to opioids, may experience respiratory depression because of these strong medications or may 'use up' the medication early in their illness and therefore have no access to pain relief later when the pain is more severe.[14*] Family caregivers who are unfamiliar with pain management medications may over-medicate or under-medicate patients with opioids, resulting in medical complications and increased suffering.[14*] When family caregivers do not feel confident and knowledgeable about pain management, patients are more likely to require hospital admission and more frequent medical interventions and need more respite care.[16*]

An intervention study was undertaken recently to test a family pain education program for family caregivers of patients with end-stage cancer.[17***] Ninety-two family members were randomized to either the family pain education program or standard care. The education program was delivered in the family's home via four 1-hour sessions. Family caregivers were provided with a comfort diary to record the patient's pain and their treatment approaches, a video demonstrating how to safely move the patient without causing discomfort, and an education booklet outlining information about safe use of medications. The results indicated that family caregivers who received the pain education program had more positive attitudes toward pain management, were more knowledgeable about pain management approaches and used medications more effectively in providing pain relief to the patient. Palliative care teams therefore need to ensure that family caregivers have the information they require when providing pain relief to the patient.[17***] Further research is needed to develop family-oriented interventions specific to the concerns families may experience in relation to other symptoms (e.g. dyspnea, fatigue). The capacity of the family to respond to patient distress is a central component of care.

Information needs

Family members consistently report difficulties accessing information.[7***,18***] Health professionals may overload families with large amounts of information or may provide information in small amounts in an effort not to overwhelm them with too much detail.[18***,19*,20*] Families are reluctant to bother busy health professionals with questions about care because they believe that health professionals are primarily responsible to the patient and that family concerns are tangential.[3,7***] The perceived unimportance of communication with the family is reinforced by the lack of time and space for this type of exchange.[18***,21***] The pace of busy work schedules may also limit time spent with families and health professionals may wrongly assume that the patient/family has understood the information conveyed.[22] In some instances, health professionals may avoid information sharing with families because they lack comfort in knowing how to communicate difficult/bad news.[22,23]

One of the most effective ways of assisting families is to provide them with liberal amounts of well-timed, simple information that helps them cope with the care challenges they face.[24] Families require information about how to provide comfort care, how to communicate within the family, how to pace their own energies, and when to call for assistance.[3]

Home care nurses are reported to be a valuable source of information[3,18***,25] and families value 24-hour access to information.[26*] In rural communities, the nurse has been reported to be particularly important to families. Nurses are often the most accessible and specific in providing information regarding how to provide care and support[18***,27] Use of a family conference has also been reported by family members to be a helpful source of information and an opportunity to clarify questions.[26*] Practical information to help families anticipate the next steps of the patient's illness is also beneficial.[24] This information allows families to 'stay in front' of symptoms, know what to expect and not be caught in a moment of crisis unprepared for deterioration in the patient's condition.

One of the particular fears that families report is a worry about how to manage care at the time of death.[18***,24,28,29] Families also appreciate knowing the common signs that indicate that death may be approaching.[28,29] Information given in a calm, specific, and reassuring manner can help families to feel prepared and able to manage. This information helps them to prepare psychologically for the patient's death and allows time to call family members who may wish to be present.[18***,24]

A recent study by Kirk and colleagues[30*] involved interviews with 38 palliative cancer patients and 36 family members to ascertain their experiences of the information disclosure process. Their results indicated that the process of information sharing was as important as the content. The timing, management, and delivery of information by

the healthcare team all need to be carefully considered. The most important content areas were information about prognosis and hope. All patients, regardless of ethnic/cultural background, wanted information about their illness, and almost all were willing to share this fully with their families. All family members thought it important that the patient be aware of the diagnosis. As the illness progressed both patients and family members reported that information needs changed and there was greater divergence between the patient's and family's needs. At the palliative phase of an illness many patients reported not wanting as much detail as they had asked for initially, and some requested that their family member speak with the healthcare professionals on their own. These findings point to the importance of the quality of the relationship between health professionals and patients and families and the need for sensitive and individualized information exchange.[18***]

Physical care needs

Families who provide care to a patient with a terminal diagnosis experience many physical demands and practical needs, which may be underestimated.[31*,32*] Family members may need to assume duties that the ill person cannot undertake, and may experience practical problems associated with transportation to treatments, child care, and unrelenting work demands.[7***] Buehler[33] undertook a longitudinal study of families caring for patients with advanced cancer in rural communities and documented a lack of available resources. This lack of support may occur, in part, because family caregivers are viewed as resources rather than as recipients of care.[11***]

In instances when the family caregiver is an older person and has health problems of his or her own, the demands of caregiving can be extremely taxing.[18***,34,35] However, family members may stretch their efforts beyond their usual limits because of a sense of duty to care for the patient. The additive effect of these burdens and strains may be notable[11***] with this type of over-functioning resulting in caregiver fatigue.[36] There is a risk that signs of caregiver fatigue may be missed or underestimated by clinicians who observe family members briefly and intermittently.[7***]

Respite services can be helpful to families in sustaining their caregiving energies. These services may take the form of external (hospital/hospice based) care whereby patients are admitted if they have intractable symptoms, they are imminently dying and home is not the desired place of death, and/or to allow the family to rest.[24] In other instances, provision of home respite may allow families time to be relieved of caregiving duties for a short period of time.[18***] Bramwell and colleagues[37*] surveyed caregivers' needs for overnight respite. They found that 73 percent of caregivers received less than 4 hours of sleep and as a result were more vulnerable to exhaustion. Further, 70 percent of all caregivers surveyed indicated that they would use an overnight

respite service. The researchers recommended further investigation of the relationship between carer exhaustion and early hospital admission and whether or not night respite would prevent hospital admission.

A recent study evaluated a community-based night respite service for terminally ill cancer patients and reported positive outcomes.[38**] Care aides were trained to provide night respite support and 53 patients received this support over an 11-month time period. Families who indicated moderate-to-severe levels of carer fatigue were identified as urgent candidates for night respite support. Almost 70 percent of patients who died were able to die at home, compared with 50 percent of patients who died at home without this service. Family carers reported that this assistance helped them to manage the patient at home. Costs associated with home deaths and the night respite service were much less than was the case for patients admitted to an inpatient facility for end-stage care.[38**]

In summary, the practical, physical challenges associated with providing care and support have notable effects on the physical and emotional wellbeing of family caregivers.[7***,39] Without adequate family interventions and targeted support, the burden placed on families may limit their abilities to provide good quality patient care.[40]

Family communication and family functioning issues

A family's ability to support a patient emotionally and practically depend to a large extent on the amount and quality of social and health professional support the family itself receives.[32] Poor communication causes more suffering to patients with cancer and their families than any other problem – with the exception of unrelieved pain.[41] Communication is essential to healthy family functioning, and families who have limited communication skills are less able to manage stressful situations.[42] Some family members may be open and clear in their exchanges about the illness, treatment decisions, fears, and doubts. Others may be reserved in their expressions of feelings, holding back worries, regrets, and uncertainty.[7***]

Families usually rely on a patients to relay information about the illness, which helps them understand the plan of care and subsequent phases of the disease. Families may feel uncertain or frustrated if they lack this information, especially if the patients assume the role of information gatekeeper in an effort to shield family members. This protective behavior is common when parents have cancer and are cautious about sharing information with their children.[43*,44*] Information shielding can also occur in reverse when family members attempt to shelter the patient from what they perceive to be unsettling information. Relationship strains may occur, contributing to conflict, anxiety, and poor communication within the family.[7***]

Families who communicated effectively prior to the illness have been found to cope more effectively during the illness than those with histories of less functional communication.[45] Questions to explore early with the family about how they communicate may allow the health professional to be alert to difficulties and help the family to talk through how they are going to share information and discuss concerns in a way that might avoid conflict and communication mistakes.[18***]

Emotional needs of family members include a need for support to help them manage issues of loss, uncertainty about the patient's illness and eventual death, communication difficulties within the family, and their own psychological distress.[46] Research to delineate the coping strategies most helpful to families reveals that the strategy labeled 'taking one day at a time' has been used to manage uncertainty.[47*] Acceptance, rationalization, and social support were also identified as useful coping strategies that family members used to cope with changes in the patient's condition.[11***,46] Offering families some of these approaches can be helpful in reminding them about how to cope, how to reach out for assistance, and how to compartmentalize the stresses they face into more manageable parts.[24]

Family members who witness a traumatic illness or death may be at risk for a more complicated bereavement reaction.[48*] Therefore, caring for the family during the palliative phase of an illness is a preventive health strategy that may place them in a better position to deal with this crisis and integrate the loss in a way that maintains their own health.[49] Those who have experienced a difficult death or observed a patient's unrelieved suffering may require special support to contend with difficult memories and feelings of regret.[7***]

SOCIAL AND FINANCIAL PRESSURES

The social and financial pressures that families encounter in response to the challenges of the patient's illness have also been well documented and may place additional strain on the family. One study conducted in the USA reported that many caregivers of terminally ill patients with moderate or high care needs reported spending 10 percent of their household income on healthcare costs and that they or their families had to sell assets, take out a loan or mortgage, or obtain an additional job to meet healthcare costs.[50] The economic impact of day-to-day family involvement in living with cancer can be profound, especially due to the unavailability of support services in many geographical areas.[51] Findings from the few cost-estimate studies indicate that families find themselves responsible for purchasing medications and home care supplies, for renting equipment, and for paying for transportation and respite services.[52]

In Canada, the financial costs associated with the move from institutional care to home care has been shown to be borne by recipients and their carers.[53] Many of these costs would be absorbed by the government if the recipients were in hospital, especially expenses related to medical equipment, special meals, renovations to accommodate disabilities, repairs and maintenance of the care setting, and in some instances prescription and nonprescription drugs. Australian data reported by Schofield *et al.*[54] confirms that caring commitments may mean that some carers are unable to work, or have to work fewer hours or in a lower paid job with financial consequences. The 'Caring Costs' study confirmed the low-income levels of most carers as two-thirds listed a government pension or benefit as a main source of income.[55]

Although these findings do not diminish the fact that the role of family caregiving can be rewarding, these studies alert us to the potential negative effects of caring over time. These studies confirm that families may have significant unmet needs related to their caregiving roles despite the significant, yet often invisible, contribution that they make to society and to the healthcare economy.

CONCLUSION

The physical and psychological distress of families during the patient's illness and in the bereavement period is clearly reported. Palliative care providers who view the needs of all family members as important are better able to assess and identify supports for those in need of assistance. In the palliative phase of an illness, attention to families who may be psychologically vulnerable, lack resources, or have concomitant health issues and concerns constitutes good preventive family care. However, there have been few intervention studies focused on reducing negative aspects of family caregiving. Harding and Higginson[56***] have called for evaluation studies focused on the family caregiving population with attention to cost-effective allocation of resources. This recommendation warrants attention and should direct future family studies in palliative care research.

Key learning points

- The most practical approach to defining the family is to permit the patient and the family members to define the family.

- Pain management is consistently identified by family caregivers as their key concern.

- Family caregivers experience both physical and emotional health strains.

- One of the most effective ways of assisting families is to offer liberal amounts of well timed, simple information.

- Families will require information about how to provide pain relief and comfort care, how to communicate within

the family, how to pace their own energies, and when to call for assistance.

- Use of targeted respite may assist family caregivers to maintain their caregiving role and allow the patient to remain at home longer.

- Family members need support to help them cope with issues of loss, uncertainty about the patient's illness, the possible death of their relative, communication issues within the family, and their own psychological distress.

- Family members who have witnessed a difficult death or unrelieved patient suffering may be in particular need in the bereavement period.

- Social and financial strains associated with family caregiving may be notable.

A transcultural perspective of advance directives in palliative care

DONNA S ZHUKOVSKY

DEFINITIONS

Advance directives are closely related to the concept of patient autonomy, a highly valued tenet of Western medicine.[1] Autonomy, intrinsic to patient self-determination, is contingent upon informed consent and informed refusal of medically indicated treatments. The goal of advanced directives is to afford the individual an element of control over future healthcare decisions in the event that he or she loses the capacity to participate in medical decision making.[2] It is important to note that while patient autonomy is a significant factor in medical decision making, other ethical principles such as beneficence and distributive justice must also be considered with each treatment decision.[3] Two main types of advance directive exist:

- Instructional documents, more commonly known as living wills or directives, that specify wishes for future health states.
- Documents that designate a surrogate decision maker, variously called healthcare proxy, medical power of attorney, or durable power of attorney forms.

In addition, the majority of states in the USA offer a more limited type of advance directive, in the form of out-of-hospital 'Do Not Resuscitate' (DNR) orders.[4*]

In today's healthcare climate, living wills have evolved from specifying treatment refusal to indicating types of treatment the patient would accept or decline in specified healthcare states or conditions, such as terminal diseases, or in irreversible conditions that ultimately become fatal without the use of life-sustaining treatments. For healthcare proxies, the role of the surrogate decision maker as initially proposed is to make recommendations based on substituted judgment, i.e. what the patient would have wanted if able to express him or herself, and if not known, on best interests of the patient, as guided by patient values.[5]

Instructional directives and proxy documents are complementary, as one cannot presuppose all future states of incapacity or illness that may occur. Neither type comes into effect unless the individual is in a state of incapacity related to decision making for the question at hand.[6] Decision making capacity is a medical determination for the relevant decision and not synonymous with competency, which is legally determined. However, the two terms are often used interchangeably. Not well understood is that the goal of advance directives is to facilitate patient autonomy for medically sound treatment choices, and does not support demands for interventions considered to be medically futile or otherwise inappropriate.[2] Regular review of advance directives is recommended, especially with changes in life status such as marriage, childbirth, divorce, or death of a spouse, as well as with significant changes in medical status, to ensure consistency with a patient's goals of care.

LEGAL ISSUES

From a legal perspective, advance directives may be statutory or advisory in nature. Statutory documents, designed to protect physicians who follow patients' wishes from liability,

are based on legal criteria codified in state law. US states will frequently honor statutory documents of other states. Although nonstatutory instructional documents do not always conform to state statutes, they, too, are legally binding if clear evidence of the patient's wishes is documented, as common law affords competent individuals the right to accept or refuse treatment, including life-sustaining interventions.[6] The state of New York distinguishes artificial nutrition and hydration from other treatment choices, placing this treatment choice in a separate category from other medical interventions. Surrogates are unable to make decisions about artificial nutrition and hydration, unless the agent reasonably knows the patient's wishes, as explicitly expressed beforehand.[7]

Regarding children, few states in the USA have statutes regulating the implementation of directives on behalf of minors and even fewer address the implementation of DNR orders in the school setting.[8] Recently, the state of West Virginia implemented the West Virginia Health Care Decisions Act, granting mature minors the legal ability to execute written advance directives and make end-of-life decisions.[9] There are limited guidelines for determination of mature minor status. However, the literature suggests that minors 15 years of age or older should be presumed competent to provide consent for major health decisions in the absence of evidence to the contrary. Adolescents between the ages of 11 and 14 are in a transition period, with many capable of competent consent. For those who have not yet realized full decision making capacity, and for children younger than 11, gradual, escalating involvement in decision making to facilitate skill development and confidence for future decisions is recommended. Although the majority of states in the USA do not specifically address end-of-life decision making for mature minors, the literature increasingly supports the role of pediatric assent in medical decision making, including for end-of-life care decisions such as treatment discontinuation and advance care planning, as consistent with the child's decision making capacity and willingness to participate.[10–13] Among healthcare professionals, it remains controversial if mature minors should have primary authority for consent that is in conflict with parental opinion or if all decisions should be made in consideration of the provider, patient, and family relationship, with parents having primary authority for consent.[9] Despite lack of specific legislation regarding the mature minor doctrine in most states, there have not been any successful lawsuits against physicians who have honored the consent of mature minors 15 years of age or older, in absence of parental consent, for more than 40 years.

HISTORY AND EXAMPLES OF ADVANCE DIRECTIVES

Historically, the earliest instructional directives in the USA date back to 1968 when the living will was developed to support the widespread belief that 'heroic' levels of technological intervention were not medically indicated if the patient's prognosis was 'hopeless'.[6] Highly technological care had become prominent at the end-of-life subsequent to the introduction of closed chest massage in 1960, precluding the need for open thoracotomy and direct cardiac massage during cardiac resuscitation. However, instructional directives did not come into common usage until the 1970s with the development of hospital policies regulating the withholding of cardiopulmonary resuscitation (CPR), in the form of DNR orders.[14] In 1974, the American Medical Association suggested that decision DNR be entered into the patient's medical record and communicated to the attending staff.[15] Two years later, a working group of the Harvard School of Public Health prepared a statement to support hospitals in their development of policies regarding the decision making process for the use of CPR. Their discussion centered upon the medical appropriateness of CPR for patients with irreversible, irreparable illness whose death was anticipated imminently, defined as a period of 2 weeks or less and the right of competent patients to provide informed acceptance or rejection of treatment. Key features of the process included determination of medical appropriateness of a DNR order by the primary physician after discussion with other clinicians involved in the patient's care, as well as with a senior physician not involved in the patient's care, and informed choice of the competent patient or with agreement of all appropriate family members for the incompetent patient. Additional steps included physician responsibility of informing family members of competent patients, after obtaining permission to do so and documenting details of the steps above in the patient's medical record, together with discussions that took place with family members upon their appraisal of the decision.[14]

Over time, the scope of instructional directives has broadened from treatment limitation to that of preferred treatment choices. Several preformatted documents have been developed that allow the patient to indicate preferences for various treatments in the context of different medical conditions. One or these, the Medical Directive, was developed in 1989 by Emanuel and Emanuel to overcome some of the limitations of early forms of instructional directives, namely, failure to accommodate positive requests for treatment, vague language affording multiple interpretations of terms used in the directive, lack of flexibility for unforeseen clinical situations and poor patient–physician communication. Composed of five sections, the Medical Directive includes an introduction, which emphasizes the importance of personal values and goals in the decision-making process and of communicating values and goals of care with the patient's family, friends, and physicians, a section containing four illness scenarios designed to elicit preferences for medical care with regard to specific life-sustaining medical treatments given different outcomes, a section for the designation of a proxy decision maker, a section for organ donation, and lastly, a personal statement.[16]

At approximately the same time that the Medical Directive was proposed, Doukas and McCullough introduced the Values History into the literature, a two-part instrument that elicits patient values about terminal medical care and therapy-specific directives.[17] Like the Medical Directive, the Values History was structured to facilitate patient–physician communication and provides for designation of surrogate decision maker and consent for organ donation. Additionally, it allows for autopsy consent and for a trial of selected treatment interventions, as an intermediate option to intervention or nonintervention. Subsequent study of this document exploring the relation between values and stated preferences for individuals in the outpatient setting indicates that respondents (N = 118, mean age 39 years, 61 percent female, 68 percent married) preferred quality of life to longevity and identified general communication issues, family burden, and physician-compliance factors as meaningful psychological values. Family burden considerations were highly relevant to the decision-making process.[18*] Five Wishes is another well-known advance planning instrument that is available in English and in Spanish versions through a nonprofit organization called Aging with Dignity.[19] Caring Conversations, consisting of a 16-page workbook, living will and durable power of attorney forms, is available from the Center for Practical Bioethics.[20]

EFFICACY OF ADVANCE DIRECTIVES

For advance directives to be effective, they must impact on care provided in a direction consistent with patient preferences. Requisite components for successful use of living wills include awareness of their existence, provision of information adequate to facilitate informed consent and informed refusal of medical treatments for future medical states based on personal values and goals of care, documentation of treatment choices in unambiguous terms, communication of choices to surrogate decision makers and healthcare clinicians and utilization of this information by surrogate decision makers and physicians when the individual is in the specified condition. To support the use of advance directives, the US Congress passed the Patient Self-Determination Act (PSDA) in 1990, requiring that all patients be asked about the existence of advance directives at the time of registration or admission to a healthcare facility, as a prerequisite for federal funding.[21] The Joint Commission on Accreditation of Health Care Organizations further recommended that such healthcare facilities have available a process facilitating completion of advance care directives, for those patients who so choose.[6]

Despite strong advocacy for advance directives from members of the medical, ethical, legal, and lay communities, they have not made a significant impact on medical care for most patients.[22,23] In most settings, less than 20 percent of patients have formal advance directives and even fewer have provided copies to their physicians.[24,25,26*,27*,28,29*] Family members, surrogate decision makers, and physicians are frequently unaware that the individual has an advance directive and are unlikely to predict patient preferences accurately more often than by chance alone,[30] often believing the patient's prior wishes to be for more intervention than the patient had chosen.[31] Furthermore, physicians frequently do not follow patients' known treatment preferences,[32] as demonstrated by the Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments (SUPPORT), a major multisite intervention of over 9000 seriously ill patients,[6,30*] and other studies.[33*]

Numerous reasons have been cited for the failure of advance directives to extend patient autonomy into periods of incapacity for medical decision making, many of which relate to the emotional distress inherent in discussing end-of-life issues. Patients and physicians are often reluctant to initiate advance care planning, waiting for the other to take the lead and/or delaying until the individual is seriously ill and/or no longer has decision-making capacity. Data from a cross-sectional descriptive survey of randomly selected primary care patients and physicians in the USA indicated that differences in opinion about the timing of such discussions and who should initiate them also plays a role. Patients felt the discussion should take place earlier in the physician–patient relationship and disease course than did physicians, with the majority of patients believing that discussions should take place in the outpatient setting while they are still healthy. More patients than physicians believed the discussion should occur with the diagnosis of a life-threatening illness (90 percent vs. 60 percent, respectively). While the majority of both groups believed it was the physician's role to initiate discussion of advance directives, patients believed so more often than physicians.[34*] Of those who complete advance directives, many do so with minimal or no physician involvement, raising the question of adequate informed consent and refusal. Communication between patients, physicians, family members and other healthcare surrogates is often suboptimal, resulting in overly optimistic estimates of prognosis by all involved.[35] The latter has the potential to influence patient decision making, as data from SUPPORT indicate that perceived prognosis may influence patient preference for life-extending versus comfort-focused care.[36*] Compounding inaccurate estimates of prognosis is a focus on isolated DNR decisions, leading to patient fears of abandonment. Lack of specificity of many instructional documents and limited awareness of patient directives and their content by relevant parties contribute to their limited impact on end-of-life care.[6,37,38*] For some individuals, advance directives may be considered irrelevant due to the presence of involved family[39*] or may not be culturally congruent with end-of-life care.[40]

Given their overall lack of influence on patient care, some authors have recommended that living wills be abandoned in favor of medical powers of attorney for those individuals who want control over future decisions. Arguments against use of surrogate decision makers include the limited

execution of formal healthcare proxy documents, infrequent and incomplete discussions with family members about end-of-life care preferences and limited concordance of proxy decision maker choices with patients, resulting in failure to extend patient wishes into the future. Furthermore, the emotional and financial burden of caring for patients with advanced disease may present potential conflicts of interest for the proxy decision maker, especially if a family member or significant other, and is psychologically stressful.[41]

Fins and his group[42] make a cogent case that the act of being selected as an individual's proxy is at least as important to the individual as articulating the patient's known preferences, despite the lack of congruence frequently seen in patient–proxy decisions. They posit that the patient effectively achieves self-determination by a combination of *substantive* moral authority, based on knowledge of the patient's wishes and *procedural* moral authority, empowerment of the proxy by the act of being chosen to use interpretative discretion to assess the current situation and make judgments, even if they counter the patient's previously expressed wishes. An empirical study of 50 patient–proxy pairs and 52 individuals who had acted as proxies for individuals who had died provides initial support for their hypothesis. Variables such as disease trajectory, clarity of prognosis, quality of instructions, and instructional valence ('do everything' vs. 'do nothing') influenced the degree to which proxies adhered to the patient's initial instructions.[42*] Additional points offered in support of surrogate decision-making documents include simplicity, little change from current practice and legislative support designating proxies for incompetent individuals that already exists in some states.[22]

To date, advance directives have not significantly altered end-of-life care for the majority of individuals. However, the widespread variation of their prevalence and of the aggressiveness of end-of-life care suggests that advance directives may yet play a role in influencing patient care. The best known example is the Oregon experience, where a state-wide effort to enhance public knowledge about end-of-life care options has resulted in high rates of advance care planning, with family members of 68 percent of decedents reporting that a living will had been executed.[43*] Physician Orders for Life-Sustaining Treatment (POLST), a more specialized application of advance directives, has been in use across the continuum of care settings at the ElderPlace (a Program for All-Inclusive Care for the Elderly), Portland, Oregon site since 1994. In a preprinted and signed doctor's order form, competent individuals or their surrogates specify treatment instructions in the event of serious illness including orders for treatment preferences related to CPR, level of medical intervention desired, antibiotic use, and artificial administration of fluid and nutrition. Use of POLST has resulted in a high level of consistency with treatment preferences (84–94 percent), but less so for desired level of intervention (46 percent).[44] A survey of living will completion rates by nursing home residents in California,

Massachusetts, New York, and Ohio further supports their potential impact on end-of-life decision making. Completion rates ranged from 2.1 percent in California to 32.5 percent in Ohio. The difference in completion rates was only partly explained by previously noted associations with race, suggesting a potential to influence advance directive use by interventions.[25*] Hickey has suggested that adoption and enforcement by all states of the uniform Health Care Decisions Act, recognition of a physician's ethical duty to assist patients in advance directive formulation and routine third-party payor reimbursement to physicians for their role in patients' advance care planning will lead to increased completion and compliance with patient directives.[23]

Pollack suggests listing simplified advance directives on Medicare cards as a means of enhancing advance directive completion, as well as availability at time of need.[45]

CULTURAL LESSONS FROM THE USA

A series of studies by Blackhall and colleagues evaluating 800 older adults residing in the USA has illuminated the role that ethnicity plays in attitudes toward patient autonomy, use of life-sustaining technology and knowledge of, attitude toward, and possession of advance directives. As a group, Korean Americans and Mexican Americans favored models of family-centered decision making over those based on patient autonomy, which are preferred by African Americans and European Americans. Korean Americans and Mexican Americans were less likely to believe that a diagnosis of metastatic cancer or of a terminal prognosis should be disclosed to the patient or that the patient should decide about use of life-sustaining technology than African Americans or European Americans. Whereas Korean Americans and Mexican Americans were most likely to favor the use of life-sustaining technology, unlike Mexican Americans, Korean Americans did not want such technology used for themselves. As Mexican Americans became more acculturated to the US lifestyle, they were more likely to prefer the patient autonomy model.[46] Of the four groups evaluated, European Americans were the least likely to endorse a favorable attitude toward life support and the least likely to want life-sustaining technologies for themselves. African Americans, despite their generally negative perception of life support, were the most likely to favor personal use of life-prolonging technology.[47*] Knowledge about advance care directives was lowest for African Americans (12 percent) and Korean Americans (13 percent), intermediate for Mexican Americans (47 percent) and highest for European Americans (69 percent), $P < 0.001$. For those with knowledge of advance directives, possession rates were low overall, at 0 percent, 2 percent, 10 percent, and 28 percent for Korean Americans, African Americans, Mexican Americans and European Americans, respectively. After controlling for ethnicity and socioeconomic status, factors associated with possession of advance directives

were personal experience with illness and more years of schooling. Factors associated with lack of advance directives were a negative attitude toward advance directives and government-assisted insurance.[48*]

Possible explanations of differences between ethnic groups in this work are elicited from ethnographic data. The apparent conflict in the expressed Korean American preference for use of life-sustaining technology in general, but not on an individual basis, relates to the concept of hyodo or filial piety, where family obligation is to prolong the life of their relative as long as possible. In this system of family-centered decision making, honoring family wishes takes precedence over patient autonomy as the 'right thing to do', analogous to the European concept of virtue. For Mexican Americans, the dichotomy between positive beliefs toward life support in general versus negative preference for personal use was not seen, perhaps due to the perception that the physician would not offer life-sustaining technology if the situation was truly hopeless. For African Americans, lack of trust in physicians on multiple levels associated with a greater wish for more prolonged life support was a more common theme than for other groups, along with the acknowledgment that it was acceptable to withhold or withdraw life support under some circumstances. European Americans based their negative views of life-sustaining technology largely on two factors: fear of cognitive impairment and of becoming a burden to family members.[46,47*,48] Like Korean Americans and Mexican Americans, the Navajo view of disclosure of negative information was unfavorable. The traditionally held Navajo concept of hozho, which combines the concepts of beauty, goodness, order, harmony, and everything that is positive or ideal, together with the belief that thought and language have the power to shape reality and control events, leads to ethical concerns that advance care planning is in violation of traditional Navajo culture.[49*] Clearly, differences in the value placed on patient autonomy influence perceptions of advance directives and their utility.

Similar attitudes and barriers to advance care planning have been found by other investigators.[39*,50*] For African Americans, numerous studies indicate that as a group, African Americans are less likely to discuss treatment preferences before death, to complete a living will or medical power of attorney or to have a DNR order before death and are more likely to prefer life-prolonging therapies than Caucasian Americans.[25,27*,31*,51*,52] Physician preferences for end-of-life treatment choices follow the same pattern by race as patient preferences.[53*] Content analysis of community-based focus groups exploring African American perspectives on end-of-life care planning and decision making revealed six explanatory themes as possible mediators of differences between the groups: death is not an option, religiosity and end-of-life care planning is a paradox, the healthcare system is a microcosm of societal and historical events, a 'trusted' family member or friend is the contract for life-and-death options, ethnically relevant initiatives are

essential to increase advance directives participation, and people are people.[54*] However, trust, frequently cited as a factor associated with negative attitudes to advance care planning and treatment limitations for the African American community, was not consistently found to be a contributing variable across studies.[27*,31]

CULTURAL PERSPECTIVES OUTSIDE THE USA

Europe

Advance directives are used even less commonly outside the USA. In a thoughtful treatise, Sanchez-Gonzalez evaluated the use of advance directives from a transcultural perspective, looking at the relative importance of different values from the perspective of the three prevailing ethical traditions in Europe: Anglo Saxon, northern (or central) European and Mediterranean.[1] To varying degrees in different parts of Europe, there is greater importance placed on virtue over (individual) rights, stoicism over consumerism, rationalism over empiricism, statism over citizens' initiative, and justice over autonomy. Consequently, family and physician contribution to medical decision making in many parts of Europe is greater than in the USA, where patient autonomy prevails. Confidence in family and physician virtue allows for decisions from a shared set of communitarian beliefs and values. Additionally, a strong emphasis on stoicism, with happiness determined by inner states of spirit and in relationships with others independent of material goods and other adversities and an aspiration to understand the universal nature of things, has led to distrust of the individual ego and of consumerism. The dominance of rationalism, with efforts to establish norms that have some universal and substantive content, as well as several of the concepts discussed above, has led to placing the common good over individual liberty in continental Europe. Consequently, best interest is favored over substituted judgment, unlike the USA, where substituted judgment is the more valued standard for surrogate decision making.[1] Interestingly, for incompetent patients without advance directives, Emanuel and Emanuel have suggested an end-of-life decision-making process that is guided by preferences of local communities of patients,[55] consistent with many of the European values noted above. Ultimately, Gonzalez concluded that autonomy has a transcultural value that must be balanced with other principles.[1]

China

China consists of many different cultures. Overall, traditional views value interdependency of family members, obligations, responsibilities to others, and the common good over individual self-determination.[56*] Dying at home in the

main hall, the most sacred place in the house, holds special significance as it denotes a full life and is crucial to bringing good fortune to living family members and to the spirit of the deceased. The spirits of those unable to die at home are barred from entering the home by the 'door god' and are unable to bring wellbeing to living descendants. To that end, dying patients are sometimes intubated to allow transfer home, where they are then extubated.[57,58*] In one retrospective study of 177 consecutive deaths of clinical trial patients hospitalized at a Chinese cancer center, 20 percent were transferred home to die. For more than 90 percent, death occurred within 24 hours of arriving home. Conversations about death universally were held with the family, but physicians rarely informed patients of the futility of CPR, often at the request of the family. While almost two-thirds of the overall population and 60 percent of those taken home to die had signed DNR orders, in only one instance was it signed by the patient. Physicians did not resuscitate 13 patients without a DNR order, but did attempt to resuscitate 30 patients with a DNR order, typically due to family insistence.[58] Similarly negative attitudes toward resuscitation were held by nonassimilated Chinese seniors living in Toronto, Canada, despite an indifferent or negative attitude toward advance directives. The 40 participants in this qualitative study based their decisions on the interrelated concepts of hope, suffering and the burden, the future, emotional harmony, the life cycle, respect for doctors and the family, values that are consistent with Buddhist, Confucianist, and Taoist beliefs.[56] In contrast, the majority of 43 older Chinese patients attending a daycare centre in Singapore, but born in Hong Kong or in the People's Republic of China, favored the use of aggressive life support measures. They also favored disclosure of the diagnosis and prognosis of a terminal illness, but were unaware of the Singapore Advanced Medical Directive Act, enacted in 1996. Of note is that the latter does not provide for a surrogate decision maker once patients are no longer competent to communicate treatment wishes.[59*,60*] In Taiwan, the Hospice Palliative Act, passed in May 2000, allows a competent person to provide signed informed consent for DNR status in the event of terminal cancer.[61*]

Japan

In Japan, an individual's death is considered a personal and private matter, as well as a familial, communal and social matter.[62] Traditionally, disclosure of diagnosis and prognosis of terminal illness has been to family members and not to the individual in question. When disclosure to patients or to families occurs, a significant minority prefers that it takes place nonverbally, an unfamiliar concept to most physicians practicing in the USA. Surrogate decision making is more common and attitudes toward advance directives and foregoing of life-sustaining therapy are less favorable

than is seen in Western medicine. However, recent surveys suggest a shift toward Western practices, with a growing preference for disclosure to those in a terminal situation, increasing use of advance directives, and expressed preferences for foregoing of life-sustaining therapy in terminal situations. For Japanese Americans, preference for disclosure is inversely related to degree of acculturation, as is the desire for informing the patient using words and direct patient participation in decision making.[62,63*,64*,65*]

The Japanese Society for Dying with Dignity (JSDD) has the largest membership in Japan of organizations assisting individuals with the completion of advance directives, which carry no legal status in Japan.[66*] Results of a population-based study indicate that disclosure of diagnosis and prognosis and expression of end-of-life treatment preferences were the most useful purposes of advance directives. Oral and written advance directives were both satisfactory. Family members, spouses, and relatives were considered to be the most suitable surrogate decision makers, with loose interpretation of directives by family and physicians being permissible. Preferences for advance directives was associated with awareness of living wills, experience with their use, preferences for end-of-life treatment, preferences for disclosure and intent of creating a living will.[64]

For those who complete written advance directives with the assistance of JSDD, a survey of family members and guardians of 1626 deceased individuals indicates a high rate of use, with presentation of the document to their physician by 64 percent, most often for patients with cancer. Care was perceived as congruent with the directive by 94 percent.[66] However, other studies suggest that following advance directives was not a priority for many physicians caring for patients at the end of life. Among the reasons cited for overriding patient wishes were family wishes to sustain a patient life, high possibility of recovery, and performing CPR to allow the patient's family time to arrive at the bedside.[67*,68*,69*]

ROLE OF ADVANCE DIRECTIVES IN END–OF–LIFE DECISION MAKING

In the USA, advance directives are a direct outcome of the emphasis placed on patient autonomy, allowing for informed consent and informed refusal of medically appropriate care options. Successful use of advance directives is a process contingent on awareness of their existence, integration of the patient's values and goals into an informed decision making process, documentation and effective communication of advance directive content to the patient's family, friends and physicians and execution under the appropriate medical circumstances. However, despite strong endorsement of advance directives by Congress, the Joint

Commission on Accreditation of Health Care Organizations and multiple medical societies including the American Medical Association and the lay public, they have not played a major role in healthcare decisions for the majority of patients and families. Focused initiatives such as POLST have successfully resulted in increased rates of advance directive completion, as well as care congruent with the individual's expressed wishes. Reasons cited for the failure of advance directives to take root more globally include generalized lack of awareness of advance directives, the difficulty in talking about emotionally charged issues, patients and physicians each expecting the other to take the lead in initiating advance directive discussions, the perception of the USA as a death-denying culture, the increasingly fragmented nature of medical care in the USA and costs associated with the time needed to guide the patient through the decision-making process.

Although varied, the prevalence of advance directive use is even lower outside the dominant culture in the USA and among different cultural groups in the USA. Differences in commonly held values underlie their less frequent use, with less emphasis placed on patient autonomy. Strong prohibitions against disclosure of diagnosis and terminal prognosis to the patient further limit discussions related to goals of care and informed decision making, requisite to advance care planning. Family-centered models of decision making typically prevail. Notwithstanding, trends toward increased disclosure and advance care planning are being seen throughout the world, paralleling changes seen in the USA over the past 30 years.

CONCLUSIONS

The provision of medically appropriate care congruent with the individual's goals and values, the basis for advance care planning, remains a moral imperative. Lessons from the history of advance directives in the USA and elsewhere suggest the need for strategic changes to more effectively achieve optimal advance care planning. Heightened physician awareness of and sensitivity to differences between cultures, diversity within cultures and of widespread differences in personal values and goals, would likely result in a more effective medical decision-making process for future medical conditions. Offering truth is a useful strategy that respects the integrity of both professionals and patients. If declined, the patient has chosen informed refusal and may then delegate truth telling and decision making to specified individuals or to family members. Such an approach is consistent with the convenantal (interpretative) approach of proxy decision-making favored by patients and proxies when the prognosis was poor, as noted in Fins *et al.*'s study.[42] Fundamental to successful advance care planning is expert communication skills integrated with caring and compassion.

Key learning points

- Advance directives relate to the concept of patient autonomy for advance care planning.
- Advance directives are contingent upon informed consent and informed refusal of *medically appropriate* treatments as relate to the patient's values and goals of care.
- Instructional directives and documents designating surrogate decision makers are the two main types of advance directives.
- Patients want physicians to take the lead in initiating discussions of advance directives.
- Family-centered decision making is of greater value than patient autonomy in some cultures and for some patients.
- Offering truth is a strategy that respects professional integrity and patient/family values from a transcultural perspective.
- Establishing advance directives that identify surrogate decision makers may be more effective than the current emphasis on instructional directives.
- Expert communication skills are integral to advance care planning.

Bereavement

VICTORIA H RAVEIS

INTRODUCTION

Although bereavement and loss are familiar occurrences in palliative care, an appreciation of what constitutes grief and an understanding of the special circumstances of bereavement in the palliative care setting may aid clinicians in attending to the needs of families facing the impending loss of a loved one. Bereavement refers to a loss through death of someone significant. A universal occurrence, it also is a particularly potent and stressful life event. Bereavement can predispose people to physical and mental illness, precipitate illness and death, and aggravate existing illness.[1***,2] Death represents a multifaceted challenge for the survivors. They must adapt to the social and economic readjustments emerging from the death and come to terms with changes in self-identity resulting from their loss, while dealing with the psychological and physiological reactions engendered by their loss. Mourning is the expression of grief and represents the process of coming to terms with this loss.[3***]

BEREAVEMENT IN PALLIATIVE CARE

The terminal period of an illness can be an extremely stressful time for the families of dying patients. Although bereavement is usually the specific event that precipitates the grieving process, for deaths that occur in the context of palliative care, a variety of circumstances occurring prior to the death are likely to impact survivors' grief.

Illness-related losses need to be mourned

When death is preceded by a chronic illness, grieving is inexorably tied up with mourning the losses experienced during the course of an illness. These losses include altered relationships, changes in lifestyle, the forfeit of future dreams that will never be realized, as well as losses related to illness-induced changes (e.g. progressive debilitation, increasing dependence, and excessive pain).[4]

Caregiving demands may complicate recovery from bereavement

Families are commonly involved in the provision of emotional and practical assistance to their ill family members in palliative care situations. While the benefits to the patient of familial caregiving are readily apparent, this care provision is not without cost to the care providers. Financial stress, neglect of their own health, physical and psychological exhaustion from providing care, and the social isolation resulting from restricting outside activities to carry out caregiving responsibilities, are some of the routine consequences endured by families providing illness-related support and care.[5] In addition, during the final illness period, families often direct all their energy and attention toward tending to the patient, delaying or inhibiting any advance psychological preparation for the impending death.[6] The multiple stresses and demands that the illness and its treatment have imposed on the survivors increase their risk for morbid bereavement outcomes.[5*,7*]

Anticipatory grief

Palliative care situations enable families to be forewarned about an impending death, permitting their preparation for the impending loss. Anticipatory grief refers to the process whereby survivors rehearse the bereaved role and initiate working through the emotional changes associated with a death.[4] It is generally thought that anticipatory grief mitigates the intensity of the grief reaction following the actual death, leaving the survivor less vulnerable to maladaptive reactions. However, the evidence on the adaptive value of being forewarned that a death will occur is inconsistent.[8] Some investigations have shown that bereaved who have had opportunity for anticipatory grief adjust better to their loss,[9*,10*] while other research has not demonstrated any benefit.[11*,12***] One factor that may mitigate any advantage derived from advance forewarning of the death is the circumstances leading up to the death. A long and protracted illness, or one marked by intensive caregiving demands, may impede the bereaved individual's ability to initiate preparations for the death and deplete personal resources for coping with the impending loss.[13*] Another risk factor is the development of premature grief, whereby family members socially and emotionally withdraw from the dying patient in advance of the death. This can result in the bereaved experiencing guilt after the death over having abandoned their dying relative.[2]

Experiencing death

In Western society, dying is 'medicalized' and the family is generally distanced from death.[14] Death in a home setting is unfamiliar. With the provision of palliative care, families are intimately exposed to the dying process. Anticipating its occurrence and the resultant responsibility associated with this event can induce considerable distress and anxiety. Families worry that they will be unable to address their relative's potential suffering at the end and express concern that they will be unable to cope with the challenges of being 'in charge' during this dying event.[6]

OVERVIEW OF THE GRIEF PROCESS

Freud's seminal essay on 'Mourning and melancholia'[15] provided the foundation for contemporary understanding of grief and bereavement. His work conceptualized mourning as a prolonged inner struggle to adapt to and accept an irreversible loss. Grief therapists have delineated four tasks that define the mourning process.[3***] The bereaved needs to: (i) accept the reality of the loss (i.e. face the reality that the person is dead, will not return and that reunion is impossible); (ii) acknowledge and work through the emotional and behavioral pain associated with the loss; (iii) adjust to an environment in which the deceased is missing (for the

widowed this involves coming to terms with living alone, facing an empty house, and managing finances alone); and (iv) withdraw emotional energy from the deceased and reinvest it in other relationships. These tasks are not necessarily performed in sequence. Overlap and revisiting of tasks can occur. The clinical evidence remains equivocal as to whether all these tasks need to be accomplished.[16***,17***]

The dual process model of coping with bereavement[18] represents an integrative approach to describing the ways bereaved individuals come to terms with a significant loss. It posits that the bereaved undertake both loss-oriented and restoration-oriented coping. Loss-orientation refers to dealing with or processing some aspect of the loss experience itself, particularly relating to the deceased. This is analogous to grief work. Restoration-orientation focuses on the secondary sources of stress that the bereaved need to deal with, such as changes in financial status or social loneliness, e.g. the bereavement tasks outlined above.[16***,17***] However, the dual process model introduces a third concept – oscillation. Coping with bereavement is posited to be a dynamic process, one in which individuals confront their loss some of the time and at other times avoid such confrontation. Oscillation is necessary to provide a balance to this process and prevent the adverse mental and physical costs arising with unremitted grieving.

Bereavement specialists and cross-cultural researchers[14,19,20*] have increasingly noted that understanding of the grief process has been strongly influenced by Western thought. Its applicability to non-Western societies merits reflection, given the fundamental world-view differences in how death is perceived in different cultures. For example, in Asian cultures, through practices such as ancestor worship, death represents a transition to a different state in which deceased relatives remain important participants in the world of the living and communication is still considered possible.[21*] Proponents of the dual process model stress that it accommodates individual, situational, and cultural variations in coping with bereavement.[18]

PHASES OF GRIEF

Immediately following a death, bereaved individuals are usually in a state of shock. They feel numb and experience disbelief over the event, even when the death has been anticipated, as in palliative care.[22] During this period, cognitions may be impacted. The bereaved may experience a sense of confusion and have difficulty concentrating.[3***,23***] During the acute mourning period, these initial grief responses give way to intense feelings of loss and longing for the deceased. It is not uncommon for the bereaved to feel a sense of the deceased's presence or to experience auditory or visual hallucinations about the deceased.[3***] The bereaved may also exhibit restless behavior, revisit places that relate to the deceased, and treasure or revere objects that

belonged to the deceased.[3***,24***] As the realization of the loss becomes more evident, the bereaved may engage in frequent crying spells, have difficulty sleeping, withdraw from other people, show little interest in outside activities, and experience a loss of appetite.[3***,9*,23***] Individuals who are grieving can experience a variety of psychological and physiological reactions of varying intensity and duration.[1***,3***,9*] The most commonly expressed emotions include shock, numbness, sadness, anxiety, loneliness, fatigue, anger, relief, and guilt. Bereaved individuals often report somatic complaints as well, such as weakness, lethargy, loss of appetite, tightness in the throat or chest, shortness of breath, and sleeplessness.

DURATION OF GRIEF

Although there is considerable variability in the rate at which individuals adjust to bereavement, the clinical and epidemiological literature support that in Western societies most bereaved return to a normal level of functioning 1–2 years after their loss.[1***,2,16***] Grief-related distress is generally highest in the first year following the loss, although elevated rates of distress can persist for more than 2 years. Societal mores can influence grief duration. For example, Taiwanese cultural ideology proscribes 'one man per lifetime' and widows are expected to grieve for the rest of their lives.[21*]

NORMAL AND PATHOLOGICAL GRIEF

Lindemann's landmark study of bereavement,[25*] following the Coconut Grove nightclub fire, focused attention on the intensity and duration of expressed grief. This work also introduced the distinction between normal and pathological grief as important dimensions in understanding the grief process. Grief that is chronic, persistent, intense, inhibited, or delayed is regarded as pathological or complicated.[9*] However, an understanding of what constitutes normal grief is heavily influenced by Western conceptions of death and dying and does not accommodate different cultural and ideological perspectives.[19] While there is consensus that grief is universally experienced, response to loss is culturally bound. Wailing, unrestrained crying, self-mutilation, or prostration may be common and acceptable means of expressing grief in some societies,[14] but regarded as indicative of an intense or severe grief reaction by other cultural groups.

VULNERABILITY FACTORS FOR ADVERSE GRIEF REACTIONS

The clinical and research literature on bereavement suggests a constellation of situational and individual factors that can affect the course and outcome of the grieving process.[1***,9*,26***,27***] A number of these factors are commonly present in palliative care situations.

Protracted illness

Bereaved relatives whose loved one suffered a long, lingering illness actually adjust more poorly to bereavement than those whose loved one died after a short illness.[28,29*] This outcome may reflect the impact of providing informal support and care during an extended illness and the stresses of having lived with a protracted illness course.[6,13*,30*]

Disease course

Terminal conditions that impact patients' functioning and quality of life, such as severe, chronic pain, are difficult for family members to witness. Their distress is exacerbated when they also feel helpless in alleviating or managing these conditions,[30*] further increasing their risk of severe grief reactions.[9*]

Stigmatized death

When death is from an illness that is stigmatized or associated with unhealthy or socially unacceptable lifestyles, such as alcoholism or drug abuse, the family may be less open about the cause of death or the circumstances leading up to the event. As a consequence, the naturally occurring support systems available to the bereaved may be less forthcoming. The family may also experience conflicting emotions or encounter difficulty resolving their feelings about the deceased. In communicable illnesses such as human immunodeficiency virus (HIV)/acquired immune deficiency syndrome (AIDS), the bereaved may be infected as well or may be dealing with multiple deaths or advanced disease of other family members.[31]

Nature of the loss

The death of a spouse is considered to be one of the most stressful life events, although the loss of a child is regarded as particularly problematic for the survivor to resolve.[1***] A high level of dependency or an ambivalent relationship (feelings of love/hate, need/resentment) between the deceased and the bereaved often culminates in a severe grief reaction and difficulty in accepting and resolving the loss.[32*]

Life circumstances

Vulnerability to poor adjustment is increased by the occurrence of additional severe stresses concurrent to the bereavement, such as multiple losses or life changes.[26***] Deficits in social support or restricted social resources can

also contribute to adverse grief outcomes. Limited financial resources prior to the death or declining income as a consequence of the death can precipitate problems in grieving. Widowhood can have especially adverse economic, social, and psychological ramifications for older adults and bereavement reactions may be severe.[13*]

Individual characteristics

The bereaved individual's preexisting physical health condition, history of substance abuse, and/or premorbid mental illness[32*] can contribute to adverse bereavement outcomes. Personality characteristics, such as low self-esteem or a low internal sense of control are also associated with increased distress after the death. In Western societies, men are at higher risk for bereavement related mortality; women experience more affective distress.

HEALTH CONSEQUENCES OF BEREAVEMENT

Bereavement can predispose people to physical and mental illness, precipitate suicide and death, and aggravate existing health conditions.[1***,2,33] In Western societies, the recently bereaved have been shown to display an increased incidence of depressive symptoms and somatic complaints, as well as changes in their endocrine, immune, and cardiovascular systems. Although most individuals eventually return to a normal level of functioning, bereaved individuals have higher rates of utilization of medical and mental health care services (i.e. increased hospitalizations, prescribed drug use, and physician and mental health clinician visits) compared with nonbereaved samples.[24***,34*] Bereavement is not a transient life crisis. It can have enduring negative consequences for some individuals. Some bereaved individuals, in an attempt to cope with their grief, intensely engage in behaviors that can be injurious to their health, such as alcohol or substance abuse.[35*,36*]

PRINCIPLES OF BEREAVEMENT SUPPORT IN PALLIATIVE CARE

There are five broad principles of bereavement support that apply in the palliative care setting: (i) view the patient and family as one unit of care, (ii) enable open discussion of illness and death-related concerns, (iii) provide emotional support, (iv) facilitate practical assistance, and (v) respect cultural, ethnic, and religious practices.

View patient and family as one unit of care

Palliative care offers the healthcare practitioner multiple opportunities to attend to the wellbeing of affected family members prior to the patient's death.[37*,38*] The terminal illness period is stressful to the family. Patients and families should be viewed as one unit of care. Attending to the informational, emotional, and practical support needs of the family may make the dying experience less stressful for the family, facilitate their grieving, and reduce their risk of adverse bereavement outcomes.[39***] As a secondary benefit, addressing family members' needs during this period can facilitate their remaining engaged in the patient's care provision.

Enable open discussion of illness and death related concerns

Attending to families' concerns about the patient's condition and care, and providing reassurance that appropriate therapeutic and ameliorative measures are being utilized, can comfort families and reduce later recriminations. Enabling open communication and discussion of emerging concerns can avert the development of future regrets, facilitating families' grieving process.[13*]

Provide emotional support

Supporting survivors in their grief during the terminal phase of the illness is also important in facilitating adjustment after the death. In palliative care, most families are aware of the nature of their relative's condition and its prognosis. Families can experience anger, sadness, regret, resentment or guilt regarding the illness, the consequent burdens they are required to assume, and the impending death. They may also feel isolated and alone. Families need to be given permission to express their feelings and be reassured that these feelings are normal.[13*]

A family's contact with the palliative care team often ceases with the patient's death. For many families this is a significant loss. Its impact can be lessened by a condolence card or brief sympathy call from a member of the care team. Anniversaries of the death or important family events are also times when grief is intensified.[24***] A follow-up note or call from the palliative team on these occasions may be beneficial.

Facilitate practical assistance

Families often become very involved in the dying patient's care, neglecting their own health and setting unreasonable expectations of what they personally should accomplish. It is common for families to be fearful about leaving the patient for any length of time, curtailing outside activities and cutting themselves off from their broader social network. The palliative care team may need to encourage them to respect and attend to their own needs.[13*] Assisting the family with arranging for respite services, or suggesting ways to mobilize other network members, with the goal of reducing the care burden on the family, are means of facilitating

needed practical assistance. Families may also require assistance in ensuring that issues related to the dying patient's finances and legal matters are attended to and that procedures for adhering to the patient's preferences for care at end of life are established (e.g. advance directives, health-care proxy).

Respect cultural, ethnic, and religious practices

Bereavement takes place within a social context in which rituals and customs provide for the sanctioned public articulation of private distress.[1***] When individuals are prevented from performing such activities, their grief can become complicated and their mourning prolonged.[40*] Institutional policies that limit children's visiting rights, restrict the number of visitors in a room, or bar the performance of special services and ceremonies can impede families from carrying out specific practices required at death. Terminal illness provides forewarning of the death. This affords the palliative care team an opportunity to become aware of and address any particular needs and requirements associated with specific mourning customs and rituals.

BEREAVEMENT RESOURCES, PROGRAMS, AND TREATMENTS

There is a plethora of supportive and treatment programs that have been developed to assist bereaved individuals through their grieving process. Efforts to establish evidence-based practice guidelines regarding the content, format, timing and targeting of bereavement services have been hampered by variations in the format and content of the bereavement services, small sample sizes, and the limited number of rigorously designed evaluation trials.[39***,41***,42***,43***,44***]

Most evidence-based reviews have not explicitly distinguished between bereavement services that are initiated or delivered during the terminal phase of the illness and services that begin after the death.[41***,43***,44***] However, recent best practice guidance offered by the National Institute of Clinical Excellence on Supportive and Palliative Care[39***] supports the value of initiating theory-based bereavement care during the terminal phase of an illness for those in need. Additional recommendations are to implement an ongoing assessment plan to enable the identification of those at risk and the matching of services to their needs.

Supportive services

Bereavement-related supportive services are provided in a variety of treatment modalities and venues. Hospice and palliative care settings routinely make available one or more types of bereavement support services to affected family members. Community groups, churches, and charitable organizations, such as Cruse Bereavement Care in the UK, also sponsor a range of services. Some programs are delivered by mental health clinicians; others use trained volunteers supported by professionals, such as the 'Widow-to-Widow' program in the USA. Supportive counseling, delivered individually or through a group session, helps to normalize the bereaved individual's experiences while also supporting their grief. Peer support and self-help groups involve bereaved individuals offering friendship and empathy of shared status. The duration of these various bereavement services can range from a single session or meeting to ongoing programs that are initiated during the terminal illness period and continued after the death. Although the clinical evidence base is inconclusive,[41***] participant satisfaction is high and clinical and anecdotal reports document the efficacy of these types of services in reducing bereavement distress, supporting grief, and facilitating mourning.[1***,2]

Preventive intervention programs

Consensus is stronger regarding the utility of theory-based bereavement interventions developed for individuals at high-risk for complicated or pathological grief or other adverse bereavement outcomes.[9,39***,41***,44***,45***] Palliative care settings provide the opportunity to initiate delivery of preventive interventions during the terminal phase of the illness, providing targeted support and counseling to individuals at increased risk[39***] with the goal of reducing their risk factors and increasing protective factors.[45***] Screening tools such as the Index of Bereavement Risk[9*] are helpful in identifying individuals at 'high risk'. Using appropriate assessments ensures that this type of resource is delivered to those who will derive the maximum benefit.[46*]

Psychotherapeutic interventions

Most bereaved individuals will not require psychotherapy or specialized grief therapy.[3***] However, persistent depressive or somatic symptoms that do not lessen in intensity over time; prolonged social withdrawal; expressed difficulty adjusting to the loss; and/or engaging in health-endangering behavior, such as drug or alcohol abuse, are triggers for referral to a mental health professional for evaluation.[1***,2]

Pharmacological therapies

Pharmacological treatment may be appropriate in some circumstances. Antidepressants, tranquilizers, and sedatives are prescribed to lessen the intensity of a variety of persistent and severe bereavement-related reactions (e.g. depression, anxiety, sleeplessness) that impair functioning and exacerbate the bereaved individual's distress. While it may be clinically indicated to intervene pharmacologically to

remediate intense bereavement-related reactions, such treatments warrant discretion.[1***] A review of case–control studies demonstrated a beneficial effect for pharmacological treatment of depression and sleep quality. However, these benefits persisted only while the subjects received the medication and there was no demonstrated impact on their resolution of grief.[41***]

CONCLUSIONS

Although there may be considerable individual variation in the experience and expression of grief, grieving is a normal response to a significant loss. Understanding of the grief process has been substantially influenced by Western thought. Consequently, clinicians should be careful to not ascribe pathological or abnormal labels to mourning responses when the cultural meaning or appropriateness of these actions are not well understood. Although the cognitive and emotional responses abate over time, some bereaved are at increased risk for psychological and physical health consequences following their loss. Clinicians involved in palliative care are in contact with families at a point of heightened vulnerability. The provision of emotional support and compassionate care by the healthcare team during this stressful period may facilitate families' grieving process and reduce adverse bereavement consequences.

Grief specialists[45***] advise, supported by clinical evidence,[41***,43***,44***] that preventive interventions are not necessary for most bereaved individuals. Consensus opinion is that such an approach may do more harm than good, impeding the activation of the bereaved individual's natural support systems and disrupting the pattern of the normal grieving.[43***,44***] Only a small proportion of individuals experience grief reactions of such severity or chronicity that necessitate professional intervention. An understanding and appreciation of grief and the individual and situational factors that may complicate mourning will aid clinicians in determining when professional intervention is indicated. As Raphael et al.[45***(p. 587)] succinctly state: 'There can be *no justification for routine intervention* for bereaved persons in terms of therapeutic modalities – either psychotherapeutic or pharmacological – because grief is not a disease'.

Key learning points

- Grief is expressed with a constellation of psychological and physiological reactions.

- Grieving is a process comprised of numbness, searching and pining, depression and recovery.

- Normal grief and mourning practices reflect cultural and ideological belief systems.

- Bereavement can predispose some people to physical and mental illness and precipitate death.

- Benefits of anticipatory grief are mitigated by care provision, illness duration, and cause of death.

- Patients and families should be viewed as a unit of care.

- Attending to carers' needs during the terminal phase of illness can forestall adverse outcomes.

- Facilitating culturally appropriate death rites and mourning practices benefits the bereaved.

Children of palliative care patients

ESTELA BEALE

INTRODUCTION

Children of palliative care patients present unique challenges for the palliative care professional. This group of children represents a hidden high-risk group whose needs are often minimized or overlooked by overwhelmed parents and are unknown to most of the medical staff. The reasons for the neglect of this population vary. There is a common belief among parents and caretakers that children are generally adaptive and that they will adjust to their circumstances. Also, parents and caretakers sometimes voice the belief that children, particularly younger ones, do not really understand what is going on and, therefore, it is best not to discuss the situation with them.[1–5] In all of these cases, the children who are about to lose a parent often do not receive the information and attention they need at this critical time. Thus, it is important that members of palliative care teams be aware of the needs of these children and provide appropriate intervention.

Many factors must be taken into consideration in determining the best way to help a child cope with their parent's terminal condition and adjust to the idea and subsequent reality of the parent's death. However, the short-term and long-term bereavement process of these children may be considerably mitigated by early intervention during the parent's terminal phase. Effective intervention must be appropriate to the developmental age of the child. Other critical factors that strongly influence children at this time are their relationship to the well parent, family characteristics, and the stability of their home and social environment.

This chapter focuses on children of parents with terminal cancer. A patient with terminal cancer presents the palliative care professional with a unique set of situations that can create severe distress in children, including dramatic fluctuations of the patient's symptoms due to the cancer treatment or the course of palliative medication, and the potential of an extensive terminal phase with increasingly alarming physical and mental deterioration. Communicating the bad news of a cancer diagnosis is difficult enough for doctors, so it is not surprising that parents dying of cancer, who are coming to terms with the existential issues surrounding dying, are often at a loss as to when, how, and what to tell their children about cancer and death.[6–9] It often falls to a member of the palliative care team to advise and assist the parents in comforting and communicating with the children at this critical time.

The research and clinical experience of a wide range of medical professionals from many countries and cultures is providing a foundation to assist us in developing effective interventions for children of palliative care patients. This chapter reviews the research concerning the main issues that affect these children and the types of intervention that appear most promising.

FACTORS INFLUENCING A CHILD'S RESPONSE TO A TERMINALLY ILL PARENT

Developmental age

Throughout the past several decades, developmental theorists have tried to understand the impact of parental loss on a young child. Attachment theory was first espoused by Bowlby[10] who, in groundbreaking research, demonstrated that when primates are separated from the mother early in life their reaction escalates from a state of protest to marasmus and death. Since then other researchers have confirmed the

instinctual roots of attachment, which assures the safety of infants who use intuitive behaviors to engage their caretakers and to guarantee their caretaker's presence and attentiveness. Internalization of primary caretakers is a process that becomes established by the time a child is 2 or 3 years of age. Once this process of internalization is accomplished, the child can sustain prolonged separations yet retain the memory of the parent. For the child to be able to obtain optimal emotional, social, and psychosexual maturity, a predictable, caring environment is required.

Separation from the primary caretaker produces anxiety, which is manifested differently depending on the child's developmental stage, and is exacerbated by a terminal illness. Specific adverse reactions at this age tend to be bodily, such as sleeping and feeding difficulties, constipation, and bedwetting.[11] However, there is still much discussion about whether or not such young children are capable of mourning.[12,13] By 5 years of age, most children can distinguish between a short separation and death. At this point some characteristics of personality are most likely established. In addition, a variety of other factors will now influence the child's development, such as the relationship to the well parent, the family structure, and the child's general social circumstances, as well as genetic makeup. These children often become overprotective of the well parent and may withhold showing them any signs of distress. At the death of the parent, it is characteristic of this age group for there to be increased activity, often resulting in behavioral problems.[11] Several lines of research indicate that children from 5 to 11 years should be informed that the parent is terminally ill and told what to expect.[14–22]

Developmental factors also shape the adolescent's response to the terminal illness of a parent. Support by health professionals, coping strategies, and the adolescent's own mastery of adaptive tasks are posed by the terminal phase of the parent's illness.[23] Open communication between parents and children is of utmost importance.[24] Often the parent's illness creates the need for greater assistance in the home that clashes with the adolescent's developmental tasks of withdrawing and achieving emotional independence from the parents. An adolescent's inconsistent behavior and mood swings typically become exaggerated under the stress of a parent's illness. The adolescent's advanced cognitive abilities may lead to more intense grief than younger children due to their increased ability to comprehend the enduring consequences of death. Some adolescents experience prolonged emotional disturbance during the parent's illness and for several years after the parent's death. These adolescents tend to exhibit severe depression, or alcohol and/or drug abuse, or refusal to attend school, and oftentimes suicidal ideation.[24–29]

Researchers who have used development-derived age categories to study the impact of development on children's response to terminal illness and death of a parent have reported the emergence of behavior patterns. Further clarification of such patterns could help the clinician determine more effective age-specific interventions.[24,28,29]

Situational factors

Situational factors that can affect a child's response and adjustment to the death of a parent have been gaining attention among researchers. Raveis et al.[30] provided a comprehensive review of these studies and conceptualized situational factors into three broad domains: background characteristics, factors associated with the parent's death, and attributes of the family environment.

Background characteristics include the background of the child, the parents, and the family. The most commonly studied characteristics include the age and gender of the child and the gender of the deceased parent. Less studied characteristics include birth order, family size, and the presence of siblings. Factors associated with the parent's death include length of illness, advance knowledge of the impending death, and the degree to which the child was aware that the parent would die. Particularly in the terminal illness period, factors that appear to impact the child's grief process include stress, alterations in lifestyle, the absence or withdrawal of the ill parent, changes in the household activities, and economic stress of the family due to a prolonged illness. The primary attribute of the family environment is the surviving parent's distress level and adjustment to the death. The ability of the surviving parent to care for the child at this time is critical.[30–33] In a longitudinal study of 25 preadolescent children living on a kibbutz who had lost their fathers in the Arab–Israeli war of 1973, Elizur and Kaffman found that pretraumatic family and environmental factors were significant determinants of the duration and severity of bereavement.[14] Their findings demonstrated that childhood bereavement symptoms tend to become exacerbated when the stress of the loss is compounded by pertinent child, family, and situational factors. In most cases, the combination of several factors determined the intensity of the bereavement response rather than the exclusive influence of any single factor. The results suggested that the child's emotional response during the early months of bereavement is largely determined by pretraumatic antecedent variables, whereas posttraumatic factors became more influential during the years following bereavement. This study points out the importance of the availability of a supportive, stable family environment as well as the accessibility of professional intervention.

Kranzler et al.[20] reported on the acute bereavement reactions of a cohort of preschool-aged children who experienced the death of their mother or father. The aims of the study were to describe the children's acute state, to examine developmental influences that might impact on their vulnerability, and to identify important outcome mediators. The study supported both the importance of preexisting relationships in the family, and the effects of ongoing adversity, especially depression in the surviving parent. It also provided acute bereavement data that support the retrospectively determined findings of Harris et al.[34] and Breier et al.[35] who concluded that although the death of a parent creates a vulnerability, ongoing provoking agents,

particularly inadequate parenting after the loss, increases the child's risk. The surviving parent's ability to cope with his or her own grief and capacity to respond to the emotional and other needs of their young children is critical. The young child's sensitivity to deficits in parental caretaking may create a particular vulnerability to parental loss.

For school-age children, the social environment can also play a significant role in the child's adjustment to the death of a parent. By the time a child is 10 years old, he or she has usually developed a social network that includes relationships with teachers, classmates, and friends outside school. A study by Lowton and Higginson[37] provides suggestions for creating a healthy social environment for a grieving child. The surviving parent or caretaker should meet with the child's teachers and parents of his or her friends to make sure they are aware of the situation so that they will understand any marked changes in the child's behavior and provide the support needed when they are unavailable. In addition, they should know that although the child needs to grieve, he also needs to reestablish normal relationships with friends and classmates.[37] Given the amount of time a child spends in school each day, teachers and classmates can play a major role in the child's bereavement process. The teacher can provide a safe place for the child to express their feelings.[38] For most children, loss and fear go hand in hand, and the fearful child cannot concentrate in school. The key to a teacher helping a grieving child is the appreciation that recovery from loss requires the reshaping of existing relationships with family members, classmates and teachers. In dealing with loss in the classroom, the teacher should pay close attention to the child's mood, their play themes, stories, and drawings. The better the teacher can understand the child's feelings, the easier it will be to comfort and support them. Each child who has experienced loss should be free to communicate his or her pain and bewilderment only when they are ready to do so. By being attentive, sensitive, and supportive, a teacher can become an important emotional bridge for a child at times of loss.[39] The teacher can also help the child's classmates to communicate messages of condolence and to understand the changes in their classmate's behavior. It is important that children understand that their grieving friend may act differently, may withdraw, or seem angry, but that this does not mean that these changes will last. The teacher should explain to children that their regular friendship may be an important source of support for their grieving classmate.[40] A healthy social environment, in and outside school, provides a grieving child with opportunities to reestablish relationships and to feel a much needed sense of connection and normalcy.

Communication

Studies by Waechter and others provide support for the belief that giving a child opportunities to discuss their fears does not heighten anxiety. Also, providing the child with understanding and with acceptance of their feelings and conveyance of permission to discuss any aspect of the parent's illness can decrease feelings of isolation and alienation, and dispel the sense that the illness is too terrible to discuss.[17–19] Waechter points out the striking dichotomy between the child's degree of awareness of the prognosis, as inferred from his or her imaginative stories, and the parent's belief about the child's degree of awareness of the parent's prognosis.[19] This dichotomy suggests that knowledge is communicated to the child by the changes that they encounter in their total environment after the diagnosis is made, and by their perceptiveness of various nonverbal clues. This disparity presages a deepening isolation that is exacerbated when the child becomes aware of the evasiveness that meets expressions of his or her concern.

Hilden et al.[21] found that when given the opportunity to communicate, children can conquer their fears as well as express their love in the terminal phase of a parent's illness, and that honesty is indeed the best policy with children of all ages. In this way, the reality of the situation, no matter how awful it is, can be shared in an open manner. Trying to protect children from knowledge about what is really happening often confuses the child even more than circumstances alone and escalates concerns about events that are beyond their control. A study conducted by Pfeffer et al.[22] reported that the children in their sample were likely either denying or reluctant to acknowledge problems in the emotional domains assessed, for reasons that were directly or indirectly related to the loss of their parent. For example, they may have been reluctant to acknowledge their own feelings of depression for fear that doing so would upset other family members.

However, reports of bereaved parents regarding their children's psychological distress and symptoms of depression revealed lower incidences than found in the children's reports of their own distress and psychiatric symptomatology. Bereaved parents may be so overwhelmed by their own grief and mourning that they are not fully aware of the level of distress of their children, or they may not be able to cope with their children's psychologically distressed states. There should be no curtain of silence drawn around the child's worst fears.[16,18,33,41,42]

Children who are forewarned of the imminence and inevitability of death have lower levels of anxiety than those who are not, even children within the same family. The practitioner needs to be aware that some children may need specialized help in recovering from depressive and other symptoms that are associated with bereavement. An editorial by Kroll et al.[15] cites several studies specifically related to parents dying of cancer. These studies reiterate the importance of communication between parents and children and provide support for the claim that parents underestimate the impact of a terminal illness on their children. The results suggest that emotional restraint in the surviving parent made it difficult for the child to express

feelings, which led to a sense of intensified loneliness, and increased anxiety and confusion.[32] Elizur and Kaffman[14] and Kranzler et al.[20] found that the ability of bereaved children to report grieving emotions correlated significantly with improved functioning.

SHORT–TERM AND LONG–TERM EFFECTS OF CHILDHOOD BEREAVEMENT

There has been some progress in assessing the short-term effects of the bereavement process in children. The most consistent finding in the literature is the association between parental bereavement and depression. The results of several studies cited in a meta-analysis by Lutzke et al.[43] compared bereaved children 1–12 months after a parent's death with a comparable nonbereaved sample of children or adolescents. These investigations revealed higher rates of depression in the bereaved children.[20,44,45] The differences were more striking in the studies that assessed overall negative affects such as sadness, crying, or moodiness than those assessing symptoms more typical of clinical depression. Other studies revealed a relationship between anxiety withdrawal and childhood bereavement, particularly among adolescents 1–6 months after a parent's death.[46–49] Studies of bereaved children 1–2 years after parental death have shown small to moderate differences of self-esteem and academic success between bereaved and nonbereaved children.[47,50,51]

Studies regarding the long-term effect of childhood parental loss have been inconsistent or inconclusive.[45,48] The evidence from many of these studies provide mixed evidence for the changes in psychological symptoms of bereaved children over time.[43] Some of the studies indicate a significant difference in depression and suicide in adults bereaved in childhood,[52–54] whereas other studies show no significant difference in this group.[55–57]

There are several reasons for the lack of consistent results and agreement among researchers studying the short-term and long-term effects of bereavement on children. These range from the use of nonrepresentative samples of bereaved children to small sample sizes to the use of a wide range of methods for data collection. which makes it difficult to compare otherwise similar studies.

INTERVENTIONS FOR THE CHILDREN OF PALLIATIVE CARE PATIENTS

A study by Sivesind and Beale[58**] showed a high percentage of children of a terminally ill parent sought reassurance, and most of them considered themselves to be caregivers of their dying parent. Faced with the parent's obvious deterioration and fear of the parent's death, a strong wish to do everything possible to keep the parent alive was triggered. It also appeared that while the child was lost in frenetic

activity he or she was not faced with as much anxiety and grief as might otherwise occur or as might be expected.

In contrast to the standard account of developmental stages, small children demonstrated a remarkable awareness of the parent's medical condition and its implications.[59***] Disruptive behavior alternated with some desperate attempts to be helpful. The helpfulness was always associated with the wish to help the parent get better. These findings are consistent with the findings of Siegel et al.[60*] The latency age group tended to present academic difficulties, which the parents tended to relate to the disruptions caused by the cancer. Among children whose families were secure, this provided enough stability for the children to free themselves from the worries of the illness and continue with their day-to-day life. Those in situations where financial or family problems prevailed felt much more at sea and the potential loss was one more assault to throw them into a state of helplessness. The children from this group attached themselves to the therapist, recognizing him or her as one trustworthy person in their life. Results of this study suggest that children with dying parents manifest significant distress as well as a greater understanding of their parent's illness than is usually suspected. Three types of intervention were found to be useful: normalization for both patient and family (50 percent), expressive-supportive counseling (100 percent), and occasional cognitive reframing (35 percent).

In an article by Black,[11***] the author states that:

> Children are rarely prepared for the death of a parent or a sibling, and yet we know from studies of bereaved adults that mourning is aided by a foreknowledge of the imminence and inevitability of death.[42] Children who are forewarned have lower levels of anxiety than those who are not, even within the same family.[41]

After the death of the parent, she suggests that young children in particular may need to see the dead parent, but that it does not have to be the well parent who accompanies the child during this viewing. This could be done by a member of the care team whom the child feels comfortable with. A controlled trial of family therapy with children bereaved of a parent showed that the post-bereavement morbidity of 40 percent at 1 year could be reduced to 20 percent by six sessions of family meetings.

These meetings focused on helping the family share their mourning with each other and encouraging communication about the dead parent.[61**,62*] The author believes that preventive counseling is properly the responsibility of the primary care team, utilizing the resources of bereavement counseling services as necessary. Finally, the practitioner needs to be aware of the small number of children who may need more specialized help in recovering from depressive or other symptoms that may be associated with bereavement.

Christ[29*] developed a psychoeducational intervention to facilitate the adjustment of children to the terminal illness and subsequent death of a parent. The intervention emphasized a parent-guidance approach.[63*] As part of this

intervention, a telephone supportive intervention was also developed as a control condition.

> A social worker telephoned the well parent every four to eight weeks. The goal of this intervention was to maintain contact with the well parent between psychological evaluations, to provide referrals to community based therapists or support groups when such a referral was requested, or to appropriate hospital personnel when questions such as uncertainty about planned treatment procedures, billing, or untoward reactions of the ill parent were raised by the well parent. Since the data generated by this intervention were insufficient for qualitative analyses, only data from families who participated in the psycho-educational intervention were used for the qualitative arm of the analyses.

On the basis of clinical experience, the interventions started during the terminal illness. The researchers found that the family member's responses differed substantially during the terminal stage of the illness from responses following the death. 'This clinical experience was confirmed by the quantitative analyses of depression and anxiety measures that indicated that children were significantly more anxious and depressed during the pre-death period than at the end of the reconstitution stage'.[60*,63*]

A typical psychoeducational parent-guidance intervention spanned about 14 months and included six or more 60–90-minute therapeutic interviews during the terminal stage of the illness and six or more after the death. The therapeutic engagement was emphasized during the second interview. It was the family's option to include the patient in these interviews. At each meeting, ways of handling problems with the children were discussed. A separate interview was then done with each child. This was followed by an informing interview with the parent in which the parent was given an assessment of the children's adaptation to the illness. A family interview that included the well parent and all of the children in that family was then done and was followed by two or more biweekly to monthly parent interviews. Beginning 2–4 weeks after the death of the parent, a similar schedule of interviews was followed. Additional child and/or family interviews were scheduled as requested.

After the final interview, the social worker initiated bimonthly to monthly telephone contacts with the surviving parent until the final post-death psychological assessment was completed about 14 months after the death of the parent. Additional telephone contacts were scheduled if significant family crises emerged either during the psychologist's final assessment or during the social worker's final telephone contact. Finally, if necessary, individual parent, child and/or family sessions were offered.

Dr Paula Rauch is the founder of a parent-guidance program at Massachusetts General Hospital called 'Parenting at a Challenging Time' (PACT). The program provides individual and group parenting support by child psychiatrists and psychologists for patients with cancer, and their spouses and children. Of the program Dr Rauch says, 'I tell parents – because it's true – that they are the experts on their children. My role is to be a co-pilot navigating with them the unfamiliar waters of a life threatening illness.' Through lessons learned from this program for adults with cancer, Dr Rauch has developed a series of guiding principles for supporting children and parents facing cancer.[64***]

Hahn et al.[33**] developed a parent-guidance model of communicating the parent's terminal illness to children to try to positively affect the children's adjustment process to the terminal illness and death of a parent due to cancer. The specific goals of the intervention were to facilitate the competency of the parents and increase communication among the family members about the illness and impending death. The intervention consisted of 3 hours of providing information, advice, and communication training to both parents. The authors report that this model seems promising and points to the importance of a standardized intervention program for children with a terminally ill parent.

CONCLUSIONS

Several themes emerge from these studies and are relevant to both the short-term and the long-term care of children who experience the death of a parent from cancer. Healthcare professionals who intervene should be aware of these themes:

- Previous family history affects the child's bereavement process.
- A child's increased anxiety is directly correlated with a lack of information about their parent's cancer diagnosis.
- Anxiety increases when information is available but there is no opportunity for discussion with the child.
- Children of parents with cancer are at a higher risk of psychological disturbance.
- A large percentage of bereaved children experience a major depressive disorder in adulthood.
- Meeting with a mental health professional provides an avenue for supportive discussions, which in turn model for the family how discussions can be conducted to clarify issues, dispel fears, bring people together, or plan for the future.

It is important to remember that making recommendations to families in such a situation is difficult. There is no clear-cut solution for dealing with a family's reaction to terminal cancer. When a parent is dying of cancer, discussions among parents, children, and all other adult caretakers are important. However, these discussions are part of a process that should begin when the patient is first aware of their terminal condition. This may coincide with their referral to a palliative care team. The mental health professional should contact the family at this entry point and

establish a connection. An assessment of the parent's adaptation to the illness, and of the family and other support systems is important. The children should be assessed independently to determine developmental age, level of information, adaptation to the critical situation, understanding of facts and wishes and fantasies about the future. Finally, the interventions have to take place before despair or resignation sets in so there is enough motivation to accomplish a higher level of communication and possibly resolution of conflicts before death is imminent.

Interventions for children of palliative care patients and their families have two different aspects: (i) the structure of the meeting (or the form) and (ii) the content. The structure determines where the meeting takes place, when it happens, who is present, and how long it takes. The site should be comfortable, quiet, and relatively private so there are no distractions or interruptions. The family and the professional should meet when the patient first enters the palliative care service. Ideally, the ill parent should be conscious and have enough energy to be able to connect with the children as well as to continue participating in whatever limited way in their lives. Time should be sufficient for the discussion so that the meeting is not ended prematurely. The professional acts as a consultant to the family by promoting disclosure, clarifying the goals of the meeting, and eliciting information from the different participants, especially the children.

The content of the meeting is determined by the discussion, which is not arbitrarily confined to this situation but uses this time to revisit events. It is of primary importance to explore the information, speculations, and conclusions that the children have reached so far. This provides a springboard for clarifications, more information, and beginning a discussion of the ill parent's prognosis. When this is new information to a child, he or she will need time to react and possibly talk about feelings. It is also important to pay attention to the child's tolerance for information and pace the discussion based on the child's ability to absorb. The child may not want to hear or continue the discussion. The challenge is to know how much to push without assaulting the child with unwelcome facts and when to back-off and wait.

This discussion is personal, intimate, and private, requiring a great deal of acceptance and support. The professional will model this through empathetic statements and reassurance. This is a time when the expressions of love, regret for the truncated life, gratitude, and reassurance of unending memory will solidify the bonds and, paradoxically, facilitate the ability to let go. As this is a very personal, intimate subject, parents are ideally the ones to have this conversation with the child. However, parents are so often burdened with the weight of the illness and all of their other responsibilities that they are not able to take on this task. As previously stated, the two parents, or just the well parent with a professional assistant, may create the optimal situation to clarify issues, provide reassurance, intensify trust and attachment, and prepare the child for the final farewell.

ISSUES FOR THE FUTURE

The research studies, theories, intervention strategies, and guidelines discussed above are providing a body of knowledge and clinical experience from which we will be able to develop more effective intervention strategies for the children of palliative care patients.

Many difficulties are associated with framing these types of study – the large number of variables involved, the difficulty of determining appropriate control groups, small sample sizes, etc. However, there is general agreement among investigators from different countries and cultures that early intervention for children of palliative care patients holds great hope for positively affecting these children's bereavement process and ultimately their adjustment into adulthood to their childhood experience of losing a parent. Much more research is needed in this area.

Key learning points

- Previous family history and social circumstances affects the child's bereavement process.

- A child's increased anxiety is directly correlated with a lack of information about his or her parent's cancer diagnosis.

- Anxiety increases when information is available but there is no opportunity for discussion with the child.

- Children of parents with cancer are at a higher risk of psychological disturbances.

- A large percentage of bereaved children experience a major depressive disorder in adulthood.

- Meeting with a mental health professional provides an avenue for supportive discussions, which in turn model for the family how discussions can be conducted to clarify issues, dispel fears, bring people together, or plan for the future.

- The reactions of the healthy parent to the spouse's illness are critical to the children's and the patient's adaptation to the illness and to the loss.
