Contents

O man! Take heed!
What says deep midnight's voice indeed?
"I slept my sleep—,
"From deepest dream I've woke, and plead:—
"The world is deep,
"And deeper than the day could read.
"Deep is its woe—,
"Joy—deeper still than grief can be:
"Woe says: Hence! Go!
"But joys all want eternity—,
"—Want deep, deep eternity!"

Friedrich Nietzsche
Thus Spake Zarathustra
The Drunken Song, Section 12

About the Editor

H. James Birx, Ph.D., D.Sci., is professor of anthropology at Canisius College in Buffalo, New York. He received both his M.A. in anthropology and Ph.D. with distinction in philosophy from the State University of New York—University at Buffalo. His writings and lectures in natural science and process philosophy embrace both a cosmic perspective and an evolutionary framework. During the past 40 years, his teaching experience has included biological anthropology, sociocultural anthropology, forensic anthropology, theories in anthropology, and interpreting evolution.

Born in Canandaigua, New York, Birx grew up on a nearby farm and attended public schools in the East Bloomfield Central School District. During these years, he was greatly influenced by motion pictures, which introduced him to prehistoric life forms, ancient civilizations, and the exploration of outer space. Such films as *King Kong* (1933), *Quo Vadis* (1951), and *2001: A Space Odyssey* (1968) resulted in his having a lasting interest in paleontology, anthropology, and astronomy.

At the State University of New York at Geneseo, Birx was introduced to the academic discipline of anthropology, as well as serious music (particularly opera) and philosophy. His reading of the compelling works of Charles Darwin and the neo-Darwinians of the 20th century solidified a lifelong commitment to the factual theory of organic evolution and its far-reaching implications for understanding and appreciating the place our recent species occupies in this dynamic universe. However, he became aware of the crucial distinction between the fact of evolution and those different interpretations of this process that are given in science, philosophy, and theology.

At the State University of New York–University at Buffalo, Birx furthered his studies in anthropology, specializing in human craniometry. He was particularly interested in fossil hominids and the great apes. Next, under the guidance of world-renowned distinguished professor Marvin Farber, Birx completed his doctoral degree in philosophy with a thesis on Pierre Teilhard de Chardin. His ongoing focus on evolutionary thought had expanded to include such diverse thinkers as Samuel Alexander, Henri Bergson, Giordano Bruno, Marvin Farber, Ernst Haeckel, Stephen W. Hawking, Ernst Mayr, Friedrich Nietzsche, Herbert Spencer, and Leslie A. White.

Extensive worldwide travels have taken Dr. Birx to scientific sites and academic conferences from Australia to Russia. His research interests have taken him to Athens, Ayers Rock (Uluru), Cairo, the Galapagos Islands, Giza, Koobi Fora/Masai Mara, Machu Picchu, Rarotonga, Rome, Stonehenge, Teotihuacan, Uxmal, and the Wyoming Dinosaur Center (among many other significant locations).

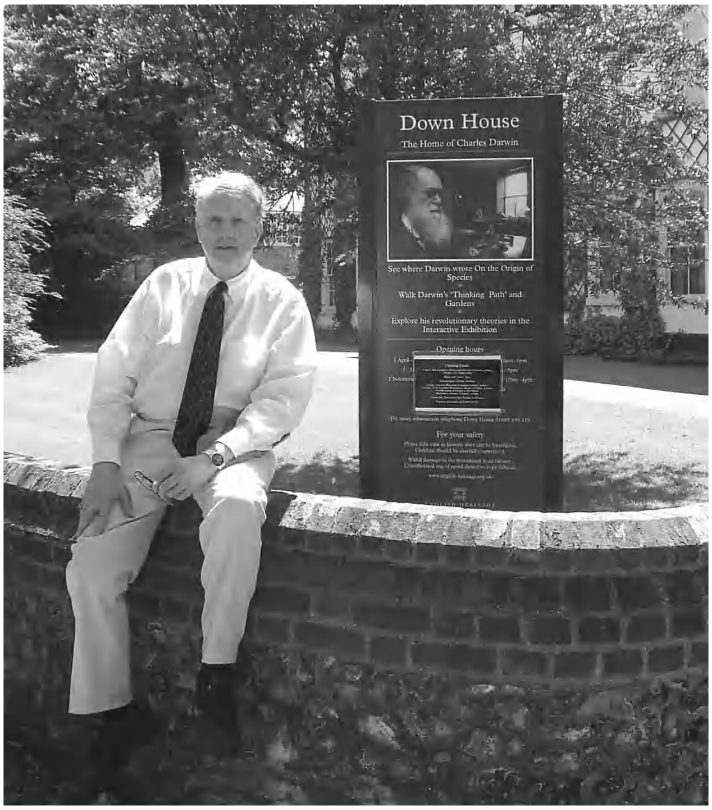
Dr. Birx has been a visiting scholar at the University of Cambridge and twice at Harvard University. He has also given invited presentations at Harvard, Princeton, Yale, MIT, Johns Hopkins University, University of Oxford, University of Hawai'i at Manoa, University of Kansas, University of Montana, University of San Francisco, Rockhurst College, University of Auckland, Tacamoa Theological College in Rarotonga, Trinity College in Dublin, University of Zaragoza, Catholic Academy Schwerte in Germany, both the Free University and Humboldt University in Berlin, University of Nis in Serbia, Comenius University in Slovakia, Moscow State University, Ludwig Maximilian University of Munich, Max Planck Institute for Evolutionary Anthropology in Leipzig, and both the Jagiellonian University and the Pontifical Academy of Theology in Krakow. He has also given invited presentations for the New

York Academy of Sciences, the Russian Academy of Sciences in both Moscow and St. Petersburg, and the Slovak Academy of Sciences in Bratislava. Dr. Birx has organized conferences at St. Petersburg State University and the State Darwin Museum in Moscow, among others. He has been an invited conference participant in Australia, Canada, Costa Rica, Egypt, England, Germany, Greece, Mexico, New Zealand, Panama, Slovakia, and Spain.

Dr. Birx has published over 400 chapters, articles, introductions and reviews, authored six books, and edited 11 other volumes, receiving awards for both his *Theories of Evolution* and the five-volume *Encyclopedia of Anthropology*. His other works include *Human Evolution*, *Interpreting Evolution: Darwin & Teilhard de Chardin,* and the scientific monograph *Craniometry of the Orchid Site Ossuary.* Recently, in Germany, he was one of the editors for and contributors to *Eugenik und die Zukunft*, *Pierre Teilhard de Chardin: Naturwissenschaftliche und Theologische Perspektiven Seines Werks,* and *Wagner und Nietzsche: Kultur-Werk-Wirkung*. He is presently editing the two-volume *21st Century Anthropology: A Reference Handbook* for Sage Publications.

Dr. Birx was the recipient of the 2003 Professional Achievement Award from the State University of New York at Geneseo, where he holds the title distinguished research scholar and where the annual H. James Birx Distinguished Scholar Award has been established. He is also a research associate at the Buffalo Museum of Science and a member of both the scientific board of the Nietzsche-Forum Munich and the international scientific advisory board of the Ethics Center at the Friedrich Schiller University of Jena in Germany, where he was a visiting professor for several summers. His professional listings include *Who's Who in the World.*

Birx has been interested in time since childhood, when he first learned about dinosaur fossils and distant stars. This encyclopedia and other present writings reflect an outgrowth of his ongoing interest in science and philosophy. Anticipating a neo-Enlightenment, Birx's own ideas include the will to evolve, dynamic integrity, emerging teleology, *Homo futurensis,* exoevolution, and cosmic overbeings.



H. James Birx, Charles Darwin's Down House/Museum in Downe, Kent, England.

Introduction

What is time? Did it have a beginning? Will it ever end? These are profound questions that have been asked by serious thinkers over the centuries, from early speculations among the ancient Greeks to the startling discoveries in the modern sciences. Both philosophers and theologians have offered dynamic worldviews to accommodate new facts and ideas about time and change. Because of its elusiveness, time still challenges those individuals who strive to understand and appreciate the flux of reality and the pervasive influence of time on all objects and events within it (including our own species). Perspectives on time range from subatomic particles to cosmic evolution. Temporal changes may encompass merely attoseconds or billions of years. Remarkable advances in technology, particularly in telescopes and microscopes, along with rapid improvements in computers, have greatly increased our scientific knowledge of this universe in general and our planet in particular. The history of life on Earth stretches back about 4 billion years, while human culture began less than 3 million years ago. Even so, this expanding cosmos is expected to endure for billions of years into the future. And, no doubt, human views about time will change over the coming centuries if our species survives.

This encyclopedia surveys those major facts, concepts, theories, and speculations that infuse our present comprehension of time. Its inclusive orientation recognizes the contributions of not only scientists and philosophers, but also theologians and creative artists from various fields. Especially significant are the temporal frameworks that were offered by Charles Darwin (1809–1882) and Albert Einstein (1879–1955). To grasp the modern awareness and appreciation of time requires that an individual embrace both evolutionary biology and relativity physics. The awesome perspective of cosmic evolution now includes such incredible objects as quasars, pulsars, and black holes. The human mind struggles to glimpse an evolving universe with billions of galaxies, each with billions of stars. When looking beyond our planet into outer space, one actually sees this universe as it existed millions of years ago; as such, one is gazing back into time. Furthermore, when one digs deep into the earth, one is also going back into time: Rocks, fossils, and artifacts are the remains of evolutionary time.

Ideas and Perspectives

The ancient Greeks pondered time and change. Of special importance was the idea from Heraclitus that this cosmos is endlessly changing, manifesting ongoing cyclical patterns. Later, Plato and Aristotle interpreted this universe in terms of geometry and biology, respectively. A philosophical dispute emerged as to whether reality is a static being in which change is an imperfection or an illusion, or an eternal becoming in which permanence is an illusion. Since antiquity, ingenious attempts have been made to synthesize change and fixity in a worldview that does justice to both. Such attempts are found in the cyclical cosmologies of Eastern philosophies.

With the coming of Christianity, religious thinkers attempted to reconcile an eternal and perfect personal God with a temporary and imperfect material universe. Concerning time, different beliefs emerged about the divine creation of this finite cosmos and its ultimate destiny. Saint Augustine of Hippo and Saint Thomas Aquinas offered subjective and objective views of time, respectively. For both, the origin of this universe was held to be an event that occurred only several thousand years ago. This created cosmos had the earth at its center and the human being occupying a special place in static nature. The end of time was held to be in the near future. Until the emergence of modern astronomy and physics, earlier believers could never have imagined either the vast age of this universe or the complex history of life forms on our planet.

During the Italian Renaissance, the artistic genius Leonardo da Vinci (1452–1519) reflected on the marine fossils he discovered in rock strata while walking in the Swiss Alps. He reasoned that these fossils were the remains of once-living organisms in the remote past; natural forces had elevated the fossil-rich sedimentary layers of the Mediterranean Sea over thousands of years. In fact, at a time when the common consensus maintained that this universe was created only a few thousand years ago, Leonardo's dynamic view of earth history held that our planet is at least 200,000 years old. Furthermore, his cosmology held the universe to be eternal, infinite, and filled with other planets. Taking change seriously, Leonardo claimed time to be the evil destroyer of everything. Speculating on the end of the earth, he foresaw a future catastrophic event in which fire would destroy all living things on the planet (including our species).

At the end of the Italian Renaissance, the monk Giordano Bruno (1548–1600) challenged the entrenched Aristotelian philosophy and Thomistic theology that dominated Western thought. Using his critical intellect and remarkable imagination, he envisioned an eternal and infinite universe with an endless number of stars and planets. His cosmology also included other inhabited worlds with intelligent beings. Consequently, Bruno's bold interpretation of this universe paved the way for new ideas about time and change. It may be argued that he ushered in the modern cosmology, which is free from geocentrism, anthropocentrism, and a fixed ceiling of stars. His worldview even anticipated the relativity framework in modern physics.

With the Age of Enlightenment, natural philosophers stressed the value of science and reason. Rejecting earlier beliefs and opinions, they emphasized critical thought and open inquiry. For them, history was a progressive process, and scientific advances promised freedom from dogmatism and superstition. These enlightened thinkers established an intellectual atmosphere that was crucial for paving the way for the emergence of the social sciences, including anthropology and psychology. The new social sciences would supplement the established natural sciences. Extolling the value of individuals, the academic stage was now set for exceptional naturalists and philosophers to make substantial contributions to understanding and appreciating both cosmic time and earth history.

At the end of the Enlightenment, long before nanotechnology and genetic engineering, the visionary philosopher Marquis de Condorcet (1743–1794) foresaw ongoing advances in the natural sciences resulting in future human beings enjoying an indefinite life span.

At the beginning of the 19th century, naturalists began to take the study of rocks, fossils, and artifacts seriously. Their investigations challenged the traditional ideas concerning the age of our earth, the fixity of species, and the recent appearance of the human animal on our planet. Historical geology, comparative paleontology, and prehistoric archaeology became distinct sciences that together offered an incredibly vast temporal framework. Over the decades, the accumulation of empirical evidence clearly demonstrated the enormous age of our earth, the evolution of species over eons of time, and the great antiquity of the human animal. Throughout geologic time, the fossil record even revealed that many past species had become extinct. Nature was no longer perceived as manifesting a divinely preestablished design; the alleged fixed order of our planet was now replaced by pervasive and ongoing change. Earth time was now recorded in the millions of years, and the origin of this universe had occurred in a remote past lost in the immensity of cosmic time.

During the recent past, four great thinkers had the luxury of time for reflection: Charles Darwin, Albert Einstein, Alfred North Whitehead, and Pierre Teilhard de Chardin. Each contributed original and lasting insights into the nature of time in terms of evolution, relativity, or a process worldview grounded in philosophy or theology.

The Evolution Framework

A major contribution to recognizing the significance of time came with Charles Darwin's scientific theory of organic evolution. The brilliant naturalist had synthesized facts and concepts from various disciplines (especially geology, paleontology, and biology) into a new interpretation of life on earth in terms of continuous change. The indisputable facts demonstrated the mutability of all species; plant and animal types had evolved over vast periods of time. This paradigm shift from fixity to change turned the Aristotelian/Thomistic worldview upside down. The evolutionary perspective alarmed philosophers and theologians, as well as naturalists; in fact, the rise of natural philosophy challenged natural theology. One could no longer view this planet, life forms, or our species in terms of permanence. Time took on a new meaning and significance for those who replaced the biblical story of creation with the Darwinian theory of evolution. Furthermore, biological evolution opened up new areas for scientific research, particularly concerning the mechanisms of inheritance. With the discovery of the DNA molecule in 1953, genetic information supplemented the fossil record in substantiating the evolutionary history and organic unity of life forms on our planet.

However, one must distinguish between the factual theory of organic evolution and those various interpretations of this process that appear in the philosophical literature. Interpretations of evolution range from materialism and vitalism to spiritualism and mysticism. Even so, these dynamic worldviews take both time and change seriously. It is not surprising that some philosophers extended their interest in evolution to include the history of this universe. Herbert Spencer wrote about a cyclical cosmos, Friedrich Nietzsche taught the eternal recurrence of this same universe, and Henri Bergson claimed that time itself is the metaphysical essence of creative evolution. In the 20th century, an inevitable conflict emerged between those biblical fundamentalists who clung to a strict and literal interpretation of Creation as presented in Genesis and the scientific evolutionists who accepted the new temporal framework that is clearly upheld by the empirical evidence in geology, paleontology, and biology, as well as the results from radiometric dating techniques. In fact, this conflict between traditional religion and modern science continues today and shows no sign of ending in the foreseeable future.

The Relativity Framework

With more sophisticated telescopes and computers, astronomers discovered that our universe has been expanding and evolving over billions of years, with countless galaxies forming and dying over incredible periods of time. Furthermore, some scientists have speculated that there has been sufficient time for organisms, including intelligent beings, to emerge on other worlds elsewhere in this cosmos. On the subatomic level of reality, particles appear and disappear instantaneously; it has even been argued that some subatomic particles may actually travel backwards in time. Obviously, this modern perspective is far removed from the Aristotelian/Thomistic worldview.

After the beginning of the 20th century, the genius Albert Einstein presented to the intellectual world his special and general theories of relativity. The physicist challenged the basic ideas of Galileo Galilei and Isaac Newton by denying that space and time are independent absolutes and, instead, maintaining that they constitute a space-time continuum in a four-dimensional reality (with time being the fourth dimension). Moreover, for Einstein, there is no fixed frame of reference in this universe from which absolute judgments may be made concerning time and motion; his only fixed constant is the speed of light. His new interpretation of this universe had startling ramifications for comprehending the four cosmic forces (especially gravity) and those consequences that result as the velocity of an object approaches the speed of light. With the probability of dark matter, dark energy, and wormholes existing in this universe, our cosmos is far stranger than the ancient thinkers could have imagined and far more complex for human beings to grasp now than it was a mere century ago. In fact, the more scientists explore this universe, the older and larger and more peculiar they find it to be.

Dynamic Worldviews

With a greater awareness of time came thinkers who speculated on the distant future of our species and this universe. The visions of Joseph Ernest Renan (1823–1892) and Miguel de Unamunoy Jugo (1864–1936) offered an interpretation of reality that saw the end of this universe in terms of a distinct cosmic entity analogous to a single human being. However, ongoing advances in astronomy and cosmology revealed an expanding universe with a size far beyond the imagination of most 19th-century thinkers. As such, human-centered worldviews in natural philosophy and process theology were now regarded with suspicion by many scientists. Even so, two impressive attempts were made to give our species an important role in evolving reality.

To accommodate relativity physics to a dynamic view of this universe, philosopher Alfred North Whitehead (1861–1947) offered a process cosmology that emphasized pervasive creativity from epoch to epoch. For him, endless reality is the manifestation of interrelated and ongoing events, with these events forming inorganic, organic, and reflecting societies. The realm of events or actual occasions reflects structures or eternal objects throughout the everlasting advance of this cosmic continuum. Whitehead envisioned no final end or ultimate goal for cosmic time. His worldview is a form of panentheism; both God and nature are involved in the continuous process of creating novelty throughout eternal reality.

To accommodate natural theology to cosmic evolution, the Jesuit priest and geopaleontologist Pierre Teilhard de Chardin (1881–1955) interpreted our dynamic universe in such a way as to argue for the uniqueness of both this earth in general and our species in particular. However, his cosmology is actually a planetology. Over vast periods of time, directional evolution (as he saw it) passed from inorganic, through organic, to human stages of development, thereby forming three distinct layers: the geosphere, biosphere, and noosphere, respectively. For Teilhard, the arrow of time is now preparing our earth for the spiritual Omega Point, the planetary end of time for human evolution in the distant future. He believed that a personal God is both the first and the final cause of reality, with evolutionary time unfolding between the beginning and the completion of cosmic existence. It is not surprising that Teilhard was silenced for his acceptance of evolutionary time. His bold ideas, grounded in a scientific framework but mystical orientation, were far removed from natural theology and traditional belief.

The Human Factor

Following geology and paleontology, the emerging discipline of anthropology embraced the evolutionary framework and extended this theory to account for the origin and history of our own species. The human animal was placed within the primate order, because it shared many obvious biological similarities with the apes and monkeys. As the search for hominid fossils continued during the 20th century, major discoveries were made in the eastern hemisphere. In time, empirical evidence favored Africa as the birthplace of the earliest hominids, and the evolution of our species was seen to have taken place over 2 million years. Today, both fossils and the DNA molecule substantiate the concept of human evolution. Furthermore, accumulating archaeological evidence, ranging from stone implements and burial sites to bone carvings and cave murals, offers an ever-clearer picture of prehistoric sociocultural evolution. Like species, past societies with their cultures have emerged and thrived, only to vanish. Of special interest for modern anthropologists is the origin of symbolic language as articulate speech. Some linguists speculate that the evolution of speech may have had its beginning in the hominids of Africa over 1 million years ago.

The evolution of the human brain has given our species a superior intellect with a capacity for reasoning, memory, and creativity. With the coming of civilization, group behavior accelerated cultural evolution. The emergence of consciousness is mirrored in the rapid flowering of material culture. One intriguing area of modern research involves investigating the evolutionary relationship between morality and the brain. If future space travel takes human beings to other planets and even beyond, then our species would still carry within it the genetic information linking it to the apes of today.

The engaging motion picture *2001: A Space Odyssey* (1968) depicts evolution from past fossil apes, through our species, to a future starchild. Within its cosmic perspective, this film includes superior beings that exist elsewhere in the universe. If humans ever make contact with such possible creatures, then one wonders what information they would communicate to us about the nature of time beyond our present comprehension of it.

A quintessential example of an artwork that focuses on time is Richard Wagner's epic tetralogy *Der Ring des Nibelungen* (1876), with its changing characters and altering events unfolding within a dynamic cosmology of pervasive symbolism and mythic significance.

Other artists have also attempted to portray the fluidity of time. One recalls the ingenious paintings of Salvador Dalí, for example, *The Persistence of Memory* and *The Discovery of America by Christopher Columbus*. Novels focusing on historical eras include Gustave Flaubert's *The Temptation of Saint Anthony* (1874) and Henryk Sienkiewicz's *Quo Vadis* (1896). Likewise, major authors have dealt with the stream of consciousness. Such insightful novels include James Joyce's *Ulysses* (1922), Thomas Mann's *The Magic Mountain* (1924), and Marcel Proust's *Remembrance of Things Past* (1913–1927). Yet, despite centuries of human inquiry, time itself still eludes scientists, philosophers, and theologians.

We are constantly aware of time. Tides, erosion, lunar phases, solar eclipses, returning comets, recurring seasons, and alternating days and nights illustrate for us that this universe is always changing. The birth, development, and death of organisms are a sobering reminder of the finitude of life forms on our planet. With such awesome and disturbing examples of time and change, it is not surprising that great minds have attempted to grasp the flux of reality. Even measuring time and change to ever-greater degrees of certainty is an ongoing challenge to modern science and technology.

* * *

I first became fascinated with time as a youngster impressed with dinosaurs and stars. In high school, I learned about the theory of evolution that linked these two interests within a cosmic continuum that also includes humankind. Later, university studies introduced me to the academic disciplines of anthropology and philosophy. As years passed, I found it increasingly difficult to comprehend how anyone could doubt the fact of evolution in light of overwhelming empirical evidence, from fossils to genes. Of course, the acceptance of our changing universe requires using a disciplined imagination that is open to the astonishing sweep of cosmic time. It is a humbling moment, indeed, when one first realizes the insignificance of our species against the awesome background of an incomprehensible universe that is utterly indifferent to human existence. Yet, the very fact that one may ponder the age of stars and evolving life forms gives meaning and purpose to our consciousness, no matter how ephemeral it may be.

My own extensive travels and academic interests have taken me to numerous sites where the brute reality of objective time expresses itself in no uncertain terms. Relevant experiences have included my discovering *Allosaurus* in Wyoming, exploring the unique Galapagos Islands, searching for fossil hominids at Koobi Fora, admiring the enigmatic Sphinx of Giza, and visiting the Inca ruins of Machu Picchu in the ancient Andes (to name only five). Such glimpses of pervasive change remind us of our own fleeting existence. It is hoped that the *Encyclopedia of Time* will contribute, to its readers, a greater understanding of and deeper appreciation for the elusive phenomenon experienced as time.

Acknowledgments

At Sage Reference, I was particularly fortunate to have the confidence and support of Rolf A. Janke, vice president and publisher. His vision and commitment to this project were essential for its advancement and fulfillment. Likewise, as its development editor, Sanford Robinson gave meticulous attention to the content and relevance of the entries and provided ongoing enthusiasm for this comprehensive and unique work. The excellent preparation of this *Encyclopedia of Time* would not have been possible without his steadfast interest and exceptional skill.

The production of this multidisciplinary encyclopedia benefited substantially from the diligent concern for all details given by production editor Kate Schroeder and copy editors Kristin Bergstad, Colleen Brennan, and Cate Huisman. I am deeply indebted to them for their dedicated and invaluable assistance.

Also at Sage, I am very grateful to Ravi Balasuriya for his outstanding artistic contributions.

Furthermore, I am especially indebted to Sylvia S. Bigler, whose persistent focus on all facets of preparing the entries for publication was an enormous benefit. This encyclopedia would not have been possible without her professional administrative assistance throughout the whole project.

The range and depth of the subjects covered in the *Encyclopedia of Time* clearly attest to the ongoing interest in and significance of investigating the concept of time from multiple perspectives. It is a heartfelt pleasure for me to acknowledge the contributing authors for their scholarly entries. The following writers were particularly helpful in providing numerous entries or essential contributions for this work: Stefan Artmann, Clemens M. Beckstein, Robert Bollt, James Pleger Bonanno, Patricia N. Chrosniak, Jill M. Church, Suzanne E. D'Amato, Terry Wayne Eddinger, Michael Joseph Francisconi, Betty Anne Gard, John K. Grandy, John R. Grehan, Helmut Hetznecker, Pamela Rae Huteson, Debra M. Lucas, David Alexander Lukaszek, Gerald L. Mattingly, James V. Morey, Ralph Neuhaeuser, Neil Patrick O'Donnell, Donald R. Perry, Debika Saha, Hans Otto Seitschek, Stefan Lorenz Sorgner, Victor J. Stenger, Mark James Thompson, Jacek Stanislaw Tomczyk, Greg Whitlock, and Patrick J. Wojcieson.

Over the years, these individuals have been indispensable in offering encouragement and providing inspiration: Christopher C. Dahl, Linda A. Dinsdale, Marvin Farber, Edward G. Garwol III, Shirley A. Garwol, Debra G. Hill, Claudia A. Hoffman, Albertha F. Kelley, Rose M. Malone, Dianne Marie Murphy, Sophie Annerose Naumann, Joseph F. Rizzo, and the Reverend Edmund G. Ryan.

For their ongoing loyalty during the preparation of this three-volume work, I am most appreciative to Sylvia S. Bigler, Pat Bobrowski, David Alexander Lukaszek, and Stefan Lorenz Sorgner. They enlivened the time I spent on this project.

Abelard, Peter (1079–1142)

Peter Abelard (Petrus Abaelardus), the most famous intellectual of the 12th century, addresses the problem of time especially in the context of his reevaluation of Aristotelian logic, which he knew from the *Categories* and *De interpretatione*. Although in his *Dialectica* (c. 1117), Abelard still follows the realist approach of many of his contemporaries, in his *Logica Ingredientibus* (c. 1119) he moves toward an ontologically more parsimonious position. According to him, time has to be understood as "a quantity according to the permanence of which we measure the existence of all things, when we show something to be, to have been or to come into being at a certain existing time (*quaedam quantitas* [. . .] *secundum permanentiam cuius rerum quarumcumque dimetimur existentiam, cum monstramus esse aliquid, fuisse vel fore tempore aliquo existente*)."

Abelard contradicts the suggestion that everything has its own time, while arguing for one single time which is suited to measure everything, including itself. This time pertains to the whole world and can be predicated on every element within it. It is indivisible, insofar as in all the different elements of the world there is one time, as there is one unity in the human body or in the whole world with its different elements. On the other hand, Abelard denies the objective reality of a "composite" time, that is, of time insofar as it consists of successive elements such as hours, days, years, and so on. These time elements are only constructions of the human mind which constitutes the presence of every span of time that is conceived by a human being. In reality, though, there is only one simple, indivisible flux of subsequent, inseparable instants. Consequently, one can speak of a composite time and its parts "according to the imposition of names, not according to the existence of things (*secundum nominum appellationem, non secundum rerum essentiam*)."

The problem of time and eternity plays only a minor role in Abelard's thought. He states only that time can be regarded as a part of "eternity," because time, which began to exist together with the Creation, covers only a small stretch of that totality, which can be called the eternity of God's existence (Abelard's starting point here is the same quotation of Cicero that his contemporary, William of Conches, uses for his third definition of time). In Abelard's later works on theology, however, one can find in his linguistic remarks some kind of a *via negativa* theology of time: Humans are not able to speak directly about God, because human language consists of sentences that contain verbs. Verbs, however, always designate a change, which falls within the realm of time. Thus the human language is absolutely not suited for speaking about God, and consequently theologists have to invent analogies (*similitudes*) to describe God's peculiar nature.

The problem of time and eternity is also in the background of Abelard's discussion about the foreknowledge of God and human freedom: To God, every instant of time is present such that he knows what will be happening according to human free will, but this does not mean that human freedom does not exist.

Abelard's theory of time represents, in a typical contrast with that of the Platonist William of Conches, one of the first approaches of a philosopher of language to the problem of time, which results in a skeptic stance toward superfluous ontological assumptions.

ADAM, CREATION OF

Throughout history many explanations have been given about the creation of the human species. The monotheistic Abrahamic traditions—Judaism, Christianity, and Islam—believe in the Creation story of Adam. This account is found in the Book of Genesis, the first book of the Torah, which comprises the first five books of the Hebrew Bible (for Christians, the Old Testament). The word *genesis* in Latin means birth, creation, or beginning. According to the Book of Genesis, God created the entire world in 6 days. On the 6th day he made in his own image Adam, the first man, out of dust from the ground. He was given dominion over all things on earth, both great and small. God then decided that Adam should not be alone, and from his side created Eve, the first woman. God told them to be fruitful and multiply, and all of humankind descends from their union.

All of the Abrahamic faiths are proponents of creation ex nihilo (out of nothing). This is the belief that nothing in the universe but God and the heavens existed before the Creation. However, each faith emphasizes different aspects of the story. There are two versions of the Creation story offered in Genesis. This dichotomy seems to stem from the fact that the Books of the Torah are compiled from various ancient stories and not written by one author. The first chapter is known as the "P" or Priestly version and was written in about 715–687 BCE. The second chapter is the "J" or JHWH version, from the Hebrew word for God, written between 922 and 722 BCE. This explains why Genesis 1 and 2 offer two similar but slightly different accounts of the same event and why the language used does not always match up.

The J story describes the Creation of man simply. "And Yahweh God formed man from the dust of the ground and breathed into his nostrils the breath of life, and man became a living being" (Gen 2:7, Revised Standard Version).

In the P version it is written, "Then God said, Let us make man in our image. So God created man in his own image, in the image of God he created him; male and female he created them" (Gen 1:26–27). The language of this passage has caused debate among scholars and theologians. First, the use of the plural tense when describing the creation implies that more than one man was made. Second, it says "male and female," implying that men and women were made at the same time.

Some believe that man was made to be, like God, a hermaphrodite (God having no gender). Then God decided it was not good for this human to be alone and thus removed a piece of it, leaving two separate parts, male and female. There are Jewish scholars who bring these two stories together by emphasizing the passage in the J version, "Therefore, a man shall leave his father and his mother, and shall cleave to his wife and they shall become one flesh" (Gen 2:24). This language suggests that man and woman were once one and need to be together as partners to be whole again.

The origin of the name Adam is also a topic of discussion. There are two popular explanations. In the Sybilline Oracles, verses composed from the 2nd century BCE to the 5th century CE, it is said that the name is an acronym for the four directions in Greek: *anatole* (east), *dusis* (west), *arktos* (north), and *mesembria* (south). A 2nd-century (CE) rabbi put forth the idea that the name comes from the words *afer, dam,* and *marah,* Hebrew for dust, blood, and gall.

Most branches of Christianity accept the version of Creation in Genesis. There is debate as to whether the text should be taken literally or figuratively. Some Christians join together the ideas of modern science with the biblical account—for example, saying the Creation happened as described but over billions of years, thus supporting geological evidence. However, strict biblical proponents believe Creation actually occurred in six 24-hour days and that the earth is only a few thousand years old. The Christian belief in original sin also derives from this story. Christians believe that at Creation humans were infallible but that through their own weaknesses evil came into the world. "Wherefore, as by one man sin entered into the world, and death by sin; and so death passed upon all men, for that all have sinned" (Rom 5:12).

The Islamic tradition states that Adam was created from mud from all over the earth and that is why there is such diversity in humans' physical appearances. The story in the Qur'an claims that after God made man, he was inanimate for 40 days and then sprang to life. Muslims agree that Adam was given power over all other things. Because God spoke to him directly, he is also considered a prophet of the Muslim faith.

Many theologians consider Adam and Eve to be analogies for all people who challenge God. Their story of banishment is a stark warning for people of faith. However, others view them as real people from history. The Book of Genesis contains a genealogy of their descendants, who include historic kings and leaders of the ancient world. Early European Christians interpreted the Bible as being historical fact, and early scientists even calculated the time of their creation to be approximately 4000 BCE.

Modern archaeological finds have aged the earth closer to 4.5 billion years and disputed the concept that all things on earth were created at the same time. The classical theory of evolution denies the creation of man directly by God and suggests a slow progression of life from simple one-celled organisms to complex life forms like human beings. The study of genetics suggests that if the population of a species is ever only two, the species would inevitably become extinct. But the Bible's description of Adam and Eve's old age at death, nearly 900 years, suggests a way in which two could have created enough offspring to perpetuate the species.

Afterlife

Many people believe that some aspect of the self continues to exist after death. Throughout history most religions and philosophies have offered a rationale for, and description of, life after death to encourage adherence to their codes of belief and conduct.

Theorists view the relationship between the afterlife and time in various ways. Some view the afterlife as a timeless state of existence after death or after the end of the world. Others view it as a state of never-ending time. Still others view it as the cyclical repetition of incarnation in various forms.

Early Egyptian writings describe the king's ascent to the sky where he becomes a star and is admitted into the company of the gods. Later the promise of immortality was extended beyond the Pharaoh and his family to the general population. Some Egyptian writings describe the journey of the dead in the underworld. Those who pass the tests on the journey would arrive at the realms of the blessed, which are located either on earth or in heaven.

In contrast to the Egyptians, most people in the ancient Near East (including Sumerians, Assyrians, Babylonians, Canaanites, and Israelites) believed that the dead continued to exist in an underworld, which was only a gloomy reflection of their former life. The Hebrew scriptures describe the dead as "shades" (*rephaim*) who descend to Sheol, a dark and dusty pit located under the earth. Some passages speak of a hope in Yahweh's help and presence beyond death, but scholars debate whether such passages indicate a belief in either immortality or resurrection. The clearest references to the resurrection of the dead are Isaiah 26:19 and Daniel 12:2. Ecclesiastes 3:19–21 suggests the ascent of the righteous dead to heaven.

The Zoroastrian texts of Persia describe a bridge that leads over hell to paradise. The righteous pass over successfully, but the wicked fall off the bridge into hell where they suffer eternal darkness and sorrow. The good person passes through three levels of heavens to arrive at paradise ("garden" or "park"), a blissful place free of pain and suffering.

Hinduism believes in an endless cycle of death and rebirth (called *samsara*). Karma, the law of moral cause and effect, determines the future existence of the person. Through the practice of yoga, one can acquire true knowledge that the physical world, including death, is an illusion and thereby obtain *Samadhi,* the highest level of spiritual perfection. The union of *Atman* (the essential self) with *Brahman* (that which is truly real) will result in liberation (*moksa*) from samsara. Between death and rebirth, people are rewarded in heaven or punished in hell based on the nature of their deeds.

In contrast to Hinduism, Buddhism insists that death is an unavoidable fact of human existence that must be accepted. To overcome the desire for exemption from death, one should follow the Eightfold Path in order to achieve *anatman* (or *Anatta*), a state of *nirvana* or "non-self." Karma determines in which of six realms a person is reborn. Some Buddhists, however, reject the idea of reincarnation. Buddha's contemporary, Confucius, accepted the reality of death also but was agnostic regarding life after death. However, many Confucianists today believe in the reincarnation of the soul.

Early Greek thought reflects the concept of a shadowy underworld called Hades, but increasingly it was supplanted by the concept of astral immortality. Orphism and Pythagoreanism promoted an explicit concept of the immortality of the soul, and Plato (and later, Cicero) developed extensive arguments to defend this view. In contrast, Epicureans believed that the person ceases to exist at death, Aristotle was skeptical of individual immortality, and Stoics disagreed among themselves. The mystery religions offered attainment of astral immortality to all who would submit to their secret rites of initiation. Greeks and Romans generally abhorred the idea that the body would have any role in the afterlife. The Romans believed in the apotheosis (exaltation to divinity after death) of certain emperors such as Julius Caesar, Augustus, and Claudius.

Second Temple Judaism, influenced by Persian and Greek thought, developed various conceptions of the afterlife. Some writings teach the immortality of the bodiless soul, but the resurrection of the body became the more popular view. Some writings describe the righteous as transformed into stars or angels. However, they are also said to dwell on a transformed earth. Some Jewish writings divided Sheol into two compartments so that after death the righteous experience the delights of paradise and the wicked suffer the torments of hell.

In the 1st century CE, the Sadducees denied any conception of an afterlife, but their views were not widely held. The Pharisees believed in the resurrection of the body. The Jewish philosopher Philo of Alexandria argued for the preexistence and immortality of the soul. Josephus described the Essenes as believing in the immortality of the soul, but evidence from the Dead Sea Scrolls suggests that they actually believed in resurrection of the body. Apocalyptic literature often described the abodes of the blessed and the place of punishment for the condemned. Rabbinic Judaism and modern Judaism have taught an intermediate state and future resurrection of the dead, but some Jews have held more to a Platonic concept of the immortality of the soul.

Both Jesus and Paul accepted the Jewish concept of the resurrection of the body. They taught the conscious existence of the disembodied individual between death and resurrection. Later Christians claimed to find warrant in the New Testament for two other views of the intermediate state: soul-sleep and immediate resurrection. Christians believe that after the Judgment the redeemed will experience the blessings of a renewed heaven and earth, and the unredeemed will either be annihilated or consigned to a state of eternal torment. Later Christian theologians attempted to integrate the Platonic concept of immortality with belief in the resurrection of the body. Through the centuries, Christian mystics and theologians have attempted to describe the blessings of the afterlife.

According to Islam, the dead receive a foretaste of either heaven or hell while they are in the tomb. Martyrs will be admitted immediately to heaven where they receive a special reward. On the last day, the souls of all humankind will arise and be reunited with the body. After being judged according to their deeds, they will spend eternity either in the bliss of heaven or in the torments of hell.

Throughout human history, people have claimed to experience visions of the afterlife. These accounts often took the form of tours of heaven or hell. More recently, some have argued for the reality of the afterlife on the basis of the phenomenon of "near-death experiences."

AGING

Aging is a physiological process of change that occurs in organisms over time. Indeed, in all cultures the aging of humans is the primary symbol for time's passing. This entry focuses on the biological theories of aging and of the way in which the aging process affects human beings.

Theories of Aging

There are many theories that attempt to explain the cellular and molecular processes involved in aging. Some evidence appears to support the assumption that the aging of a given species is programmed in some way. Monozygotic twins, for example, are much more likely to have nearly the same life span than are dizygotic twins. In laboratory settings, the maximal life span of specimens is often similar. For example, the median life span of a housefly is around 30 days and of a rat approximately 3 years. The maximum human life span is approximately 100 years, although in rare instances, individuals have lived as long as 115 years. In general it is possible to distinguish between systemic and genetic theories of aging.

Systemic theories propose that there is a systemic pacemaker for aging. One theory claims that the hypothalamus, a structure in the brain, has the function of a biological hourglass that begins to deteriorate in its hormonal output with the progress of time. This could lead to disorganization in the body's homeostasis (balance of body functions).

A second theory is that the involution of the thymus, an immune system organ responsible for the imprint of T lymphocytes (T cells), leads to lower immunity. This could lead to more malignant processes in the human body.

Third, the autoimmune theory explains aging as an autoimmune process. Following this theory the body produces different antibodies against its own structures. These autoantibodies accumulate and lead to organ failures and dysfunctions.

Genetic theories are divided between damage and programmed theories. In contrast to systemic theories, they explain aging not by focusing on the organs, which work as an hourglass, but propose that aging happens in every cell of the human organism.

Damage theories of aging explain the process of aging by the accumulation of events damaging the genetic code of a cell. Oxygen radicals, which are developed in the metabolism of the cell, are being considered as one of the main mechanisms. Oxygen radicals damage the genetic code. Evidence for the relevance of oxygen radicals is given by the fact that the content of the enzyme superoxide dismutase, which catches free oxygen radicals, is proportional to the life span of different species. Cells of mice (life span 3 years), for example, have a low content of superoxide dismutase, gorillas (life span 55 years) a much higher one, and humans have one of the highest to be found in mammals. Other mechanisms discussed are oxidation, radiation, and glycation.

Theories of programmed aging conceive of aging as a process that is in some way programmed in the genetic code. The most famous among these theories is the "length of telomere" theory. Telomeres are repetitive DNA sequences at the ends of chromosomes that stabilize the chromosomes. After every cell division, the telomere, which is about 2,000 base pairs long, is shortened by 50 base pairs. When a critical length is reached, the cell cannot divide itself any more and often dies by apoptosis (programmed death of a cell). The telomere can also be elongated by the enzyme telomerase. Cells that express telomerase are factually immortal. In mammals this enzyme can be found only in cells of the germline, in stem cells, and in more than 90% of carcinomas. In Hutchinson-Gilford syndrome (progeria) there is a genetic mutation that leads to faster shortening of the telomeres. People with this syndrome age far more rapidly than other people and die at the age of around 13 of stroke or cardiac infarction. Patients with this syndrome have atherosclerosis, osteoporosis, arthrosis, and aging of the skin, but other typical aging problems like dementia, hardness of hearing, diabetes mellitus, and cataract are missing.

This leads to the observation that no single theory of aging is sufficient to explain all phenomena that occur in aging. The process has to be multifactorial.

Aging of the Human Organism

It is possible to understand the word *aging* in two different senses. In the wider sense it deals with the whole human development; in the narrower sense it means the process of senescence, which under normal physiological conditions begins for most organs at about age 50. Death can of course occur at any phase of human development, but it occurs often the end of the described processes of aging. The physiological changes over time are the main physical characteristics of the passing of time for humans.

Three phases can be differentiated in the process of human aging. First, the embryonic phase from conception to birth; second, childhood (here understood to span the time from birth to the end of puberty); third, the time from sexual maturity to death. This differentiation is not fully sufficient if the focus lies on the organs.

The embryonic period begins with the fusion of the nuclei of sperm and ovum. After this moment the cell begins its development into a human being. After about 4 days of cell division, a trophoblast and an embryoblast are distinguishable. The first will develop to the organs of nutrition and implantation of the embryo, and the embryoblast will further differentiate itself to the fetus with functioning human organs. Between the 5th and 6th day the embryo implants in the mucosa of the uterus. The further differentiation takes place by three so-called blastoderms, which develop into the organ systems. This differentiation ends between the 8th and the 12th week of development. After this point all the organs exist, but they still have to run through a process of maturation until they are able to keep the newborn alive. Under natural conditions this point is reached around the 32nd week, although a normal pregnancy lasts 37 to 40 weeks. With intensive care it is possible for a newborn to survive from the 22nd week onward.

After birth the human development is characterized by growth and maturation of the musculoskeletal system and of most of the organs. The gonads start to grow during puberty (beginning between the 10th and 14th year); until then their size remains constant. After puberty the human skeleton usually stops growing around the 18th to 22nd year. The process of senescence begins at different times in the different organ systems. In general there is a so-called organ reserve, which is the difference between the maximal and the basal organ function. The basal organ function is sufficient to keep the organism working properly under physiological conditions. If there is a change in these conditions, the organ reserve is needed to compensate for these conditions. The cardiac output, for example, can be five times as high as the basal output. For most of the organs this organ reserve declines from the 30th life year onward.

The brain loses about 20,000 neurons per day from the 20th year on, a process finally leading to senescent atrophy of the brain. A symptom of this is a slight form of dementia, the benign senescent forgetfulness, which is physiological. Alzheimer's disease is not regarded as physiological, as it involves the development of plaques that are deposited in the neurons, and results in an abnormally high loss of neurons. In lower amounts the plaques can also be found in the normal senescent brain. The dopaminergic system in the brain also degenerates, which leads to stiffer ambulation. Parkinson's disease is another extreme form of a process of aging that can be found primarily in elderly people. In Parkinson's disease the peripheral nerves are demyelinating, meaning that their fatty covering or sheath slowly shrinks. This process leads to slower reactions. Other synthesizing activities of the brain are also deteriorating.

The endocrine system goes through different changes. In women the cyclical ovarial function terminates during menopause, usually between the 45th and 55th life year. Men, on the other hand, can have constant levels of testosterone from the 20th to 90th life year. In general the answer of organs to hormonal signals deteriorates, which may lead to illnesses. In the case of insulin, which is secreted by the pancreas, this process can lead to diabetes mellitus.

Presbycusis, with the difficulty of hearing high frequencies, is usually caused by degeneration of regions in the inner ear because of noise exposure during life. Decreased vision is most commonly a consequence of the reduced flexibility of the lenses although there are many other possible degenerations of the eye, such as in the vitreous body and the retina.

The lungs become less and less compliant, while the chest becomes stiffer and the cough reflex is reduced. These events lead to a lower level of oxygen in the blood and to an increased rate of respiratory infections.

In the cardiovascular system the arteries become stiffer because of atherosclerosis; this leads to higher blood pressure. The heart muscle fibers usually become atrophic. Atherosclerosis of the coronary arteries can lead to disturbances of perfusion, which are followed by cellular necrosis.

With aging, the function of liver, kidneys, and gut is reduced. Like all other organs, these also become atrophic as a result of cells not being replaced after their physiological death. In general there is a lower amount of total body water and a higher amount of body fat. The connective tissue of the body is progressively reduced in its flexibility from the 30th life year on. This leads to wrinkles of the skin, which may be the most obvious sign of human aging.

Albertus Magnus (c. 1200–1280)

Albertus Magnus (Albert the Great), was a Dominican priest born in Bavaria, who in his lifetime attained a reputation for immense learning. After study at the University of Bologna, he taught at several universities, including the University of Paris, where he received his doctorate and was the teacher of Saint Thomas Aquinas. His knowledge was encyclopedic, encompassing theology, philosophy, logic, astronomy, music, botany, zoology, and mineralogy.

Albert's theory of time shows those tendencies that are typical for his whole philosophical project: Aspects that are inspired from Aristotle find their place within a framework largely determined by Albert's theological and noetic interests, which echo Averroes and some Neoplatonic sources (Boethius, Pseudo-Dionysius, *Liber de causis,* Proclus's *Elements of Theology*). By integrating such very divergent streams of thought, Albert's philosophical synthesis became the point of departure for various developments in subsequent medieval thought (e.g., Saint Thomas Aquinas; the Averroists; the German Dominicans, including Meister Eckhart; Renaissance Aristotelianism; and Nicholas of Cusa).

This integration also holds true for his ideas on time, which are explained in what follows, according to Albert's systematic presentation in his "Sum of the admirable science of God" (*Summa de mirabili scientia Dei;* written after 1270). As do other Platonic thinkers (William of Conches, Nicholas of Cusa), Albert discusses time always in the horizon of eternity; even in his *Physics* commentary he adds a treatise on eternity to his explanations of Aristotle's theory of time, which is concerned mainly with movement. Albert defines eternity and time in the traditional way as duration of God or of changeable objects, respectively. The most specific definition of time is that it is "a passion of the first movement and by that the measure and number of all movements." Furthermore, Albert distinguishes from time and eternity a third form of duration, "eviternity" (*aeviternitas* or *aevum*), which "is a duration existing in the middle between time and eternity." This eviternity has a beginning (*duratio principiata*) but does not have an end; although the objects of eviternity are free from bodily changes or movements, they are subject to some succession. This is because they have, as do all created objects, a tendency toward the "nothing" (*nihil*), which means that they are not capable of receiving at one moment their whole perfection (*totum simul*). This explanation of *aevum* is a typical Christian adaptation of a Neoplatonic concept, which can be found in Proclus and Boethius.

For Albert, however, all three forms of duration are determined by the particular moments that constitute them; that is, Albert applies the Aristotelian concept of a "now" as the constitutive element of time also to eternity and eviternity. Even more important is regarding time as the distinction of an "in-which-way-it-is" (*quo est*) and a "what-it-is" (*quod est*). Albert distinguishes these two aspects, following Boethius, in any nonmaterial objects. In the case of time, both aspects can be grasped only by understanding the "now" as the fundamental unity that constitutes the flow of time.

In his commentary (1254–1257) on the third book of Aristotle's *De anima,* Albert connects these ontological speculations with the fundaments of ethics. Here, Albert presupposes an "absolute good" (*bonum simpliciter*), which he takes from the Greek words meaning "practical good" which had been translated into Latin as "actual good" (*bonum actuale*). From this absolute good, Albert distinguishes a "good for the moment" (*bonum ut nunc*), which is valid only in time, whereas the absolute good is "always good" (*bonum semper*). Whereas this eternal good is right at any place and in any respect, the "good for the moment" may be an apparent good, which is incorrectly regarded as good; this may lead human beings to false action. Thus, the Aristotelian theory of action is embedded in an ontological theory that distinguishes a temporal good and an eternal good. In this way, Albert's Neoplatonic theory of time becomes the background for his understanding of Aristotle's practical philosophy.

Alexander, Samuel (1859–1933)

Influenced by the Darwinian movement of the late 19th century, the philosopher Samuel Alexander developed a dynamic worldview that focused on time and emergence. He presented a comprehensive metaphysical system in his major work *Space, Time, and Deity* (1920). Alexander distinguished between spacetime or motion as the infinite whole of this universe and those finite units of spacetime or motion that fill the endless cosmos. As such, evolving reality is a complex continuum of interrelated events grounded in the psychic point-instants of spatiotemporal motions.

Alexander maintained that the dynamic universe manifests an innate creative trend that generates new emergent qualities throughout cosmic time. The resultant hierarchy of empirical levels consists of motion, matter, life, mind, and a future deity. Consequently, through time and evolution, the existence of each higher level emerges from the preceding level of reality (from the metaphysical perspective, it was time that generated spacetime).

As an emergent evolutionist, Alexander held that mind, or consciousness, emerged from and is dependent upon life, just as life emerged from and is dependent upon matter. Furthermore, matter emerged from and is dependent upon motion. This whole creative process is ultimately grounded in time, the quintessential quality of all existence. The appearance of our own species is a recent event within the spatiotemporal progress of cosmic evolution. Because the universe continues to evolve, a new quality or level of existence will emerge in the future. Presumably, emergent evolution will continue to generate empirical qualities as long as time exists. Clearly, Alexander's dynamic worldview is in sharp contrast to earlier ideas and traditional beliefs that taught the sudden and complete creation of the entire universe with all its entities fixed in nature.

In his scheme of abstract ideas, Alexander attempted to reconcile pantheism and theism in terms of emergent evolution. To do this, he made a crucial distinction between the infinite God that already exists now and the finite deity that will appear sometime in the future within the creative advance of this universe. Because God is held to be spacetime or motion, this represents the pantheistic aspect of his metaphysical system. However, in this dynamic universe, a new finite quality will emerge from the level of human consciousness. Alexander claimed that this new level of existence will be the deity. As such, deity is the next empirical quality to appear within the creative evolution of time. This is the theistic aspect of Alexander's metaphysical system. The emergent deity will be only a finite, yet the divine, quality of God as the infinite universe itself. Therefore, God is totally imminent, but the deity is transcendent in terms of the time to come; in philosophy, this position is a form of panentheism.

Samuel Alexander's metaphysical reconciliation of pantheism with theism (i.e., imminence with transcendence) clearly demonstrates how challenging the evolutionary framework was to entrenched religious beliefs and established philosophical ideas about God and time. Previous views of humankind within a world of fixed objects and recurring events needed to be replaced by a dynamic interpretation of this evolving universe and everything within it. Alexander's systematic interpretation of emerging reality was a rigorous attempt to take both time and change seriously.

Alexander the Great (356–323 BCE)

Alexander was a Macedonian king whose extraordinary military conquests ensured him a lasting place in the annals of war and empire. Despite the brevity of his life, Alexander enjoyed a favorable locus in time; his career would be the bridge linking what historians refer to as the Hellenic and Hellenistic periods of ancient history.

Alexander the Great (*Megas Alexandros* in the vernacular), otherwise known as Alexander III, was born in Pella, Macedon, the capital of the kingdom, in 356 BCE. The exact date of his birth is uncertain but is traditionally assigned to July 20. Alexander's youth was marked by a rocky relationship with his sovereign father, Philip II of Macedon, though sources indicate Philip II was proud of his son after Alexander tamed his legendary steed, Bucephalus ("ox-head" in Greek). Alexander's mother, Olympias of Epirus, on the other hand, seems to have enjoyed a close relationship with Alexander. Speculation continues as to whether Olympias and Alexander were co-conspirators in the assassination of Philip II.

Nevertheless, both parents thought Alexander deserved the best in education, and Philip II arranged for private tutelage from the Greek philosopher Aristotle, who nursed young Alexander on rhetoric and literature, including Alexander's favorite work, Homer's *Iliad*. Alexander often likened himself to Achilles, the celebrated hero of the Trojan War, and claimed descent from the hero by way of Olympias's lineage. In fact, one of Alexander's tutors, Lysimachus, referred to Alexander as "Alexander Achilles," and referred to himself as Phoenix, the famous tutor of Achilles in the *Iliad*. From his father's line, Alexander was linked genealogically to Hercules. By extension, Alexander was therefore related to Zeus, but this idea was further cemented by Olympias, who proclaimed that it was Zeus himself who had impregnated her, leaving Alexander as the resulting offspring. Ideas of his own divine descent remained with Alexander throughout his life.

After the assassination of Philip II in 336 BCE, Alexander rose to the throne; although years earlier, in 340 BCE, Alexander had been appointed to act as sole regent in Macedon when Philip II went to attack Byzantium. Alexander quickly crushed any hopes of rebellion in his southern Greek neighbors, whom Philip II was able to bring under his control, largely due to the economic and political distress caused by the Peloponnesian War. In 334 BCE Alexander began perhaps his most famous conquest, that of the Persian Empire, held under the leadership of King Darius III.

It was during these conquests that Alexander is reported to have loosed the infamous "Gordian Knot," which, according to prophecy, was a feat to be accomplished only by the king of Asia. Whether the intricate knot was loosed by a stroke of Alexander's sword, or by his removing the pole pin to which the knot was attached, remains unsettled. Regardless, the prophecy had been fulfilled by Alexander, and so it followed that he became the next king of Asia Minor.

Alexander had conquered much of the known world, including Phoenicia, Egypt, and Mesopotamia, and extended the boundaries of his empire to Punjab, India, the site of Alexander's epic battle against the satrap Porus, immortalized in Handel's operas, *Alessandro* and *Poro*. Along the way, Alexander had established some 70 towns and outposts, many of which bear his name, including perhaps most famously, Alexandria, Egypt. Alexander's image became commonplace in many of these towns, in the form of either plaques, busts, or statues.

Alexander's conquests were unique in that he was not as much of a destroyer as a preserver, especially regarding the traditions and the customs of the peoples he conquered. For instance, during his Persian campaigns, he adopted the custom of *proskynesis* (symbolic "kissing towards" a hand of a social superior to acknowledge rank), much to the chagrin of his Greek subjects. Proskynesis was believed to be a reservation for deities and was considered blasphemous by his Greek troops. Alexander was not yet considered a deity in their view, despite his own claim of divine descent.

On June 10, 323 BCE, Alexander met a sudden death in the palace of Nebuchadnezzar II of Babylon, which had become the cultural capital of Alexander's empire. Theories abound as to the cause; malaria, poisoning (both alcohol and other toxins, such as arsenic, have been considered), typhoid fever, and even the West Nile virus have all been named as possible culprits. The matter of the division of his empire was asked of the dying Alexander. One supposed response was the Greek word *krateroi,* an ambiguous statement that could have meant either that his empire was to be bequeathed to the "stronger" or to Craterus, one of Alexander's leading commanders of his army. Regardless of what was said, chaos ensued after Alexander's death, and wars over rightful succession were waged.

The empire was eventually divided into three new empires: the Seleucid Empire of Persia and Mesopotamia, the Antigonid Empire of Macedon and Greece, and the Ptolemaic Kingdom of Egypt (which included the land of Palestine). Though the land remained divided, it still maintained a cohesion that had been established by Alexander the Great. The new Hellenistic period had dawned upon the ancient world, and with it a profoundly Greek linguistic and cultural influence spread far and wide across the empire Alexander had created.

After Alexander's death, literature based on the life of the historic king of Macedon flourished. "Alexander romance," legends, myths, and lore surrounding the life and conquests of Alexander, continued to be written, revised, and expanded well through the Middle Ages. Even in contemporary times, Alexander continues to be represented in popular media, including cinema. One such example is Oliver Stone's 2004 film *Alexander,* which garnered both praise and controversy for its approach to the subject.

Alighieri, Dante (1265–1321)

For Dante Alighieri (1265–1321), one of the greatest poets in history, earthly time was intimately related to Judeo-Christian eternity, the timeless abode of God. In his treatise *De vulgari eloquentia* (written in the early 1300s; sometimes translated as *On Eloquence in the Vernacular*), he argues that the first language was created by God and would be spoken today if humanity's presumption in building the Tower of Babel had not spurred God to fracture that pure idiom into a myriad of different forms of speech. In both the *Vita nuova* (or *New Life,* early 1290s) and his *Commedia* (*The Divine Comedy,* c. 1310–1321), Dante transforms Beatrice, with whom he had fallen in love as a boy, into an agent of divine revelation. The allegory is developed systematically in the latter work, in which Beatrice assists the Dantean pilgrim in his quest for spiritual self-understanding and redemption. Significantly, God's grace comes to the protagonist of the *Comedy* (through the mediation of Beatrice and others) *before* he explicitly asks for divine mercy: This aspect of the poem is a literary rendering of the orthodox Roman Catholic teaching Dante knew well. Also in accord with the church, the Italian poet believed that human past, present, and future are enfolded in eternity, over which God presides. It is no wonder, then, that Dante should have portrayed the fictional pilgrim version of himself in the *Comedy* as a struggling penitent for whom, nevertheless, at least the *potential* for salvation had already been worked out ahead of time.

Dante Alighieri was born in 1265 in Florence, Italy. Although not descended from the most important families in his city, he nevertheless took part in its political life, serving for 2 months in 1300 as one of its seven "priors." While he was away on a diplomatic mission to Pope Boniface VIII the following year, a rival faction took control of power and, once firmly established, banished various prominent political opponents from Florence. One of these was Dante, who wrote the *Divine Comedy* and other works in exile. He died in 1321 in Ravenna, where his remains are still located despite repeated entreaties by the Florentine civic authorities for their return. Although as a young man Dante had married Gemma Donati and had had three sons and a daughter with her, he idealized Beatrice Portinari, whom he had known when they were both children and who died in 1290. In the *Comedy,* this earthly woman attains supernatural stature: She symbolizes, among other things, divine revelation and helps to convey God's intentions for humanity to Dante directly.

Dante's view of time was heavily indebted to traditional Christian thought. He and his contemporaries believed that God dwells in eternity and that human beings, though temporarily confined within linear time, are ordained for higher, transcendent ends. Even from across the abyss between eternity and time, God, in this view, discloses his will to human beings in history rather than remaining wholly aloof from us. To be saved, we are obliged to conform our own individual wills to the divine order, though we are ultimately free to accept or reject that saving grace, as God intended.

Nevertheless, to attribute Dante's conception of time solely to his reading of the Bible, the church authorities, and medieval theology is to underestimate the complexity of his thought. The political observations scattered throughout the *Commedia* and concentrated in the *Convivio* (*The Banquet*) and the *De monarchia* (*On Monarchy*), both written probably when Dante was in his 30s, illustrate the poet's debt to the cultural traditions of ancient Greece and Rome as well, especially the latter. Many scholars have noted his use of classical authorities, particularly Virgil. In Dante's view, providential history as unfolded in the Bible and church tradition could turn to good account even the "pagan" past, whose philosophical and literary achievements had proved a source of discomfort for some medieval writers and thinkers before (and after) Dante's time.

Especially vivid manifestations of his notions of time appear in Dante's verse masterpiece, divided into the three sections or "canticles": Hell, Purgatory, and Paradise (*Inferno, Purgatorio,* and *Paradiso*). Hell is reserved for those who, while alive, indefinitely postponed repentance in order to enjoy their dissolute lives. Despite differences in the gravity of their sins and thus the harshness of their punishments, what all of the damned share is the infinite time they have in which to suffer the consequences of their spiritual negligence. On his journey through hell with his guide, the soul of Virgil, Dante confronts sinners who are usually eager to talk to him at length and so gain some respite from their torments. When he reaches purgatory, Dante sees that souls undergoing expiation there have less time for conversation, as they are eager to end their purgation and ascend to heaven. Even so, the poet Dante's abiding interest in literary influences allows for the occasional prolonged discussion, as when in the 22nd *canto* ("song" or chapter) the shades of the Roman poets Virgil and Statius talk at length about the whereabouts of other ancient writers. Digressions about poets and poetic craft are never permitted to overwhelm the larger theological import of the *Divine Comedy,* however: Even within those digressions, reference is often made to the specifically spiritual condition of the souls of those departed writers. In the *Paradiso* section of Dante's long poem, there is neither the despair found in the *Inferno* nor the sense of expectation characteristic of the *Purgatorio.* Aided by the great mystic Saint Bernard of Clairvaux, the Dantean pilgrim beholds heaven, the blessed souls therein, and images of the Trinity itself. The narrator finds himself struggling to understand this vision of timelessness and to convey it to readers bound in time. Ultimately, however, he puts his faith in God's eternal love, which, he now sees, governs the entire universe despite our inability to understand fully how he does so.

Altamira Cave

Altamira Cave's recognition as the "Sistine Chapel of Quaternary Art" is well deserved, given the cave's magnificent paintings (and engravings) and importance to our understanding of similarly decorated caverns throughout Europe. Found in 1879 by an intrepid little girl who happened to stumble upon this incredible find, Altamira Cave is located in northern Spain. The cave zigzags through the ground, extending almost 300 meters in total length. The ceiling varies in height to a maximum of 12 meters and in width to 20 meters. The age of the cave is a story in and of itself. While many scholars early on doubted Altamira Cave's artwork was ancient in origin, its antiquity eventually became well established, with a large proportion of occupations of the cave occurring between 18,000 and 14,000 years before the present (BP) as determined in part through the use of carbon-14 dating of charcoal from artwork within the cave.

The paintings and engravings within Altamira Cave depict an assortment of abstract images, including a variety of animal species and miscellaneous designs. Often designed with the use of iron oxides to provide an array of colors, the images range from basic charcoal outlines to detailed color images. Designs vary from abstract images of bison, deer, stag, horses, goats, and humans to images whose identity is questionable.

Additional material discovered within Altamira Cave provides information regarding its human occupations. These miscellaneous items include a variety of lithics such as projectiles and multiuse tools as well as bone and antler tools. Other items found within Altamira Cave include the remains of multiple animal species including horse, goat, fish, and deer. Collectively, all the materials provide information regarding Paleolithic populations. However, one important question in particular remains unanswered. Why were the paintings and engravings made? Theories about the images being part of a ritual or a form of magic have circulated for years. The images have also been argued to be nothing more than art for art's sake. Ultimately, we will likely never know the answer to this question.

Altamira Cave's assemblage provides researchers with a glimpse of the activities carried out by its occupants, making Altamira a time capsule of sorts. Time is an especially important issue for Altamira Cave from one additional perspective: Time is a commodity that Altamira and other caves with Paleolithic art are running out of. The paintings within caves like Altamira have been adversely affected by changing environmental conditions partially caused by the volume of visitation these archaeological sites have received. Government agencies are now limiting visitors' access to Altamira and other caves in an attempt to preserve the art within them. Time will tell if their efforts are successful in saving these relics of the distant past.

Amnesia

Amnesia is the condition in which a loss of memory occurs and extended periods of time are forgotten. People afflicted with amnesia experience difficulty accurately estimating time, sometimes even after a recovery in which they fully regain their lost memories. Symptomatically, amnesic patients typically underestimate the time they spend engrossed in any particular activity. They also overestimate time that has passed after a certain activity ended. Even though they are coherent in their thought processes, amnesic and postamnesic patients maintain difficulties in dating past events and in constructing frameworks of time.

These amnesic memory losses may result from many organic occurrences, or medical issues like brain injury or trauma, shock, fatigue, disease, infection, or illness. They may also be triggered by addictions to drugs or alcohol. Amnesias that are not organic or associated with a detectable injury or illness are usually called psychogenic amnesias. These memory losses can be caused by suggestion under hypnosis, or they may arise spontaneously as a result of psychological conflict or stress. This may also be a defense mechanism in which a victim of amnesia represses unpleasant memories. Psychogenic memory losses are often reversible.

Organic memory disorders are the most frequently observed category of memory loss. These losses may be transitory, such as the loss of time and memory during or after binge drinking alcohol or experiencing an epileptic seizure. Memory losses that are more enduring are most often associated with brain disease or head injuries. There are three main types of organic amnesias: anterograde, retrograde, and transient global. Anterograde amnesia is the loss of memory of events or time occurring after a trauma. A patient is unable to maintain and store memories of current events or new experiences after an organic episode. Retrograde amnesia occurs when the memories occurring immediately before a trauma or disease are forgotten. Posttraumatic or traumatic amnesia are posttraumatic confusional states that can last for several hours, days, or weeks after regaining consciousness or recovering from such traumas as a blow to the head. With severe or extensive retrograde amnesia, a person afflicted can lose up to 20 years of memories prior to the trauma.

Alternately, psychogenic amnesias are not caused by physical injury or disease. The loss of personal memories, such as one's identity or past personal experiences, is a psychogenic memory loss and is most often linked to a substantial emotional occurrence, acute conflict, or significantly stressful experience.

Hysterical amnesia is sometimes motivated by a patient's need or desire to escape a traumatic or frightening event or series of events that had caused great conflict or anxiety. It is not linked to a physical condition or medical disorder. This loss is also commonly referred to as repression or motivated forgetting. Although hysterical amnesia sometimes extends to forgetting school-based knowledge, such as reading, spelling, or arithmetic, this type of memory loss is most often related to dementia or organic conditions or injuries. Repressed memories can often be recovered through psychotherapy. Memories can also be lost if a hypnotist suggests to the hypnotized patient that he or she should not remember anything from the session. Hysterical amnesia has two main types: One involves a failure to recall particular past events, and the other type involves failure to register current events.

Some amnesic episodes last for extended periods of time, during which people may begin new life patterns. They may wander away from home or work, leaving their life behind for hours, days, or weeks. When people recover from such periods, also called fugue states, they usually remember only the time previous to and occurring after this fugue state. The time and the events that occurred during the amnesic period or fugue state are entirely forgotten.

Anaximander (c. 610–c. 546 BCE)

Among the Presocratic philosophers, Anaximander of Miletus, a student of Thales, had neither an elaborate nor a fully articulated concept of time, but the word *chronos* (time), which emerges in the one preserved statement of his lost book, signifies a personified cosmic power. In this much-discussed and variously interpreted fragment, time is depicted as a mighty arbiter that, like a magistrate, amends injustice by determining the compensation and the retribution that things at a continuous, cosmic strife are to pay to one another. The notion of time as a judge, whose assessment no act of injustice can escape, also appears in the political and moral reflections of Solon, approximately a generation later. Generally speaking, these reflections imply that a culprit will be punished sooner or later and that time is the best judge of who and what we are.

Anaximander's time acts as a judge in the cosmic affairs in the sense that it determines when the predominance of one occurrence is to be replaced by the predominance of some other, opposite occurrence, and this process is reversible. By these phenomena he presumably understood warring opposites, like hot and cold, light and darkness, wet and dry, seasonal and mortal changes, progressive drying out of moisture by fire and vice versa.

As something that is "boundless," time fixes the boundaries of certain processes, punishing any kind of excess. Restricting the supremacy participants in a cosmic strife, Anaximander's time creates balance in the world as a unified whole. Consequently, the role of time is not only to lay down the sequence of physical occurrences but also to maintain measure and stability in nature's functioning. It is a criterion used to determine the birth, development, duration, and the limits of one occurrence in relation to another.

The shift of hot and cold, of the seasons of the year, of old age and youth as well as their mutual limitations are governed by the same periodic law. Anaximander believed that physical cycles happen in a strictly defined periodical order, which applies to both celestial and meteorological phenomena. With his notion of time as a cosmic judge that dispenses justice by imposing inevitable and immutable norms in the functioning of physical processes, Anaximander, in a way, inaugurated the concept of natural law in Western science and philosophy.

Results concerning the measurement of time are also attributed to Anaximander. He introduced in Greece the *gnomon,* an upright stick for measuring shadow lengths, which was used to give the time of the day, the position of the sun on the elliptic, and the seasons of the year.

Anaximines (c. 585–c. 525 BCE)

Anaximines is, after Thales and Anaximander, the third most ancient of the Greek philosophers. He belongs to the Presocratic philosophers, a range of thinkers who had little in common except their having lived before Socrates. These three philosophers hailed from Miletus, in Ionia, and are known as the Milesian school of Presocratics. Even less is known about the life of Anaximines than of his two predecessors. He was the son of Eurystrathus and is thought to have been about 25 years younger than Anaximander and to have been active around 546–545 BCE, the time Sardis was captured by Cyrus, king of Persia. He is described variously as the companion and the teacher of Anaximander. Only a few fragments of his writing have survived; his thoughts are known only from later writers who paraphrased them. He died probably between 528 and 525 BCE.

The contribution of Milesian philosophers like Anaximines was their seeing the need for finding a single source that could serve as a general explanation for the natural world. Their world abounded with supernaturalist and mythological explanations and explanations, but the Milesians had a naturalistic turn of mind. Homer attributed the origin of all things to the god Oceanus, whereas Thales taught that water was the prime element in all things. Anaximander posited instead the concept *Apeiron,* a composite of the four elements of earth, air, fire, and water. Anaximines shared with Thales in preferring a naturalistic explanation, but thought air (sometimes translated as mist) rather than water was the primal element.

Anaximines probably believed air had a better claim as the primal element than water because it had a better claim to be genuinely unlimited. And there was possibly more than a symbolic likeness to the notion of "breath," which was traditionally thought by the Greeks to be a source of life. An important fragment of Anaximines says: "As our soul, being air, holds us together, so do breath and air surround the whole universe." Even the gods sprang from the air, Anaximines was said to have believed.

The most valuable insight by Anaximines is his understanding that air can take different forms, according to the degree to which it is rarefied or condensed. When rarefied it can become fire; when condensed it becomes wind. Condensed even more, air turns into water, then earth, then stones. Before Anaximines, differences between primal elements could only be quantitative, but now they could be qualitative along a scale. This ranging of properties along a scale and attributing various qualities to them is probably the principal debt we owe to Anaximines, for that is a method of crucial importance to science.

Angels

In the Western spiritual traditions, angels are understood to be heavenly or divine beings that are greater than humans in knowledge and power, but less than deities. The word *angel* comes from the Greek word *angelos,* which means "messenger." In Hebrew, angels are called *mal'ak,* which also means "messenger." Both words are used to mean either divine or human messengers. Only in Latin and later Western languages is the term used solely of divine beings. Although not necessarily eternal, angels do not die; their relationship to time is thus somewhat ambiguous.

Angels in Early History

The idea of angels first appeared in Sumeria around 3000 BCE. The Sumerians were polytheists who believed that messengers mediated between the gods and humans. Also, they believed people had a spirit companion with them throughout their lives, perhaps a primitive version of a guardian angel. Archaeological excavations have discovered home shrines with images of winged humans, which seem to be dedicated to these spiritual beings. This trend continued into later Babylonian and Assyrian cultures. Around 650 BCE, Zoroaster claimed an angel revealed to him the tenets of a monotheistic religion, later called Zoroastrianism. Zoroastrianism portrays Mithras as an angel, along with a hierarchy of six archangels and many lesser angels. Zoroastrian angelology influenced Judaism, Christianity, and Islam.

Angels in the Bible

In the biblical text, angels appear to be genderless attendants of God. They are created beings. Though they are not timeless, they do not die. Their roles are to praise God, serve in the heavenly council, and carry out God's bidding. Many are heralds, but some are warriors and guards. As spiritual beings, angels are usually invisible (formless) but can take on humanlike form, even to the point of being indistinguishable from other humans. The Bible does not always distinguish between the angels and God. For example, an angel of the Lord appeared to Moses in a burning bush, but two verses later the text says God called to Moses from the same bush.

The Hebrew Bible mentions at least two other types of heavenly beings—seraphim and cherubim. Seraphim are heavenly fiery serpents with six wings. In medieval Christianity, they are assigned to the highest order of angelic beings as attendants to God's throne. Cherubim are also winged beings, perhaps with human characteristics. Such beings guarded the Garden of Eden after the expulsion of Adam and Eve. As described in the Book of Exodus, golden images of two cherubim sat upon the Ark of the Covenant facing each other. Their wings spreading toward each other formed the mercy seat of God.

Angels are sparsely mentioned in the early writings of the Hebrew Bible, or Old Testament. In this section, they function primarily as messengers; however, they also serve as protectors and guides, agents doing God's bidding, attacking enemies, and leading God's people. In later Old Testament writings, angels become more prominent with a shift in roles and nature, perhaps due to Babylonian and Zoroastrian influence. Here, angels reveal secrets about the future and interpret visions and dreams. The Book of Daniel provides the first occurrence of named angels—Gabriel and Michael. Daniel also introduces the beginning of a hierarchy of angels, where Michael is called the "great prince."

From the time of Constantine the Great (280–337 CE) and afterward, angels have regularly been depicted as having wings as shown on this statue in Seville, Spain.

Source: Duncan Walker/iStockphoto.

During the Intertestamental period (4th to 1st centuries BCE), angelology greatly expanded, perhaps due to Persian influence (specifically Zoroastrianism). Angels were thought of as too numerous to count. They began to be placed in an ordered hierarchy, giving rise to the development of archangels. Also introduced is the idea of "fallen angels," thus the beginning of the dualistic idea of good and evil angels. In this thought, angels have free will and the ability to choose to disobey God. Some angels were a part of angelic armies. Other angels took on the role of protector or guardian angel. For example, Raphael protects Tobit as he travels to Media.

In the Christian Bible, or New Testament (1st century CE), angels announce the birth of Jesus and continue to carry out God's works. They attend to Jesus's needs while he is in the wilderness; however, they are inferior to him. The Book of Jude speaks of angels who rebelled against being held for the Day of Judgment. In the Book of Revelation, angels play a prominent role in the final battle between good and evil forces. The archangel Michael leads an army of angels into a battle against Satan. Satan loses the battle, and he and his angels are cast down to the earth.

Angels in Islam

Islam portrays angels in a manner similar to Jewish and Christian views. They are seen as servants of God and agents of revelation to humans. However, in Islam, angels do not possess free will and cannot sin or disobey God; thus they cannot be evil. Angels exist in a hierarchy and have specific tasks. For example, Jibril (Gabriel) dictated God's message to the prophets, including giving the Qur'an to Muhammad. Angels accompany each person on Earth in order to record that person's deeds—both good and bad.

Angels in Later History and in Art

Angelology continued to develop after the New Testament period. Pseudo-Dionysius, a person associated with a 5th-century CE philosopher, arranged angels in nine orders, divided into three hierarchies containing three choirs each. Saint Thomas Aquinas, a scholastic (1225–1274 CE) following Pseudo-Dionysius, added that the hierarchies are arranged according to their proximity to the Supreme Being. The superior angels have more knowledge of truth and enlightenment than do lower ones. This view of the angelic hierarchy continues to be the generally accepted Catholic view.

Protestant reformers such as John Calvin downplayed the earlier development of angelology. They tended to de-emphasize a hierarchy and focus on the role of guardian angel. In the Age of Enlightenment angels began to be marginalized or even dismissed as mere fantasy. A diminished emphasis on angels continues to be a main Protestant position.

Art presents a good view of the development of angelology. Angels are regularly depicted as having wings from the time of Constantine the Great (280–337 CE) and afterward. Byzantine artists frequently depict angels in military uniforms, especially Gabriel and Michael wearing officer uniforms. This trend continued into later periods. Also, artists tend to depict angels in pale or white clothing, except during the Renaissance when red and blue garments became the norm. During the Renaissance, angels erroneously began to be associated with *putti*—chubby winged babies—and began to be depicted as such until this appearance became normative. Angels continue to be a common theme in the arts, including in the modern film industry.

As intermediaries between God and mortals, angels are usually thought of as inhabiting the spiritual realms of heaven and earth. However, some people believe angels also inhabit other worlds in this universe.

Anselm of Canterbury (1033–1109)

Anselm, Archbishop of Canterbury, was a great theologian of the medieval Western church. Some consider him the father of scholasticism (the philosophical approach to faith through reason). He is known for his ontological argument for the existence of God and for his theory of substitutionary atonement.

Anselm was born in Aosta, Italy. In 1059 he became a Benedictine monk and resided at the abbey of Bec in Normandy. In 1063 he was made prior and then was appointed abbot in 1078. He held this position until 1093, at which time he became Archbishop of Canterbury. He remained the Archbishop until his death in 1109. King William II, and later, Henry I, called Anselm to England where they disagreed on investitures and other issues of church and state. Contrary to the king, Anselm believed that the church was independent of the king and was under the sole leadership of the Pope. Because of Anselm's position, King Henry I exiled him to continental Europe for much of the time he was Archbishop. In 1720, Pope Clement XI declared Anselm a "Doctor of the Church."

Anselm, like Saint Augustine of Hippo, believed that Christian faith comes through revelation, not philosophy. However, Anselm thought reason allowed one to understand one's faith more fully and therefore found philosophy helpful for theology, especially in proving the existence of God. Anselm expounded on this belief in his work called *Monologion* in 1077. Anselm's most famous work on the ontological existence of God, called *Proslogion,* came out a year later. In this work, he asserts that God is greater than the greatest conceivable being. He argues that this being must exist because if he did not, then God would be inferior to this being. Furthermore, he argues that a nonexistent being cannot be declared to be; therefore, God must exist. Also, he argues that God is eternal and timeless. If God were bound by the laws of time, then he would not be the greatest conceivable being; therefore, he must not be constrained by time. Anselm's arguments are difficult to follow. Furthermore, they are short and succinct, so much so that philosophers and theologians continue to debate their meaning.

In another major work, *Cur Deus Homo* (Why God Became Man) completed in 1098, Anselm employed the same method of using reason to understand faith in explaining the incarnation of Christ and in developing his theory of substitutionary atonement, that is, why Christ has to die for humanity. This work takes the form of a dialogue with another monk at Bec. His basic argument is that because sin is against an infinite God, then its penalty is infinite. Because humanity sinned, only a human can pay the penalty. Thus, the incarnate Christ, God made human, is the only one who can legitimately pay the penalty and redeem humanity. Anselm's theory gained wide acceptance in the 12th century, was held through the Protestant Reformation, and continues to be the dominant understanding of the atonement of Christ today.

Anthropic Principle

The anthropic principle, which rose to popularity in the 1980s, is conspicuous among attempts at answering the question of the position of human beings in the universe. The application of the principle basically means determining limiting suppositions of models of the universe that must respect its recent state, deductive without contradictions from the past states. Real existing phenomena in the universe, especially the existence of an observer, a human being (which gave the name to the principle), act as strongly limiting suppositions of the selection of all possible states of the universe in its past. This entry reviews the sources of those considerations.

Starting Points

The starting points could be divided in at least two related groups: the existential and epistemological causes of the anthropization of the universe. The existential sources could be briefly characterized by the word *surprise:* surprise of human beings at the "starry sky above," astonishment provoked by the organization of the surrounding world, as if waiting for guests at a prepared table. The surprise does not diminish with the increasing knowledge of nature and its laws; rather, the surprise is increased by the fact that humans do not deal with a single improbability but with a chain of improbable events during the whole history of the universe, starting with the big bang until the present. For example, the elements and anti-elements' ratio during the moments close to the beginning of the expansion of the universe had to allow, after reciprocal annihilation and radiation, precisely the quantity of elements remaining as the building material for the universe. This universe can be neither too dense (it would collapse again to the singularity) nor too thin (the matter would then spread out quickly and there would be no material for construction). At the same time, the presently observed stars had to be preceded by the stars of the first generation that created heavier chemical elements and dispersed them after their annihilation to the surrounding space where these elements could become building stones of emerging planetary systems. The created planets must be at an optimal distance from the central star, which must have a relatively stable form. Tolerated deviations—the range enabling the creation of life and basic physical interactions—are expressed by fractional parts of a percentage, while the physical possibility of these deviations is expressed in tenths of a percent. The real macrospace must have exactly three dimensions; no other physically possible case allows the existence of life. There is also the numerical coincidence: the size of proton 10^{27} centimeters and the size of the observed universe 10^{-27} centimeters.

As it concerns the accuracy of the "setting" of the speed of the expansion of the universe (for example), even a deviation that ranges from $1{:}10^{30}$ to $1{:}10^{29}$ would mean the existence of the universe without life. Is it all just a coincidence, very improbable, yet still a coincidence? Or is it an impact of something that is beyond reach, something humans are not able to embrace with knowledge, which, despite all progress, is still limited?

Versions

B. Carter, who named the principle, formulated its two basic versions in 1968:

Weak—The presence of observers in the universe determinates its time dimension; the universe has to be at least as old as to allow the emergence of an observer. The existence of the observer is thus the determinant for statements concerning the physical state of the universe and the conditions that enable this proper existence. The concatenation of this type of condition offers the most probable picture of the past of the universe.

Strong—The presence of an observer determines not only the time dimension of the universe, but also the whole system of features. The strong version states that in every physically real universe, an observer must once appear, so every universe has to create the conditions for the existence of observers.

In the following years, the proponents of the anthropic principle modify the formulations and two completely new versions appear:

Participatory—This version puts the universe and the observer on the same level; their existence is thus conditioned reciprocally. The version stems from the fact that physically possible states of the universe allow life in only a very narrow range, and the probability of the realization of the universe in this narrow zone is very limited (a slight deviation and the universe would still exist, only without any life); even lower probability could be found in the presumption that these particular improbable relations would organize in a chain of continuous conditions that would culminate with the creation of an observer. Based on the final improbability, the participatory version of the anthropic principle draws the conclusion that reason had to participate in the realization of the present improbable state of the universe. There is, however, no explicit mention of the Reason-Creator. Rather an analogy can be observed with the knowledge of micro and macro worlds; for example, in the physics of elements, in the same way as the subject becomes an inseparable part of the object during the observation and makes a natural part of the macro world, it is possible to find the subject in the mega world when its past and recent structures are studied. Nevertheless, if the statement is hidden or explicit in the strong and weak version of the anthropic principle, a double understanding of the role of the subject in the universe can be observed.

1. *Ontogenetic role*. In the literal meaning, the spirit is considered as the crucial agent in the construction of the universe. "The more I examine the universe and the details of its architecture, the more evidence I find that the universe in some sense must have known we were coming" (Freeman Dyson, *The Argument from Design: Disturbing the Universe,* 1979). Why is the spirit "favorable" to life and intelligent observers, and why does it construct a universe where the observer is welcome? (The response is right at hand: The spirit creates according to "its own image.")
2. *Noogenetic role*. The spirit realizes the universe by accumulating its knowledge. This interpretation refers directly to the example of the position and role of the observer in quantum mechanics: "A phenomenon is not a phenomenon without being an observed phenomenon. Observers are necessary to bring the universe into existence" (John Wheeler in the discussion on the congress of cosmology, Krakow 1973. http://ptta.pl/pef/angielski/hasla/a/anthropicprinciple.pdf). The universe is real only when it includes its observer; if it is real, the universe must be able to welcome this observer.

   According to the participatory version, the existence of the universe is as important for the observer as is the existence of the observer for the universe. If the universe is supposed to be real, it must have qualities that would enable the existence of the observer.

Intelligent observer—The fourth and the last version of the anthropic principle is its final version: Intelligent systems of processing information have to appear in the universe, and they will never disappear after their emergence. An intelligent observer is the aim because it gives meaning to the existence of the universe.

As previously mentioned, in the background of all these interpretations of the anthropic principle is the surprise at the character of the universe that allows the creation of life, while it would be more probable to dispose of at least slightly different features. Why did the universe "choose," out of many possibilities available at every moment of its evolution, such a slightly probable succession that led to the creation of life? If the question is asked in the sense of the weak version of the anthropic principle and if its heuristic value is used, then the question "why" is appropriate because it offers a possibility to choose out of the number of possibilities only those that lead to the creation of life, which undoubtedly exists, in order to complete the picture of the past of the universe that best describes the past events. The question becomes more problematic when the strong or the participatory version of the anthropic principle is considered, because the answer is looked for in the activity of the spirit that is "responsible" for all. However, that means only that the primary "why" falls apart into many other questions that cannot be principally answered. The original surprise that had a positive constructive character as it led to the research of the most probable version of the image of the universe is gradually, in its consequences, changing into uncritical astonishment and resignation to continue the research.

While the main point from which the strong, and especially the participatory, version of the anthropic principle start is the improbability of the state of the universe, there is another solution available. The French astrophysicist M. Lachièze-Rey problematizes the proper notion of probability: "As it concerns the original and continuous setting of the condition of the universe, we do not have (apart from the law of the increasing entropy) any precise law of probability and we can hardly decide what data are probable. We do not know what we would like to know." (M. Lachieze-Rey, C.N.R.S. Institute d'astrophysique, private communication, Paris 1991) Another possible answer is offered by the inflation theory of the universe. The inflation theories are used as a more physical solution and they are put in opposition to the anthropic principle; however, based on preceding experience, it would be more prudent and appropriate to avoid the excluding "either–or" (for what remains, I will try to show that such an extreme solution has not been fruitful) in order to try to unite the positive features of both perspectives. What solution will offer this proposition? Especially, the earlier-mentioned surprise at the readiness of the universe for life will obtain again its constructiveness, and it will be possible to use the heuristic characteristics of the weak version of the anthropic principle. The fact that the inflation theory studies the possibility of the existence of an infinite number of physically independent universes with variable physical parameters changes the improbability into a highly probable phenomenon, if not a statistical need. Most of these independent universes have physical conditions that do not allow the creation of life, but it is not surprising that there has been at least one universe in the infinite number that unites a combination of conditions that enable life. Human beings should not be surprised at having appeared just in this "vital" universe. It remains "just" to disclose the past of the real universe with respect to the fact that past states had to contain such qualities that led to the creation of life; they had to be "biogenetic." Among these physical solutions are not entirely proved but promising theories, for example, Linde's modification of inflation models.

> This work on inflationary models showed that the present state of the universe could have arisen from quite a large number of different initial configurations. This is important, because it shows that the initial state of the part of the universe that we inhabit did not have to be chosen with great care. (Stephen Hawking, *A Brief History of Time: From the Big Bang to Black Hole*)

Moreover, according to Stephen Hawking, "Must we turn to the anthropic principle for an explanation? Was it all just a lucky chance? That would seem a counsel of despair, a negation of all our hopes of understanding the underlying order of the universe." (Stephen Hawking, *A Brief History of Time: From the Big Bang to Black Hole*)

Even if the anthropic principle is not motivated by anthropocentrism, a common ground can be found. The whole history of cosmology—from ancient history until the present—is basically, in a rough scheme, a history of the dethroning of humans from the center to the periphery of the universe. The anthropic principle seems to restore the privileged position of human beings, their reason and life, by saying that the history of the universe led to the creation of human beings. Nevertheless, related to the inflation theory, the anthropic principle offers results that correspond to the previous tendency (concerning the spatial forms of centrism), more precisely expressed—results that correspond even more that anyone could ever imagine. It makes insignificant not only human beings but also the whole universe that can appear only as one of many universes. The partisans of the anthropic principle would certainly protest against mentioning the anthropic principle in the context of anthropocentrism. It is true that the anthropic principle does not place human beings in the center, but living observers, whatever planet they live on. However, that does not change the fact that the idea of the center is conserved where the subject of knowledge is central, whether it is a human being or any other existing thinking being. A comparison can be made between Aristotle and the anthropic principle. The compatibility of Aristotle's considerations and the anthropic principle could be observed in the applied method that leads to the idea of the privileged position of subject. Thanks to the observation of a falling stone, Aristotle came to the conclusion that heavy objects tend to fall down and that the earth, not able to fall anywhere because of its heaviness, forms the center of the universe; it is the "down" for everything else. The anthropic principle stems from the simple presumption that an observer does exist. To ensure the existence of the observer requires specific, precisely defined conditions. To "offer" these conditions in a certain moment, the universe had to be precisely limited in its past and realize many, even very improbable, possibilities. This fact leads the followers of stronger versions of the anthropic principle to the conclusion that the universe is oriented to the creation of life, which had to appear. Some of them are even persuaded that the spirit directly participates (ontogenetically or noogenetically) in the construction of the universe appropriate for life.

Aristotle's stance and the anthropic principle stem from the irrefutable arguments, purely empirical ones (a stone falls down, observer does exist), and lead to the idea of a privileged position of human beings in this universe; in the case of the anthropic principle, which is a far more large-scale framework than Aristotle's was, the idea is still maintained that a thinking being in particular and life in general hold a privileged position in this cosmos.

Inevitability

Are humans actually able to create a non-anthropocentric image of the universe? The proper essence of the cognition process—principal epistemological anthropocentrism—leads to the assumption that every image created by human beings will bear the traces of its producer. If we suppose that the real universe exists and is unique, we have to realize continuously our subjective role in the formation of the image of the world, and we have to get rid of the illusion of objective knowledge that reflects reality and consider as more adequate the one that would consciously include itself and its creator. It is obvious that even in this case, we could obtain approximate results only. In a possible solution of the anthropocentric principle, it would mean acknowledging that the universe is anthropic and non-anthropic at the same time.

Just as a distinction can be made between the final and the limited, thanks to the relativistic physics of spacetime and modern cosmology—even the pair "final and infinite" is only a relative opposition—some other polarities previously considered irrefutable should now be abandoned, including yes or no, white or black, man or woman, word or action, subject or predicate, anthropic or non-anthropic. We humans are continually confronted with the dualities of the world; however, we have to realize that they are the dualities of our world, the world of human scale. To what extent is this "yes or no" perspective useful in other, completely different levels? In the world of elementary particles and galaxies? Nevertheless, even "our" world corrects its own oppositions in many ways. What used to be good could be bad today; a friend could behave as an enemy; the disguises of love and hate are hard to recognize. The universe is anthropic in terms of what we know about it and non-anthropic in our ignorance of it.

ANTHROPOLOGY

The human preoccupation with time extends into humankind's study of ourselves: anthropology, the science of humanity's past, present, and future. Only by studying ourselves, and how our ancestors behaved in the past, can we learn about our nature. In the past, human societies rose and fell, subject to external and internal factors. We respond to the environment we find ourselves in, struggle to adapt to or overcome obstacles, and attempt to thrive and perpetuate ourselves. To be human is to have a human nature, and the more we learn about our past the clearer it becomes that we have not changed much in the past 100,000 years since developing into what we call "modern humans." By studying past and present human mistakes and triumphs, we hope to improve our own future.

Anthropology is a broad discipline that has been steadily growing since its inception in the 19th century. It contains many subbranches and undoubtedly will acquire more as time passes. In North America anthropology is known as a "four-field" discipline. Its major branches are biological anthropology, archaeology, sociocultural anthropology, and linguistic anthropology.

History of Anthropology

Given human nature, it is clear that our ancestors began speculating about their origins long before the written word was invented. The early creation myths of ancient civilizations such as Egypt and Mesopotamia that have come down to us in writing, date to the 2nd millennium BCE When true "anthropological" thinking came about is a matter of speculation. The term *anthropology* is a 19th-century combination of two Greek words: ἀνθρωπος, *anthropos,* "human being, man," and λόγος, *logos,* "knowledge"), and the earliest writing we have on the scientific speculation of human origins is Greek as well. The 6th-century BCE philosopher Anaximander (c. 610–c. 546 BCE) lived in Miletus in Ionia (modern western Turkey, i.e., Anatolia) and became a part of a school of philosophy called Milesian (named after Miletus). Although his works survive in only one fragment, citations by later classical authors provide us with what little we know about him. Among his influential ideas, which ranged from astronomy to cartography, he developed the earliest known "scientific" hypothesis of human evolution. Anaximander believed that the earth was once composed entirely of water and that the first life forms came from there, and in this he was basically correct. Furthermore, according to Anaximander, when parts of the earth dried up, some of the fishlike animals came up on shore, bearing human beings within themselves like fetuses, which then emerged from their aquatic parents when fully acclimatized. However, Anaximander's ideas that humans developed somehow from other organisms were eclipsed by those of Plato (c. 428/427–c. 348/347 BCE) and Aristotle (384–322 BCE), two later philosophers whose ideas would dominate Western thinking for centuries to come. Plato was a believer in *essentialism,* a point of view that maintained that any given entity was created as perfect and possessed a series of characteristics, all of which any entity of that kind must have. Plato believed in eternal, ideal forms, which are reflected in material objects although far superior to them; these ideal types (Platonic ideals) had neither the need nor the ability to change. Aristotle believed that all creatures were arranged in a *scala naturae,* or "great chain of being": a system of 11 grades of perfection beginning with plants and ending with human beings. Higher creatures gave birth to warm and wet live offspring, and the lower ones bore theirs cold and dry, in eggs. These ideas were prevalent for centuries, essentially hindering any thought of human evolution or change through time. The 5th-century Greek (also from western Anatolia) Herodotus (c. 484–c. 425 BCE), often referred to as father of the study of history, could also be considered the father of another aspect of anthropology: ethnography, the writing down of firsthand observations of foreign cultures. In his travels throughout the ancient world, Herodotus was using many methods in common with those of modern anthropologists, such as locating the best-informed people to provide information about history and customs.

The medieval world saw little progress in anthropology. When Catholicism grew in power following the era of the Roman Empire, its dogmatic insistence upon a literal reading of the Bible, according to which God created each and every species as is, and that no species, once created, could be destroyed, held sway. The belief that the earth was fairly young also prevailed. The English bishop James Ussher (c. 1581–1656) developed a chronology based upon a careful reading of the Old Testament and concluded that the earth was created on the evening of October 23, 4004 BCE; how he arrived at such a specific date was in fact a remarkable act of scholarship.

By the 17th century CE, geologists were becoming increasingly dissatisfied with this sort of thinking because it failed to explain the collections of fossils and what was understood of geology; in chronologies such as Ussher's there was simply not enough time. In the 17th and 18th centuries the exploration of the globe drastically changed how people thought of the world. Human and animal diversity across the earth was too vast to be explicable in terms of a common ancestry in the Garden of Eden; change through time must therefore have taken place. The existence of fossils, in their geological contexts, of creatures that nearly, but not quite, resembled modern ones, was additional evidence for change. The presence of creatures such as dinosaurs, without modern equivalents, spoke strongly for the notion of extinction, also in contrast to the earlier beliefs regarding Creation. In the 18th century Carolus Linneaus (1707–1778), a Swedish botanist (who initially had believed that species were unchangeable), classified every species as a member of a genus, which in turn were classified into the progressively more general categories: family, order, class, phylum, and kingdom. The Linnean taxonomy was the culmination of 2,000 years of thought, and its development made Linneaus reconsider his earlier belief in the fixity of species.

Geologists in the 19th century were eventually unconvinced that the earth was less than 6,000 years old and believed that the earth formed and changed in the past by means of the same processes that existed in the present. The concept of *uniformitarianism* replaced the older notion of *catastrophism,* which held that catastrophic events (such as the Biblical Flood) were responsible for wiping out earlier life forms. The naturalist Charles Darwin (1809–1882) forever changed scientific thought with his volumes *On the Origin of Species* and the *Descent of Man,* in which he espoused the mechanism of natural selection to explain the variability of life on Earth and that ultimately humans were descended from apelike ancestors. The concept of evolution was thus born. At the same time, although unbeknownst to Darwin, an Austrian monk named Gregor Mendel (1822–1884) did pioneering experiments on the principles of inheritance using pea plants. Despite all these rapid and astounding developments in scientific thought, it would take more than half a century for ideas concerning inheritance, natural selection, and evolution to merge into the concepts we are familiar with today. By the 1950s enough research had been done so that the basics were widely understood. (The search for human ancestors had been under way since the late 19th century.)

Other branches of anthropology were also coming into their own. Archaeological excavations of sites such as ancient Troy began in the late 1800s, and the first ethnographers, ancestors of modern cultural anthropologists, were recording their observations on cultures and languages that were steadily vanishing in the face of Western encroachment. The four fields of modern anthropology—biological, sociocultural, archaeology, and linguistic—were all in place by the dawn of the 20th century.

Biological Anthropology

Also known as physical anthropology, biological anthropology is concerned primarily with the physical and biological attributes of humans and human ancestors as a species of animal. Biological anthropologists study human beings using much the same methodologies that they would use for other animals. Until recently, biological anthropology dealt largely with human bones and fossils, but advances in the fields of genetics and molecular biology have extended the discipline to include these aspects as well. Consequently, the study of human genetics, known as *molecular anthropology,* is included in the category of biological anthropology. Therefore the term *biological anthropologist* is rather general and may designate a specialist in a number of different areas, such as human evolution (paleoanthropology), nonhuman primate biology (primatology), variation among modern human populations, and forensic investigation (forensic anthropology).

Paleoanthropology

The study of human evolution (paleoanthropology) is the study of the processes that led to our becoming modern humans, which began around 65 million years ago with the emergence of the first primates. As human beings are primates, paleoanthropologists study the skeletons and fossilized remains of not only humans and human ancestors, but also nonhuman primates as well. Fossils in general are dated using the potassium-argon (K-Ar) method that measures the decay of potassium into argon gas; this dating method, like others, is constantly being refined.

In just over 100 years, scientists have amassed fossils from an increasing variety of human ancestors and distant relations. The field can be said to have originated in 1856 with the accidental discovery of the famous Neanderthal skeleton, named after the Neander Valley, Germany, where it was found. A long time passed before other important discoveries, such as that of *Homo erectus,* or "Peking man" by Eugène Dubois and "Java man" at the Trinil site in 1819. DuBois's discovery was remarkable because he had set out to find exactly that: a human ancestor. Unfortunately, few members of the scientific community accepted his "missing link," and DuBois retreated from the limelight, keeping his precious fossil remains under his bed and showing them to few. In the late 19th and early 20th centuries, great debate raged over where human ancestors originated. Racist beliefs of the time tended toward Asia rather than Africa. However, in the 1920s, important discoveries were made in Africa, most notably Raymond Dart's "Taung child," or *Australopithecus africanus,* one of the earliest human ancestors. Later important discoveries in Africa include that of *Australopithecus robustus* and *Homo habilis* by Louis Leakey in the 1950s and 1960s, and then the earliest-known hominid ancestor, *Australopithecus afarensis,* or "Lucy," in the 1970s by Tom Gray and Donald C. Johanson. Added to these basic genera are also (among others) *Homo ergaster, Homo rudolphensis, Homo georgicus, Homo heidelbergensis,* and *Homo florensiensis,* the most recent find that continues to amaze people. (*Homo florensiensis* appears to be a diminutive descendant of *Homo erectus* that gradually "shrank" after reaching the small island of Flores; it is estimated that the creature was under 4 feet tall.) It is certain that the more fossils that are found, the more complex a picture will emerge of the process of human evolution. It is a far cry from the "ladder" that earlier scientists had imagined and now resembles more a complicated web, with numerous branches, dead ends, convergences, and overlaps. The timeline of human evolution is constantly being modified, and any given textbook is guaranteed to be somewhat out of date by the time it is published because of an ever-increasing body of evidence. Although the fossil record is by nature very fragmentary and there are many gaps in our knowledge, we do have a broad understanding of the various factors that led our ancestors on the path to critical developments such as bipedalism and tool making. Because organisms are inseparable from their environments, paleoanthropologists must consider the big picture when hypothesizing about human evolution, climatic change being an essential variable. Genetic research has also contributed greatly to our understanding of evolution. While opinions are constantly fluctuating, genetic evidence has recently demonstrated that Neanderthals (*Homo neanderthalensis*) and *Homo sapiens* were too different in terms of their DNA to have been able to interbreed (modern humans having coexisted with Neanderthals for thousands of years). Neanderthals therefore were probably not our ancestors, but rather one of many hominid "offshoots" that left no descendants. Mitochondrial DNA (mtDNA) evidence has also called into question the hypothesis that *Homo erectus* developed independently into modern humans in different parts of the world (Africa and Asia), as the fossil evidence suggests. Genetic evidence supports a different hypothesis: the "Mitochondrial Eve," or "Out of Africa" school of thought, in which modern human beings developed only in Africa and then spread out, gradually replacing earlier populations of *Homo erectus.* Debates over large issues such as this demonstrate how much we have to learn about our own ancestry.

Primatology

As we can never observe what our ancestors actually looked like, or how they behaved, primatology, the study of nonhuman primates, is an essential component of paleoanthropology, and a very diverse discipline in and of itself. Some subjects that it comprises are primate anatomy, field studies of primate behavior, and experiments with communication and animal psychology. Observing nonhuman primate behavior in both the wild and in captivity gives anthropologists a scientific basis for hypothesizing on ancestral human behavior. Primates are our closest relatives in the animal kingdom and include Asian and African apes and monkeys, as well as the prosimians: lemurs, lorises, and tarsiers. Issues especially relevant to human evolution include social behavior, food gathering and sharing, patterns of conflict, communication, learning, and tool use. Perhaps the most famous primatologist is Jane Goodall (b. 1934), who has popularized the discipline on television and film through her work with chimpanzees and through her numerous scholarly and popular publications (such as children's books).

Forensic Anthropology

Forensic anthropology entails the identification and analysis of (generally modern) human remains. Forensic anthropologists are trained to recognize such things as time since death (based on the decomposition of soft tissue and bone); taphonomy (postdepositional changes); ethnic group, age, and sex of the individual; physical characteristics such as height and weight; abnormalities and trauma; and cause of death. Forensic anthropologists are able to assist in murder investigations and the identification of remains of victims of accidents, war, and genocide. Forensic anthropologists are also called upon to identify remains of the victims of mass-slaughter events and to locate and repatriate the remains of soldiers who died overseas. As more sophisticated techniques develop, the ability of these specialists to help solve crimes in cooperation with law enforcement agencies has grown. It comes as no surprise, then, that popular culture has, in recent years, highlighted the work of forensic anthropologists on television shows (both documentaries and dramas) and in novels.

Archaeology

Archaeology is primarily the study of past cultures through the excavation and analysis of material remains. Given the absence of time travel and the relatively short period in which history has been written down (about 5,000 years), archaeology is our only window into the past. In Britain and elsewhere in Europe, archaeology is considered a separate discipline from anthropology, although clearly related. In the United States, archaeology is still largely considered a branch of anthropology. Archaeologists study change through time. The archaeologist usually has a particular research question, or hypothesis, in mind before proceeding to fieldwork. A site appropriate to testing this hypothesis is then selected or searched for. Archaeological sites can be as massive as the Pyramids of Giza or as small as a 1 × 1 meter pit excavated into the ground where human beings have left any kind of trace behind. An archaeologist may use a combination of techniques to acquire data, such as surface survey of ruins, mapping, and excavation. Depending on the type of site, different methods are employed, and these vary from country to country as well. Archaeologists differ from paleoanthropologists in that they study the period following the advent of modern humans, although excavation techniques naturally are not very different. Like paleoanthropologists, archaeologists are above all concerned with the temporal perspective of human culture, that is, the diachronic perspective.

Archaeologists are, by nature, almost obsessed with time; dates are the subject of endless discussions and debates. Archaeologists have a number of tools at their disposal to date a particular site. Where available, written documentation is often the most accurate and valuable tool. (For example, the Maya were master astronomers, calendar makers, and date keepers.) This can be in the form of an inscription on a temple, stating when and by whom it was dedicated, or by a simple coin bearing a date. However, as writing has existed for only around 5,000 years, many archaeologists must rely on other means. The most basic means of dating a site is through the study of stratigraphy. A stratum is a layer of deposition, and in principle, the lower layers contain deposits older than the upper ones. However, this gives the archaeologists only a relative chronology, in that one thing can be said to be older or younger than another thing, without an absolute reference point. More scientific means are necessary to secure an actual date. The most precise scientific method for this is dendrochronology, or tree-ring dating. Using a vast database of tree-ring chronology throughout certain areas of the world, archaeologists can, in some cases, pinpoint the year in which a piece of wood, such as a house-post, was cut down (long-lived species of trees are necessary for this). However, this method works only for areas in which wood is preserved, namely, arid ones such as the American Southwest. A more universal method is C-14 radiocarbon dating, which measures the decay of the unstable isotope carbon-14, which is absorbed by all living organisms. This method tells us, within several decades, the date of an organism's death; a piece of charcoal from a fire pit, for example (the date comes from death of the piece of wood that was later burned). This method is usable for sites as old as 60,000 years; for (mainly fossils) prior to that, potassium-argon (K-Ar) dating is used. Thermoluminesence dating is a technique for dating ceramics, where they exist (it measures when the object was fired). Changes in artifact styles, especially pottery styles (shapes, forms of decoration, etc.) are also extremely important and are often used as a chronological basis.

An archaeologist's fieldwork is only a fraction of the process. Once all the data collection has been done, the material—which usually consists of broken tools, ceramics, and midden (food remains)—is transported back to a laboratory where analysis is undertaken. Among things that archaeologists look for are what kinds of food were being consumed and what kinds of objects were being produced and used. Patterns through time are carefully studied and hypotheses postulated. Because archaeologists recover only a small fraction of the remains that a given culture leaves behind, they must often resort to other aspects of anthropology to fill in the gaps. Linguistic data can be extremely valuable, as can ethnographies about either the culture's descendants or those of a similar one. To reconstruct the environment of the culture in question, an archaeologist will often collaborate with environmental specialists who study ancient pollen (palynologists). Other specialists, such as geologists and climatologists, and geneticists, are also brought into the field. Within archaeology there are many subdisciplines, such as archaeozoology, which studies animal remains, and archaeoastronomy, which focuses on ancient astronomies. Archaeology also is not confined to the surface of the earth; underwater archaeology focuses largely on shipwrecks and other submerged sites. By nature, archaeology is destructive: A site, once excavated, no longer exists. Extensive record keeping during excavation is therefore essential. Whereas the basic tools of the archaeologist, such as the shovel and trowel, have not changed much since the discipline began in earnest in the late 1800s, advances in technology continue to contribute to the sorts of questions that can be addressed. Computer modeling and simulations, geographic information systems, DNA studies, geochemical sourcing, and stable isotope analysis are but a few examples of the means now available.

Of increasing importance in archaeology is cultural resource management (CRM). In the past 30 years, CRM has grown in importance throughout the Western world. Although the laws vary from state to state, any building project participated in by the U.S. government is required to hire archaeologists to make sure that any site disturbed or threatened is assessed, studied, and documented. At the higher levels, professional archaeologists may have doctorate, master's, or bachelor's degrees. CRM is especially critical when human remains are unearthed, especially those of Native Americans (including Hawaiians). CRM, however, is hampered by difficulties such as time constraints, report submission, and legal and ethical issues. Much of the findings obtained through CRM, therefore, are not widely circulated or published, although everything must, by law, be put on record in the local State Historic Preservation Division's office. Although usually separate from academic institutions such as universities, many professional archaeologists are among the finest scholars working.

Sociocultural Anthropology

Also known simply as cultural anthropology (mainly in America) and social anthropology (in Britain), sociocultural anthropology is concerned with how human beings function, behave, and relate to one another within society. It treats human beings as transmitters of that complex set of standards and behaviors that we call culture. As human beings, the passage of time is naturally of great importance to us. How different cultures calculate and mark the passage of time is of great concern to sociocultural anthropologists. Rites of passage are rituals cultures employ to assist their members during life's important transitions, and they are an important component of any given culture. Key events are birth, puberty, the transition into manhood or womanhood, marriage, status changes, procreation, and ultimately death. The French ethnographer Arnold van Gennep (1873–1957) made a special study of rites of passage in *Les rites de passage* (1909). Van Gennep's work has influenced scholars throughout the 20th century, notably Joseph Campbell (1904–1987) in his studies of mythology and heroic archetypes, and Victor Turner (1920–1983) in his work on comparative religions.

To understand a given culture, cultural anthropologists generally spend a great deal of time doing their fieldwork, which can take years. They must immerse themselves completely into the society they are studying; this study necessitates learning the language and acquiring a new set of social skills. Within cultural anthropology there are two principal components: ethnography and ethnology. (*Ethnology* is a term often used in Europe to describe cultural anthropology as a field.) An ethnography is a description of every possible aspect of a given culture: its sociopolitical organization, religion, economy, laws, kinship system, and gender relations being among the main components studied. Ethnology is the broader, cross-cultural study of societies that bases itself upon the descriptive data of ethnographies.

To compile an ethnography, the anthropologist must observe and participate in as many aspects as possible (participant observation), within reason and morality, and strive not to interfere with the culture itself. Cultural anthropologists must be efficient and extensive note takers and learn to extract as much true and valuable information as possible by speaking with and interviewing members of the community. Known generally as *informants,* these local experts must be, above all else, reliable. In interviewing, the anthropologist must be extremely diligent so as not to lead the informant in a particular direction so as to extract a desired answer. Paying informants is also a sensitive issue fraught with the risk of obtaining misinformation. Information gathered must be confirmed from multiple reliable sources before it can be taken as fact. Perhaps the most famous case of misinformation given to an anthropologist is Margaret Mead's (one of the all-time "great" anthropologists) *Coming of Age in Samoa.* A classic still in print, the work made Mead's career. Years later it came out that her informants had made up much of what they told her, thus negating a large part of the work's value.

Among the most famous and influential thinkers in cultural anthropology were Franz Boas and Bronislaw Malinowski. Boas (1858–1942) was born in Germany and received his doctorate in physics in 1881. He later made his name in anthropology while working with the Native Americans of the Pacific Northwest; became a professor at Columbia University, where he started the first Ph.D. program in anthropology in the United States; and was a key founding member of the American Anthropological Association (Margaret Mead was Boas's most famous student). Boas insisted that each culture be examined in its own context and not compared with others in time and space. Bronislaw Malinowski (1884–1942) was born in Poland and did his fieldwork in New Guinea and the Trobriand Islands. His most famous work, *Argonauts of the Western Pacific* (1922), is a classic in the field, detailing the trading practice of the Kula Ring, a complex network of gift giving and alliances. Malinowski eventually became a professor at Yale University.

Sociocultural anthropology is often thought of as having to deal with "primitive" peoples in far-off areas such as New Guinea or Africa. However, since the early 20th century there are no more places on Earth where people live in complete isolation and ignorance of the modern world. As a discipline, therefore, sociocultural anthropology often has to turn its looking glass onto peoples closer to home, as it were. Today's sociocultural anthropologist may, for example, study some aspect of an ethnic minority neighborhood or the effects of the Internet upon a given population segment. The boundary between sociocultural anthropology and sociology is thus constantly being tested and blurred as the world we live in continues to shrink.

Linguistic Anthropology

Human beings are the only animals on Earth that have actual language, as opposed to communication. How we express ourselves, in terms of words and grammar, is inextricably linked to how we understand and interpret the world around us. Languages have a dazzling array of expressions to reflect the passage of time. For example, basic verbal concepts such as tense (the absolute location of an event or action in time) and aspect (how an event or action is viewed with respect to time, rather than to its actual location in time) are emphasized and combined differently from one language to another. How a given culture views time is embedded in its language. In Western culture new terms for measuring time in increasingly smaller or more precise intervals are constantly appearing. Computers, for example, work in terms of *nanoseconds* (a billionth of a second), a term first used in 1958 when it became measurable.

Linguistic anthropologists study languages from various perspectives. By understanding the relationships between modern languages, and, when available for study, their ancient ancestors, linguistic anthropologists have been able to hypothesize about when and where various populations lived, migrated, and interacted. In studying a particular language family, linguistic anthropologists examine all the members, find commonalities in vocabulary and grammar, and reconstruct an ancestral language that can then be placed, tentatively, in time and space. This means of working backward to understand past populations is an invaluable asset to archaeologists, who often resort to linguistic data as additional evidence. Linguistic anthropologists also study the relationship between modern language speakers and their cultures (sociolinguistics) and how languages work in terms of grammar and syntax. Linguistic anthropologists can help modern peoples better understand and maintain their languages, thus salvaging data that might otherwise become lost.

Applied Anthropology

Applied anthropology refers to the use of anthropological methods and theories to solve practical problems; virtually every aspect of anthropology can be put to such use. Medical anthropology is a subfield within cultural anthropology and is concerned specifically with human health and disease. Medical anthropologists focus on such things as traditional healing practices and conceptions of health and illness and how they relate to the society as a whole. Medical anthropologists are well positioned to put their knowledge to practical use (applied anthropology) by improving public health care and raising health-related awareness among the communities they study.

Anthropologists can also assist development agencies in their efforts to help developing nations. An anthropologist can provide knowledge and details about a given culture that would otherwise be unavailable, such as social needs, environmental constraints, and traditional labor organization. An anthropologist can also provide an impact assessment, by determining what the consequences of a given project would be on the local environment, in terms of pollution or deforestation, for example. All the factors are critical for the success of the long-term goals of a given project.

Ethnologists and linguistic anthropologists can also put their skills and knowledge to use in modern communities by clarifying the importance of such things as kin ties and dialect differences. The perspective offered by anthropologists can be invaluable when dealing with problematic cross-cultural situations.

Time and Anthropology

As anthropologists are scientists that study living and dead populations, time is always "of the essence." While a variety of theories about anthropology abound, causing endless debates among those so inclined, it is generally recognized that people do not behave according to hard scientific laws. Although generalizations can be made about subjects such as warfare, social complexity, migration, diffusion, the role of the individual, and gender issues, to name but a few, what an anthropologist concludes is often more of a reflection on the time and place he or she lives in than an absolutely objective assessment of the material.

As people, we cannot, of course, travel back in time. The only way we can observe and learn about the past is through observation of organic, material, and written remains. It is impossible to predict what anthropology will be like in, say, 100 years. New developments in science and technology will undoubtedly transform the discipline, as they have done in the past. Nevertheless, the basic goals of the anthropologist will remain constant: to study the past and present of humanity and the long journey it has taken and continues to take. As is the case with any other scientific discipline, an anthropologist's findings are fixed in space and time, and conclusions are never absolute: They are always subject to change, refinement, discussion, and perhaps dismissal. The best any anthropologist can hope for is to develop an interpretation that, for the moment anyway, is as valid as the data permit.

Apocalypse

Apocalypse is a term referring to divine revelation of hidden knowledge, usually of the future, conveyed by God through symbolic visions to a chosen prophet or believers. The English term is derived from the Greek *apokalypsis* (translated variously as "revealing," "uncovering," or "lifting the veil") and related to the Latin *revelatio,* which conveys a similar meaning. Early Jewish and Christian references understood an apocalypse to include any writings that revealed divine will to humans. Such examples in the Hebrew Bible, or Old Testament, include the appearance of God to Moses on Mount Sinai (Ex 24 and 34) and messages received by prophets, particularly as described in the Books of Daniel, Isaiah, Jeremiah, and Ezekiel, among others. In the Christian Bible, or New Testament, the words of Jesus are often considered revelations of God's will. This is reinforced in Matthew 11:27: "All things have been delivered to me by my Father; and no one knows the Son except the Father. Nor does anyone know the Father except the Son, and he to whom the Son wills to reveal him." In the contemporary secular sense, however, "apocalyptic literature" has become generally associated with writings that describe events preceding and culminating in the end of the world in its present form, usually through devastation, without reference necessarily to the salvation of the righteous. While this meaning, which refers exclusively to the "end times," is not precise, it has derived, in large part, from the last book of the New Testament, the Book of Revelation.

In Christian tradition, Apocalypse is the alternate title for the last book of the New Testament, interchangeably referred to as the Book of Revelation, Apocalypse of John, or the Revelation of Saint John the Divine. It is believed that the term Apocalypse, as a title for the Book of Revelation, was first used by German theologian Gottfried Christian Friedrich Lücke between 1832 and 1852. Lücke applied the term *apocalyptic* to other writings, such as the Old Testament Book of Daniel, which alluded to the future and, particularly, end times. Lücke also studied and wrote extensively on the authorship of the Book of Revelation, the only completely prophetic book of the New Testament.

Apocalyptic passages are also found briefly in the Gospel of Mark (13:1–37) when Christ reveals signs of the end times to his disciples, involving natural disasters and the rising of false prophets.

The author of the Book of Revelation is self-identified as "John, the servant of God" (1:1); however, it is uncertain whether he is also the apostle John, author of the fourth gospel. John described divinely inspired visions he received on the island of Patmos, off the coast of Turkey, most likely between 68 and 96 CE while he was in exile for preaching Christianity (1:9–10). In John's vision, Christ appears to him and directs him to write to the faithful with words of encouragement as well as warning. The book, comprising 22 chapters, describes the opening of heavenly scrolls containing divine disclosures describing great disasters (6); God's defeat of evil forces in the battle of Armageddon provoked by the false prophet or Antichrist (16:14–16); the Second Coming of Christ (19–20); the establishment of God's kingdom on Earth, referred to as the Millennium or a period of 1,000 years of peace and justice (20); and the final judgment, followed by the descending of a new heaven and earth replacing the old and referred to as the New Jerusalem (21).

The Book of Revelation is addressed to the seven Christian churches of Western Asia, and chapters 1 through 3 refer to each church, specifically warning the faithful not to compromise with the prevailing and dominant pagan beliefs. During the 1st century CE, Christians were considered members of a minor Jewish sect, although a threat to the Roman Empire and thus subject to persecution. Early Christians were also in conflict with Jewish religious authorities and therefore faced conflict on two fronts. Apocalyptic literature, in general, has been addressed to people suffering persecution and seeks to strengthen their fortitude, often predicting the end of the world, when evil will be destroyed and justice will prevail. The Apocalypse of John has been subject to more analysis, perhaps, than any other book of the Judeo-Christian Bible because it is filled with symbolic language and ambiguous imagery open to a wide range of interpretations. The number seven is particularly evident, for instance, in references to seven letters (1), seven torches and seven spirits of God (4:5), seven seals on the scrolls (5:1), the Lamb with seven horns and seven eyes (5:6), seven angels and seven trumpets of warning (8:2), the seven-headed beast (13:1), and seven bowls of God's wrath containing the seven last plagues (15:1). The number four also appears repeatedly. With the breaking of the first seal in chapter 6, John envisions the Four Horsemen of the Apocalypse coming forward as destroyers representing Pestilence, War, Famine, and Death, each riding a horse of a different color (white, red, black, and "sickly green," often referred to as pale).

Because the exact date of the final confrontation is not revealed in the Apocalypse of John, descriptions of the end times marked by famine, war, earthquakes, disease, and natural disasters have been interpreted for centuries as signs of the impending end of the world. Since the 1st century of the Christian era, periods of extreme crisis and upheaval, either natural or social, have led to resurgences in Millennialism, or the belief that the end times are imminent. Such beliefs were strongly held during the first hundred years after the crucifixion of Christ, reappeared during the medieval period and the Reformation, and have resurfaced in the 19th and 20th centuries. The Holocaust and the post–World War II creation of the state of Israel in 1948 also led to speculation about the fulfillment of prophecy. Twenty-first–century concerns over global survival, including nuclear devastation, global warming, cosmic threats, and the spread of pandemics are seen by some as signs that fulfill the vision of the future as presented in the Apocalypse of John.

Many major world religions and cultures adhere to eschatologies (doctrines concerning the "end times") that describe the return to Earth of revered deities or prophets and the establishment of justice, usually involving judgment and a battle resulting in the triumph of good over evil and the establishment of a period of peace and justice. In Islamic tradition (particularly Shi'ite) a messianic figure, Mahdi (in Arabic, "divinely guided one"), will bring justice to Earth before the end of the world. Islam, in general, holds that only God or Allah knows the future. However, the Qur'an refers to the end times: "The day will come when this earth will be substituted with a new earth, and also the heavens, and everyone will be brought before God, the One, the Supreme" (14:48). Some Islamic interpretations place that date at 2280 CE, which is revealed through numerological codes within the text. In some Buddhist traditions, Maitreya (the future Buddha) will descend to earth to restore Dharma (the law).

Whereas the Judaic Old Testament provides the basis for belief in the establishment of an eventual messianic kingdom, Christianity holds that the end times have already been initiated with the birth of Jesus Christ in Judea (what is now the West Bank in Israel). Judaism, however, holds that the Old Testament prophecies have not yet been fulfilled, and Jews still await the first coming of the Messiah. However, Christians believe that the Book of Revelation or Apocalypse of John is a prophetic book that serves as culmination of both the Old and New Testaments. But the issues arising from the Apocalypse of John continue to be applied to contemporary events in an effort to interpret the future in light of the present. This is illustrated in Apocalypticism, a contemporary belief that the significance of events, both present and future, is hidden and will be revealed in a major confrontation. It is both a religious and secular concept that is reflected in literal interpretations of the Bible, as well as serving as a secular theme in contemporary art forms, particularly books and films that pit good against evil with the fate of the world hanging in the balance. And theologians, and political and cultural analysts have continued for centuries to debate the identification of the Antichrist and the signs that will indicate the coming of a new order.

In 1947, atomic scientists at the University of Chicago created a symbolic doomsday clock to measure global human survival based on the threat of nuclear war. The clock was set at 7 minutes to midnight, with midnight representing catastrophic destruction. The clock was advanced to 5 minutes to midnight in January 2007, based on nuclear proliferation and environmental factors. Despite these scientific estimations, which have fluctuated over 60 years between 11:43 and 11:58, the future remains hidden and open to speculation. This is reinforced in the Gospel of Mark, when Christ offered an apocalyptic insight to his disciples regarding the destruction of the world in its present form: "As to the exact day or hour, no one knows it, neither the angels in heaven nor even the Son, but only the Father. Be constantly on the watch! Stay awake! You do not know when the appointed time will come" (13:32–33).

Apollodorus of Athens (c. 180–c. 120 BCE)

Apollodorus was a versatile Greek scholar and historian who worked in the 2nd century BCE. He was the author of many treatises on Greek mythology, grammar, and history, but his best-known works are *On the Gods* and *Chronicles,* a verse history of Ancient Greece from the fall of Troy in the 12th century BCE to the events of his own era. His work is an important link to pre-Homeric history and provided later writers with fertile resources for their interpretation of Greek history.

Apollodorus studied as a youth with the scholar Aristarchus in Alexandria and the Stoic Diogenes of Babylon. After traveling to Pergamum, Apollodorus settled in Athens and produced a number of scholarly works and commentaries on myth and history. The *Chronicles* is a four-volume encyclopedia that situates Greek history according to the ruling *archons,* or political leaders, each of whom held office for 1 year. This enabled later historians to identify events, philosophical schools, and major figures according to the rulers of the period in question. Apollodorus thus gives to Greek history not only a sense of continuity in time but also insight into the personalities that shaped the political climate of Greece at some of its most important cultural moments, such as the age of Socrates, Plato, and the tragic playwrights. The *Chronicles* are based on earlier research by Eratosthenes, but they enlarge the historical scope and strive for a more precise chronology of events. They are also notable for being written in iambic trimeter, a verse meter borrowed from comedy that may have helped in memorizing the stories. Although the *Chronicles* is Apollodorus' most influential work, his essay on Homer's Catalogue of Ships from the *Iliad* was also widely read and used as a critical source, notably by Strabo in his *Geography.*

Often attributed to Apollodorus is the famous *Library,* a compendium of Greek myth from epic and other archaic sources that became the most comprehensive guide to the heroes, legends, and gods of ancient Greece. But this work must have been written by a later author, probably in the 1st or 2nd century CE; it chronicles events that happened well after Apollodorus' death in around 120 BCE. The author of the *Library* remains anonymous but is sometimes referred to as pseudo-Apollodorus to distinguish him from the author of *On the Gods* and *Chronicles.*

Aquinas, Saint Thomas (1225–1274)

Born in Aquino, Italy, Saint Thomas Aquinas was noted for his scholastic synthesis of the philosopher Aristotle and Christian theology. This Dominican monk taught at the University of Paris and was best known for his two "summations" of medieval thought, *Summa Theologica* and *Summa Contra Gentiles,* but wrote in many other genres including Bible commentaries, all of which exerted a lasting influence on Christian thought.

Beginning with Boethius, medieval Catholic theologians had disagreed about the concept of time; among Aquinas's important achievements was his sorting out of these arguments. Aquinas's best discussion of time is in the first book of the *Summa Theologica,* Question 10, which discusses the eternality of God and compares eternity to time. Aquinas brings out six points of inquiry.

First, what is a good definition of eternity? Aquinas bases his definition on one given by Boethius in his *De Consol:* "Eternity is the simultaneously-whole and perfect possession of interminable life." Some scholars have stated that the use of the word *interminable* connotes a negative assessment of eternity. Also, the word *life* does not match with the ontological definition of eternity. The whole is improper when compared to the simplicity of eternity. Eternity is not instantaneous. The whole and the perfect are redundant. Also, eternity is not a possession. In response, Aquinas appeals to simplicity; for that, human beings must understand eternity by means of time. Time is both being and living. Time is the apprehension of the measuring of movement by the causality of time in the past and the future. Later in the first book, Aquinas saw the existence of time as a measure of duration. Therefore, eternity is the holistic and perfect apprehension of what is outside of movement. We can measure time, because it has a beginning and an end. Eternity is immeasurable. So what is eternal is interminable and has no succession and cannot be possessed.

Second, is God eternal? Some scholars object that because God is the creator of eternity, so he cannot be eternal. God is before and after eternity. One can measure eternity but not God. Time (as past, present, and future) is applied to God in the Bible, although the creeds apply eternality to God. In reply, Aquinas connects time to change, and eternity to immutability. Yet, God is not eternal only; but God is "His own eternity." For Aquinas, this is a "participated eternity" utilized from scripture through royal metaphors and images of time so that we may understand that eternity is nothing else but God himself.

Third, does eternality belong to God alone? While some see eternality in righteousness, judgment, and necessity, Aquinas said that because God alone is eternal, only God's sharing that eternality with his creation would allow someone or something other than God to be eternal.

Fourth, how does eternity differ from time? Some object to the difference between eternity and time because time is a part of eternity, their natures differ, and eternity swallows up time. Yet, a disagreement may arise because time has a "before" and an "after." For Aquinas, they are two different things, for eternity has a permanence and time is "a measure of movement: . . . that eternity is simultaneously whole, but that time is not so."

Fifth, how does aeviternity differ from time? *Aeviternity* (sometimes translated "everlasting" or "endless") is the eternity shared by God on the creation. For some thinkers, there is no difference between aeviternity and time because both measure duration and neither is eternal. Aquinas answers that they do differ and that aeviternity stands between time and eternity. While some differentiate among the three concepts in that "eternity has neither beginning nor end, aeviternity, a beginning but no end, and time both beginning and end" Aquinas sees this as an "accidental" case. Other thinkers then see a distinction based on "something old and something new": these three to consist in the fact that eternity has no "before" and "after" but that time has both, together with innovation and veteration, and that aeviternity has "before" and "after" without innovation and veteration.

Aquinas disagreed with this contradiction in terms: "The being that is measured by eternity is not changeable, nor is it annexed to change. In this way time has 'before' and 'after'; aeviternity in itself has no 'before' and 'after,' which can, however, be annexed to it; while eternity has neither 'before' nor 'after,' nor is it compatible with such at all."

And the sixth and final study is whether there is only one aeviternity. Some thinkers argued that there are multiple aeviternities based on all the spiritual entities in heaven. For others, aeviternity "is [a] more simple thing than time, and is nearer to eternity." Aquinas answers with a discussion that ties the oneness of time to aeviternity: "Therefore time is referred to that movement, not only as a measure is to the thing measured, but also as accident is to subject; and thus receives unity from it" For Aquinas, it would be necessary to say that there is one aeviternity only.

Saint Thomas Aquinas showed a difference between eternity, aeviternity, and time. Eternity has neither a beginning nor an end. Only God is eternal. Aeviternity has a beginning but has no end. Only the part of creation that accepts God's gift of eternity takes part in it. Then, time is the measured duration of movement that has a beginning and an end.

Aquinas and Aristotle

The relationship between Saint Thomas Aquinas and his sources Aristotle and Saint Augustine of Hippo illustrates a salient trait of medieval philosophy, namely, its voluntary dependence upon authorities, whose (often divergent) answers to a given problem had to be taken seriously, according to the standards of that time. Because of this, medieval thinkers attempted to solve philosophical (and theological) problems in a way that took into account all relevant sources. If an important source seemed to contradict the personal opinion of a philosopher, the philosopher then usually looked for an interpretation of that authority that could be integrated into his own solution; only in rare cases was the position of an acknowledged authority rejected. Consequently, for Aquinas, as for his contemporaries, a good theory on a certain topic had to do justice to both Aristotle's and Augustine's ideas on that subject, because of their authority in philosophy and theology, respectively. An examination of Aquinas's texts on time, however, reveals a completely different picture: Whereas Aquinas expounds Aristotle's theory at great length, he pays very little attention to Augustine's theory. This entry provides reasons for this remarkable exception to medieval standard practices and serves as an introduction into the most important theories of time that appeared between classical antiquity and the Latin Middle Ages.

Aristotle and Augustine on Time

Aristotle's and Augustine's texts on time—the fourth book of Aristotle's *Physics* and the eleventh book of Augustine's *Confessions*—describe two theories that seem difficult to reconcile with each other: Whereas Aristotle defines time as the "number of changes in respect of before and after" (Phys. IV 11, 219b 1; R. Waterfield, Trans.) and makes its existence and definition dependent upon change or, as the medieval translations had it, motion, Augustine defines time exclusively as a "distension of the mind" (*distentio animi*). Furthermore, Augustine explicitly denies that motion can be an adequate definition of time and that there can be time at all without the human mind, which counts the uninterrupted stream of the sensible world. In spite of not addressing directly Aristotle's definition (which he probably did not know), Augustine cannot have seen in it a serious option. Aristotle, on the other hand, is somewhat ambiguous regarding the relation between time and soul. He writes that there could not be time, if there is not be a soul, because without a soul there would not be any number to determine change and therefore time. However, he grants "that there might still be whatever it is that time is" (IV 14, 223a 21–29). Previously (219b 5–9) he had defined time as that number "which is numbered," not "that by which we number," that is, not as the mental activity of numbering, but as the flow of things that is apt for being counted, such that time should not depend entirely upon an activity of soul. Furthermore, it may well be that he is not talking here about the individual human soul but about soul as a cosmological phenomenon. Thus he would surely have rejected Augustine's solution.

The Aristotelian Tradition Before Aquinas

As with many of his contemporaries, Aquinas's theory of time is largely inspired by Aristotle's solution. Aquinas's most important discussion of that subject can be found in his *Physics* commentary. However, he did not have the Greek original of Aristotle's text, but a medieval Latin translation that had been carefully corrected by his contemporary, William of Moerbeke. Indeed, it is very close to the Greek and enabled Aquinas to discuss Aristotle's solution independently from older commentaries. This was important because the medieval understanding of Aristotle drew heavily on the interpretation that the 12th-century Arab philosopher Ibn-Rushd (Averroes) had given of Aristotle's texts. Averroes's interpretation rests upon the assumption that Aristotle's discussion of the dependence of time upon the soul concerns the human soul and does not have any cosmological implications. Consequently, Averroes draws a clear distinction between an "actual time" or "perfect time" that can exist due only to the activity of the human mind, and a "potential time" or "material time" that consists simply of the changes that take place within the material world. He even stresses that outside the mind (*extra mentem*), "there is nothing other than something which is moved and motion." Thus Averroes presented to medieval readers an Aristotle who is much more "Augustinian" than is the Greek original. Apart from Aristotle and Augustine, the medieval discussion relied on some further sources. Most of them (Proclus, Boethius, the *Liber de causis*) transmitted a Neoplatonism of the Greek type. This meant that they advocated unambiguously the existence of time outside the human mind, defining time as an image of eternity. No less important were the Latin translations of the Arab philosopher Ibn Sina (Avicenna), who discussed a whole range of explanations of time. He opted too for an extramental existence of time in the thing itself and attempted to show the incoherence of an approach that makes time dependent on an activity of the soul; thus his conception could be read as a refutation of both Augustine's and Aristotle's/Averroes's approaches. Thus medieval readers were not so much faced with an antagonism between Aristotle and Augustine; rather, there was an apparent conflict between both of them on the one hand and the Neoplatonic and Avicennian tradition on the other.

Albert the Great and Medieval Discussions of Time

Confronted with this alternative, most medieval thinkers opted clearly for the second alternative, assuming, against Augustine and Averroes, the real existence of time outside the human mind. This was probably due to some presuppositions that were fundamental to their own religion. For a Christian, many philosophical problems were determined largely by the question of the relationship between God and humankind. What was interesting about time to medieval authors, was, then, the relation between time—the mode of duration of the sensible world—and eternity—the mode of duration of God. As the mode of duration of God's creation, however, time had to have a form of existence outside the human mind; otherwise this creation could hardly be an image of God's own way of existing. All these points can be found in the work of Aquinas's teacher, Albert the Great (Albertus Magnus), who did the painstaking work of explaining the newly discovered Aristotelian writings to his contemporaries, while taking into account nearly all important earlier discussions and authorities; thus he created a synthesis that was the point of departure for many contemporary accounts of time (including that of Aquinas), even if their authors did not agree with everything Albert had said. Albert first discusses time around 1246, in his "Summa on the Creatures" (*Summa de Creaturis*) and again in his commentary on Aristotle's *Physics* (around 1255). In both works, he reads Aristotle with the help of Averroes's explanations. His result is that Aristotle, Averroes, and Augustine are quite close to each other, insofar as all of them reject a real existence of time outside the human soul; in this regard, Augustine seems even somewhat more radical than Aristotle and Averroes, because the last two authors grant to time at least a potential existence outside the soul. Albert, however, rejects all three approaches and sides with Avicenna and the Greek Neoplatonists, defending the real existence of time outside the soul. It exists "according to the habitual form of a distinction of the numbered elements," as Albert concludes from the fact that the soul is counting the single elements of time, while time itself is continuously flowing. Thus Albert ascribes existence not only to permanent, unchanging entities but also to timely succession. Consequently, he openly rejects not only Aristotle's and Averroes's solution but also that of the church father Augustine—a remarkable case within medieval literature. Albert justifies his reproach by denying to Augustine a competence in natural philosophy. Furthermore, he affirms that the relationship between soul and time should not be discussed within the realm of physics (natural philosophy) alone but also in philosophy or metaphysics, as Averroes had already postulated. Albert himself, though, includes a lengthy discussion of time for reasons of convenience in his *Physics* commentary, where he adds his own treatise on eternity that differs from Aristotle's text. Albert's opting for a realist theory of time found many successors in subsequent periods. Even the conservative theologian Henry of Ghent (1217–1293) stated explicitly that Augustine's theory of time was false. Indeed, the thesis that time has no existence outside the human soul was officially called heretical in the famous condemnation of 1277, 3 years after Aquinas's death.

Aquinas and Aristotle

Albert's student Aquinas depends largely on the approach of his master, especially regarding the prominent role that Aristotle must play in any discussion of that subject. But Aquinas develops two explanations of his own, both of which differ markedly from that of Albert and both of them relying on Aristotle's *Physics*. This becomes clear already in Aquinas's early commentary on *The Sentences* of Peter Lombard (around 1255), where he quotes the fourth book of Aristotle's *Physics* in most of the relevant sections, though he discusses time, following Boethius and Albert, within the schemes of three modes of duration: time, eternity, and eviternity. In his concrete explanations of what time is, however, he follows Aristotle, in many cases as Averroes interpreted him. This holds true also for the relation between time and soul: Although the changes within the sensible world are the matter of time, its form, the numerical measure, is constituted by the human soul; thus Aquinas, at this time of his career, does not follow Albert but rather Averroes and is not so far from Augustine, whom he does not, however, quote in this context. Whereas here and in other writings only casual remarks are made regarding the problem of time, a more complete discussion can be found in Aquinas's own *Physics* commentary, which was completed around 1269, 10 years after the *Sentences* commentary and after Albert's *Physics* commentary. This commentary is, however, quite different in form from Albert's, because Aquinas confines himself to explaining the content of Aristotle's text without any lengthy discussions like those that had been given by Albert to help clarify Aristotle's position. Consequently, Aquinas's commentary sticks much closer to Aristotle's own statements, without mentioning by name authors such as Averroes, Avicenna, and Augustine. Concerning the relationship between time and soul, Aquinas interprets Aristotle's solution as implying the existence of time, even if there would not be any soul that could count it. Only the act of numeration, not the existence of the things that are numbered and not the existence of the number itself, depends on the existence of soul. This new interpretation of Aristotle's text was possible because Aquinas could use the improved translation by William of Moerbeke, who rendered the sentence quoted earlier in this entry as "that there might still be that time is somehow being (*utcumque ens*)," suggesting that time should have some extramental reality. However, Aquinas further qualifies his position by saying that only the indivisible aspect of time exists in reality (i.e., a single instant of time), whereas time itself, not different from motion, has no firm being (*esse fixum*) in reality. Consequently, time receives its totality (*totalitas*) by "the ordering of the soul which numbers the before and after of change." Consequently, without the numbering soul, time exists only imperfectly (*imperfecte*). While this formulation resembles Averroes's solution, Aquinas differs from him by acknowledging that time does not only potentially exist outside the soul and by not mentioning the distinction of matter and form in this respect. Thanks to Moerbeke's improved translation, Aquinas is able to ascribe this solution to Aristotle himself, while Albert still reproached Aristotle together with Averroes and Augustine for denying to time its existence outside the soul.

Aquinas and Augustine

Augustine, unlike Aristotle, was not an important source for Aquinas's theory of time. In fact, in Aquinas's discussions of the problem, the name of Augustine appears rarely, and there are no quotations of the 11th book of the *Confessions*. This has been interpreted as a consequence of Albert's critics of Augustine's theory of time and of his assumed lack of competence in natural philosophy, but it may also be due to the methodical presuppositions of Aquinas's *Physics* commentary. In any case, it must have been convenient for Aquinas not to mention that his theory of time was implicitly criticizing the authority of Augustine; with Averroes, a renowned but ambivalent philosopher was at hand who could be criticized for advocating the unacceptable theory that the existence of time depends upon the human soul. There was no necessity to mention the venerable church father Augustine in such unreliable company.

Aquinas and Augustine

The concepts of time as depicted by Saint Augustine of Hippo (354–430) and Saint Thomas Aquinas (1225–1274) were to become two foundational perspectives in the philosophical and theological discourse of Christianity. Both writers sought to explain temporal issues regarding God and

Creation (e.g., conflicting accounts in the first two chapters of Genesis), the universe, and humankind in terms of logic, mysticism, or both, that would be philosophically justified. Influenced by earlier philosophers, such as Aristotle, Boethius, Plato, Plotinus, and Porphyry, both Augustine and Aquinas developed their constructs of time and its relationship with the divine in a way that reflected the prevalent thinking within a novel theological framework.

Although both philosophers' theological constructs agreed in the nonliteral interpretation of Creation (including all species) and the universe, their differences in the concept of time as it concerns God and human beings are reflected in Augustine's and Aquinas's respective views of ontology. Essentially, the basis of their differences reflects the major influence of Aristotelian and Neoplatonic perspectives. This would have a consequence in terms of defining eternity, finitude, infinity, and the objective/subjective reality of time. To synthesize the two major influences of Aristotle and Plotinus (Neoplatonism), among other philosophical perspectives, is to illuminate a dichotomy that appears to incorporate and express the common psychological dynamics of humankind. This delicate balance of rational explanation and conscious mysticism of the unknown appears to explain more about humankind and humanity than about the ontological status of God. Nevertheless, the element of time could be seen as a commonality or connection with the divine being that appears to transcend cultural barriers. In this manner, both Aquinas and Augustine attempted to illustrate the shared humanity of humankind under a reconcilable and loving God.

The major works of Aquinas and Augustine, *Summa Theologica* and *Confessions,* respectively, outline the concepts of time and its significance for humankind in relation to God. Aquinas held the view that God created the known material world via the First Cause. This God, dwelling in his own essence, infinite in perfection, immutable and eternal, is beyond the concept of time. This view is based on the ontological concept that God, belonging to no genus or species, has no beginning or end; thus the concept of time that incorporates the range of time (beginning, middle, and end) cannot be applied to a being that not only lacks form and matter but also potentiality, as seen in genus or species. Furthermore, God's very act of creation, as depicted in the motion and limits of the universe and aspects of life moving from potentiality to a state of actuality, is encompassed within time. Comparatively, all things existing from God are relatively infinite but not absolute. In human temporal matter, human teleology follows ontology within the encompassing view of the soul (substance). According to scripture, however, there will be a conclusive end and a day of judgment. Cosmologically, then, it would appear that time, at least for the universe and humankind, would end or perhaps change (viz., the reference to a New Jerusalem or new beginning).

Aquinas's temporal view of the universe appears to be objective. The movement of the celestial bodies, in themselves comprised of form and matter, would imply duration or time. This duration as evidenced by motion would be independent of humankind's existence. Both time and space would appear to be infinite but not absolute. Although Aquinas had made distinctions among eternity, time, and *aveum* in *Commentary on Metaphysics,* the concept of time as tied to the soul has conflicting perspectives of objective time. Time, which excludes God, is based on actualization (in degree) of potentiality as decreed in form and matter. However, whether time is objective in all instances—for example, the universe as compared to humankind—remains elusive. Lacking a rational soul, the universe cannot experience time. Yet, the motion itself is indicative of time. Even considering being and nonbeing, the coexistence of multiple temporal stages would be indicative of either an active participation by God in temporal time or infringing on the free will of God, humankind, or both. Theologically, it becomes a grand masterpiece by which each stroke of the brush depicts a lapse of time.

Augustine, by comparison, held a differing notion of time and the relationship between God and humankind. For Augustine, God had created both angelic nature and formless corporeal matter. By the very act of creation, the material world ex nihilo, God had created an existence from the indivisible and unorganized to the material reality of experience. In this manner, all things were due to, or a response to, the Creator. Consequently, Augustine held that time did not exist before this creation event and was held bound by the natural conclusion of the created event; namely, the impending dissolution of material existence. God, an eternal and omnipotent being, is not bound by the constraints of time. Time, as Augustine held, is an extension of the human mind and its ability to comprehend successive events. However, God is eternal, whereby time past, present, and future are presented as one and not successive events. The conceptual arrangement of time, for Augustine, becomes a subjective experience. These experiences are independent and purely human. However, human concepts of time, when juxtaposed against the concepts of God, give the eternal attribute to God. It is unknown if this eternal aspect is dependent on the created, whereby the end of humankind would suggest the end of God's eternity even though God is beyond time. Such a contradiction in definition would require a resolution in a God that is spatiotemporally isolated, a mystical and incomprehensible being not touched by the fabric of either space or time but who somehow becomes interactive with the created.

Aquinas and Augustine presented a unique aspect of time. This concept of time, though dependent on the act of creation, requires an ontological distinction. Ontology and relationship between God and the created are essential in understanding this temporal nature of being (and nonbeing). This ontological aspect of God or the supreme *Logos* remains elusive; that is, the laws of noncontradiction prevent epistemological certainty. However, today these views in their totality must be conditioned, whether rejected or modified, by the advancements of modern science. Reflectively, time becomes the common thread by which ontology and epistemology converge.

ARCHAEOLOGY

Time is an essential part of archaeology, serving as a focal point of archaeological inquiry and an important component of archaeological analyses. Archaeology, likewise, is integral to the understanding of time and its effects, not just in the uncovering of dates to significant events in the history of humanity, but by providing evidence regarding changes and developments in humanity, including its biological makeup, technology, and traditions. By virtue of its intimate alliance with time, archaeology provides not only a greater understanding of what humanity has endured through history but also a means to learn about what humanity will possibly see in the future.

Early Conceptions of Time and Humanity's Existence

How old is the universe? When was the earth created? When did humans first walk on the earth? When was the first writing system created? How long did it take for humanity to develop from earlier primate species? When were the bow and arrow first utilized? When did writing first surface?

Today, archaeologists, in conjunction with scholars from multiple fields, have a variety of methodologies at their disposal to determine answers to these questions. However, with the field of archaeology not attaining any cohesive structure until the 19th century, individuals from other occupations provided the initial research that dictated our understanding of humanity through time, and their conceptualizations were often supported by unique sources. One of the more prominent such conceptualizations in history was based on the Judeo-Christian Bible.

An Irish clergyman, Archbishop James Ussher, looked to the Hebrew Bible for clarification of the earth's creation. Ussher's estimate, which he generated based on an interpretation of chapters in the Bible, indicated the earth came into existence circa 4004 BCE. In effect, humanity's developments and accomplishments, which include the spread of humanity throughout the world as well as humankind's domestication of animals, cultivation of plants, and generation of multiple writing and language systems, were achieved during a period of less than 6 millennia. Today, such a time interval is difficult to accept given our more thorough understanding of geological processes and our ability to date natural materials directly, but 400 years ago when Ussher unveiled his estimate, many accepted this as the age of the planet and the duration of humanity's appearance and development. Yet, like most theories, Ussher's estimate was challenged by new thoughts about time and the antiquity of both the planet and our species.

Ussher, one among many who looked to religious documentation and beliefs to date the earth and humanity, preceded other noted scholars who sought the planet's age, although the next wave of researchers looked elsewhere for answers. Of particular importance among them were the uniformitarianists. These scholars, including James Hutton and Charles Lyell, spent considerable amounts of time observing the geology of the earth and natural processes like erosion. Noticing the length of time needed for the natural landscape to change, whether through water action, wind damage, or other act of erosion, the uniformitarianists argued that it would have taken considerably longer than 6,000 years for the earth to form mountain ranges, lakes, rivers, and canyons. Such observations ultimately led to questions about humanity's development alongside the planet's landscape. Enter the evolutionists.

The impact of uniformitarianism was profound in that it promulgated the idea that the earth and humanity had existed for a great deal of time and that changes were continually occurring. It was in this atmosphere that Charles Darwin, Alfred Wallace, and other scientists developed their ideas of humanity and other species evolving over millennia. Looking at biological organisms as opposed to rocks, strata, and natural processes, supporters of evolution reasoned that changes to species, like the formation and disintegration of rock, took time. With the discovery of remains relegated to earlier hominid species during the late 19th century, the idea that humanity had been around for a significant number of years became embedded in the minds of numerous scholars and accepted by many in society as well. Collectively, these early concepts of time and the duration during which the earth formed and humanity and other organisms emerged provided a framework of understanding. Today, archaeologists ask many of the same questions, although their tools for answering such questions provide more accurate answers.

Modern Measures of Time in Archaeological Analysis

Archaeologists today have a broad range of tools at their disposal to determine the age of artifacts, sites, and human remains. The exactness of each of these methods varies considerably, but for the most part, they provide a substantial benefit to the understanding of time. In a general sense, the technologies referenced here are divided into two categories, the first of which is absolute dating methods.

Absolute Dating Methods

Absolute or chronometric dating methods are the most recent dating methods developed; they are utilized to date artifacts and sites alike. Although the name implies these methods of dating can obtain an exact date for the object analyzed, the reality is that archaeologists actually obtain a range of dates during which the object was created. Still, absolute dating techniques are a world apart from relative techniques and are of special importance to our understanding of human history, particularly in the evolution of humanity through time. Of the absolute dating methods most often used by archaeologists, radiocarbon dating, or *carbon-14 dating,* is undoubtedly the most prominent and widely utilized. Radiocarbon dating can be used to date organic material such as bone or wood that is from 500 years old to 40,000 years old. The principle behind this method is that after a living being dies, whether plant or animal, the radiocarbon within the specimen begins to decay. Because the decay rate of radiocarbon is known, it is possible to determine the age of organic material based on how much radiocarbon is remaining. The actual process of determining dates based on the radiocarbon method is rather complex, especially with regard to the care required in the collection and containment of samples. Yet, the reward of utilizing this technology is a more precise date for an artifact or archaeological site than a researcher would receive from relative dating techniques (discussed in the next section).

A second absolute dating method utilized by archaeologists is potassium-argon dating. Used to date rocks from 50,000 years old to 2 billion years old, the potassium-argon procedure involves the observance of potassium-40, or rather the argon created by decaying potassium-40 particles, that collects within rock over time. The actual procedure allows archaeologists to date sites and artifacts based on their association with dated rock material.

Dendrochronology, establishing a timeline based on tree ring sequences, is another example of an absolute dating method that has provided archaeologists with a means of determining the age of artifacts and sites. Profiles of tree limbs and trunks reveal a series of rings indicative of the tree's growth patterns. Knowing that thick rings denote good growing seasons and thin rings denote poor growing seasons, researchers can establish environmental patterns that trees endured through time. Once environmental seasons are developed for a region, and for an extended period of time, future tree ring samples discovered can be compared to established sequences providing indications of the age of the tree specimen. In this way, a tree fragment used to construct a building, wagon, or fence can be dated.

A final method of absolute dating is the use of historical documentation. Newspapers, diaries, and photographs provide a significant amount of information with which to date events, places, and people. Additionally, coins, stamps, and other objects with dates inscribed on their surface can also provide estimates for artifact assemblages in which they are recovered. Such direct historical links are arguably one of the most accurate methods for measuring time.

These absolute measures of time, while not 100% effective in establishing periods, reflect the advances archaeologists and other scholars have achieved in dating sites and objects. They are very different from earlier methods that only provide a basic or *relative* measure of time.

Relative Dating Methods

Christian Thomsen, a Danish 19th-century curator, initiated a sorting of artifacts based on the ideas of a three-age system reminiscent of earlier classifications separating artifacts into materials made from stone, bronze, and iron, although his system showed remarkable improvements and analysis of archeological finds. However, although Thomsen's dating and classification system provided a significant improvement in the understanding of the past and dating of archaeological material, such methods of ascribing dates or measuring time fail to provide anything more than a general idea of when an artifact was used in relation to a fixed or already determined point in time. This includes dates of when a person died or when a site was occupied. Of the variety of relative dating techniques used by archaeologists, there are two that are commonly used. The first and most fundamental of these is *stratigraphy.*

Stratigraphy is straightforward in its conception, but it is far from being uncomplicated in its implementation. From a basic standpoint, stratigraphy is a careful observance by archaeologists of the layers of earth as they excavate. By noticing and acknowledging the placement of artifacts and soil features, it is possible to gauge the date of an object by its provenience and relative position to other artifacts. Essentially speaking, the deeper an artifact is within the soil, the older it is relative to the objects that lay above it. This system of observation and analysis becomes significantly more complicated by the disturbance of archaeological sites by human interaction with the ground or by natural occurrences such as earthquakes, flooding, and glacial activity. However, from a basic level, this is a manner of gauging the age of an assemblage whether it be an artifact, burial, or collection of artifacts. A second method of relative dating often utilized by archaeologists is *seriation.*

Although not as simple in explanation and implementation as stratigraphy, seriation is nevertheless a rather straightforward approach to determining the relative age of an artifact and associated assemblages. The approach of seriation as employed by archaeologists centers on the collection of artifact types and the observance of styles or varieties of artifacts produced by a society. Whether the types of artifacts collected and observed are pottery or projectile points, ornamentation or clothing, the principle behind this dating method is the same. After collecting artifacts of a specific type, such as a stone spear point, from a number of sites, the percentage of each variety of spear point is calculated. Given that every variety has a period of time during which it is popular, sites can be aligned or placed in order of occupation based on the presence of each variety. Limitations of this technique include the fact that excavation may fail to uncover all specimens of a variety found at a site. However, when used in conjunction with other dating methods, whether absolute or relative in nature, seriation can be an extremely effective means for determining the age of a site.

Archaeological Knowledge and Time

Archaeological reconnaissance, often conducted by researchers from other fields of study, has brought an awareness of major achievements made by humanity in the past. In that way, archaeology has provided knowledge of the past that otherwise would have remained lost. Of particular importance to such discoveries are sites and artifact assemblages related to human origins, early innovations, instances of human migration, and effects of contact on culture change.

Human Origins

Researchers have discovered much about humanity's development over time through archaeology. With major discoveries of early hominid remains surfacing in the late 19th century, archaeologists have had sufficient time with which to decode much of the past, although many answers to our questions about human origins remain elusive. As for some of the more significant discoveries in this area of research, a few stand out among the most critical. At Laetoli, in Tanzania, Africa, for example, Mary Leakey, in the late 1970s, uncovered a trail of footprints preserved by volcanic ash. The footprints, created by three australopithecines (*Australopithecus afarensis*), provided evidence that human ancestors were walking erect (bipedalism) by around 3.6 million years before the present (BP), a major discovery about humanity's development in time that archaeological efforts recovered.

Not far from Laetoli, and also in Tanzania, archaeologists uncovered more evidence regarding human origins and development. In the Olduvai Gorge, the Leakey family spent decades searching through the multiple layers of the canyon, which dated as far back as approximately 2 million years BP. The reward for their painstaking efforts included the remains of early hominids *Australopithecus boisei* and *Homo habilis,* both dated to nearly 1.8 million years BP. Additionally, among the remains of giraffes, antelopes, and elephants, the Leakeys uncovered lithic tools. Collectively, the hominid remains and tools found at Olduvai Gorge provided a clearer understanding of the emergence of the Homo line from earlier hominids and the initial tool tradition created by humankind, namely, the Oldowan tradition. A final discovery connected to archaeological excavations and humanity's development through time revolves around caves in Europe whose walls were decorated by paintings created during Paleolithic times.

Lascaux, Chauvet, and Altamira are among the many caves discovered since the 19th century with wall paintings scattered throughout multiple chambers. Often discovered by chance, these caves are adorned with paintings and engravings depicting human beings and an array of animal species, many of which are now extinct. Early on, these caves were often thought of as hoaxes, because many people found it hard to believe that Paleolithic peoples could have created such impressive renderings. Yet, as absolute dating techniques were created and improved and as more analysis was done on artifacts and remains recovered from the caves, it became clear that by nearly 30,000 years ago, human populations were able to create art depicting great detail and often abstract in nature, which indicated an advancement in human mental capacity.

Early Innovations

Humanity's continual adaptation to ever-changing environments still provides the impetus for technological innovation. Through archaeologically based examinations of the past, the innovations created by humanity have been unearthed along with the knowledge of when such technologies first surfaced. In the Mesopotamia region along the shores of the Euphrates River, for example, excavations of the ancient city of Uruk uncovered the earliest forms of writing, which date to roughly 5,400 BP. Although they were little more than clay tablets with tabulations made of merchandise in the form of depictions of ore, tools, food, and livestock, this discovery helped determine the earliest mode of writing. In a similar vein, researchers have uncovered evidence of when specific plants were domesticated in the New and Old Worlds.

Maize provided a main staple for many societies in South, Central, and North America, serving as a major contributor to the rise of large, nucleated villages and cities. The question is, where did it originate? Despite continued debates over maize's domestication, excavations throughout areas near and in the Tehuacán Valley indicated that maize was cultivated as long as 5,000 years ago. As for Old World domesticates, excavations in the Near East, near present-day Syria, Jordan, and other Middle Eastern nations, recovered plant remains that showed changes to barley and wheat composition, which followed the increased use of tools for processing food. The appearance of these plant alterations and technologies indicates that barley and wheat were cultivated roughly over 10,000 years ago. Once again, archaeological analysis provided insight into the time frame during which human activity occurred.

Migration

When did human populations first reach North America and the rest of the New World? When did the first New World culture emerge? To this day, multiple interested parties debate this question. From among scientists, estimates of when humankind first reached North, South, and Central America ran from 2,000 years to upward of 30,000 years ago. Native Americans, meanwhile, look toward their oral traditions for guidance on this issue with many arguing that they always have lived on the New World continents. Archaeological analysis has provided insight into this inquiry and has since the early 1900s when Paleoindian-related artifacts were uncovered near Clovis, New Mexico. Consequently, archaeology has proven effective in discovery information about when migrations occurred in time.

As for migration into North America, having already established that projectile points found near Folsom, New Mexico, were dated to roughly 10,000 years ago, researchers argued that the earliest peoples to enter North America had to have preceded the Folsom-using populations because the Clovis points were found in a layer of soil below Folsom points. Thus archaeological research provided an idea as to when the first culture (Clovis) surfaced and when humans first reached the New World (c. 12,000 BP). Excavations in Pennsylvania at the Meadowcroft site have uncovered evidence going back even farther, with assemblages dated beyond 15,000 BP. Collectively, these findings give ample evidence that human populations entered North America not long after 20,000 BP. Excavations in South America indicate that people reached the New World relatively early as well. At Monte Verde in Chile, evidence of stone tools and wood supports for structures has been unearthed after having been preserved in bog conditions for millennia. The radiocarbon dates acquired from the site date to roughly 13,000 BP. Today, debates regarding dates obtained from Monte Verde and Meadowcroft remain. However, from the combined evidence, archaeological research has provided some understanding of when in time humans first reached the New World, setting a window of likelihood from tens of thousands of years down to a few thousand.

The effectiveness of archaeology, although questioned by some, is tremendous in that the analysis of material culture recovered from the archaeological record continues to provide clues as to when various hominid forms surfaced, when innovations occurred, and when humans migrated to different parts of the globe. Archaeology also has assisted in determining when contact and culture change occurred between two or more human populations.

Contact and Culture Change

The initial arrival of European explorers, missionaries, and emigrants to North America occurred at a time when record keeping was not standardized or thorough. Many of the Europeans who arrived were illiterate; others recorded nothing more than lists of supplies. All told, records of the effect of contact between Europeans and Native Americans were void of great detail, leaving questions as to when contact occurred in many instances and how long it took for both populations to integrate styles or commodities utilized by the other. Archaeology fills this void. With excavations ranging in size from a few test units to entire sites being uncovered, archaeologists have amassed large collections from Native

American village sites dating to the contact period. Iroquoian village site assemblages dating to the early 1600s, for example, contain European products ranging from glass beads, copper pots, and components from firearms. From an analysis of material recovered, it is clear that Iroquoian peoples soon learned to rework the European objects and materials, copper and iron kettles for instance, into utilitarian objects such as weaponry and hunting implements (spear points, arrowheads, knives, etc.). What is the importance of archaeology to the understanding of contact between two populations? It assists in discovering roughly when contact occurred when no written record exists and how long it takes for the technologies and resources of two peoples to be shared.

Important Archaeological Sites and Their Temporal Significance

The mere mention of the word *archaeology* usually generates images of broken stonework, pottery sherds, stone projectile points, and monoliths strewn across a field. On a larger scale, people equate the study of human material culture with a few sites throughout the world that hold special temporal significance.

Cahokia

Located along the Mississippi River near St. Louis, Illinois, Cahokia was once one of the largest municipalities in North America. With extensive settlement of the area beginning roughly 1,300 years ago, dependent upon maize production and eventually reaching a size of approximately 40,000 people, Cahokia eventually developed into a series of populated sectors positioned around large, earthen mounds used for multiple purposes, including burial and public interaction. The largest of these mounds was the multileveled Monk's Mound, which reached a height of approximately 30 meters, covered an area greater than 5 hectares, and served as the center of Cahokia itself. Extensive analysis of Cahokia determined that the inhabitants traded extensively, lived in a stratified society, and utilized the wealth of natural resources available in addition to cultivating a variety of plants. In view of time, Cahokia's mounds are of particular significance, because the size, shape, and use of public space varied considerably, including areas where wooden beams were placed in order to plot and record astronomical events such as equinoxes. Cahokia additionally served as a prime example of a tradition known as *Mississippian,* which archaeologists equate with societies that shared multiple cultural characteristics, including the erection of earthen mounds and the dependence on maize cultivation between 1,300 BP and 500 BP.

Cuzco

The site of Cuzco, located in the Peruvian hinterland, was the capital of the Inca Empire. Supported by extensive canal and road systems and a repository for precious commodities from throughout South America, Cuzco served as the axis for the empire. Clergy, aristocracy, military commanders, and craftspeople lived within the immediate municipality while the general populace occupied the outlying regions. Cuzco exemplified the complexity of Inca architecture with buildings and temples made of fitted stone blocks, many of which serve as foundations for modern buildings to this day. Likewise, the Inca system of roads, which stretched thousands of kilometers throughout the empire and included depots and quarters to shelter and resupply travelers, were centered around the capital, making Cuzco the focal point for trade and control.

Much of Cuzco's history was recorded in documentation provided by Spanish explorers who first traveled throughout South America approximately 500 years ago. Ultimately, the Spanish and Incas clashed. The confrontation led to the Incas destroying Cuzco and the Spanish gaining considerable control of the region. In time, the Spanish forces rebuilt the city, preserving much of Cuzco's outline. Today, it is possible to see how Cuzco was organized by the Incas and what importance its structures served to the empire overall by the distribution of building types throughout the site. Additionally, the site—specifically its origins, development, and eventual reconstruction on the part of Spanish forces—reflects the metamorphosis that Inca civilization went through after contact with European entities.

The Pyramids of Giza

The pyramids at Giza often form the heart of people's image of the ancient civilization that populated the banks of the Nile. For many, pyramids were constructed and utilized by every Egyptian ruler during the ancient civilization's millennia of existence. As for the design of their pyramids, Egyptians erected step and flat-sided varieties with the larger structures reaching over 150 meters high and covering over 4 hectares in area. Yet, the larger pyramids at Giza, which include the Great Pyramid of King Khufu and are larger and more complex in their internal designs than later pyramids, are not typical of every dynasty that ruled Egypt. These early pyramids date to the Old Kingdom, approximately 4,200 to 4,700 years ago. Later Egyptian rulers constructed less elaborate burial chambers, with pyramids even being abandoned for tombs cut out of rock in later centuries.

Lascaux Cave

Europe is home to multiple caverns whose walls are decorated with paintings and engravings depicting abstract and realistic images of humans and of animals, many species of which are now extinct. Lascaux, located in southern France, is one of the more renowned of these sites. Spanning over 200 meters in total length, this cavern includes hundreds of engravings and paintings of humans, bison, horses, and other assorted animals. As for the techniques for applying the renderings to the cavern walls, the artists generated colors using charcoal, iron oxides, and manganese oxides, while engravings were created likely through the use of an assortment of flint tools. Since the initial discovery of such cave renderings over a century ago, a variety of arguments have surfaced as to the purpose of these art forms. Yet, whether these ancient paintings and engravings were believed to serve as magic or just art for art's sake is not the most crucial question.

With the advancement of dating techniques making it possible to directly date the cavern's renderings, researchers were able to determine that Lascaux was decorated approximately 17,000 years BP. This discovery, along with the complex nature of the mediums and painting/engraving techniques utilized by the artists, indicated that Paleolithic populations were more capable than researchers originally thought possible, both in their conceptualization of their world and their place within it.

Stonehenge

Located in the county of Wiltshire in southern England, Stonehenge remains one of the most noted archaeological sites to both enthusiasts and archaeologists alike. With initial construction beginning approximately 5,000 years ago, Stonehenge underwent multiple stages of construction over a span of roughly 1,500 years. The result of these stages was the erection of the monoliths for which the site is known. Additionally, the site's engineers established embankments, ditches, and other components, which have been partially damaged, rearranged, and destroyed by subsequent visitation to the site. Today, speculation as to the purpose of the site has included the belief that it serves as a calendar for predicting celestial events such as equinoxes and eclipses. However, the only calculation that appears credible is the timing of the summer solstice and its alignment to Stonehenge's Heel Stone and Avenue. However, the loss and movement of Stonehenge's monoliths and earthworks makes even this assertion questionable.

Teotihuacán

The ancient city of Teotihuacán has long augmented the landscape near present-day Mexico City. With occupation of the area beginning approximately 2,100 BP and continuing until roughly 1,000 BP, Teotihuacán developed into one of the largest cities in the world with a maximum population of over 100,000 people at times. As for total area of occupation, Teotihuacán expanded quickly through the centuries, ultimately covering approximately 20 square kilometers. The structures that were erected by the site's inhabitants were stone and plaster buildings, particularly living quarters and temples. Teotihuacán's occupants lived in various sized apartment compounds capable of sheltering multiple families, with total populations of over 100 persons in some instances. The temples were equally diverse in size and were positioned among the apartment compounds. All told, over 4,000 structures were erected at Teotihuacán, with the Pyramid of the Sun, which stood over 60 meters high, standing above everything else.

Interspaced among all of these structures were marketplaces, courtyards, and roadways that connected all of Teotihucán's living spaces and helped forge the footprint of this mammoth city.

Today, Teotihuacán is a favorite destination and research topic for both archaeologists and tourists alike, and every year, continued excavation and analysis of artifacts reveal more about the site's residents and their contact with neighboring peoples. Such investigation of the ruins of Teotihuacán is far from being a recent development, however. Throughout time, later populations, including the Aztecs, visited the site and utilized its space for their own purposes. The significance of this reality is that archaeological sites are often multicomponent in nature, playing host to several occupations. While each occupation will vary in its duration of stay and area of activity, the importance of each occupation is nevertheless an equal contributor to the site's history and time itself.

Zhoukoudian Discoveries

The Zhoukoudian caverns, located near Beijing, have yielded *Homo erectus* remains since the early decades of the 20th century along with an assortment of lithic tools and evidence of early fire use. While many specimens recovered were subsequently lost during World War II, the impact of the remains is still intense. Temporally speaking, the range in Homo erectus remains discovered in the Zhoukoudian region reflects the continual evolution of the species over the course of nearly 300,000 years (550,000 BP to 250,000 BP), particularly with regard to brain size.

Conclusion

Humanity's cultures are ever changing through time. Equipped with the technologies and theories of multiple fields, archaeologists continually seek to understand these changes through the careful collection and analysis of the material culture human populations have left in their civilization's wake. Although the interests and theoretical foundations among archaeologists vary considerably, and even as newer avenues of research such as paradigms based on critical thought and gender theory have taken center stage, an emphasis on time remains of central importance to most archaeological research.

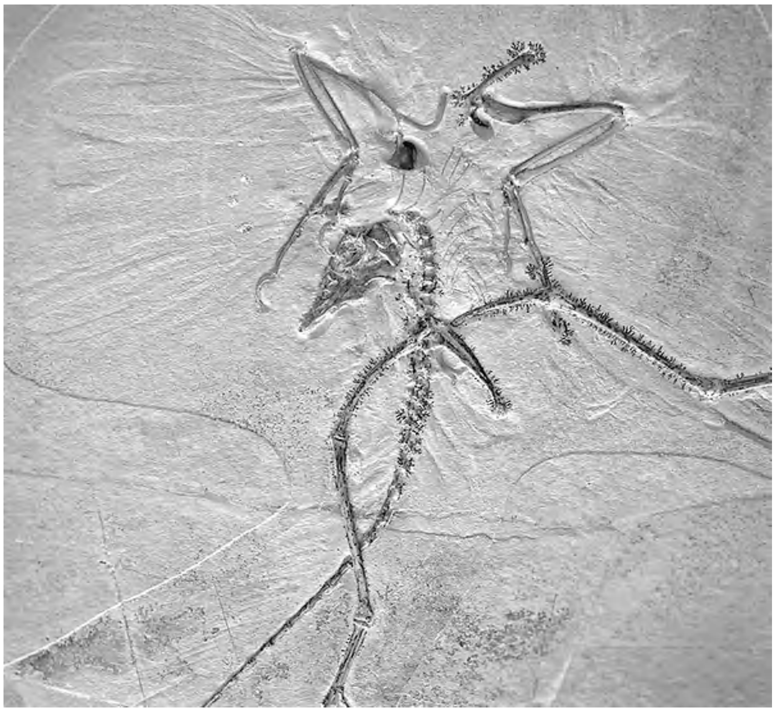
ARCHAEOPTERYX

Archaeopteryx is a dinosaur known from Jurassic fossils that remarkably exhibits feathers and other features once thought exclusive to birds. Specimens are regarded as among the most beautiful and significant ever found, as they document an important example of ancient life on the evolutionary path of flying birds arising from dinosaur ancestors. The first description of this "dinosaur-bird" in the 19th century famously helped ignite the evolution debate, and *Archaeopteryx* remains a relevant symbol of scientific enlightenment even today.

Adult *Archaeopteryx* was a crow-sized, bipedal, feathered dinosaur approximately 0.5 meters long. Although its exact evolutionary relationship has long been enigmatic, it is widely acknowledged to be a basal member of the Eumaniraptora, a branch of theropod dinosaurs that evolved in the Middle Jurassic and some of whose descendants would later give rise to modern birds, Aves.



Archaeopteryx *is an early, bird-like, feathered dinosaur, dating from about 150 million years ago during the Jurassic period, when many dinosaurs lived. Current research on this fossil and others using hi-tech methods has greatly strengthened our ideas about the evolutionary tie between dinosaurs and birds. This* Archaeopteryx *example, coined the "Thermopolis" specimen, is one of the most recently described discoveries.*

Source: Courtesy of Wyoming Dinosaur Center/Scott Hartman.

Specimens of *Archaeopteryx* have been discovered mostly in the 150-million-year-old rocks of Solnhofen, Germany, where finely laminated limestone preserves an exceptionally rich and diverse record of fossilized ancient life. The prehistoric landscape that formed this momentous resource is thought to have been a low, shrub-covered archipelago. Lime-rich mud washed into and filled its shallow lagoons, burying and preserving the mortal remains of its surrounding inhabitants, including dinosaurs, mammals, reptiles, fish, plants, and insects. Thanks to the fine-grained nature of the sediment and other taphonomic factors, the fossils of the Solnhofen limestone are often exquisitely detailed. Even soft tissues are preserved, such as the feathers that marked the epochal discovery of *Archaeopteryx* (which means "ancient wing" or "flight") in the 19th century.

Because of its being extensively covered with well-developed feathers, the *Archaeopteryx* has long been termed the world's most primitive bird. Indeed it seems to display many aspects common to modern birds and conducive to flight: arms with feathers to form broad wings, primary asymmetric "flight" feathers, small body size, hollow limb bones, relatively large brain with well-developed locomotor regions, and, the boomerang-shaped furcula (or "wishbone") commonly found in modern birds.

Unlike modern birds, however, *Archaeopteryx* also had jaws with sharp teeth, clawed forelimbs that extended forward of the "wing," and a long bony tail similar to other carnivorous dinosaurs at the time. Moreover, a plethora of recent discoveries of feathered dinosaurs with similar traits have been found, predominantly in China, that indicate that *Archaeopteryx* has no unique characteristics shared with birds that cannot be found in dinosaurs.

The flight capability and habits of *Archaeopteryx* have long been controversial. The latest specimens show that the extent of primary feathers along the bones of the arms was more limited than first thought, thereby decreasing the area available for a flight surface if used as a wing. Additionally, the lack of certain structures in the shoulder girdle combine to rule out powered flight, although limited flapping and gliding may have been possible. The first toe, called a hallux, is not fully reversed so as to specialize in grasping onto branches as in arboreal dwelling birds. And the second toe had a hyperextensible claw, similar to dromaeosaurid theropod dinosaurs but not modern birds. Collectively these suggest that *Archaeopteryx* retained the predominantly ground-dwelling habits of its forerunners and could not sustain powered flight.

Archaeopteryx was therefore not so much a bird as it was essentially a feathered dinosaur. Although most likely not a powered flyer, *Archaeopteryx* displayed the first feathers suitable for flight. It has been speculated that these originated as useful for insulation or to assist grip and changes of direction when pursuing prey, before being co-opted to develop novel aerodynamic capabilities such as gliding or flying short distances.

The remains of *Archaeopteryx* are among the most significant and famous of all fossils. The discovery of an apparent transitional form between reptile and bird catapulted *Archaeopteryx* onto the world stage just as Western society was hotly debating Charles Darwin's new concept of evolution. To some, the beautiful form of this "dinosaur-bird" supplanted historical images of Creation; it provided clear evidence that each species descended from its precursors and that these changes could be traced in the fossil record. Its fossils continue to provide an iconic example of life's mutability over time.

Aristotle (384–322 BCE)

For the Greek philosopher Aristotle, the most prominent disciple of Plato and founder of the so-called Peripatetic School, time is one of the fundamental constituents of reality. In his *Categories* he refers to time—without further discussing it here—as one out of ten "kinds of being," as "when" (*pote*). As a continuous quantity next to place and line, surface and body, time, for Aristotle, pertains to the category of quantity (*poson*). In *Physics,* however, he uses the concept of time in juxtaposition with the concepts of nature (*physis*), motion (*kinesis*), place (*topos*), infinity (*apeiron*), continuum (*syneches*), and emptiness (*kenon*) as a fundamental concept of his philosophy of nature. And although in the logic founded by him, time is of no concern to Aristotle (a "temporal logic" still being a far cry), it is the implicit horizon of human decisions and actions in his ethics. Unlike in modern philosophy, in which it figures as an eminent subject, time, for Aristotle, is merely an "accident" of reality, inasmuch as this latter is grouped around the concept of substance (*ousia*). Thus, on the one hand, all categories outside of the substance number among the accidents. On the other, just as motion and quiet, the number—and with it time—belongs to that which is "generally perceptible" (*koina aistheta*) in the phenomena, that is to say to that which is not restricted to a specific sense such as smelling or hearing but that belongs to all perceptions in general. Although they are, as a matter of consequence, universal constituents of humans' experience of reality, these categories exist in themselves merely as accidental qualities of a substance in motion.

Nevertheless, Aristotle's treatise on time in *Physics* (IV 10–14) is indubitably one of the most elaborate and influential contributions to the clarification of the essence of time. It evidently does not allow the inclusion of time in a metaphysical system, as that was later accomplished by the founder of Neoplatonism, Plotinus. Already the early critics such as the pre-Christian Peripatetics and the Neoplatonic commentators of Aristotle therefore object less to his phenomenological analyses than both to the fundamental lack of clarity with regard to the metaphysical status of time—that is, more precisely, of its definition as number and measure—and to the function performed by the soul in measuring and perceiving time. The judgment passed on Aristotle's analysis of time by modern critics has to be seen, for the most part, in the light of their own theories of time, some of which take their origin from the *aporiae* of the Aristotelian text. For Henri

Bergson, Aristotle is the first philosopher to have spatialized time and to whose concept of time Bergson opposes his concept of duration (*durée*). Martin Heidegger, on the foil of his existential-ontological concept of temporality (*Zeitlichkeit*), regards Aristotle as the exponent of a "vulgar" concept of time whose characteristics are timekeeping, the use of clocks, and the "uninterrupted and unbroken succession of the now" (Heidegger, 1988, §19). Modern characterizations of Aristotle's theory of time range from "the first philosophical theory of measuring time" (Janich, 1985) to "the phenomenology of the ordinary conception of time" (Wieland, 1992, p. 334; translation by entry author).

Taking his definition of time as "number of motion with respect to before-and-afterness" (Phys. IV 11, 219b1–2) as a starting point, this entry discusses Aristotle's theory of time with respect to six different topics: time and movement, time as number and measure, time and the "now," time and the soul, the use of clocks and the measurement of time, and time and eternity.

Time and Movement

A central problem of time is the question of its existence, for time is that which "exists either not at all or only hardly and vaguely so"; it is composed of what is past and future, both of which are nonexistent: the one being no more, the other not yet. Therefore it seems that time "does not participate in the substance"; that is, it does not exist as a substantial but only as an accidental being. The being of time is dependent upon movement that is itself, just as time, only of accidental being, inasmuch as it concerns processes that affect a temporal substance in motion. With respect to the relationship between time and movement, Aristotle distinguishes two views, both of which he opposes: Time is (1) the movement of the universe and (2) the celestial sphere itself. Although he does not assign these positions to anyone, the first can be related to Plato (as is done, according to Simplicius, by Eudemos, Theophrast, and Alexander of Aphrodisias). In the *Timaios,* Plato describes time as the "moving image of eternity" and ties its measurement up with the heavenly spheres and the planetary orbits. The second position is presumably Pythagorean. Archytas, for instance, is supposed to have called time the "expansion of nature as a whole." Despite the fact that Aristotle rejects both positions as insufficient, he adopts their assumption that time and movement are linked with one another. In doing so, he brings out two aporiae: (1) While movement is always the movement of a thing that is being moved, related exclusively to this thing and the place of its movement, time universally encompasses all things. (2) Movement can be faster and slower, whereas time passes steadily and thus serves as a measure, not of itself, but of the velocity of movement. It follows that time is not identical with movement, yet also not independent of it.

To prove that the relationship between time and movement is one of reciprocity, Aristotle puts forward the argument of the "Sardinian sleepers," a myth according to which there are men in Sardinia who, lying next to the heroes there, fell into a sleep devoid of all memory. Philoponos regarded this sleep as a 5-day healing sleep, and Simplikios identified it as the legend of the Heraclidae who had died after the colonization of Sardinia and whose bodies, as though they were fallen asleep, had outlasted time; to sleep in their vicinity was said to induce momentous dreams. Aristotle's philosophical point in referring to this myth is that the Sardinian sleepers miss the time during which they were sleeping because they connect the now perceived before falling asleep with the now perceived when waking up again and, leaving out the time that has passed meanwhile, experience it as a continuity. As time is always limited by two nows, no time seems to have elapsed when we perceive—or believe to perceive—one and the same now. From the fact that our perception of time is tied up with the perception of a movement—and be it but the soul's inner perception of itself—it follows that time and movement mutually imply one another. And although this relationship is one of mutual implication and one might first analyze movement with regard to time, Aristotle begins his systematic enquiry into the essence of time with the question of what time is with regard to movement—for the methodical reason that, within the framework of *Physics,* movement has already been discussed, whereas time has not and is still unknown.

Time as Number and Measure

Time is not identical with movement but with one of its aspects: "that by which movement can be numerically estimated." The number, in the sense in which Aristotle is using the term, is first and foremost the number of things we count, mathematical numbers being the result of an abstraction (*aphairesis*) from the numbers of things we have counted. Aristotle therefore criticizes the Platonic philosophers for reclaiming their ideal numbers from the numbers of things counted and for treating these ideal numbers as substances. Hence, "number," for Aristotle, is an equivocal concept that, on the one hand, designates the "countable" number (i.e., the number of the things that are being counted) and, on the other, the number "by which we count" (i.e., the mathematical, abstract number). The counted number refers to a quantity of things of the same kind. Because each of these things is understood as one indivisible whole, every specific area has a unifying measure of its own: harmony, for instance, the quarter note, or, when we want to count horses, the single horse. Again, the mathematical number (that by which we count) can be understood either as an abstract sequence of numbers that we apply to concrete things when we count (Ross, 1936, p. 598), or as the abstraction from the number of things counted, one of which, when we count them up, we use as unit (Wieland, 1992, pp. 318–322). Accordingly, the number by which we count serves as unit: "We measure the 'number' of anything we count by the units we count it in—the number of horses, for example, by taking one horse as our unit. For when we are told the number of horses, we know how many there are in the troop; and by counting how many there are, horse by horse, we know their number." Because one (*monas*), the first principle of all numbers, is "in every respect" and per se indivisible, the number as the "plurality of (discrete) unities" (*plethos monadon*) is the measure with the highest precision, whereas continuous quantities are measured by units that, to our perception, seem to be simple and indivisible. As noted by Richard Sorabji (1983), seeing that Aristotle considers time not only as "number" but also as "measure of motion," one can say that he is obviously not using these concepts synonymously (pp. 86–89). Julia Annas (1975) points out that, as a matter of consequence, Aristotle's language with regard to time either lacks unity or, more likely, what we really count, when we think we count different nows, are simply the periods of time limited by these nows (pp. 97–113).

Time, defined as "the number of motion with respect to before-and-afterness," is for Aristotle part of the counted number, not of the number by which we count. Hence, as both Wieland (1992, p. 327) and Sorabji (1983, pp. 86–89) note, the unit by which we count is not time itself, but, first, a now posited sooner or later and, second, a certain period of motion that we take as a unit in order to count up, and measure, a number of movements of the same kind. Time and motion mutually imply one another when it comes to measuring them: "For by time we measure movement, and by movement, time." By defining a particular motion as a unit of time we consequently attain a first unit of time with which we can measure other motions ("number of motion," after all, refers in the first place to such temporal units as day, year, or season of year). As a matter of consequence, the thing that is being counted has two aspects: On the one hand, we measure time by counting particular movements of the same kind that we have defined beforehand; on the other, we count the now or the number of nows: "And just as motion is now this motion and now another, so is time; but at any given moment, time is the same everywhere, for the 'now' itself is identical in its essence, but the relations into which it enters differ in different connexions, and it is the 'now' that marks off time as before and after." Just like a point in a line, the now functions as a limit between two periods of time, not primarily in that it is the end of a past and simultaneously the beginning of a future—if it were, the now would be a standstill and as such incapable of time and motion—but rather like the outmost points of a line that serve to demarcate a certain lapse of time. The smallest number of a unit of time is two or one, two with respect to the two nows that delimit time (the former and the latter now), in particular the two nows that constitute a certain period as a unit for measuring time; and it is one with respect to the unity of the now that, as the principal measure of time, serves both as a dividing and an integrating factor. Aristotle's definition of time as "number of motion with respect to before-and-afterness" combines these two aspects of the number, for what counts is not the former and the latter now, but both of them taken together in their capacity to limit a particular motion and the time it lasts, thus serving as a counted number that measures motion with respect to its temporal boundaries.

Time and the Now

The reality of time is a problem that Aristotle solves by way of the now: "In time there is nothing else to take except a 'now.'" As between time and movement, also the relationship between time and the now is one of mutual implication: "It is evident, too, that neither would time be if there were no 'now,' nor would 'now' be if there were no time." The now is not a part of time but the boundary between two periods: past and future. Thus, contrary to what is imputed to him by Heidegger (1988, §19), time for Aristotle is not a succession of nows. Nevertheless, the aporia remains as to whether the now is always one and the same or always new. Each of the two suppositions entails a dilemma. (1) The now cannot always be a new one, not only because nows that are not different from one another are capable of a simultaneous coexistence, but also because the way in which a former now disappears cannot be explained; neither can it have disappeared all by itself (seeing that it once was) nor can it have transformed itself into a later now, for then there would be an infinite number of nows between itself and subsequent nows, which is impossible. (2) The now cannot always be one and the same, because then completely different periods of time would be marked off from one another by the self-same boundary; moreover, all points of time past and future would then coincide with one another in a single now. For Aristotle, the solution to this aporia lies in the fact that the now has two aspects: On the hand, the now, understood as the potential division within the continuous flux of a movement and of time, is essentially always new, capable of actualizing itself as a boundary between "sooner" and "later" and of being perceived as an indivisible whole. On the other hand, the now is always the same. As such, the now is the first principle of, and yet different from, time.

An objection that was raised against Aristotle's definition of time (e.g., by Strato of Lampsacos, a Peripatetic of the 3rd century BCE) is that time is per se continuous, whereas both number and now are discrete, a criticism that is inaccurate, because for Aristotle time is the countable aspect of motion: In counting continuous periods of time and motion, we mark these off from one another by discrete nows. Time, thus, has passed, if we perceive "before" and "after" (*aisthesin labomen*) with regard to motion, that is, when we take the self-same now for two nows, one earlier, the other later, and think (*noesomen*) of its two limits as distinct from the interim that they contain. No time has elapsed, however, when we perceive the now as one and the same, that is, when there is no sooner or later with regard to motion. "Before-and-afterness" is what results if the soul is counting the nows and inserts them into the sequence of numbers. It is the successive order of this sequence, and not an inner sense of time, that is decisive for the irreversibility of the nows. Otherwise, seeing that "before" and "after" are temporal expressions, the definition of time as "number of motion with respect to before-and-afterness" would be circular and the essence of time would depend on the activity of the counting soul. Thus, although it is itself discrete, the now establishes, as a first principle, the continuity of time, for in marking off now the one, now the other period, it divides time as a limit (*peras*) and is itself always different, yet in remaining always the same, holds time continuously together. The now herein resembles the point when it divides a line. On the one hand, it is always the same, for it always performs the same function of dividing the line; on the other hand, it is not the same inasmuch as it always divides the line in a different place. And, as Wieland (1992) notes, because it is in the nature of noetic thinking to be capable only of thinking of indivisible and discrete contents, it (i.e., the noetic thinking) attains continuity only by the successive positing of discrete marks, immediate continuity being a prerogative of the perception (p. 326).

Aristotle regards the now as a nonexpanding limit, that is, as the beginning or the end of a period of time. In some places, he considers the now as a presence of minimal extension, which, as an integral part of time, overlaps with past and future, for example, the now in the sense of "today." In his analysis of time, however, he does not work with such a concept of now but uses the concept of a nonexpanding limit. Among scholars there is disagreement whether one can reformulate Aristotle's theory of time in the terms of the static "earlier, simultaneous, later" as opposed to the dynamic "past, present, future"; some have noted that Aristotle does not clearly distinguish between a static and a dynamic terminology (e.g., Sorabji, 1983, pp. 46–51). On the whole, one could say, as Wieland (1992) does, that Aristotle has a rather static concept of time, using it as an "operative concept of experience" rather than seeing it as the continuous flux it is for modern philosophy (p. 326).

Aristotle precludes the likely objection that his definition of time suffers from circularity by inducing "before" and "after" as spatial concepts: The thing that is being moved can be perceived in different places in a room, first in one, then in another. The continuity of time is directly grounded on the continuity of motion and indirectly on the continuity of magnitude (*megethos*). Inasmuch as things are different from one another according to their respective position (*thesei*), "before" and "after" have their origin in spatial dimensions, that is, in the hierarchical order of the different elements that are the principles of place (e.g., earth below, fire above) and in relation to which the position of other substances can be determined as lying closer (*enguteron*) or farther away (*porroteron*). This concept can be transferred to anywhere; for example, when we determine the starting and the finishing line in a race or when we say that the upper arm is farther away from the hand than the forearm. Temporally, "before" and "after" are determined with regard to their respective distance from the present now. Analogous to their respective position in space, they are also determined with regard to motion and time.

One can therefore not really accuse Aristotle, as did Henri Bergson, of a spatialization of time. On the contrary, his theory of time provides an epistemological foundation developed from the recurring discrimination between what is "before" for us (*proteron hemin*) and what is "before" objectively (*proteron physei*). Like Koriscos walking from the marketplace to the Lyceum, "before-and-afterness" is what motion is at any one time (*ho pote on*). This, however, is not yet in accordance with the Aristotelian definition of motion itself, namely, that it is the "progress of the realizing of a potentiality, qua potentiality." And it is "before-and-afterness" that constitutes the extension of time, whereas time is in itself defined as "that which is determined either way by a 'now'" and as "the number of motion with respect to before-and-afterness." Ontologically, it is impossible to reduce time and motion to spatial dimensions, seeing these are static and reversible, whereas motion and time are dynamic and irreversible. The sole purpose that their reduction to spatial dimensions serves is that it makes the temporal correlations that can be grasped only intellectually and the nonfixable locomotion more comprehensible. If time and movement agree with spatial magnitude with regard to the latter's quantity, continuity, and divisibility, then the importance of this magnitude is merely one *for us,* helping us to understand the quantity, continuity, and divisibility of movement and time. Time and movement are only accidentally quantitative and continuous, namely, inasmuch as that thing, which they are affections of, is itself divisible. This is the magnitude of extension and not the substance in motion itself (for this is divisible only with respect to its form and matter) that enables us to perceive motion. Thus, not only time and motion but also motion and spatial magnitude can be measured with mutual regard to one another. Motion and continuity of the magnitude of extension, on the other hand, are merely products of the mathematician's abstraction, that is, of his or her disregard for all other sensual qualities of the object. In other words, the mathematic fixation, both of locomotion (understood as the distance covered by the object) and of time as the numerical aspect of motion, is to facilitate the methodical description of a phenomenon that is per se unfixable and therefore indescribable. Contrary to what is occasionally asserted, time and motion are not per se identical with their respective measurement. Rather, they are determined by their ontological relation to the body that is being moved, a relation that can be described gradually as accidentality or nonbeing.

Analogous with time, motion, and line, as well as the relationship among their respective unifying principles, the now, the thing that is being moved, and the point, is one of epistemological foundation. Being for themselves always identical with themselves, they are the origin of unity. But in being subject to change according to different circumstances, they are also the origin of difference—and this is precisely the essence of their being principles: the now as that in which the beginning and the end of a period originate, the thing that is being moved as the principle in which the beginning and the end of a movement originate, and the point as the principle in which the limits of the line originate. The way in which the point functions as the origin of the line is principally the same as that in which the now and the thing that is being moved function as the origin of time and motion, respectively. The point divides the line in marking off the two sections of the line, the beginning of one from the end of another. But whereas the point fulfills a double function with regard to the line, the now and the thing that is being moved are, with regard to time and motion, respectively, always different from themselves, because they never come to a standstill. What all three relationships have in common is the fact that the continuum cannot be the sum of the discrete elements. Neither is the line made up of a number of points, nor motion composed of the different sections of movement the thing that is being moved has traveled through, nor yet time merely a succession of nows. The whole point of Aristotle's theory of the continuum is that while the continuum in itself is actually undivided, it is potentially capable of an infinite number of subdivisions. Thus, as a temporal limit, the now simultaneously is the end of a past and the beginning of a future, with every single period being potentially capable of numberless further subdivisions, that is, of numberless further nows as limits between past and future. Actually, each of these nows functions as the unity and the first principle of the continuity of time, namely, in that it links up the numberless periods of time divided into past and future both with itself and with one other.

The thing that is being moved is the ontological foundation of the now. The thing that is being moved is this particular something (*tode ti*), that is, a something that belongs either to the category of substance (*ousia*) or to that of the what (*ti*). Although the essence of "this particular something," which is deictically proven to be one identical and unmistakable same, can be determined in general terms, it is at the same time, namely, in being qualified as "this particular," only comprehensible on condition that changing circumstances exist in which this "something" does remain the same. Only the thing that is being moved, and not motion itself, is now characterized as "this particular something." Aristotle defines quantity as that which can be subdivided into parts, each of which is a single unity and a "this particular something." Number, understood as a quantity of discrete and countable unities, is based on the unity of the concrete substance, whereas measure, understood as that which determines the dimensions of a continuum, is based on the perceptible quantitative moments of this substance. And just as motion and the thing that is being moved occur simultaneously, also the number of motion, time, and the number of things that are being moved, the different nows, always coexist with one another. The thing that is being moved is a concrete substance, and while motion, inasmuch as it is merely an accident of this substance, borrows such properties as quantity, continuity, and divisibility accidentally from the magnitude of extension it runs through, it borrows these properties per se from the substance that is being moved. It is always Koriscos, who at some point covered the distance between the marketplace and the Lyceum, describing a succession that is not merely the connection of its disjointed members and that can be explained as a unit only because it has a beginning and an end.

Time and the Soul

In the last chapter of his treatise on time, Aristotle takes up the question whether without the soul time could exist, the intellect in the soul being understood as the only faculty in nature that is endowed with counting. Inasmuch as time had heretofore been linked with the outside, in other words, the physical world, this question seems to entail the aporia whether time, for Aristotle, is objective or subjective. Aristotle furnishes evidence for both interpretations when he remarks that, if there were no soul, time could but exist in the form of a temporal substratum (*ho pote on ho chronos*), that is, in the form of motion and the order pattern of "before-and-afterness" involved in it, which is time only on condition that it is countable. The Peripatetics were the first philosophers to discuss this aporia: Kritolaos (2nd century BCE), for instance, argued that time did not exist as an independent reality in its own right (*hypostasis*), but merely as an object of thought (*noema*),whereas Boethos of Sidon (1st century BCE) thought that time existed independently of the soul's counting. Plotinus objected that time as a quantitative magnitude would be as extensive as it is, even if there were nobody to measure it. Saint Thomas Aquinas's solution to the aporia, which he gives in his commentary on Aristotle's *Physics*, is that time as well as motion exist independently of perception and that the number and that which is countable only potentially, not actually, stand in need of someone counting. Thus, whereas the essence of time depends on the soul as on that which is capable of counting, time understood as the temporal substratum is independent of the soul as that which is potentially counting and, both with regard to its essence and as temporal substratum, completely independent of the soul that is actually counting. For a phenomenological interpretation that does not take the ontological difference between the essence and the substratum of time into account, the meaning of the aporia is the constitution of time. According to this interpretation, time does not exist within the soul, for instance, as the latter's inherent order pattern, but the soul is the necessary yet not sufficient condition for the existence of time in the world. Thus, as in Wieland (1992), "Time is neither *through* the soul, nor *in* it; it is only *not without* the soul's activity" (p. 316; translation by entry author). Time as number bears an immediate relation only to the movement of things, whereas to the things in themselves it bears an indirect relation. The soul is being presupposed only insofar as it counts the different nows that mark off the different periods of motion and of time. The measure it uses in doing so is not its own but the product of its comparing a particular movement or period of time (which has been taken as the respective unit of measure) with the movement or period of time to be measured. The soul is consequently not the origin of time understood as subjective time, nor does it simply state the objective time of the outside physical world, but, as Franco Volpi (1988) notes, it manifests and constitutes time as "the phenomenological form of Becoming [. . .] for the human experience of the natural world" (p. 58; translation by entry author). What the Aristotelian analysis of time does not take into account, however, is the question Heidegger (1988, §19) tries to answer in his exaggerated interpretation of Aristotle as to how far the objective experience of time is the manifestation of the soul's own temporality.

The Use of Clocks and the Measurement of Time

Having realized that time and movement mutually imply one another, Aristotle considers the notion—known to us from Einstein's theory of relativity—of measuring time relatively. Seeing that any coherent movement can be measured numerically, he argues for the possibility of a simultaneous coexistence of several times, analogous with different movements parallel to one another. However, in order to measure the respective duration of these relative times, there has to be an absolute first temporal measure from which their simultaneity can be determined, "just as if there were dogs and horses, seven of each, the number would be the same, but the units numbered differently." Thus, with regard to the measurement of time there is a difference neither between the different forms of movement (apart from local motion, Aristotle also mentions the change of qualities and of quantity and the genesis and disappearance of the substances) nor between the different velocities of movement. The uniform rotation of the heavens is the "first measure," because the number of its orbits, for example, days, months, and years, is the easiest to discern; it is with regard to this rotation that other, less uniform movements are measured. The only methods people in Aristotle's days had at their disposal when they wanted to measure temporal units inferior to the day were sundials and, independently of celestial rotation, water clocks. And although the principle of modern clocks—that is, the uniform circular movement capable of being subdivided into units of equal size—had not yet been invented, one could say, with Friedrich Solmsen (1960, pp. 149–150), that Aristotle's analysis of time anticipated the theoretic fundamentals of the clocks that were developed much later.

The measurement of time can take the form of either counting periods or measuring spatial distances that involve nonperiodic processes, both of which involve two procedures. The first consists of two movements, one periodic the other irreversible, and is best illustrated with regard to the pendulum clock, where the periodic movement is marked by the pendulum and the irreversible one by the cogwheel mechanism that causes the hands to move clockwise. The second method consists of measuring a given distance by comparing it to a distinct distance. Aristotle is familiar with both forms of measuring: The rotation of the heavens is a periodically recurring process whose different orbits, in their relation to one another, generate the numerical units of day, month, and year. Both our perception of time, namely, in that it enables us to distinguish "before-and-afterness" and the sequence of numbers by way of which earlier and later periods are marked off, can be seen as the corresponding irreversible processes. Whereas the periodic rotation of the heavens furnishes the actual measure of time, the act of measuring involves the comparison of different movements. Time measures movement "by determining a certain unit of movement which shall serve to measure off the whole movement (as the cubit serves to measure length by being fixed upon as a unit of magnitude which will serve to measure off the whole length)." Or: "It is by the movement-determined-by-time that the quantity both of movement and time is measured." It follows that the measurement of time is based on a comparison of movements transferred to a spatial distance. In Aristotle's theory of time, the measuring of periods and that of distances thus complement one another.

Time and Eternity

Contrary to Plato's theory of time, according to which time is the "moving image of eternity," in Aristotle's analysis of time there is neither a mention of eternity nor an attempt to establish a relation between the temporal number associated with movement, on the one hand, and the unity Plato associated with eternity, on the other. Rather, unity in Aristotle is reduced to the unifying measure of that period of movement that has been chosen as the measure of time. The importance and dignity that Plato attributes to the celestial bodies with regard to the concept of time are, in Aristotle, reduced to the idea that the rotation of the heavens, on account of its easy discernibleness, is an excellent, yet not the only, measure of time. What is certain also to Aristotle is the perennial being of time, and the reasons he gives for this are the following: (1) Every now is always the end of a past and the beginning of a future period; an ultimate temporal unit would therefore find its end in a now that, being a limit, is always also the beginning of a future; that is, time is what always is. And, according to this argument, just as time is perennial, so is movement. (2) Seeing that they have always existed and that, without time, there would be no "before-and-afterness," it is impossible for both movement and time to come into being or to disappear. The ultimate guarantor for the perennial being of time, however, is God, Aristotle's Prime Mover, who, being himself timeless and unchanging, guarantees, through the medium of the ever-revolving heavens, the unity, perpetuity, and ubiquity of time. The only characteristic Aristotle attributes to that which is "perennial" is that it is "not in time," that is, that its essence cannot be measured by time. In contradistinction to the traditional idea, the passing and disappearing of things is, for Aristotle, not caused by time but by movement. And although he admits that time depends on the periodical rotation of the heavens, for him the cyclical notion of time that the Presocratic philosophers and even Plato still adhered to, is irrelevant to Aristotle.

Aristotle and Plato

Aristotle's conception of time essentially relies on Plato's speculations on this subject. This is apparent from Aristotle's definition of time: "number of motion in respect of 'before' and 'after.'" Time and movement are also closely related in Plato's *Timaeus*, where it is said that time is "a moving image of eternity" that moves "according to number." According to Plato, time is in its very nature measurable, as before the heavens came into being there was no time. The planets were created to mark off and to "stand guard over the numbers of time," which implies that they define the units with which we measure time.

Even though according to Aristotle time is measurable and the primary measure of time is the movement of the celestial spheres, which is the fastest regular movement, this is not the core of his definition of time. First, time is a kind of number, with which we do not count, but it is something that is countable. Consequently, the second essential feature of time is its continuous nature, since the numbers with which we count are a discrete plurality, but the numbers with which we count are continuous and therefore so is time.

Additionally, time is a number in the sense that it consists of a series of "nows," which are countable. Due to the fact that time is a number, composed of countable units, it is fundamentally ordered in the way that the "before" and "after" order in which numbers stand, reflects the earlier and after nows, the earlier and after times.

The chain of nows is so arranged that each now presupposes always something before and after the given now. Although according to Plato movements and changes are inevitable and orderly (they must be regularly repeated in order to be measured), order is not defined by Plato as a before-and-after order, as Aristotle holds.

The second aspect in which Aristotle follows Plato in order to depart from him is the question of the relation between time and eternity, namely, between what is in time and what is outside of time. Plato distinguishes between two senses of lasting forever (*aidios*). One sense of everlasting is lasting as long as time does. The heavens are *aidios* in that way, because they were created along with time and they are indestructible. The other sense of *aidios* is having no beginning and no end. In contrast to the celestial bodies, which last throughout time and move constantly, the eternal being exists outside of time, and it is never subject to any change whatsoever. Therefore, it is only appropriate to ascribe an "is" to the eternal being and never a "was" or "will be"; in other words, it is always present and never past or future.

Following Plato, Aristotle considers that the entities that do not have beginning or end are outside of time. Aristotle, however, rejects Plato's view that time is created, which is supported by two arguments. The first argument begins with the claim that there has always been motion or change, which is made plausible by the claim that any beginnings of motion or change must be initiated by earlier motion or change. The second argument relies on the assumption that each now is a beginning and an end of time, from which follows that there is no first now. Aristotle's refutation of the view that time is created has serious implications for his own conception of time and its relation to eternity.

The most significant consequence is that for Aristotle the class of the entities that are outside of time is bigger than Plato thought, and it includes the things that exist throughout time. Namely, because time is beginningless, there is no difference between the entities that last as long as time does and entities that have no beginning. All of them are outside of time.

Aristotle refers to two criteria for determining what is "being in time." According to the first criterion, being in time is being surrounded by time, and something is surrounded by time if there is time before and after it. Because time has no beginning or end, the duration of the entities surrounded by time is finite. According to the second criterion, the entities are in time if their being is measured by time, or they are outside of time if their being is not measured by time.

In contrast to Plato, Aristotle holds that heavenly bodies, although mobile, are somehow outside of time, for the reason that their being cannot be measured by time. As these bodies are in everlasting movement, there is no total period of time within which they are moving, and consequently their existence cannot be measured in terms of time. According to Aristotle, from the fact that the celestial bodies are, in a sense, outside of time, it does not follow that they do not stand in temporal relations. They can be successively past, present, and future, but they endure unalterably through all time. Aristotle held that the stars, the planet Earth, and all species (including our own) are eternally fixed in nature. There is no creation, no evolution, and no extinction in his thought.

Apart from the heavens, nonexistent "things" that necessarily do not exist are not in time, such as the diagonal of a square's being commensurable with its side. Their opposites—in this case the diagonal's being incommensurable with its side—always are. In Aristotle's view the "things outside the heavens," such as God, are, in a more radical sense, outside of time. God is primarily eternal, an "absolutely immobile and perfectly active" being. Even though the heavenly spheres are not subject to generation and destruction, they are "being moved" by the first "unmoved mover," and therefore in principle they are capable of being otherwise, while God, the first mover himself, is unavoidably what he is—the perfect and eternal activity.

Armageddon

The word *Armageddon* appears in the Bible only in the New Testament Book of Revelation 16:16. It is mentioned in the context of the sixth bowl of judgment (Rev 16:12–16) as the place where the kings of the whole world will gather for battle "on the great day of God the Almighty" (v. 14), which refers to the Parousia of Christ. In the Book of Revelation, it is the penultimate battle of history; the final battle will occur 1,000 years later at "the beloved city" of Jerusalem (Rev 20:7–10). Some interpreters think that the two descriptions of battles actually refer to the same event in different ways. Later Christian theologians used Armageddon as the name for the final battle of history during which the opponents of God and his church will be destroyed by Christ at his coming. Also, the image has been commonly used in Western culture to refer to a final battle or cataclysm that will bring the world to an end. In Christian theology and popular conceptions, the image of Armageddon relates to time as a future event associated with the end of history.

Interpreters have disagreed over the identification of the place. Revelation 16:16 indicates that the name is derived from Hebrew, so interpreters have offered at least six explanations of its Hebrew meaning. First, it is a combination of the Hebrew word *har* ("mountain") and the name Megiddo. Megiddo, a city located beside the Jezreel Valley near the intersection of several trade routes, was occupied from 7000 to 500 BCE. At least 34 battles have occurred there throughout history, including the first battle of recorded history. Thirteen of those battles had occurred by the time Revelation was written. Although Megiddo is a 70-foot-high tell, no mountain is located near the site. Second, if *ar* is derived from '*ir* (the Hebrew word for "city"), then it refers to the city of Megiddo.

Third, it refers to Mount Carmel, which is located 5 miles northwest of Megiddo. Mount Carmel was the place where, in the Hebrew Bible, the prophet Elijah defeated the prophets of Baal (1 Kgs 18:20–46). Fourth, the Hebrew phrase is constructed from *har* ("mountain") and *mo'ed* ("assembly"). This interpretation assumes that the Greek *gamma* transliterates the Hebrew *ayin.* The Mount of Assembly is referred to in Isaiah 14:13 as the heavenly court where the king of Babylon would seek to exalt himself above God. As Mount Zion was viewed as the earthly counterpart of the heavenly throne room (Ps 48:2), Armageddon refers to the attack on Jerusalem by end-time Babylon. Fifth, *magedon* is derived from the Hebrew *gadad,* which means "to cut" or "to gash." Therefore, the name means "marauding mountain" or "mountain of slaughter," the place where the armies of the earth are gathered together to be exterminated. Sixth, it combines *har* and *migdo* ("fruitful"), referring to Jerusalem. Revelation 14:14–20 and 20:7–10 also associate the last battle with Jerusalem.

Because of the difficulties in specifying the origin of the name, many interpreters believe that the author of the Book of Revelation was not thinking of a physical locality but was using the association of Megiddo with warfare as a theological symbol of the rebellion of evil against God and God's final defeat of evil. Armageddon would then be the culmination and epitome of all previous rebellions against God that have occurred throughout history. The author may be alluding to Zechariah 12:11 to express the idea that the nations that stand against God will mourn as they face God's judgment.

Revelation 16 never describes an actual battle. During the seventh bowl judgment (Rev 16:17–21), a voice from the heavenly temple declares, "It is done." In association with the end of the world, a great earthquake destroys Babylon and huge hailstones from heaven torment people. The reason that no actual battle takes place is because, in the view of the author of Revelation, Christ has already defeated the forces of evil in his death and resurrection.

The description of Christ's Parousia in Revelation 19:11–21 appears to be another description of Armageddon, although the term is not used in that context. There the kings of the earth have gathered their armies together to make war against the rider on the white horse, but they are destroyed before the battle even begins.

Asimov, Isaac (1920–1992)

Isaac Asimov was a famous American author and scientist whose work helped to popularize science in American culture. He wrote or edited more than 500 fiction and nonfiction books, making him one of the most prolific writers of all time. Asimov was deeply interested in the concept of time, which he addressed throughout his work.

Asimov is widely regarded as one of the masters of science fiction, along with Arthur C. Clarke and Robert A. Heinlein. His publications are wide-ranging and include topics as varied as astronomy, Shakespeare, Greek mythology, and Bible studies.

Asimov was born in Petrovichi, Russia, on January 2, 1920. His family immigrated to the United States and settled in Brooklyn, New York, when he was 3 years old. As a youth he developed an interest in reading science-fiction magazines and writing short stories. During World War II he served in the U.S. Naval Air Experimental Station and later in the U.S. Army. Following the war, Asimov attended Columbia University, where in 1948 he received a Ph.D. in biochemistry. In 1949, he joined the staff of the Boston University Medical School and remained there throughout his career.

His most popular works of fiction include *I, Robot* (1950), which was adapted into a film version in 2004; *The Foundation Trilogy* (1951–1953), which describes the fall of the Galactic Empire; *The Caves of Steel* (1954); *The End of Eternity* (1955); and *The Gods Themselves*. Asimov also wrote nonfiction works, including *The Intelligent Man's Guide to Science* (1960), *Asimov's Guide to the Bible* (1968–1969), and *Asimov's Guide to Shakespeare* (1970).

A self-proclaimed humanist, Asimov emphasized science and rationalism throughout his work. His fiction explores the role of humankind in the universe, extending back in time to the origins of life. He was deeply concerned with the concept of time and development in history. Although generally written for entertainment, Asimov's fictional work often addressed problems and troubles that humankind has faced in the past or may face in the future. Fascinated by technology and the potential of human intellect, he included robots and other futuristic inventions in his stories. His nonfiction is celebrated for making complex ideas in science clear to the common public. His books were written for both children and adults.

Asimov was given numerous awards and honors during his lifetime.

He was also a member of the American Humanist Association, for which he served as president from 1985 to 1992. In later years Asimov wrote three volumes of autobiography: *In Memory Yet Green* (1979), *In Joy Still Felt* (1980), and *I. Asimov: A Memoir* (1994, posthumously).

Asimov died on April 6, 1992. Ten years after his death his family revealed that he had died from complications due to AIDS, which he contracted from a blood transfusion during heart bypass surgery. His doctors advised the family to withhold the cause of death from the public due to stigma associated with the AIDS virus at that time.

Astrolabes

The term *astrolabe* designates several related observational instruments used primarily for astronomical and navigational calculations, the most common and historically significant of which is the planispheric astrolabe. Others include the rare linear and spherical astrolabes and the simplified mariner's astrolabe. The astrolabe's basic function was observing the angular distance between objects, such as between a star and the horizon. Planispheric astrolabes were also designed to make calculations and predictions based on a rotating planar projection of the celestial sphere, which enabled the user to, among other things, tell time. These astrolabes illustrated the annual path of the sun and the daily rotation of the stars, which could be related to the current time or predicted for any specific time. Thus, the planispheric astrolabe was, in some sense, an observational tool, a calculator, a clock, and a calendar all in one. In fact, it was the design of the planispheric astrolabe, with its two-dimensional depiction of the celestial rotation, that inspired the familiar circular face of the mechanical clocks that began to emerge in the 14th century. On astronomical clocks, popular in the 15th and 16th centuries, the planispheric projection used on the astrolabe was retained inside the center of a 24-hour clock face.

Although the exact origin of the astrolabe is unknown, it is thought to have developed in Greek antiquity, perhaps as early as Hipparchus but at least by the time of Ptolemy in the 2nd century CE. Although the astrolabe fell out of use in the West during the latter portion of the 1st millennium CE, its popularity flourished in Arabic culture for centuries. Particularly noteworthy is the work of 10th-century Islamic astronomer Abd al-Rahman al-Sufi, who is said to have described some 1,000 uses of the astrolabe. The instrument reentered Western astronomy

Astrolabes were used by early astronomers and navigators to measure the altitude of stars and planets. This is a replica of a small astrolabe, about 45 milimeters in diameter.

Source: Norbert Speicher/iStockphoto.

during the 11th century through contact with Islamic culture, alongside the rediscovery and translation of classical texts. Hermann the Cripple (1015–1054), a Benedictine monk, wrote of the astrolabe in Latin around this time; Geoffrey Chaucer wrote the first English treatise on the subject 3 centuries later.

Planispheric astrolabes are similar in shape to modern pocket watches. Typically made of brass or other metals, the instrument is built around a circular base plate called a *mater.* The back of the astrolabe is engraved around the outside of the mater with a scale of degrees for measuring angles, as well as other scales to indicate the position of the sun on the ecliptic. Attached to the center is a rotating sighted bar called an *alidade,* which is used for measuring angles in the sky. Such observations can be taken by holding the astrolabe vertically by an attached ring, moving the alidade to align a celestial object with both sights, and reading the degrees indicated by the alidade on the scale. The front of the astrolabe is used for representing the observed rotation of the heavens in a planispheric projection. The top layer of the front consists of the *rete,* a skeletal rotating plate that represents the positions of the stars and the ecliptic path of the sun. Beneath the rete is a detachable plate marked with celestial coordinates that can match the position of the rete to the altitudes observed with the alidade. These plates are necessarily specific to particular latitudes; hence most astrolabes were provided with multiple interchangeable plates. The front of the astrolabe typically also included a scale of hours around the outside and a pivoting ruler to aid in measurements. The mariner's astrolabe was a simplified version of this instrument used only for observing celestial altitudes at sea.

The versatility and ingenuity of the astrolabe made it popular among astronomers from antiquity until the beginnings of modernity. A sighting instrument, a calculator, a star map, a clock, or a calendar, the astrolabe had numerous applications to astronomy and navigation as well as astrology. Because it recreates and measures the rotation of the heavens, the astrolabe has also much connection with the measurement of time. Astrolabes could be marked to indicate both uneven and even hours of the day and could relate the time of year based on the sun's position in the ecliptic. A notable symbol of classical and medieval astronomy, the astrolabe is also the primary precedent for the circular clock format used around the world today.

ATTILA THE HUN (C. 400–453)

Prior to Attila's rule, the West had not experienced such a threat from a single, fearsome leader born of a nomadic people. His conquests gave the Huns control of a region extending from the Danube River to the Baltic Sea, and from the Rhine River to the Caspian Sea. In terms of impact on the course of history, there would not be another conqueror such as Attila until the rise of Genghis Khan 750 years later.

The Huns, excellent equestrians especially during battles, migrated from Central Asia and settled in Central Europe north of the Roman Empire in the late 300s. Little of Attila's early life is known, including the exact year of his birth. He and his elder brother, Bleda, inherited the Hunnish kingdom from their uncle, King Ruga, when he died in 434.

The Treaty of Margum of 435 required the Eastern Empire to pay an annual fee to Attila and was the first of many humiliating agreements. From 435 to 439, Attila campaigned to consolidate control of Hunnic provinces in the Caucasus and trans-Volga regions. In 443, the First Peace of Anatolius between Attila and the Eastern Romans further humbled the empire. Bleda died a year later, leaving Attila as sole ruler. Historians debate whether his death was a murder or an accident.

Here Attila, King of the Huns, points at storks leaving the city of Aquileja and predicts that it is a sure sign of a Hun victory, 452. Attila was a fierce warrior on the battlefield, and through his aggression he posed an extreme threat to the Romans and nearly conquered Rome itself.

Source: Kean Collection/Getty Images.

In 447, Attila's army conquered the Balkan territories, destroying many cities in their wake. They reached Constantinople but did not succeed in taking it. The Second Peace of Anatolius was imposed on the Eastern Romans. It called for an increased annual fee, repatriation of former Huns, and for the Romans to evacuate all the territories south of the Danube River. Two years later, an assassination attempt on Attila on the orders of the Eastern Roman emperor, Theodosius II, was foiled, and the emperor was once again embarrassed.

In 451, Attila invaded France (Gaul) in hopes of conquering the Western Roman Empire. A combined army of Germanic and Roman forces stopped him in the Battle of Chalons-sur-Marne, near Troyes. It has been described as one of the 15 decisive battles of world history. Approximately 100,000 people were killed. Attila invaded northern Italy and conquered 12 cities in 452. A papal delegation led by Pope Leo I persuaded Attila to leave in return for a large sum of money and the right to launch another invasion. In 453, on the night of his wedding to the last of several wives, he died as a result of a suffocating nosebleed probably induced by intoxication. His sons divided his empire, but internal strife soon destroyed the power of the Huns. Eventually they were absorbed into the people of the Balkans. During Attila's lifetime he was a major threat to the Roman Empire, but his challenge did not outlive him. Nevertheless, he is well remembered in history, drama, and literature.

ATTOSECOND AND NANOSECOND

Humans live on a timescale measured by minutes and seconds, whereas atoms and molecules exist on a timescale measured by femtoseconds and attoseconds. A nanosecond is roughly one billionth of a second (1×10^{-9}). An attosecond is one billionth of a nanosecond, or a quintillionth of a second (1×10^{-18} seconds). Throughout the 1990s, scientists had no way of measuring on an attosecond timescale and were using a femtosecond timescale to view the movements of atoms. A femtosecond (1×10^{-15} seconds) is one quadrillionth of a second, much faster than a nanosecond and only 1,000 times slower than an attosecond, yet enough to make a difference. According to Niels Bohr's model of the hydrogen atom, electrons take about 150 attoseconds to orbit the nucleus. From a human perspective, a single second in comparison to this electron's orbital revolution is roughly the same as 200 million years.

In 1954, Manfred Eigen noted chemical reactions that transpired in nanoseconds, introducing the world to a whole new field of chemistry. Prior to Eigen, these reactions were invisible to human observations.

To view atomic and molecular activities requires rapid strobes of laser light beyond the speed of nanoseconds. The overall movement of these atoms can be seen when viewed at femtoseconds; however, to view the activities of the electrons, these pulses need to be short and quick enough to capture attoseconds. Paul Corkum created the first idea of how to measure an attosecond, and the first recorded measurement of an attosecond in 2002 is attributed to a group of scientists in Vienna led by Ferenc Krausz.

The process of viewing electrons on an attosecond timescale requires the rapid, repetitive pulsation of a laser through one of the noble gases, such as neon. This results in the collision of an atom's nuclei with its electrons, creating attosecond bursts of X-ray energy. These X-ray bursts can then be focused and redirected to create attosecond pulsations. These attosecond pulses can then be turned toward an atom to track the motion of an electron. One such activity that scientists were able to map was that of the Auger process, the rearrangement of an atom's electrons to fill a gap created by the loss of an inner shell electron. After knocking an inner shell electron out of its orbit around an atom's nucleus, scientists have been able to view the movements of the electrons to fill in the gap and the resulting expulsion of another electron, the Auger electron.

Despite the advancements made in the studies of attoscience, scientists are still far from discovering the smallest amount of time, known as Planck time (1×10^{-43}). Planck time is the amount of time it takes light to travel across the smallest unit of measurement, Planck length. Beyond these measurements, the traditional spacetime continuum and gravity begin to break down and quantum mechanics needs to be taken into consideration.

AUGUSTINE OF HIPPO, SAINT (354–430)

Born Aurelius Augustinus at Thagaste in Roman North Africa (today's Algeria) of a pagan father and Christian mother, Saint Augustine of Hippo was formally educated as a rhetorician, but sought pagan, Manichaean, and Neoplatonic answers to questions about reality. After his conversion to Christianity, he became a monk, and in the year 396 was appointed bishop of Hippo Regius in North Africa. He wrote sermons, devotions, prayers, letters, polemical writings (against Manichaeans, Donatists, and Pelagians), and doctrinal treatises (e.g., *On Christian Doctrine* and *On the Trinity*). He is best known for his autobiography of his conversion, *The Confessions,* and his apologetic of divine providence, *The City of God.*

Saint Augustine, 1480, fresco, Ognissanti, Florence: Saint Augustine of Hippo is regarded as one of the great fathers of the early Christian church. He was converted to Christianity in 386 and became the bishop of Hippo, in North Africa, in 396.

Augustine helped to develop the Christian view of time, particularly in the following writings: *On Music, The Immortality of the Soul, The Literal Meaning of Genesis,* and chiefly in *The Confessions,* his account of his early life up to his conversion to Catholic Christianity and his decision to enter service to the church. The first ten books contain this story, and the final three contemplate God and Creation. In Book 11, amid a discussion on the creation of the cosmos, Saint Augustine enters into a meditation on time. The bishop of Hippo does not give us a scholastic argument, but in humility, an extended prayer and dialogue on time and eternity, in which he asks God to reveal to him the mystery of time, "this most intricate enigma."

Saint Augustine first asks about God in relationship to time. He notes that God is eternal and changeless and, as time means change, then time is not eternity. Time is a creature, a creation of God; thus God is exempt from the relation of time. Eternity is fixed and time is never fixed: "No time is all at once present." Before creation, there was no time—no past and no future: "Before all times God is: neither in any time was time not."

Next, Augustine discusses humanity in relation to time: for Saint Augustine, it is always present and never past or future. Using images of time, motion, age, and words, he discusses the extent of the present and our perception of intervals of time. Although we recognize a past in memories (as in our childhood) and future (as in contemplating our next action), they are not present. He then proposes three categories of time: "a present of things past, a present of things present, and a present of things future," all perceived by memory (present past), sight (present present), and expectation (present future).

After addressing humanity in relation to time, Saint Augustine discusses the measurement of time. Humans measure time in space, in that we perceive time as an extension or distention a stretching of our humanness. Yet not only do humans measure time as a movement in space but we also measure time even when things are standing still. So time, then, is not the motion of a body. Time is measured by long time and short time, "a protraction," though we do not measure the past, present, and future. It is in the human mind that times are measured in proportion as they pass by in short or long. So, the human mind expects, considers, and remembers time: "that is that which it expects, through that which it considers, passes into that which it remembers."

Finally, Saint Augustine sees time as a distention, a distraction in life (*ecce distentio est vita mea*). He concludes that time, needing the human mind to consider it, cannot exist outside of creation and is not eternal. Therefore, God is eternal as are all those things that are co-eternal with God (the Word and the Spirit).

For Saint Augustine, while time is inscrutable, time is a mutable creation of God. Time is always present and measurable only in proportion to that present. Because time is measured by human beings, it is human beings that have the sensation of time stretching and spreading each human in the journey of time.

Aurora Borealis

> The Valkyrior are warlike virgins, mounted upon horses and armed with helmets and spears. When they ride forth on their errand, their armour sheds a strange flickering light, which flashes up over the northern skies, making what men call the aurora borealis, or Northern Lights.
>
> Bulfinch's *Mythology,* 1855

Throughout time, humans have gazed at the sky to behold the splendor of the universe and contemplate the unknown. Certain times of the year, at the polar zones of Earth, there is a majestic show of lights and colors that occurs in the night sky. The lights that are viewed from the north skies are called *aurora borealis,* a combination of the name of the Roman goddess of the dawn, Aurora, and the Greek name for north wind, Boreas. The aurora borealis is visible only in the northern skies and is thus also known as the northern lights. This phenomenon also occurs in the southern skies; the counterpart is known as the *aurora australis,* with the name being derived from the Latin word for "of the South."

The cause of these great lights starts far away from Earth, at the center of our solar system. The solar corona is the outermost portion of the sun and also the portion that produces temperatures that range in the millions of degrees. This corona, at times, ejects a rarefied flow of hot plasma (a gas consisting of both free and positive electrons) into outer space. This ejection of plasma is known as the solar wind. The solar wind travels through space until it nears Earth.

Earth's magnetosphere consists of the area dominated by its magnetic field. Extending far beyond Earth's atmosphere into outer space, the magnetosphere blocks much of the solar wind and causes it to disperse. Solar winds contribute energy and material to the magnetosphere, causing the electrons and ions present in the magnetosphere to become energized. Once energized, these particles move along the magnetic field lines toward the polar regions of the atmosphere. The light is emitted shortly after this transfer occurs and is usually dominated by a greenish glow, produced by emissions of atomic energy, and also a dark-red glow, especially at high altitudes and lower energy levels. These two colors represent transitions of electrons and atomic energy, in absence of newer collisions, which continue for extended periods of time and account for the fading and brightening that occur. Other colors, such as purple and blue, can be seen when atomic energy and molecular nitrogen interact, but these displays tend to be of shorter duration.

The aurora borealis, or northern lights, shines above Bear Lake, Alaska. The lights are the result of solar particles colliding with gases in Earth's atmosphere. Early Eskimos and Indians believed different legends about the northern lights, such as they were the souls of animals dancing in the sky or the souls of fallen enemies trying to rise again.

Source: U.S. Air Force photo by Senior Airman Joshua Strang.

The best place to see the aurora is near Earth's magnetic poles. It can, however, be seen in temperate latitudes during times of heavy magnetic storms. These storms relate directly to the 11-year sunspot cycle and are strongest during the peak. These strong storms can continue to occur for up to 3 years following the peak. In September 1859, one of these strong magnetic storms occurred and produced what is thought to be the most spectacular aurora ever witnessed in recorded history. The aurora was the result of the Carrington-Hodgson white light solar flare, which was emitted on September 1, 1859. This flare was one of the most intense coronal mass ejections in recorded history. The aurora was seen across the United States, Japan, Australia, and Europe. It was this aurora that allowed the link to be seen between auroral activity and electricity. Many of the telegraph lines that were in use across North America and Canada encountered interference during this aurora. Several other telegraph lines had been powered down but, nevertheless, they picked up a geomagnetically induced current through the lines and allowed the telegraph operators to continue communicating. Since then, the phenomenon of the aurora has continued to intrigue many people. In the future, scientific research in outer space may shed more light on the aurora phenomenon.

AVICENNA (980–1037)

Avicenna is the Latin name of Abū Alī al-Husayn ibn Abd Allāh ibn Sīnā, an Islamic Persian philosopher and physician, who was born in Afsana near Bukhara and died in 1037 in Hamadan, both located in Persia.

After education in all the known sciences by teachers in his father's house, Avicenna worked as physician and advisor to the local sovereign. In 999 the Samanid house was defeated by a Turkish dynasty and his father died—two reasons for Avicenna to flee from his hometown. During the following years Avicenna served as physician and scientist under several rulers in different regions until his death at the age of 57. His works became famous and were used in the education of students in European universities until the 17th century.

Avicenna's philosophy is based on his study of Aristotle. As he did not understand Greek, he studied Arabic and Persian translations of the texts. Avicenna's main works are *The Canon of Medicine,* which sums up the knowledge of healing in his time, and *The Book of Healing,* which is meant to be a paraphrase of the works of Aristotle.

As does Aristotle himself, Avicenna believes God to be the first cause of all things. God is the first existent and as such not influenced by the workings of time. Time begins only with the creation of the world. God is not interested in single incidents but is the mover of all things, the moving principle.

According to Avicenna, prior to their creation in the material world, all things already exist in the intellect of God. Only after they have been created can they also be perceived by the human intellect.

According to Avicenna's philosophy, the continuity of time is broken within each human soul. Any act of the soul divides time into a "before" and an "after," into past and future. The present exists in the moment of action. Soul and body are two separate substances: Whereas the body is mortal, the soul stays immortal. As a consequence, resurrection of the human body does not exist.

Avicenna's thinking exerted considerable influence not only in the Islamic world but also over European philosophy in the Middle Ages, especially on Albertus Magnus and Saint Thomas Aquinas.

B

Baer, Karl Ernst Ritter von (1792–1876)

Karl Ernst Ritter von Baer was the modern founder of embryology and comparative embryology, as well as an accomplished zoologist and biologist. No longer a familiar name, Baer was in his time a genius acknowledged by his greatest contemporaries in science.

Baer was born in Landgut-Piep, Estonia, on February 17, 1792, into a rather wealthy aristocratic German-speaking family. At that time, Estonia was part of Russia, and Baer was a patriotic Russian.

The young nobleman studied medicine at Tartu, Estonia, and then Würzburg, Berlin, and Vienna, from 1810 to 1814. Only 3 years later he became director of the zoological museum at Königsberg, Germany. Baer's scientific genius went beyond anything wealth and privilege alone could supply, however.

He wrote a treatise in Latin on mammalian eggs and human origins in 1827; in fact, Baer had discovered a mammalian egg in the Graafian follicle, settling specific questions about human procreation. Baer also discovered the notochord in early vertebrate embryos.

The rest of his published works were in German. A preeminent man of science in Germany, Alexander von Humboldt, presented Baer with a medal from the French Academy. Much later, Albert Einstein wrote a short piece on Baer's law. Baer's law states that erosion is greater on the right bank of rivers in the northern hemisphere and greater on the left bank in the southern hemisphere, a law that perhaps occurred to him as he studied the fishes of the Caspian and Baltic seas.

Yet Karl Ernst von Baer "led two entirely different scientific lives, the first in Prussia, the second in Czarist Russia," as Jane Oppenheimer described his career.

In 1834 Baer became Professor of Zoology and Anatomy at St. Petersburg in the Russian Empire.

Not an evolutionist, he criticized the ideas of Charles Darwin. Baer favored instead his own notion of "developmental history" (*Entwicklungsgeschichte*). Baer discovered that the stages of embryonic development of higher animals resemble the stages of embryonic development of lower animals. Embryos of one species may be indistinguishable from the embryo of a much higher creature. This notion of developmental stages proved important for the rise of evolutionary theory.

He worked on his major project on the developmental history of the animal kingdom, *Üeber Entwicklungsgeschichte der Tiere,* from 1828 to 1837. Like Aristotle long before him, Baer studied chick embryos. And like Aristotle, Baer endorsed the notion of epigenesis (that the embryo becomes progressively more complex).

He also studied fishes and wrote in particular of his investigations into their developmental histories in a separate work in 1835. Baer showed that vertebrate organs derived from germ layers by differentiation, an important scientific discovery. He also demonstrated that embryos of higher animals share analogous features in embryonic development, the so-called biogenetic law. Embryos of higher animals develop through stages analogous to those of lower animals; that is, features specific to the specimen appear only after more general features have developed. Or, in the developmental history of the organism, general traits develop first.

Baer's fame spread beyond Prussia and the Russian Empire. He became a member of the French Academy of Scientists in 1858 and received the Copley medal from the Royal Society 9 years later.

Charles Darwin, in "An Historical Sketch of the Progress of Opinion on the Origin of the Species," wrote, "Von Baer, towards whom all zoologists feel so profound a respect, expressed about the year 1858 . . . his conviction, chiefly grounded on the laws of geographical distribution, that forms now perfectly distinct have descended from a single parent-form." In *Descent of Man,* Darwin referred to him as "the illustrious Von Baer" and commended Baer's observation that "the wings and feet of birds, no less than the hands and feet of man, all arise from the same fundamental form." Darwin gave his critic high praise, indeed: "Von Baer has defined advancement or progress in the organic scale better than anyone else, as resting on the amount of differentiation and specialization of the several parts of a being—when arrived at maturity, as I should be inclined to add" (*Festrede*, 1862).

Obviously, Baer's ideas contributed to evolutionary thought without his having accepted Darwin's theory.

Vladimir Vernadsky credited von Baer with developing the ideas of carbon and nitrogen cycles.

Late in life, Baer wrote his autobiography and published a series of speeches and short essays on widely varied subjects. He was a respected man of science until the end. Karl Ernst Ritter von Baer died November 16, 1876, in Dorpat, Estonia.

Baer on Time

Baer published a speech connecting the *perception of time* with the *rate of pulse* in mammals. His scientific paper "*Welche Auffassung der lebenden Natur ist die richtige? Und wie ist diese Auffassung auf die Entomologie anzuwenden?*" was delivered as the commemorative address to the opening of the Russian Entomological Society in October 1860. It raised the following questions: Which conception of living nature is the correct one? And how is this conception to be applied in entomology? To answer the first question, Baer found it necessary to discuss the ultimate grounds of nature: time and space.

Absolute Nonpersistence in Nature

Concerning time, the constant alteration found in nature is nothing less than a continual development, a continual evolution. Persistence of substance does not occur over time. What humans take to be persistent existence is due entirely to the human scale of time, which is far too short. If we compare this scale of time to the grand relations in nature, we discover that humans cannot take themselves to be the measure for space and time. For measurement of space, humans have taken their various body parts as standard units. Although such units may well suffice for the immediate environs, or even for the earth's surface, they shrink and disappear in contrast to the spaces of the universe and even then only to those expanses visible to the human eye. When astronomers contemplate vast astronomical distances, they use units of measurement that are more comprehensible; the distance from the earth to the sun, for example. Yet this distance is some 92 million miles, a distance very hard to grasp. Baer noted that light travels so fast that it covers this distance in only 8 minutes. If we expand our scale to the distance light travels in a year, then the distances involved in measuring the cosmos go beyond human intuition and can be expressed only in scientific notation.

To measure time, humans have adopted regularly recurring physical natural phenomena to mark units of time, whether it be the day, month, or year.

Baer considered it indubitable that the standard brief unit of time, the second, was taken from the human pulse rate, as it remains fairly steady within the individual from second to second. This is a measure of time derived from our own biological processes, but we can do no other, observed Baer. Far shorter would be the time required to become aware of a sensory impression. Such measurement of time according to a sensation has been used by all peoples, said Baer. The German word *Augenblick,* which means "moment," is literally the "blink of an eye." Such examples can be adduced at length. And yet, because lively impressions are registered quickly and dull ones slowly, there can be no generally valid measure of the duration of a sensory impression, though Baer estimated it to be between 1/6 and 1/10 of a second. The speed of the faculty of perception is, for Baer, the true and natural unit of measurement for life. "In general, it appears that the pulse stands in a definite relationship with the rapidity of sensation and movement. The pulse of rabbits is twice as fast as that of man, and children only half as fast [as adult human beings]" (p. 258). But as rabbits perceive more quickly than do children, rabbits apparently experience much more in the same amount of time. Thus the speed of the faculty of perception sets the standard of "objective" time for a species.

In his address to the Russian Entomological Society, Baer wanted to make clear that "the inner life of a human being or animal can pass more quickly or more slowly, in the same amount of objective time, and that this inner life is the standard with which we measure time in the observation of nature" (p. 258). It is only because this fundamental standard is so small that we presume an animal that we observe in nature maintains a unified size and structure. In fact the animal has changed, if ever so slightly, due to breathing and blood circulation. It has undergone countless minute changes at the cellular level in its intestines, and so on. If we observed it not for an instant, but for a day or longer, we would notice some changes in the animal.

Baer's First Thought Experiment Concerning Time

To his audience in St. Petersburg, Baer posed a fascinating thought experiment. "If we imagine for a moment that the pace of life in man were to pass much faster or much slower, then we would soon discover that, for him, all the relations of nature would appear entirely differently" (p. 259). If we can take 80 years as an advanced age, then the life duration of such a man would be 29,200 days and as many nights. Now imagine that such a long life were condensed a thousandfold. After 29 days, he would already have reached invalidity. To ensure that none of his inner experience is lost, however, his pulse rate would have to be multiplied a thousandfold, so that he would still experience 6 to 10 sensory impressions per pulse beat. Baer observed first that such a man—Baer called him the "man of a month" (*Monaten-Mensch*)—would see many things that a normal man would not. He would see cannon balls streak by, which we would not be able to see because they change position too fast for us to perceive. A man of months would see the moon go through its cycle only once and so might well infer that it began as a crescent, grew larger and fuller, until it disappeared altogether. Such a man would, though, have no conception of seasons and would be flabbergasted to know that his environs would be covered with snow, that water would freeze in winter, for example. Similarly, due to our small time horizons, we find it difficult to imagine Earth during the Ice Age or to realize that the poles were once covered with rain forest or that our nation was once covered deep in a glacier for millennia.

Baer noted, secondly, the supposition of 29 days as a life span, and the compression of years a thousandfold, to be rather arbitrary. Indeed, the compression could have been much greater, as many life forms complete their life cycle in less than 29 days. Mushrooms, protozoa, and many insects complete their life cycles in but a few days.

Suppose, then, that we shorten human life. Instead of living 80 years, let us take a man who lives but 40 years, with an additional compression of a thousandfold; then man would live only 21 minutes. Nature would look very different to such a man, whom Baer called the "man of minutes" (*Minuten-Mensch*). He would form no concept of day and night (at least by direct experience) and would see the sun sink only slightly over his entire existence, and the stars and moon would not appear to change at all. Further, what would such a man know of changes in vegetation and the organic world generally? If he spent half his life watching a bud bloom in 20 minutes, he would still not know the full developmental course of the bud. Thus, for the man of minutes, flowers, grass, and trees would seem to be unalterable entities. Even the movements of animals would not be seen by him, because their limbs would be moving far too slow for his rapid eyesight to be seen. If he lived under the night sky, the man of minutes would conclude that the stars rise from the horizon for a short period. He would be justified in concluding—because he would not be able to see the full course of the stars repeatedly or even once—that the stars only go so far above the horizon and then set again, or that they cease motion or behave in ways that stars do not in fact behave. Or he might conclude that the stars do not move, but only Earth's horizon. He would never be able to verify which possibility is true after only 20 minutes of observation. The entire organic world would appear lifeless to the man of minutes. If he lived under the day sky, he would have no reason to believe that the sun sets completely and night occurs, or that the sun would ever appear again on a new day. All the sounds that we hear would be inaudible for the man of minutes; he, in turn, might hear sounds that we could not, assuming that his ears are configured the same as ours. Our ears hear sounds only between 14 and 48,000 vibrations per second. Faster or slower vibrations we cannot perceive at all. Indeed, Baer hypothesized, the man of minutes would only *hear,* and not *see,* light.

As if this astounding thought experiment were not enough, Baer posed a further experiment to his audience. Let us take a man, whose senses remain structurally human. Let us speed up his perceptions not only a thousandfold, but instead a millionfold. But let all the rest of nature remain as it exists. Baer inferred that such a man of milliseconds would perceive the vibrations of "aether," which he hypothesized was several hundred billion vibrations per second, and which he hypothesized we see as color and light, would actually become audible, given that his sensory apparatus had such capacities. Aside from the later rejection of aether as a scientific hypothesis, Baer's point seems rational: Anything vibrating in the range of hundreds of billions per second would become audible to the man of milliseconds. Likewise, perhaps some ranges of vibration are perceived by human beings as sound, which the man of milliseconds would perceive as color and light. Based on recent experiments, Baer suggested that radiant heat consists of vibrations. Though he lived before the discovery of X-rays and radio waves, Baer went on to suggest that there might be many phenomena around us that we perceive as nothing at all. He considered the notion not at all counterintuitive, and modern science is replete with examples that validate his idea. Baer's ideas reached a sort of blend of science and poetry when he suggested that the planets might make a harmony of the spheres "for ears other than our own." But in case his audience thought him flip about his line of inference, Baer said he very sincerely wanted to "prove that, had our innate sense of time been otherwise, nature would present itself to us differently, not merely shorter or longer in her processes and narrower or wider in her effects, but rather as something entirely different" (p. 264).

Baer's Second Thought Experiment Concerning Time

Having completed his first thought experiment, Baer posed a second thought experiment to what must have been an audience in rapt attention.

> We have, previous to this point, shortened the human life in relation to the external world. . . . Let us now, conversely, lengthen it. Imagine, then, that our pulse were to go 1/1000th as slow as it actually goes. And we allow the time required for sensation to be a thousandfold increased over what we require now. If we assumed the same amount of experience, then the life time of such a person would reach a "ripe old age" at approximately 80,000 years. With such an altered standard, which we take from our own life processes, the entire picture would look otherwise. A year would seem like 8.75 hours. We would lose our ability to watch ice melt, to feel earthquakes, to watch trees sprout leaves, slowly bear fruit and then shed leaves. (*Festrede*)

Such a man would truly be able to *see* change in the enormity of a mountain range being born. We would no longer notice the lifetimes of mushrooms or lesser animals such as insects. We would be able to see flowers only once already bloomed, and then only to disappear. Only the great trees would attain our notice and gain some meaning for us in their slower aging, Baer conjectured. The sun would probably appear to leave a tail in its wake, similar to the tail of a comet or the tracer from a cannonball.

As if this thought experiment were not enough, Baer finally asked his audience to imagine this 80-millennial human lifespan multiplied a thousandfold. That is, imagine a man living 80 million years in Earth time, but who would have only

189 perceptions in an entire Earth year. So every perception would require almost 48 hours to complete. Only 31.5 pulse beats would occur in the body in an entire Earth year. "If we increase the magnitude of the man's life, which has already been slowed a thousandfold, by another thousandfold, he would experience external nature completely differently again." Such an 80-million-year man would not perceive the sun as a discreet circle but would see it as a glowing solar ecliptic, somewhat less bright in winter. The change of seasons would be a whirlwind: For only 10 pulse beats of the year, Earth would be snow and ice; for 1.5 pulses the melting snow would drench the land in spring; and for another 10 pulses, Earth would turn green.

Conclusions From the Experiments

With this observation Baer ended his second thought experiment concerning time. He was at pains to point out to his audience that these experiments in thought had not presupposed any new senses for man in order to experience different relations of time in nature. He observed that other animals have perceptions not accessible to man. So an alteration in man's senses would give humankind an entirely different picture of the world.

> We have taken man quite simply as he is [said Baer] and only asked how the entirety of nature would appear to him, if he carried inside himself a different standard of time.—It is indubitable that man can measure nature, both space and time, only according to himself, because an absolute standard does not exist. Earth's surface seems very large to him, because he can see across only a very small portion of it. But the same is only very small in relation to the Sun or to the universe. If man had the size of only a microscopic monad, even if he were to retain the entire sharpness of his intellect, a pond would appear as immense as an ocean.—It cannot be otherwise with his standard of time, by which we measure the effectiveness of nature, because we can measure only extension by standards of space. In fact, we have seen that the narrower we take man's innate measure of time to be, the more rigid and lifeless the entirety of nature appears to be, until finally, due to the brevity of life, the passage from day to night would not be observable whatsoever. (p. 267)

Baer's thought experiments concerning time have proven his grand metaphysical claim at the beginning of his address to the Russian Entomological Society. Because the physical forces that are inherent in water, heat, and light wear away everything in nature, the audience may no longer doubt that all apparent persistence is only transitory.

With a resonance of the metaphysics of Heraclitus, Baer grandly concluded that " all *persistence* is only an *appearance. Becoming,* in the form of development, is the *true* and *persisting* thing, through which all individual things are created in passing" (pp. 268–269). Baer's ideas went well beyond entomology into physics and beyond physics to infer what is ultimately real. "Matter in itself (*Stoff an sich*) and force in itself (*Kraft an sich*) exist only in the mental faculties. They are mere abstractions of our understanding. In reality no matter exists without properties (powers), just as we know no force which does not work from matter. Both are transitory, however, and the laws of nature are the remaining necessities by which they alter each other" (p. 269).

Thus we find in Baer's vision a world of relational forces and a set of natural laws by which the forces work. The organism measures time according to endogenous processes, primarily pulse rate, and for each organism, time begins and ends with the stages of its own developmental history.

Bakhtin, Mikhail Mikhailovich (1895–1975)

Mikhail Mikhailovich Bakhtin was a Russian literary and language theorist as well as a cultural philosopher. Though his ideas and concepts were diverse and complex, the search for the unity within differences and various interrelations ruled his work. Bakhtin was interested in time and space throughout his life and had developed his literary concept by the 1920s. Two decades later he clearly enunciated his considerations about the *chronotope* and adapted Einstein's physical category of time–space for the aesthetics. He favored relativity theory for the purpose of relational meanings but refused relativism. In his later works Bakhtin introduced the concept of *carnival,* a feast with the unique sense of time and space.

Bakhtin was born in Orel, south of Moscow, on November 17, 1895. Beginning in 1919 he published several works on the history and theory of literature, language, psychology, and culture, occasionally under the names of friends. He studied philology in Odessa and St. Petersburg. Owing to his religious activities during the political rule of Stalin, he was sentenced in 1929 to exile in Kazakhstan. Together with problems with the Soviet government and the suppression or loss of several publications, Bakhtin also suffered from a bone disease, which caused him pain and eventually resulted in the amputation of his right leg. Bakhtin spent his last years in Moscow, where he died on March 7, 1975. In his early years Bakhtin convened the so-called Bakhtin circle, a group of intellectuals who were interested in diverse subjects such as German literature and philosophy, religion, and politics. Bakhtin's reading of the German classic philosophers, including Kant and Hegel, and the advances made by contemporary physicists such as Einstein and Planck influenced his wide range of ethical, aesthetic, and epistemological issues.

His concerns with ethical problems led him from the act to rhetoric and communication. In the early composed and posthumously published *Toward a Philosophy of the Act* (1986) he rejects the theoretical concepts of traditional formalism and substitutes for them his phenomenological or descriptive concept of dialogue. By recognizing the similarities between the act and the word, he exchanges the abstract system of language of the traditional disciplines for the metalinguistic concept of communication, in which the utterance, the context, and its interrelations are essential elements. To describe dialogic interrelations Bakhtin introduces the concepts of *carnival, heteroglossia,* and *polyphony.* In his first and influential paper "Problems of Dostoevsky's Work" (1929), Bakhtin uncovers the polyphonic novel as a new kind of novel. In a creative and active process the author enters dialogic relations with its characters and the recipient as well. When his seminal paper was translated into English, Bakhtin added a chapter on his concept of carnival and redefined the book in *Problems of Dostoevsky's Poetics* (1963). In *Rabelais and His World* (1965) Bakhtin deepens his idea of carnival and introduces the concept of the grotesque. During the feast of carnival, people live in a concrete imaginary or utopia, whose foundation is laughter, by turning the world upside down. The collection *The Dialogic Imagination: Four Essays* (1975) includes one of Bakhtin's most important analyses of the novel, as well as treatises on heteroglossia, dialogism, and the chronotope.

Barth, Karl (1886–1955)

Karl Barth was a Swiss Reformed theologian whose paradigm-shifting critique of theological liberalism made him perhaps the most influential theologian of the 20th century. In the course of his critique Barth introduced a novel conception of time that made a valuable contribution to discussions of the relationship between time and the God of Christian faith. Though Barth's ideas about time evolved throughout his career, this entry concentrates on his mature thought as spelled out most explicitly in *Church Dogmatics* II.1 and III.2.

To understand Barth's position on any topic one must remember three convictions that undergirded his work: (1) All attempts to discern truth must begin with God; (2) knowledge of God is properly derived only from God's self-revelation; and (3) God has revealed himself most definitively in Jesus Christ. These convictions are operative in how Barth did and did not talk about time. For instance, Barth did not begin with an analysis of the scientific community's latest insights about the origin of the universe or the human race. Though Barth was neither ignorant of, nor inimical to, such theories as evolution, he regarded them of no use to theology because they begin with human observation, not divine revelation. This should not be taken, however, as a naive rejection of science on Barth's part. Rather, Barth refused to pit science against theology out of his conviction that these fields of inquiry had such disparate objects that any comparison would be futile.

Because Barth refused to discuss the nature of time independent of God, his discussion of divine eternity served as a convenient entry point. Though Barth affirmed the classical Christian conviction that God is eternal, he warned against trying to define eternity by beginning from purely human terms, whether positive or negative. He was particularly averse to formulations that equate eternity with timelessness, tie eternity to the world's process of becoming, or infinitely extend time forward and backward. Instead, he rooted divine eternity in, and compared it to, God's Trinitarian nature. According to Barth, as the three persons of the Godhead (Father, Son, and Holy Spirit) constitute one being manifest in three modes that are held together by a perpetual interrelationship of love, so divine eternality is the mutual interrelationship of three distinct but not separate temporal forms (past, present, and future) that comprise one undivided duration.

Thus, in his limitless eternity, God also experiences temporality, but in a categorically distinct way that is beyond human comprehension. To the extent that humans experience time as lack of unity, constancy, and simplicity, God can have nothing to do with it. Yet God's unique temporality serves as the basis of his free choice to enter limited human time on behalf of humanity. Through Jesus, God has taken temporal time into his own eternal being and brought about its healing and renewal. By becoming contemporary with humans, Jesus opened the possibility that humans may enjoy fellowship with him and share in the new time inaugurated when he reconciled the world to himself. Barth's view of time—like his view of most topics—ultimately points to God's free decision to save humanity through Christ.

Baxter, Stephen (1957–)

Stephen Baxter, a British engineer and science fiction writer, collaborated with Sir Arthur C. Clarke on two novels in the series *A Time Odyssey*, which explores the nature of time. In the first novel, *Time's Eye*, powerful alien beings (the Firstborn) are experimenting with humans by taking different time slices from human history and creating a patchwork in which these various slices are loosely woven together. Cosmonauts and UN peacekeepers from the year 2037 are brought into contact with a British army unit from 1885 that includes Rudyard Kipling and later encounters Alexander the Great's army, which must confront Genghis Khan's horde. When the displacement first occurred, a temporal and a spatial shift occurred: The sun was at its zenith in 2037, and then it moves across the sky to a position of late afternoon; it was as if the process of time had altered its history. The various characters in the story are "castaways in time," in a new world they call Mir.

A Spacetime Tapestry

One of the interesting conundrums that arises is that those from 2037 know of Rudyard Kipling, in this time slice a young man, and what he will go on to do. How much of his future should they tell him? And how much of what they tell him influences what he is to become? Or if (when) he dies in Mir, is there a Rudyard Kipling in England in 1900 who will still write his books? They also discover a discontinuity from horizon to horizon at one point where the time slices have been stitched together, which is explained by tectonic shifts over the thousands of years difference in the time slices. The rips in the "tapestry" of spacetime were sewn together piecemeal to create this new reality, so the Firstborn could observe (through great "eyes" in the sky) how these humans would behave in these disjointed circumstances. One of the time-displaced travelers, Bisea, is sent "home" to 2037 by the Firstborn because she asks them to do so (through the Eye).

This is where the second book, *Sunstorm*, picks up Bisea's story. She comes home to a gigantic disruption of all electrical and communication signals by geomagnetically induced currents prompted by an unusual sunspot. Research following this event revealed that a much more devastating occurrence would strike Earth, from the sun, in less than 5 years, a sunstorm that would destroy Earth. Scientists build a kind of shield in space to deflect as much of the sun's eruption as possible, and it is roughly 90% successful. Three superintelligent computers, Thales, Aristotle, and Athena, play a major role in saving Earth. What the humans discover, through Bisea's insight from her time in Mir, is that the Firstborn had caused the sunstorm deliberately, to stop the wasting of useful energy by humans on Earth. As this plan had failed, surely they would try again.

Parallel Corridors of History

An earlier book by Baxter, *The Time Ships*, delved even more deeply into time and time travel. Baxter's story purports to pick up where H. G. Wells's *The Time Machine* had left off. The Time Traveler goes on a new journey, but not as far forward in time as before (to 657,208 CE). He is captured by Morlocks, but these are very different from those he met before—civilized, very technologically advanced. One of them, Nebogipfel, takes an interest in him and concludes that the Time Traveler himself had caused a Divergence of Histories by relating to friends the details of his last journey. One of the friends, the Writer, had written it down, and it served as a warning. The population had avoided the conflict of that other history, had continued to grow, and had harnessed the power of the sun.

The Time Traveler learns of the work of Kurt Gödel in the 1930s, whose incompleteness proof showed that the quest for knowledge could never be completed; the Morlocks had taken on the task of accumulating knowledge, an infinite task. The Time Traveler, whose real intent was to go back to his own time to destroy his original time machine, convinced Nebogipfel to go with him on the pretense that it would be a quest for more knowledge. Nebogipfel explained to him another theory of Gödel's, of rotating universes that explained the existence of parallel corridors of history and the possibility of journeys forward or back in time and to other parallel histories. (This theory can, in fact, be found in Gödel's work.)

The Time Traveler visits himself as a slightly younger man (one of the paradoxes of time travel) to try to convince him not to build the Time Machine, a destroyer of worlds. His earlier self points out the logical difficulty of the Time Traveler being there to persuade him not to build the Time Machine as if the machine had never been built. A juggernaut from 1938 appears (another time anomaly) to protect the development of the science of the Time Machine and carry the Time Traveler and his earlier self forward to a London at war with the Germans. The Time Traveler and his earlier self meet and talk with theorist Kurt Gödel, who had deduced the existence of multiple histories. They have to flee a serious bombing attack in a new Time Car, and travel *back* in time roughly 50 million years. Their Time Car is wrecked in the landing, and they begin slowly reconstructing it. They are found by a British expedition from 1944 that has come back in time to find time-traveling Germans and keep them from altering history to suit their own evil purposes. When the British find the Germans, the Germans drop a bomb and the British must flee because of the dangers of the residual radiation. The British set up a colony safely removed from the bomb site and begin raising children.

The Next Stage of Evolution

Nebogipfel finishes rebuilding the Time Car, and then the Time Traveler and his earlier self travel forward into an unknown future. They find a colonized moon and a set of inhabited space stations, and then (by 1891) they find an Earth abandoned for travel farther out into space, leaving an Earth where the environmental equilibrium had been destroyed. They are about to die in this ice-world, but they are rescued by pyramid-like machines, the Universal Constructors, who have repaired the damage done to their bodies. These "machines," as Nebogipfel points out, are really "alive"—they reproduce and have memories, and they are conscious. They are the descendants of humans. They inhabit a Sea of Information, and they will not die out as a species, as humankind had. Day after day, Nebogipfel tapped into the information sea of the Constructors, and discovered that the Constructors intended to build huge Time Ships to go deep into the past. They want the Time Traveler to go with them, to the beginning of time. The project might take a million years, so Nebogipfel proposes that they go forward a million years in their Time Car to join the expedition. They do so, then begin (disembodied, absorbed into the information sea) the journey back through time. Near the end they travel through "cosmic shrapnel" and Nebogipfel tells the Time Traveler that space is folding on itself, that space and time are twisted until they are indistinguishable, a One. He and the Constructors (their consciousnesses) begin passing forward in the time of a new universe, one that was best ("optimal") for the Constructors. The Time Traveler is returned to his body and his original Time Machine and, along with Nebogipfel, to his home in England, where he gives the Plattnerite (the substance that powered the Time Machine) to his younger self. He then remounts the Time Machine and takes it forward to 802,701 CE, a day before the time when he had lost his beloved Weena on his first time voyage (back in one history, among the many); this time he manages to save her.

Thus Baxter mingles science fantasy with science truth and science speculation to expand the limits of our thought about time.

Becoming and Being

A quality that distinguishes philosophers and scientists from the rest of humanity is a willingness to confront and systematically explore issues and ideas that, for most people, seem so fundamental as to be unworthy of attention. Basic to philosophical thinking and discussion is the effort to define the very terms of reality, including *becoming* and *being* and their relationship to time. This becomes clear in an overview of Plato's idea of being and the thoughts of other major philosophers, including Aristotle, Gottfried Leibniz, Henri Bergson, and Alfred North Whitehead, and their divergence from being with their own ideas of becoming and how this connects with ideas of time. Plato held that the notion of *being* was what constituted absolute reality. Being holds that true reality is fixed in nature, unchanging regardless of time and space, whereas a changing reality is the false reality of perception. Opposed to being is the thought of *becoming,* where reality takes on a process or a change in order to create the reality we perceive, often termed *process philosophy*.

Plato

Reality is different for everyone, in the sense that to some degree we all perceive things differently.

Perceptions can also change for an individual from day to day: Either the perceived entity has taken on a different form, or the person perceiving the entity has changed in some way—in terms of experience, knowledge, values, and ideas. Plato (c. 427–c. 347 BCE) held a dualistic view of reality: the perceived world of dynamic, unfixed, and fluctuating perceptual reality, or *becoming;* and the unchanging, fixed, absolute reality, or *being*. Plato claims that because humans perceive their reality through the senses, the reality they know is skewed. This is because the senses are inaccurate, making the knowledge of this reality erroneous. By Plato's logic, true reality can be perceived only by the soul, or conceptual thought, and not the bodily functions that often alter a fixed reality. Plato refers to this fixed reality, which is perceived only by the soul, as the Idea or the Universal. The true reality of an object exists outside of the perceptions we gather from it through our senses. To Plato, the things that the senses perceive come out of a movement between the senses and the things perceived. Both are in a state of change, and where these changes meet, there is perception.

Becoming is subject to space and time. Our perceptions are rooted in time, as we see things change throughout time and perceive them differently throughout different periods within time. What we perceive are only particulars of an Idea; they can only represent an Idea, but are not the Idea itself. For example, when you see a horse you are seeing a perception of the Idea of a horse, and the "horseness" or Idea is separate from the particular horse that we have a sensory perception of. Being is not bound by time. It is fixed and unchanging for all eternity, thus making it absolute reality. According to Plato, this absolute and true reality is unchangeable and eternal. Time exists only as a moving representation of the eternal. Plato believes that when the heavens were created, so was this moving representation of them that we are able to perceive. Time has been around since the beginning, but it exists only in the perceptual world, as the eternal unchanging world is not subject to time. The past and the future are parts within the perceived time, that we understand the eternal to be within, but which it is not. The eternal simply "is" and never "was" or never will "be" as we understand our temporal space. The eternal is fixed and unchanging, not subject to the motion and change of time.

Process Philosophy

Major philosophers have since diverged from this Platonic way of thinking in terms of an absolutely fixed reality. The more commonly held view of today is that the world is a dynamic place and continually changing as things are becoming, not simply being. This becoming is also referred to as process philosophy. Process philosophy branches from metaphysical philosophies. Metaphysics is the study of reality and how we experience it in this world. Process philosophy offers a take on reality that claims that reality can be described in terms of processes and not things. It focuses upon the changes we perceive happening, rather than the unchanging or fixed. For a process philosopher, any type of change or process characterizes reality. Any type of change, whether it is physical, organic, or psychological, is made up of numerous phases. It flows from one thing to the next, rather then remaining stagnant or fixed within time.

Aristotle

Aristotle (384–322 BCE) was one of the first major thinkers to move away from the idea of being or fixed entities. Aristotle rejected Plato's dualistic approach to Ideas and particulars. He did not agree that our senses show us a world full of copies or representations of the real universal Ideas. Aristotle claimed that Ideas and particulars, or forms, relied on one another for existence. He held that the form we see is the reality of an object within the matter of that object. The form to Aristotle is the same as the Idea of an object is to Plato. It underlies what the object itself is and not the perception we have of the object. The difference is that Aristotle claimed the forms and matter of an object rely heavily on one another, whereas Plato believed they are separate from one another. For Aristotle, forms are able to change, but we can still acquire a reality from them. Although these changes take place, Aristotle taught that one part of an object's matter always remains the same. The part that remains the same is the matter of an object, and the part that we perceive as changing is the form of an object. Thus, change can take place, with an object still remaining what it is, as its matter is still unchanged. Aristotle held that when a change takes place, the original form of an object does not change the object; rather, a new form will instigate the change. This "new" form was always present; it just reacted on the matter to create what we perceive to be a change. Forms or matter cannot be destroyed. Matter can be changed only by many different qualities or forms, depending on what is present in its environment.

For Aristotle, these forms that we perceive are becoming or changing. Aristotle held that this change and time are linked, and time does not exist without change or motion. Aristotle related time to motion, or that which can be referred to as change, as in every instance of motion there is a change occurring. Time and change are perceived together, even if our physical senses do not perceive a change; a thought that enters the mind makes us think that a period of time has elapsed no matter how brief. Although time may measure changes, it is not change. It cannot be a change because it is everywhere and with everything. Time is a constant, and change can be faster or slower; thus they are not one and the same. Aristotle claimed that time is perceived in the present but, for the present to be there, there must have been a before and an after (even if we do not perceive these points in time). He claimed that some things that are not affected by time are not in time. These are the things that are eternal, such as heavenly bodies, which exist with time but are not a part of it. These eternal things are not affected by the before and after as the finite things are. The things that are in time are those that are changing or have motion and are finite.

Gottfried Wilhelm von Leibniz

Leibniz (1646–1716) believed that we are able to perceive the ever-evolving reality and that it is a true reality to us. He went further to claim that if perceivers can see no contradictions in the reality they perceive, then it is in fact conceivable and therefore real. To Leibniz, the concept that something that creates no contradictions is real opposes the Platonic thought that perceived things are not real. Leibniz claimed that by an object's uncontradictory nature, if that is what it has, we are able to understand it, thus making it real or conceivable to ourselves. He makes an important distinction that these things must have some basis in reality; for if they do not, then they become imaginary. This realm of possibility exists within what Leibniz terms a *region of Ideas*. This region of Ideas is what Leibniz related directly to God, claiming that it is God who makes things perceivable to us in our world. Humans, being rational, are able to perceive a divine representation of things, thus having knowledge of them.

Leibniz maintained that reality resides within centers of force, all of which are different from one another. Leibniz termed these centers of force *monads*. Monads are in everything and cannot be destroyed; therefore they are eternal. They are each individual and can come together to make up larger things. Changes within monads themselves happen irrespective of other monads, because they change internally. According to Leibniz, the monad becomes what it was always meant to be, that is, as God meant it to become. The changes that continually occur within a monad are simply allowing it to reach its full potential; that is, what it was always meant to become. Monads are present in different levels of a hierarchy, God being the highest monad. This hierarchy is determined by the degree to which something can perceive the truth. Monads reflect the universe, with differing degrees of clarity, depending on where they fall within the hierarchy. The higher the form is, the more Godlike it is, and the lower the form is, the more mirror-like it is. The lowest form of a monad has unconscious perceptions and no memory. A monad that is more highly developed will possess a memory and has conscious awareness and perceptions. A higher monad, or one that is God-like, will contain all the aspects of the lower monads as well as self-consciousness and reason.

For Leibniz, time is an illusion because it does not exist as a dimension itself outside of a particular monad. He does not think that time is only a series of moments strung together to create continuity. Leibniz's explanation of time derives from his theory of sufficient reason: Everything that occurs has a reason for its occurrence, that reason being that it is the way God intended it to change and become. As monads go through change internally, so too is time internal to a monad. As Leibniz divided his monads, he also divided time into three respective categories. The first category is atemporal, free from any limitations of time, or God. The second category is a continuous change within the monad or a realization of actuality, as God intended. The third category, is an external framework of sequential order, or the "now."

Henri Bergson

Bergson (1859–1941) termed reality as the *élan vital,* or a vital force, which is rooted in consciousness. He taught that there is change and evolution in everything at every time; nothing simply exists. Everything to Bergson was continually changing, including consciousness. We know our reality through consciousness and experience, not through scientific reasoning. Our consciousness constructs reality from past experiences and is continually moving and evolving forward. Experiences are never repeated, as they are unique to situations and time. Becoming is varied, and no experience is the exact same as another. To Bergson, becoming can be perceived as qualitative, evolutionary, and extensive. However, although it may appear to fit into one of these categories, each instance of becoming is the same regardless of how we perceive and categorize it. The real instance of becoming resides at the back of our knowledge centers and we only recreate it through our perceptions—we do not see its true essence. Bergson compared knowledge to cinematographic perceptions. That is to say, we perceive things in static "snapshots" and put them together like a moving picture to create a reality.

For Bergson, this cinematographic approach addresses time. The approach takes instances within time and makes them presentable in frames, which we can view singularly or as a stream coming together. This approach includes duration, through which a series of images is perceived by the observer and understood only by our imagination and not through our real knowledge. The imagination allows us to experience real duration or time, as time itself is immeasurable because it is constantly in motion. Bergson held that we do not perceive time as a fluid movement but rather as these glimpses of static occurrences. Perception allows us to view a progression through time rather than seeing time directly within our perceptions.

Alfred North Whitehead

Whitehead (1861–1947) placed the temporal world into *occasions of experience,* meaning that what we perceive are simply multitudes of instances grouped together to form our perceptions of them. These experiences can be placed into groups to create an interpretation of something. This line of thinking would in essence allow an occasion to be broken into a series of smaller experiences. Everything is broken into experiences, including our minds. Therefore, for Whitehead, there is no separation between the mind and the body. They are interconnected through process. These occasions of experience rely on experiences or processes that have happened before them, and they influence those that will come after them. This presents the idea that progress and duration and occurrences do not simply happen but rely on occurrences that have already taken place. These experiences are subject to free will, as each experience requires an understanding and then a reaction in order to create the next experience.

For Whitehead, the past experiences are not determined through our senses. Whitehead terms these past experiences *pastness,* and they are present behind all the experiences we have in the present. Our reaction to these experiences creates our future. For Whitehead, things are continually moving and evolving. Our current perceptions emerge from what has come before them; they emerge and become. Each occasion is forever evolving and changing in order to reach self-completion. Whitehead claimed that each of these occurrences is not determined, but each happens in relation to another occurrence that directs the occurrence toward a future. Occurrences are continually flowing into one another through a process. By this process, we perceive occurrences as the mind views them and turns them into perceptions for our physical selves to understand.

Whitehead held that we view occurrences as separate from one another, not occupying the same space within time. For Whitehead, however, this is a false view. Instead, he claimed that for us to understand occurrences, we must relate them to past occurrences. Whitehead maintained that things do not exist separately within space and time. Time, space, and occurrences are related to one another; none can exist on its own, for the process universe is becoming within time.

Bede the Venerable, Saint (c. 672–735)

Often called the father of English history, the Venerable Bede (Latin: Baeda), born in Northumbria, recorded the history of early medieval England, supported the reunification of the Celtic churches with the Roman Church, and popularized the term *anno Domini* (AD) in calendar dating. Bede's histories and chronicles became a model of historical writing and the standard reference works in Europe, especially during the Carolingian Renaissance, being copied multiple times and circulated throughout Europe. The Venerable Bede's literary works cover a variety of topics: biblical commentaries, hagiography, homilies and liturgical works, historical texts (*Ecclesiastical History of the English People, History of the Abbots of Wearmouth and Jarrow*), and scientific works (*On Nature, On Time, On the Computation of Time*).

In Bede's *Ecclesiastical History of the English People* (*EH*), completed in 731, Bede informs the readers that he was born in the territory of the monasteries of Saint Peter and Saint Paul at Wearmouth and Jarrow (founded in 674 and 680). At the age of 7, Bede's "kinsmen" entrusted him to the care of the abbots Biscop (also called Benedict) and Ceolfirth at these monasteries for his education. Bede lived a disciplined life within the monastic rule, receiving ordination as deacon at the age of 19 and priest at the age of 30. Although Bede did not travel far from Northumbria, he acquired an understanding of geography, providing place names and physical features; he recognized the various societal groups in England and Ireland and recorded the accounts of influential individuals. Bede's histories, chronicles, and letters reveal his awareness of the chronology of past events, as well as a grasp of current facts (e.g., the state of kingdoms and well-being of his community and neighbors).

Under the direction of Abbot Biscop, the sister monasteries at Wearmouth and Jarrow stood out as a center for the arts and scholarship, welcoming Continental artists, liturgical directors, and scholars. These two monasteries worked together, sharing resources and an extensive and impressive library. The Northumbrian monks and their library and archives provided Bede with an example of historical study, meticulous record keeping, and adequate sources.

Historians strongly emphasize the significance of Bede's *Ecclesiastical History of the English People.* This work provides the most accurate and detailed account of Christianity in Britain and Ireland from the late 200s to the mid-700s, recording biographies (e.g., Oswald, Columba, Aidan, Cuthbert) and crucial events. During the so-called Dark Ages, this history also explains the daily life of early medieval England and encouraged the spread of education, literacy, and a growing sense of national identity. Therefore, it appropriately became one of the earliest national histories and another important regional history of Christianity.

The Venerable Bede supported the moral benefit of history, saying, "Should history tell of good men and their good estate, the thoughtful listener is spurred on to imitate the good; should it record the evil ends of wicked men, no less effectually the devout and earnest listener or reader is kindled to eschew what is harmful and perverse, and himself with greater care pursue those things which he has learned to be good and pleasing in the sight of God" (Preface, *EH*). Although the *EH* possesses historical value, Bede primarily wrote to show the spread of Christianity in England, hoping to convert others to the Christian faith.

One hundred and fifty medieval copies of the *EH* survive (proving its immediate importance), and this work became the first English history book to be printed for the public (proving its long-term influence and historical significance). The Venerable Bede carefully chose his sources (e.g., documents, testimonies, correspondence) and explained his methodology of research and writing; the *EH* became a model for future historical accounts, particularly influencing the scholarship of the Carolingian Renaissance. In terms of church history, the *EH* resembled Eusebius of Caesarea's history of the church and also drew from the works of Jerome, Saint Augustine of Hippo, and Gregory the Great.

Works

Bede's works (e.g., *Ecclesiastical History, On Nature, On Time,* and *On the Computation of Time*) reflect his interest in and exploration of the world of natural science, astronomy, and ecclesiastical computation or calendrical calculations. Bede contributed to the medieval understanding of the calendar in two ways. First, the *EH* popularized the use of the Latin term *anno Domini* (or AD, meaning "in the year of our Lord"). The Scythian-born monk Dionysius Exiguus (c. 500–540) invented the AD system, which is an altered Alexandrian calendar consisting of a 19-year Paschal cycle. Dionysius Exiguus also dated the birth of Christ at 753 *ab urbe condita* (or AUC, meaning "from the foundation of the city [Rome]"). Although this calendar was believed to be the most accurate, it still possessed weaknesses (e.g., Christ was born during the reign of Herod the Great, around 750 AUC, instead of 753 AUC). Bede recognized Dionysius's errors but continued to use the system in all of his writings. The calendrical debate arose throughout Europe over the correct dating of Easter. From the *EH,* Bede explains that the Celtic churches followed an older calendar, which had long disappeared from Continental Christianity. Bede enthusiastically supported the Roman Church and encouraged the Celtic churches to adopt Roman practice (e.g., the dating of Easter). Historians usually recognize the submission of Celtic Christianity to the Roman Church at the Synod of Whitby in 664.

Second, Bede authored two world chronicles: *On Time* (or the *Lesser Chronicle,* 703) and *On the Computation of Time* (or the *Greater Chronicle,* 725). In these works, Bede examines the divisions of time, from the study of hours, days, weeks, and years to an explanation of the six ages of Christianity (as outlined in Saint Augustine's writings). The six ages are listed as (1) Adam to the Flood, (2) Noah to Abraham, (3) Abraham to David, (4) David to the captivity, (5) the captivity to the birth of Christ, and (6) the present age until the return of Christ. In the *Lesser Chronicle,* Bede does not place a specific amount of time on the sixth age and calculates that 3,952 years passed from the time of Adam's birth to Christ's birth. Accused of heresy for suggesting these new calculations, the venerable monk modified his chronologies and published his larger work, the *Greater Chronicle.* These two works followed Dionysius Exiguus's Alexandrian calendar, becoming the standard method of time keeping and recognizing seasonal changes and annual holidays in medieval Europe. Bede's experience with the orderly monastic life and observation of the environment in which he lived (e.g., ocean tides, agriculture) gave him plenty of reason to study the passing of time. This literary genre became a popular style of writing and influenced the production of similar manuscripts.

The Northumbrian community revered Bede as a scholar, teacher, priest, and fellow monk, calling him "Bede the Venerable." Tradition holds that the monks buried Bede at the monastery of St. Paul at Jarrow. To protect the grave from Viking invasions during the late 700s to early 800s, the monks moved his body to Durham Cathedral, where his grave remains today. Historians and scholars are indebted to the work of Bede; without his *Ecclesiastical History* little would be known of early medieval Britain and the spread of Christianity in England and Ireland. Most importantly, the Venerable Bede helped to clarify the ecclesiastical computus and popularized the use of the term *anno Domini* in calendar dating.

Beowulf

Beowulf is the name of an epic Anglo-Saxon poem written in Old English, named after the protagonist. It was composed probably around 1010 CE and is known from only a single manuscript, called the Nowell Codex after the name of its earliest (16th-century) known owner, Lawrence Nowell. It is a matter of debate whether the manuscript was the written version of an older oral tradition or the literary composition of the scribes, most likely monks, who put it into writing. What is known is that two scribes were responsible. The action of the poem takes place in what is now Denmark and southwestern Sweden in the late 5th century CE. Although the characters are all pagan, the Christian authors inject references to God and the Old Testament and occasionally comment about the unenlightened nature of the characters.

The poem begins by relating the funeral of the legendary founder of the Scylding (Danish) royal family, Scyld Scefing, whose great-grandson Hrothgar now rules. Hrothgar is a wise old king who successfully ruled his people for 30 years before his troubles began. When he was prosperous, Hrothgar built a great mead hall, called Heorot, where his thanes and warriors celebrate nightly. One night, a vicious ogre named Grendel, who lives in a nearby cave in a swamp, attacks the mead hall and slaughters a number of Hrothgar's men. It turns out that Grendel is a descendant of the biblical Cain, as are all monsters, and being an outcast, the ogre hates humankind for its joys and accomplishments. Hearing the celebrations in Heorot angers him, and he makes nightly raids upon it for 12 years. Beowulf, a young Geat (from Geatland in southwestern Sweden) warrior of surpassing size and strength, arrives at Hrothgar's kingdom with 14 handpicked companions to rid the land of Grendel. Beowulf's father had been sheltered from danger by Hrothgar years earlier, and Beowulf wishes to repay this debt, as well as earn riches and fame. That night, while the Scyldings sleep elsewhere, Beowulf and his men stay in Heorot to await the ogre's arrival. When Grendel comes, he kills and eats one of the men, then attacks Beowulf. The two fight furiously, almost destroying the building, until Beowulf tears Grendel's arm from its socket, mortally wounding him. Grendel retreats to his cave in the swamp to die, and Beowulf proudly presents the severed arm to Hrothgar, who hangs it from the roof of Heorot. Beowulf is richly rewarded and celebrated.

Later that night, Grendel's mother, an ogress of almost as much strength as her son, attacks Heorot and abducts one of the men in revenge. Beowulf sets out the next day with his men to kill her, and they find the severed head of her victim awaiting them. Beowulf is given a mighty sword by one of Hrothgar's thanes, Unferth, who previously had insulted Beowulf but now respects him. Beowulf dives into the swamp and confronts Grendel's mother. He is unable to kill her with his weapon; she gains the upper hand until the hero spots a miraculous great sword in her lair and uses it to kill her. A miraculous light illuminates the cave, which is full of treasure and also contains the body of Grendel. Beowulf uses the magical sword to cut off Grendel's head. The sword's blade then melts, and Beowulf takes his trophy and the remaining hilt back to Hrothgar. He is again rewarded and celebrated, and Hrothgar warns Beowulf of the dangers of pride and the vicissitudes of time. Beowulf returns to Geatland where his uncle, Hygelac, is king. Hygelac is later killed in battle, and when Beowulf is offered the throne, he declines it, opting instead to serve Hygelac's son Heardred, who is also killed in battle. Beowulf then becomes king and reigns well for 50 years. Disaster then strikes in the form of an outraged dragon that ravages the countryside in revenge for the theft, by a Geat fugitive, of a goblet from his treasure hoard. The hoard is 300 years old, the original property of a fallen tribe of warriors, and is cursed as well, making it of no use either to the dragon that guards it or to anyone else. The old Beowulf sets out in pursuit with a band of 11 loyal men. He challenges the dragon and they fight. Beowulf's weapons fail to harm the monster, and all but one of his men abandons him. The one true man, Wiglaf, stays to help and wounds the dragon enough so that Beowulf can kill it. Beowulf himself is mortally wounded and dies, leaving his kingdom to Wiglaf. He is buried underneath a great barrow together with the cursed treasure.

Like other epic poems such as the *Iliad* and the *Odyssey*, both composed more than a thousand years earlier, *Beowulf* continues to fascinate scholars and the reading public alike. Apart from the heroic action and adventure that the poem narrates, its timeless themes include the virtues of loyalty, reputation, generosity, and hospitality, as well as the dangers of envy and revenge. Although the character of Beowulf is larger than life, he is still a human being, a mortal man, subject to aging and the ill fortune that eventually befalls him. However, because of his great virtues—such as the loyalty to his lords that drove him to great deeds, his generosity to them and to those who served him, and his reputation as a great and noble fighter—he is remembered as the very model of a warrior king.

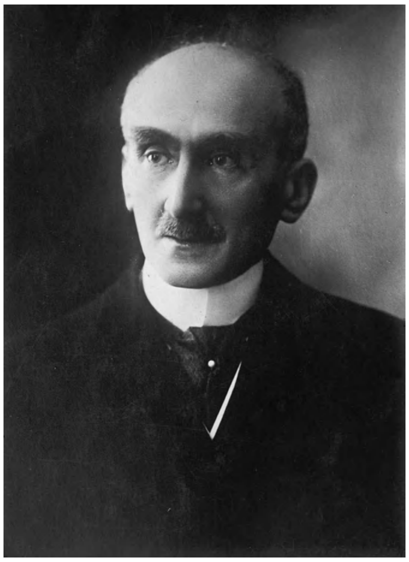
Bergson, Henri (1859–1941)

The philosopher Henri Bergson was born in Paris and studied at the École Normale Supérieure. Following graduation he taught philosophy at various *lycées* (secondary schools) in Provence, after which he taught at the Collège de France. He received his doctoral degree in philosophy in 1889 and was awarded the Nobel Prize for literature in 1928. His background in psychology is most easily recognizable in his early writings. Over his long career, he developed ever more into a metaphysician. Key among his ideas is the distinction between the mechanized clock time of scientific thinking and the way time is actually experienced.

The experiencing of time as a quantity, as a countable element of a time continuum, differs for Bergson at a basic level from the qualitative experiencing of a duration. The duration is something pure and is not expressed in quantities. It is equivalent to the immediate experience of totality. A melody or a symphony is to be experienced only as a whole. Its wholeness possesses an immediacy that cannot be broken up into its elements without losing its qualitative characteristics. Its temporal



According to French philosopher Henri Bergson, real time cannot be analyzed mathematically, and to measure time is to try to create a break or disruption in time.

Source: Library of Congress, Prints & Photographs Division, LC-DIG-ggbain-38388.

extension is *pure duration*. According to Bergson, the completely pure duration is the form that the succession of our perceptual processes assumes as our "I" yields itself to life, when it refuses to separate the present and past states. The tones of the melody fuse together, its different parts infusing each other simultaneously. Furthermore, if a melody is deconstructed into its components, then time, the medium in which one counts and differentiates, is nothing more than space.

The *pure duration* is fundamentally different from countable time. To Bergson, it was impossible to construct a synthesis of quantitative and qualitative elements. The experience of a duration is the experiencing of a quality that is immeasurable. Pure duration is an indistinguishable, qualitative manifold, which is in no way similar to numbers. It is a mistake on the part of the natural sciences not to carefully separate qualitative and quantitative characteristics. The uniformly flowing time of the natural sciences is a physical–astronomical construction. This time is seen as a line whose points represent successive moments. Admittedly, time may be mathematically expressed in such a way, but this is not really time itself. Real time is the immediately experienced time, and this is duration (*durée*). In the analysis of the experiencing of space, psychologists have stopped studying space in exchange for our perceptions, through which we achieve meaning or understanding of the concept of space. Perceptions have a qualitative character because they are not themselves extended, but their synthesis causes extension. Space is created out of mental activity, which, with one stroke, contains the different perceptions and also orders them next to each other. In this respect, space is that which allows us to differentiate multiple identical and simultaneous perceptions from one another. Humans are able to conceive of space without quality. Thus, two different realities exist for humans: the reality of sense qualities, which is heterogeneous, and the reality of space, which is homogeneous. The reality of space allows us to implement exact differentiations, to count and to abstract.

If the unlimited medium of space, which is completely without quality, is defined as homogeneous, then time, which is also defined as homogeneous, must be space, because there are no differentiating characteristics between different homogeneities. Nonetheless, people agree that time is to be seen as an unlimited medium, which is different from space and yet still homogeneous. The homogeneity thus exhibits a doubled guise according to whether it is seen to be a coexistent or a sequence. We steal time from duration by observing states of consciousness all at once and next to one another, projecting them into space. Time as a homogeneous medium is space. Duration is then to be thought of as the extension of an episode of time, taking the form of a constant line. As soon as duration is seen as homogeneous, one has imperceptibly allowed the concept of space. Bergson does not accept the true duration to be a quantity. It has a qualitative size, which has an intense character. It becomes possible to experience true duration when one becomes entirely entranced by something, for example, when hearing a melody or when one leaves the area of experience of space, for example, in a dream.

Through time measurements, duration is projected into space. Pure duration thus loses its qualitative character and is reduced to a quantitative size. Time measurements are not measurements of duration but rather the counting of simultaneities. A simultaneous process of the permeation of the occurrences of perception takes place inside of us through our memory, which is what actually creates true duration. Through an act of memory, we can compare equal positions of a periodic movement; in other words, an oscillation. Without memory we would have only one position of the pendulum or the sun, namely the present position, and thus no duration. Without periodic processes, we could not deconstruct duration into space and would have only pure duration.

Even if the measurement of time really is the projection of duration into space, it is not space that is considered here but rather duration, which is expressed with the help of space. Although time can be graphically represented using the fourth dimension of space, time is, as a phenomenon, still very different from space. In the analysis of the relationship between space and duration, Bergson comes to the conclusion that there is real space without duration, in which phenomena appear and disappear simultaneously with our states of consciousness. There is also the reality of duration, whose heterogeneous moments penetrate each other. In the outside world, there is a moment corresponding to every state; each and every moment and state must appear simultaneously, and each moment can be isolated from the others through this correspondence. A symbolic conception of duration based on space has emerged out of the comparison of both realities. This conception assumes the form of a homogeneous medium. That which connects space and duration is simultaneity, which one could define as the point of intersection between time and space. According to Bergson, the natural sciences have concerned themselves only with the symbolic conception of reality.

There would not be two kinds of recognition—one philosophical, the other scientific—if the experience would not allow us on the one hand to sequence and measure this experience in the form of facts externally ordered next to each other, and yet on the other hand would present itself in the form of mutual permeation, which is pure duration, remaining inaccessible to both law and measurement. In both cases, experience means consciousness. But in the first case, the consciousness unfolds in the direction of the external by perceiving external things. In the other case, this consciousness retreats by realizing and understanding itself. Bergson has drawn a line between the external and internal of the consciousness. The external of the consciousness is the immediately given world, which is measurable through physical processes. The internal of the consciousness is the present of the complete collection of experiences; this present completely dedicates its attention to one fact of the world and therewith pure duration, constituting a closed act. The experience is a part of the internal consciousness.

Duration and Motion

When analyzing the concept of motion as the living symbol of a seemingly homogeneous duration, Bergson ascribes to the consciousness the fusing of quantitative elements with qualitative ones, which seems to be withheld from the consciousness when analyzing duration. The motion that is observed as a transition from one point to the next is a mental synthesis, a psychological process and therefore unextended. In space there are only points in space, and regardless at which point the object in motion finds itself, an object has only one position in space. If the consciousness perceives something other than points in space, this is, according to Bergson, due to the consciousness remembering the successive positions and building a synthesis out of these. But how does it actually create such a synthesis? Obviously not through the deploying of the same positions in a homogeneous medium; this would require a new synthesis to bring the positions into connection with each other and so on into eternity. There is a qualitative synthesis at work here, a step-by-step organization of our successive perceptions among each other, a unit within the analogy of a melodic phrase.

Bergson differentiates between the extensive conception of the traversed space and the intensive perception of motion. This is the differentiation between the successive positions of a movement and its synthesis, the act of traversing. Naturally, a movement deconstructed in terms of its position in space has nothing more in common with the intensive perception of movement. A movement is not the sum of the points of its path. This insight led Bergson to the solving of Zeno of Elea's paradox. Zeno wanted, through his famous thought experiment about the race of Achilles with the turtle, to give precedence to the being of things when juxtaposed with changes in the world. The turtle asked Achilles for a head start, as Achilles was the faster runner. The only problem was that after the race had started, Achilles first had to run to the turtle's starting point; however, the turtle had already moved on by this time. Each time Achilles reached the turtle's last starting point, he had to race to the next point on which the turtle at that exact moment was located. But the turtle had already moved on. This process would allow itself to be extended into eternity without Achilles ever being able to catch up to and pass the turtle. Achilles' every step is a simple, indivisible act. Zeno's mistake was, however, that he identified this progression of indivisible acts with the homogeneous space underlying them. Achilles passed the turtle because one of Achilles' steps and one turtle step are each indivisible acts of varying lengths. Zeno does not see that space allows only a random, arbitrary process of de- and re-composition and in this way mingles space and motion. Science concerns itself, according to Bergson's point of view, not with motion and time per se but rather solely with their respective projections into space. Science deals with time and motion only after the previous elimination of its basic and qualitative element, namely, duration, in terms of time, and mobility, in terms of motion. For this reason Bergson's *duration* may be seen not as the attempt to mediate between scientific and phenomenological views of the world but rather as a separation stemming from the consideration that the experienced reality is more than can be displayed in the natural sciences, which means that scientific recognitions rest upon a reduction of reality.

James and Bergson

Comparing the concepts of time used by Bergson and the American psychologist William James is instructive, since the method used by both thinkers is based on psychology, and their concepts thus resemble each other. Bergson broke with the scientific view of the world by radically rejecting the concept of space and time presiding within the natural sciences. James, on the other hand, evaded the totality of our experience when he tried to measure the length of the *specious present* in order to determine which time spans we are able to understand or measure at one time.

The difference between James and Bergson lies in their differing evaluation of the past and its relationship to the present. Both reject the concept of a dimensionless, punctiform present, which advances like a mathematical point along a geometric line into the future. They came to this conclusion through introspection into the immediately given, the flowing of the thoughts. In addition, Bergson's distrust of graphical symbols played a role, as he believed they destroy the true nature of time through their static character. Bergson insisted that time cannot be represented in the form of a straight line as the fourth dimension of space. A straight line is a timeless object implying that its parts are simultaneously present. Only after we have radically freed our conceptualizations from our visual customs and geometric symbols are we able to understand the nature of time. Bergson avoided every kind of visual metaphor for the description of the structure of duration. When we have finally left behind us the symbolic representation of time as a straight line, we will no longer represent its parts geometrically as points. The moments of time are not punctiform moments; time is not endlessly divisible. Bergson's analysis of pure duration has a deeper meaning than a merely psychological one. He wanted to examine the nature of time in general, not time as only the "stream of thoughts." In the *Principles of Psychology* James argued for the conception that the qualitative and heterogeneous "stream of thoughts" covers and hides the underlying Newtonian homogeneous time, the original container of all changes, including those taking place in the brain. Due to James's having limited his analysis of time exclusively to the area of psychology and having en bloc accepted classical physics, he had difficulties in recognizing the true character of duration. Bergson stood, despite his anti-intellectual attitude, within the Cartesian tradition, whereas James argued out of the tradition of the British empiricists. James limited himself to the empirical, immediately given psychological data. Bergson tried to rationalize the given structure of the immediately given and to see the logical connections between the varying aspects. He found that the most disastrous and troublesome effect in understanding time is caused by the visual and geometric symbolizing of the temporal reality. This helped him to reject, in general, the concept of homogeneity and the mathematical concept of continuity.

James and Bergson were both temporalists, but whereas James elevated the character of constant change, Bergson emphasized the lingering just as strongly as the flowing. Bergson saw both aspects as complementary; he elevated the conservation of the past. When we hear a symphony, its theme is present during the entire performance such that we may recognize it over and over again. Within the melody the tones fuse together into the whole. Bergson assigned the past a special status while believing that James could not entirely free himself from visual conceptions. He observed the present as a duration with a certain length. Therewith he imagined time to be tiny pieces of time occurring one after the next. Accordingly, time would be a process constantly separating itself, which is not, as in Bergson's conception, a reality that is gradually becoming richer and growing together in the progression of duration. That life continues means that it exists in a continual flowing within which nothing is lost, but rather in which everything continues to grow, like a rolling snowball, so that everything to come is, in part, determined and infused from that which has already been. Whereas James's model has a purely linear character, Bergson's conception of time is characterized by an increasing complexity, which contains all past states and is gradually growing.

Berkeley, George (1685–1753)

George Berkeley was one of the great thinkers of the post-Descartes period of European modern philosophy. An important critic of the philosophers René Descartes and John Locke, he developed and defended a form of philosophical *idealism,* the view that only minds and their ideas are real. He had significant influence on David Hume and Immanuel Kant, and his work is still taught regularly in contemporary modern philosophy courses.

George Berkeley was born near Kilkenny, Ireland. At age 15, after some years studying at Kilkenny College, he entered Trinity College in Dublin. He became a fellow of Trinity College in 1707 and soon after was ordained in the Anglican Church. At Trinity College, Berkeley's philosophical idealism began to emerge in response to his study of figures like Descartes, Locke, Nicolas Malebranche, Isaac Newton, and Thomas Hobbes.

Berkeley's most important works were published while he was in his 20s: *An Essay Towards a New Theory of Vision* (1709); *Treatise Concerning the Principles of Human Knowledge* (1710); and *Three Dialogues Between Hylas and Philonous* (1713).

In his 30s he spent a 4-year tour in Europe as tutor to a young man. His resumption of his position at Trinity led to his appointment as Dean of Derry in 1724. At about this time he began to prepare to launch a college in Bermuda. In 1728, with his new bride, Anne Forster, he left for America (Newport, Rhode Island) to wait for British Parliament funds for this project. The money never materialized, and he was forced to return to Britain in 1731. In 1734 he was appointed Bishop of Cloyne, and thus he returned to Ireland. Here he wrote his last philosophical work, *Siris* (1744), which became a best-seller, on the medicinal and religious power of tar-water (a liquid prepared by letting pine tar stand in water). Berkeley died in 1753, shortly after moving to Oxford to supervise the education of one of his three surviving sons, George.

Berkeley's two great works of philosophy (the *Treatise* and *Dialogues*) are primarily a defense of idealism. A key part of this defense rests on a systematic attack on "materialism," namely, the view that material things exist. By material things Berkeley meant things that can exist independently *of minds*. Such independent existence had been held prominently by Descartes and Locke (who were dualists). Berkeley, argued that no mind-independent physical objects are possible. On the contrary, for Berkeley, to exist is to be perceived or to perceive—*esse est percipi (aut percipere)*.

Consistent with his idealism, Berkeley did not view time as existing independently of its being perceived by minds. Along with Gottfried Wilhelm von Leibniz, he denied Newton's idea of a fixed frame of reference for the motion of objects—namely, absolute time (and absolute space). For Berkeley, because to be is to be perceived, and absolute time itself cannot be perceived, absolute time is not real. Time for Berkeley is merely "the succession of ideas." To remove the train of ideas that minds experience is to remove any notion of time.

Bible and Time

A comparison of the Hebrew Bible (in Christianity, the Old Testament) and the Christian Bible, or New Testament, reveals differences in how the concept of time came to be understood in the Jewish and Christian traditions, respectively. The Christian viewpoint regarding time is linear; that is, the universe had a beginning and will have an end (in Greek, the *eschaton*), which will occur when Jesus Christ returns to Earth in the Second Coming to judge both the living and the dead. His arrival will be the fulfilling of a promise he made to his apostles and will be consummation of the world and time. The first mention of this concept was by Saint Augustine of Hippo in his seminal *City of God,* written during the 5th century. In 410 CE, the Visigoths sacked Rome, with many Roman citizens blaming Christianity. It was in this atmosphere that Augustine set out to provide a consolation of Christianity, writing that it was the City of God that would ultimately triumph—at the end of time. Such a view was vastly different from the view of the Hebrews.

Time in the Hebrew Bible

The Hebrew concept of time, as it had developed at that juncture in history, was concerned with the quality of time as it related to seasonal events like the rain in summer or an early autumn. In addition, the Hebrew calendar was based on the lunar cycle. The Hebrew day was one rotation of the earth on its axis; the month was one lunar cycle, or revolution of the moon around the earth; and the year was 12 lunar months, approximately the time required for the earth to travel around the sun. The Hebrew Bible divides the Jewish year according to each season of an agrarian society, such as when the women Naomi and Ruth traveled to Bethlehem to attend the barley harvest. Likewise, the concept of time centered on the hallowed events of God intervening in the Israelites' history. Time was related to an event that occurred in the natural world and how it was possibly linked to divine acts.

For the ancient Hebrews, time was concrete and real, not an abstraction. There is no evidence that they engaged in the sort of abstract philosophical speculation that is the hallmark of the ancient Greeks. Rather, the Hebrews would likely say, "The passage of time is a sequence of God's saving acts." That is, real events occurred, and humanity measured and marked life by its relationships to those events. Ancient Hebrew culture cared little for discussions regarding whether time was real or whether it was a human invention. In fact, nowhere in the Hebrew Bible is there a general word for "time" (at least, not in an abstract sense); it also has no special terms for past, present, or future. The most common or everyday expressions of time concerned the point at which some event occurred or will occur. The matter of precision in defining such moments, however, can seem vague or elusive. For example, First Kings 11:4 refers to the time "when Solomon was old," but at no point does the author refer to a specific period when Solomon began becoming old, or at what point he became old, as though he were not old the previous day and then suddenly he was old.

Ancient Hebrew culture seems to have lacked a concept of eternity, an idea developed in the West by the Greeks. For the Hebrews, a conception of whether someone could be alive without the passage of time would have been meaningless. For them, the existence of life was itself proof that time existed. There was no time where there were no life events and no life events where there was no time.

Modern society views time as chronological (60 seconds make up 1 minute, 60 minutes make up 1 hour, 24 hours make up 1 day, etc.), whereas the ancient Hebrews' sense of time was qualitative. Throughout the Old Testament, specific happenings and individuals were distinguished and then arranged in order, not by location in terms of chronological sequence but, rather, according to the impact of their occurrence. The Hebrews were awed by the importance or meaning of things and people, not by measured time. Scholars of Judaic culture have observed that for the Hebrews, events separated in time could be perceived as contemporaneous. For instance, a worshiper might experience a past act of salvation, such as the Exodus from Egypt, and experience it as if it were happening right then, even if the Exodus had occurred in the past.

For the Hebrews, the conception of time centered on one's exertions and accomplishments; likewise, they were interested in how individuals carried on in their daily lives—how they wrote, played, traveled, slept, dreamed, performed ceremonies, went to war, and prayed. God's actions were also present in time. The passage of time was a story concerning God's behavior; thus time did not exist outside of Yahweh. To spend time profitably probably meant living one's life so that others could mark their lives and tell their stories in reference to one's actions. In the Hebrew worldview, the important question was not "What should I do that makes *efficient* use of time?" but "How can I best make use of my life in this present moment?"

In the Torah, it is written that the righteous dead will be resurrected in the "messianic age" with the coming of the messiah. At that moment, each individual will be given immortality in a sin-free, perfect place. On the other hand, the wicked dead will not be resurrected at all; rather, they face complete oblivion. By contrast, in Christianity the wicked dead will face an eternity of torment in hell—not oblivion. This is not the only Judaic belief about the afterlife; some contemporary Jews believe in some version of hell. The Torah is not specific about the afterlife, nor are there any specifics about the timeline.

Time in Christianity

The New Testament states that the universe was created for humans—in science this is called the anthropic principle (meaning that everything is "just right" for life to exist). According to the Christian doctrine of *creatio ex nihilo,* the universe was created at a specific point in time. This idea has received support from secular philosophers arguing against the idea that the universe is eternal, as well as from scientific evidence indicating the reality of the "big bang." If the universe began to exist at a specific time during the past, is the Bible correct in stating that time had a beginning? In essence, if time existed apart from everything else, then the biblical use of time lacks real meaning. On the other hand, if the Bible is correct that the universe began with an act of creation, then time does not exist away from events occurring throughout the universe; thus the beginning also entailed a beginning of time.

Saint Augustine of Hippo felt that because time exists in our universe, then God must exist outside of time. God lives in an eternal present, with no past or future—hence time has no meaning to God. One need not be a believing Christian (or a believer in any deity) to accept this concept regarding eternity. Many atheists and agnostics feel that mathematics exists outside of time and is, in some sense, eternal. The Bible states unequivocally that God is eternal, meaning that he did not "begin" and will never experience an "end." How this is understood depends on which definition of eternity a Christian uses, as there are several. One might state that God exists in eternity, which is nothing less than a belief that all aspects of time (past, present, and future) have no meaning. God has existed in eternity at all times and should be expected to "live" there forever. Many individuals think that human beings can never grasp the ramifications of eternity, because it is either an infinity of what we already know (eternity is nothing more than the passage of time) or is something completely different from what we can imagine.

Related to the idea of eternal existence regarding God as Creator is the assumption that Yahweh is dependent upon no one or no thing; it was he who created everything else. If this premise is true, then the Bible's conception of his timelessness is essentially correct—God is independent of the universe, has always existed and always will, and would continue even if God obliterated all space and time.

Throughout the New Testament, the view concerning time in heaven is that it is beyond anything we can comprehend. For example, in the Book of Revelation, John saw scenes taking place on Earth in human history and scenes in heaven occurring at the same time. Time in heaven moves in the forward direction as it does on Earth. For example, Revelation 8:1 describes a period of silence in heaven lasting "about half an hour," although the meaning of time in heaven is different from what we know. For instance, one occurrence in eternity is found in the Gospels: One episode concerns Jesus standing on Mount Mizar, where he was transfigured before his disciples, Peter, James, and John. Appearing with him (c. 30 CE) were Moses (from c. 1400 BCE) and Elijah, who, according to tradition, was carried into heaven without seeing death (c. 850 BCE). All three appeared to be alive, as if they had known each other for many years, unmindful of the decades that separated them, at least in the manner that we judge time.

New Testament writers stated that time was calculated using two methods: *chronos* and *kairos* (times and seasons). These Greek words for times and seasons added immeasurably to scholars' comprehension concerning how time works throughout our universe. Chronos refers to the quantification of time and its length, how each second follows one after the other, and/or seeing time as being bounded. To grasp the significance of the word, one should read where it was used in the New Testament, including Matthew 2:7; Luke 4:5, 8:27, 20:9; Acts 20:18; Romans 16:25; and Mark 2:19. Kairos, on the other hand, refers to the value of time, how an era is known by its unique events, the crucial worth of happening, and a favorable moment. In the Bible, humanity is depicted as having a distinct beginning, a history that accurately recorded the Creator, and the drawing closer of a day of judgment when all people, regardless of wealth, prestige, or accomplishments, will be evaluated justly by God.

Time in the Work of Karl Barth

Karl Barth, the great German theologian killed by the Nazis in 1944, looked at time differently. In his opinion, the end of time (the coming of God's Kingdom) is not a future goal at the end of linear time or a process that takes place within time; rather, it is the eternal, existential test for each individual "in time." In other words, it is God's intervention in the world at any given moment. Barth did not think that having a horizontal understanding of time was efficacious, and thus he formulated an existential conception. In its more radical versions, this view conceives of time as an aspect of human self-consciousness: One's mode of existence is moored in the present, and this temporality of the present time is elemental to the human existence in the world. Hence, time is not an objective linear entity with a given past, present, and future. The past is definitively over and the future has yet to be, so only the present has being in any real sense. Theologically speaking, this means that God's word has neither a past nor future and is fully independent of humanity, though it greatly influences the present, in an existential and qualitative fashion.

With Christ's resurrection, humanity saw that God inhabited a dominion known only to God. Human understanding of the past, our place within it, and the influence of human corporeality is confirmed using this concept of time. Barth distinguished two temporal dimensions—human time and divine time. Human time is intertwined tightly with a grasp of what the past, present, and future are and is a fixture of God's creation. Humanity has a historico-corporeal reality only in the sense of how we view time; that is, the individual that gives up his or her time also gives of himself or herself. Any statement that may be said regarding one's life or death is subject to humanity's irrevocable temporal sequence. The human person is one with his or her life history.

In the New Testament, God took unto himself time, human time, and created time—all through Jesus. It was indeed real time with the triadic division into no-more, here-and-now, and not-yet. But in the risen Christ this division does not signify the transitoriness that belongs to human life inasmuch as in his Lordship over time he is present in terms of what he was (the past), of what was previously hoped for (the prophetic past perfect), and as he who will come again (the future). It could be said, then, that God has "time." This is not to say, however, that God's time is indistinguishable from ours; rather, God inhabits an eternal present that encompasses what is, what was, and what is to come.

Big Bang Theory

Today, it has become widely accepted that our universe originated with the so-called big bang. This event marks the beginning of time and the further evolution of our universe. In the standard model of cosmology, this origin arises in a spacetime singularity. The question what was "before" the big bang cannot be answered, because no physical description is available. More accurately, with reference to the singularity the concepts of time and space lose their meaning, as the scales involved (called Planck time and Planck length) are so incredibly small that spacetime can no longer be considered a continuum. Quantum gravitational effects come into play, and no consistent quantum gravitational theory has yet been developed. Physical description and understanding are therefore possible only after this period, which is called the Planck era. It is generally held that the big bang occurred about 15 billion years ago.

The idea of the big bang goes back to the Belgian mathematician Georges Édouard Lemaître (1894–1966). Many of its predictions are supported by astrophysical observations. The theory predicts that one fourth of all baryonic material should be made out of helium. Here, baryonic matter means mass consisting of "normal" nonexotic particles, like hydrogen, helium, and other nuclei, together with electrons. Observations of metal-poor objects in the universe indicate that this is indeed the case: Their chemical composition yields a helium amount of about 24%. By using this measured abundance of helium, it is possible to derive the different kinds of *neutrinos* (electrically neutral particles). It was theorized that three different kinds should exist, and this has since been confirmed by accelerator experiments.

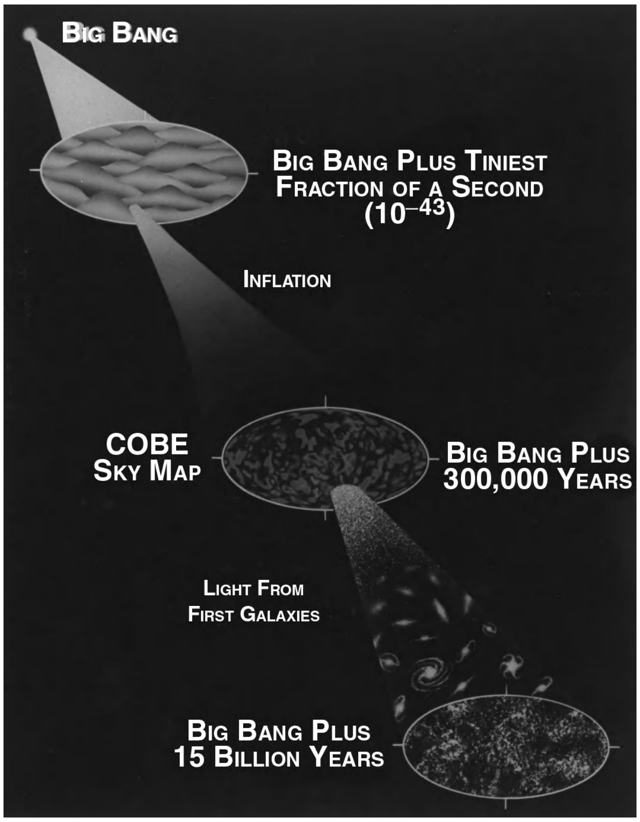
Another important hint was the detection of the cosmic microwave background (CMB) by Arno Penzias and Robert Wilson in the 1960s. The astrophysicist George Gamow predicted this thermal blackbody radiation in 1946. Actual measurements by the satellites COBE and WMAP confirm this exact blackbody spectrum. Due to the expansion of the universe the temperature of the CMB has decreased from 3000 Kelvin (i.e., 2726.85 degrees celsius) to a value of about 2.73 Kelvin (–270.42 degrees celsius). Yet one more important point refers to the structures in the universe we observe today. They originate from small fluctuations in the density. These fluctuations should be imprinted on the CMB as fluctuations in temperature, which have been detected by COBE and WMAP. Altogether, the theory of the big bang is very promising.

Briefly after its birth, our universe underwent several different epochs. It is assumed that in the beginning, all natural forces were united into one elementary force.

The expansion of the universe led to a decrease in temperature and therefore shortly to the decoupling of the forces into the four basic forces: the gravitational force, the strong force, the weak force, and the electromagnetic force. Following the Planck era, the first one that split from the rest was gravitation. The remaining forces comprise the so-called GUT force. (GUT stands for grand unified theory.) The continued decrease in temperature then led to the separation of the others, starting with the strong force (which acts between the protons and neutrons in atomic nuclei), followed by the electroweak force, which divides into the electromagnetic force (describing the behavior of magnetic and electric fields) and the weak force (which acts between electrons and light particles). This happens after a time span of about only 10^{-12}) seconds!

After the decoupling, the building blocks of the atoms, quarks, and electrons were mixed up together with the photons and other exotic particles within a hot soup. The ongoing expansion led to the gradual cooling of this soup and eventually to the condensation of the quarks into hadrons (protons and neutrons) with a slight excess over their antiparticles. The permanent decrease in temperature finally led to the building of atomic nuclei at T = 3,000 K. The primordial nucleosynthesis, as this event is called, describes the development of helium, deuterium, lithium, and beryllium. The other, heavier elements we measure today come from supernova explosions, which set free these elements from the interior of the stars, where they have been produced.

At a temperature of about T = 3,000 K, the first atoms formed. The universe cooled down enough so that was transparent for the photons, which means that interaction with other atoms was marginal. They decoupled and thereby resulted in the



Microwave Sky Map (©). This microwave sky map was made from 1 year of data taken by COBE (Cosmic Background Explorer) differential microwave radiometer (DMR) used in artist's concept depicting the crucial periods in the development of the universe after the big bang.

cosmic microwave radiation discussed earlier in this entry.

To summarize, the predictions of the big bang theory coincide well with subsequent observations. It has become an important foundation of the description of the universe.

Big Crunch Theory

The universe began with a turbulently charged explosion from a minuscule core, thrusting rapidly toward its outside limits; thus, the life cycle of the cosmos commenced. This cycle continues today. The three possibilities of this expanding universe are that the universe is "open," "flat," or "closed." An open universe means that the universe will continue to expand at an ever-increasing rate forever. If the universe is flat, then the expansion rate will slow down, but the universe will never collapse. Instead, all movement will end in an eternal frozen waste. If the universe is closed, then it will expand only until it reaches a certain point, at which the process will be reversed and the universe will shrink until it collapses.

In the universe, dark energy overwhelms everyday gravity and outweighs the visible universe by a factor of 10 to 1. If the big bang model of the universe is right, the universe is expanding, and if there is enough mass in the universe, at some point the expansion will halt and gravitational forces will cause the universe to collapse on itself. However, if there is insufficient matter, the universe will expand forever and will eventually cool off completely to die a slow death. This would be the end point of a closed universe. If, and only if, there is sufficient mass to halt the expansion, or Hubble flow, movement will be reversed. Instead of galaxies moving rapidly outward, they would move back toward the center. If the existing diffusion velocity of the universe, in units of kilometers per second per mega parsec, slows in relation to the apparent velocity of recession of a galaxy to its distance from the Milky Way, this would mean the universe is aging. If this end result occurs, the big crunch would create the conditions for a new big bang.

It had been postulated that the universe began about 15 billion years ago with a big bang, starting from an infinitesimally small point of "not anything at all" in the empty space of "nothing" in which matter and time did not exist. A very small point of matter appeared and then exploded and began expanding outward at an ever-increasing tempo. This was only the beginning, and it is still expanding today. As the universe expands, more and more matter is shaped into more complex forms. If the universe is a flat universe, then everything will stop and die in cold empty darkness. If it is a closed universe, then it will collapse in on itself.

The big crunch theory, as outlined by Alexander Friedmann (1888–1925), states that if the density of matter in the universe is sufficiently large, gravitational forces between the matter will eventually cause the universe to stop expanding; then it will start falling back in. It will eventually end in a second cataclysmic event such as the big bang. The big crunch theory is completely dependent upon whether or not matter is dense enough in the universe. If astronomers correctly calculated the quantity of matter in all visible stars and galaxies, this would be too little to stop expansion, let alone start contraction.

According to the theory, if there is enough matter in the universe, then the gravitational forces of all this matter will stop expanding and begin to collapse. Ultimately, this will lead to a new big bang after enough energy is trapped in an infinitesimally small point. This theory requires that enough dense matter exists in the universe. Unless a very large amount of dark matter is discovered, the big crunch will not happen.

It appears that the light from stars is in fact bending around what may be blackbodies. These might be the dark matter necessary for contraction. There may also be billions of loose stars between galaxies. There are billions of galaxies in galaxy clusters and billions of these clusters in strings of clusters, all in a tiny envelope in empty space. Each galaxy has not only visible matter but dark matter as well. The question is, in what quantity? Dark matter may also comprise most of the universe, but all we can detect is the light matter.

When the expansion of the universe ceases, many strange things will happen. Because of gravity, galaxies will begin crashing into one another. The red shifts of expansion, first noted by astronomer Edwin Hubble, will be replaced by blue shifts of contraction. The spaces between photons will be condensed. Wavelengths will also be shortened. The result will be an overall increase in temperatures of radiation fields.

Temperatures will average at least 300 Kelvin (K). Galaxies will increasingly crowd the night sky until there is no difference between night and day. Temperatures will continue to rise until the average temperatures will reach 1010 K, just seconds before the big crunch. All the matter in the universe will be concentrated into a point of singularity so tiny that a new big bang will soon follow.

The countdown is on for this phenomenon. If the big crunch theory is correct, the universe will come to a standstill in about 750 quadrillion (7.5×10^{17}) years. About the same amount of time will pass, maybe a little longer, before the final collapse.

Wild as it may seem, it is no more outrageous a theory than the other two major competing theories of the end of the universe. With all the combined matter of the universe, the expansion would tend to slow down considerably. If the drag on this expansion is sufficiently powerful, expansion will stop and all motion will cease. If there is enough mass, then the expansion will reverse itself and will collapse. Only if mass is insufficient will the cosmos continue getting bigger, exactly for an eternity, if not longer.

Birth Order

Birth order, also referred to as position in the family, is the timing of an individual's birth within the family structure. The effect of birth order on personality development has been the subject of increasing social science research from the late 20th century to the present. While factors such as gender, age span between siblings, cultural practice, parenting styles, and genetic makeup affect personality traits, statistical studies show that birth order also may play an influential role in the shaping of behavioral patterns lasting into adulthood.

One of the first to examine the dynamics of family structure was Austrian psychologist Alfred Adler (1870–1937), founder of the school of individual psychology. Adler believed that the relationship with siblings often foreshadowed later individual outcomes. His general hypothesis purported that oldest borns suffer from a degree of neuroticism stemming from the arrival of the second child, which diverts attention from the first. Later borns, he believed, are overindulged, and the middle borns are most likely to develop successfully. However, he produced no long-term scientific research to support this theory.

Common anecdotal wisdom has often emphasized stereotypical negative traits based on sibling order, describing the oldest as domineering, the middle as neglected, the youngest as spoiled, and only children as selfish. However, research based on long-range data contradicts these widely held but unsupported beliefs and demonstrates a complex cause-and-effect association. Comprehensive research has sought to discover a correlation between birth order and a wide array of social factors, including personality type, career choice, success in marriage, and receptiveness to new ideas.

Of particular interest to mid-20th-century investigators was the discovery of factors leading individuals to succeed in certain career fields, especially those requiring decision making under pressure. Such high-profile positions examined included U.S. presidents and astronauts participating in the early stages of the U.S. space program. Data reveal that 52% of American presidents have been first- or older borns and 21 of NASA's 23 first astronauts who flew into space were either the oldest or only children; all 7 of the original Mercury astronauts were also firstborns. Other studies show that prominent television newscasters and talk show hosts are often firstborns or only children. These data have led to conclusions linking older borns and only children with a high potential for achievement and leadership as well as possessing a desire for approval. Higher-than-average scores on verbal performance by only children and firstborns have also been attributed to a greater amount of time spent in the company of adults.

Research led by psychologist Frank Toman studied the impact of birth order on marriage, friendship, and gender roles, with emphasis on the variables of the sex of the siblings and birth spacing. Toman and his colleagues surveyed mid-20th-century European families to determine the success of marriages based on birth order of partners and the sex of their siblings. Their findings concluded that marriages were most likely to succeed between the older brother of a sister and the younger sister of a brother (or the reverse). These he called complementary sibling roles, which prepared the partners for a similar role in the marriage relationship. Persons who married a counterpart—such as the oldest in the family with same-sex siblings—were more likely to divorce, because the partners compete to play the same role rather than complement one another. Toman's theory is widely recognized in marriage and family counseling and has been used as one of a number of tools to measure compatibility.

Researcher Frank Sulloway's studies, based on contemporary and historical data, find a correlation between birth order and "openness to experience," even when factoring in other influences such as sex, social class, family size, race, and age. Later borns, he describes, are historically more likely to support causes that challenge the status quo, from the Protestant Reformation to the American abolitionist movement. He cites examples such as Mahatma Gandhi, Martin Luther King Jr., Fidel Castro, Ho Chi Minh, Susan B. Anthony, and Malcolm X as such later borns. On the other had, firstborns, he contends, are often more likely to defend traditional order.

If older borns and only children are apt to be high achievers, does it hold that those lower in the birth order are less successful? Sociologist Howard M. Bahr found this was not the case in his study of New York City adult men in rehabilitation centers. His study was comprised of adult males who were not taking responsibility for themselves or others and might be described as social "failures." He found that birth order did not appear to play a statistical role, except in the case of only children, who were overrepresented. Bahr speculated that high parental expectations, which often result in the success of children, may also account, in some cases, for a withdrawal from the unreasonable pressures often placed on an only child.

Birthrate Cycles and Family Structure

The timing of an individual's birth may shape personality, not only within the family structure but also in the broader historical context. Global social and economic conditions have a significant effect on birthrates and, therefore, family size. From 1800 to 1900, family size in the United States dropped from an average of 7 children to 3.5, reflecting the move from an agrarian to an industrialized society. During the worldwide Depression of the 1930s, the average American family produced 2.5 children, with a low of 2.3 in 1933, resulting in what some sociologists have described as the adult "silent generation" of the 1950s that largely supported traditional values and held conservative political and economic views.

The post–World War II surge in the U.S. birthrate peaked in 1957 with an average of 3.7 children per family. Improved contraception methods, introduced widely in the 1960s, coupled with social and environmental concerns, encouraged a smaller family size; in 1972 average family had 2 children. Current UN statistics show that Europe, Canada, Australia, and China show declining birthrates (less than replacement of 2 children per family). The United States and large parts of South America show a stable birthrate averaging 2 children per family, and the most rapidly growing population is occurring in countries of sub-Saharan Africa.

These birthrate cycles impact the family structure and therefore birth order patterns, with implications for society as a whole. These trends produce, in industrialized nations, smaller families with more only children and fewer middle children, possibly creating what some experts call a society of leaders and followers with fewer middle children as mediators.

Concluding Remarks

Research continues in the study of birth order and its effect on personality development and long-lasting behavioral patterns. Theorists in general have found a consistently high correlation between birth order and certain personality traits, together with gender, and other time-related factors such as spacing between siblings, and historical circumstance. Results generally describe firstborns as responsible, goal oriented, and supporters of the status quo; middle borns as flexible, competitive, and diplomatic; later borns as outgoing, creative, and tending to question authority; and only children as often exhibiting magnified traits of both the older and later borns. It would appear that the timing of an individual's birth is one of several factors to consider in personality analysis, and birth order may have a significant effect on the way in which individuals see themselves and how they respond to those around them. In turn, family size and the resulting characteristics attributed to birth order may have an impact on society as a whole.

Birthrates, Human

This entry discusses the human birthrate in the context of the historical past, contemporary, and future trends of human population. Human birthrate is at the heart of the challenges surrounding the population explosion worldwide and the divide that exists between industrial and developing nations. Birthrate is also a vital subject in light of the growing concern over environmental issues, security, and development. Meaningful discussion of the human birthrate naturally requires a consideration of time factors because historical, contemporary, and future trends of the birthrate are interpreted in terms of periods of human fertility. Furthermore, spacing, delay, and postponement of childbirth, as well as overall rates of birth, are of course measured through time.

Notions and Measures of Birthrate

Birthrate, the rate of fertility of the human population, can be determined in various ways. One way of understanding birthrate is by considering childbirths per 1,000 people per year. This is a crude estimate of birthrate. As of 2007, accordingly, the average birthrate worldwide was 20.3 per year per 1,000 total population, and thus, for the total world population of about 6.6 billion, the average birthrate was 134 million babies per year.

Another method of determining birthrate is referred to as total fertility rate, which is the average number of children a woman gives birth to during her entire life. This is a better indicator compared with the crude birthrate because it is not affected by the age distribution of the population. A total fertility rate is a measure of the fertility of an imaginary woman who passes the age-specific fertility rates of women in the childbearing-age range. Thus total fertility rate is neither the number of children counted nor the fertility of an actual group of women. It is rather the average number of children born to a woman on condition that she is subjected to all age-specific fertility rates for ages of 15 to 49 of a given population in a given year. A third method of measuring birthrate is called general fertility rate, and this method measures the number of births per 1,000 women with the age range of 15 to 49. Standard birthrate, on the other hand, compares the age–sex structure to a hypothetical standard population.

Historical Development and Trends

Birthrates and death rates were closely even and high until the 19th century. Thus population growth was slow. But with the advancement of medicine and of living standards generally, death rates started to decline, leading to a growth in population size. In addition, whenever the fertility level rises above the replacement level, it contributes to the growth of population size.

Leon Bouvier and Jane Bertrand note that the 20th century, particularly its first half, experienced an increase in birthrates. The growth rate continued in the 1960s with an average birthrate of six children in the developing nations of Africa, Asia, and Latin America. UN reports indicate that there were some declines in fertility up to the end the century. Accordingly, the birthrate fell to 3.3 children among the developing countries during the years 1990 to 1995. Nonetheless there are wide disparities in birthrates even among these countries. In this regard, the rate of fertility for sub-Saharan Africa is 5.9, whereas it is 1.9 in East Asia. The historical development and current trend both show a state of an overall decline of birthrate worldwide, even though there is a wide gap between the developed world and the developing nations.

A low level of fertility is marked at 2.5 births per woman or below. John Bongaarts and Rodolfo Bulatao remark that this level applies to most of the demographically advanced developing and industrial countries. Fifty percent of the world population lives in these countries, whereas 15% of the world population lives in countries where fertility is below 1.8 births per woman. These countries were able to achieve low fertility by getting away from higher-order births. The higher-order births are the third births, fourth births, and more. The trend appears to be a lowering in numbers of births as family styles change from larger to smaller ones. Thus, the high fertility of the developing world will continue to decline until it reaches 2 children per woman. It is a rare occurrence for a fertility rate to rise once it reaches the rate of 2 children per woman. Accordingly, based on the observed experiences of the past decades, low-fertility countries tend not to return to a fertility rate well above the 2 children per woman.

Bongaarts believes that the future trends for rates of birth can be further affected by the factors of technology and science that have relevance to childbirth. Improved methods of contraception, technologies in the areas of hormone therapy and sexual enhancement medications, techniques of sex selection of offspring, selective abortions, and genetic selection of the characteristics of the babies to be born are possible factors to influence the future trends of birthrates.

Factors of Birthrates

Bongaarts and Bulatao explain that birthrate is a function of many factors. Socioeconomic changes that compete with motherhood—such as delayed marriages, failing marriages, separation and divorce, postponement of births to later ages, increase in the size of the aging population, and changes in reproductive behaviors—are among the factors that contribute to low numbers of births. Public policies are also factors that affect birthrates. The trend toward fewer births among families in some developed nations can be reversed to a replacement level by government policies providing educational and career development support to women of childbearing age. Other factors that affect birthrates include abortion, age–sex structure, social and religious beliefs, literacy levels of females, overall economic prosperity, poverty level, infant mortality rate, and urbanization.

Socioeconomic conditions help explain fertility rates. Harsh economic conditions can delay marriage and childbirth. Similarly, high rates of unemployment and inflation can contribute to the low rate of fertility due to delayed marriages and childbirth. The conditions in which people think that they cannot afford the expenses of childrearing contribute to the tendency to postpone childbirth. The notion of the human child as economic strain adds to the possibility of low birthrates. The cost of education and other needs associated with childrearing will influence parents' decisions as to the number of children they will have. In the industrial countries, the desire for a low birthrate can be strengthened further by easy access to birth control and a low rate of child mortality.

The situation in some developing countries, however, appears to assume a different scenario. The high level of poverty and illiteracy, coupled with other social and religious factors, contribute to a high rate of birth. Due to the perceived possible economic incentive for having children both in the short term and in planning for one's old age, having more higher-order births is a natural way of coping with the reality of economic hardships. Under such circumstances, therefore, economic hardship contributes to an increased fertility rate, whereas among relatively more literate societies, economic hardship (such as unemployment and inflation) delays marriages as well as childbirth. Lower levels of education among women, lack of contraception, and the limited role of women outside the performance of household duties contribute to the high-order birthrates in the developing countries.

Events such as wars have a major impact on birthrates. According to Bongaarts and Bulatao, major conflicts like World Wars I and II have had a significant impact on fertility rates in the United States and other nations. The baby boom generation that followed the end of World War II illustrates the impact of war on fertility rates. Major socioeconomic and political changes also bring about changes in fertility rates. In this regard, the changes in Eastern Europe in the late 1980s affected birthrates in those societies, which are now considered to be low.

Institutional factors such as marriage play key roles in determining the state of birthrates in societies. The trend is a delay in marriage and an increasing rate of divorce. Postponement of marriage and failure of marriages in the forms of separation and divorce contribute to the low rate of birth in terms of both the tempo and quantity of childbirth. As part of the changes in the socioeconomic and political dynamics of societies, changes in gender roles have a bearing on birthrates. Over the last four decades, the changes in the roles of women have led to a tendency toward low order of birth. Due to an increased level of education and opportunities for woman, childbirth delays and in some cases childlessness have become societal phenomena. These developments are among the factors that contribute to the low rate of childbirth.

Replacement Level

Fertility at replacement level occurs when each generation of women exactly replaces its predecessor. This is a situation whereby each woman gives birth to just one daughter. Replacement level of birthrate is a fertility rate at which women give birth to not more children than are needed to replace the parents. Other factors being constant, replacement level of fertility maintains nil population growth. Replacement levels vary across nations. While the replacement level in developing countries equals 2.4 births per woman, it is 2.1 for the industrial world. UN reports reveal that the level remains above replacement in developing regions, while it is below in some industrial nations. During the second half of the 1990s, the average birthrates were reported to be 5.1 in Africa, 3.4 in South Asia, and 2.7 in Latin America. On the other hand, the figures are below replacement level in the developed world: 1.4 in Europe, 1.9 in North America, and 1.8 in East Asia.

Challenges and Prospects: The Case of Ethiopia

Population growth due to high rate of birth has negative consequences given the low level of economic progress to support it in the case of developing nations. This is the situation in sub-Saharan countries such as Ethiopia. Ethiopia is becoming the second most populous country in Africa, with the addition of two million people every year. At the same time, economic and social developments are declining with minimal industrial and agricultural output. The country is thus highly dependent on foreign aid. Over half of the population is economically unproductive, either too young or too old to work, and consequently supported by few working members of the society. The Ethiopian Economic Association reports indicate that the country's main economic sector is agriculture, which is becoming less productive due to overcrowding, overuse of resources, lack of modern practices, erosion, deforestation, and heavy reliance on rainfall. As the result of such crises, shortage of food and drought are becoming common phenomena in Ethiopia. Unchecked population growth in Ethiopia affects the environmental balance as well. Assefa Hailemariam argues that the densely populated areas are overcultivated apart from deforestation, which leads to erosion and land degradation.

Countries like Ethiopia need to check their population growth so that they may achieve sustainable development. The strategies that can help counter population explosion include educating young women, in general, and educating the entire population about harmful cultural practices such as early marriage and early childbearing. The education of girls can contribute to active involvement of women in the economy, late marriage, delayed birth, and active decision making with regard to reproductive issues such as spacing and delay of births. The use of contraceptive methods is a typical example: Educated women are more likely to use them than those who are uneducated. The investment in the education sector is an important factor in achieving the goal of curbing rapid population growth by maintaining low-order birthrates.

According to Sahlu Haile, traditional practices of marriage, family life, and childbirth in developing countries contribute significantly to a high rate of birth. In Ethiopia, the average age of marriage is 17, and a significant percentage of those married at this age become mothers within a few years, contributing to the high birthrate in the country, which is 5.9. Thus, delaying marriage would contribute to the delay in childbirth. To combat harmful practices, Haile recommends educating the public through formal as well as informal venues. The role of the mass media and public policies is also vital; family planning, including counseling and the provision of contraceptive methods, is crucial. Such strategies delay marriages and childbirth while also contributing to the improvement of maternal and child health. International assistance is also helpful to complement local efforts and governments' commitments in developing nations.

Concluding Remarks

The future of our planet is greatly affected by human birthrates, which have direct bearing on population size. A state of controlled birthrate growth will contribute to the stability and maintenance of a sustainable environment that can support people's fundamental needs. Conversely, unchecked birthrates will contribute to the complications of challenges in the areas of environmental crises, famine, drought, massive immigration, conflict, insecurity, and political instability worldwide. Uncontrolled level of replacement, which in the industrial world may continue to be below replacement level, will lead to scarcity of labor in the industry and even in the military forces. Likewise, uncontrolled rates of birth above the replacement level among developing nations will add to the worsening of the scarcity of resources and depletion of the environment, adding to human suffering worldwide.

Black Holes

A black hole is a gravitationally dense astronomical object with such strength that no form of energy can escape its influence. A black hole creates a warp, or gravity well, on the space it occupies. From the point of approach, a black hole exhibits a visibly flat structure that contains the condensed matter pulled into the black hole: the *accretion disk*. The size of an accretion disk is dependent on how large the black hole is. Additionally, a black hole may exhibit plumes of gas, called *jets,* perpendicular to the accretion disk. Neither accretion disks nor gas jets are proof of a black hole, as other objects such as neutron stars and quasars have the same characteristics.

Typically, a black hole forms by the collapse of a massive object, such as a star. A star needs to be at least 20 solar masses, a neutron star, or a white dwarf to have enough influence to bend space. When a star nears the end of its fuel supply, it swells to a red giant. Once the star has burned its remaining gases, the shell of the star collapses in on itself and shrinks to a white dwarf. Given time, the pressure and mass may be so intense that the star will continue to degrade and collapse inward. The gravitational signature of the star becomes a singularity, and a black hole forms.

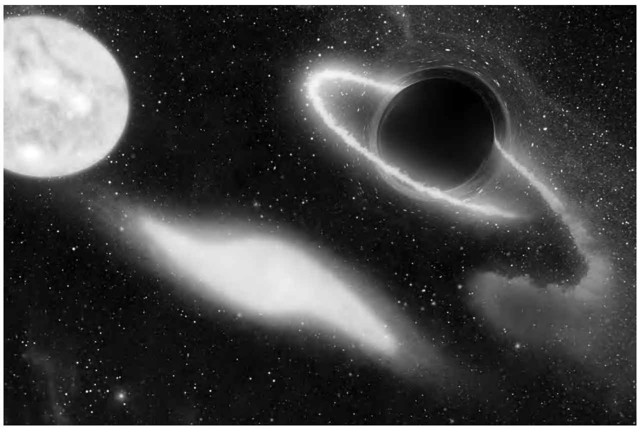
Cosmological Studies

Upon approach to the black hole, the effects of the gravitational well begin at the event horizon, or the boundary between normal space and the black hole itself. Here, the velocity needed to escape the influence of the black hole is equivalent to the speed of light. Studies of the event horizon are called *black hole thermodynamics*. In theory, time itself is affected at the event horizon; however, only theory can explain what happens once an object crosses. At the very center of the black hole lies the only physical part of a black hole, a singularity. The singularity is the point source of the gravitational anomaly; it is what remains of the former object that created the black hole.

The quantum physics leading up to a black hole are quite discernable, from Albert Einstein's theory of relativity to Stephen Hawking's theory of radiation emission. However, once the event horizon is breached, modern quantum physics no longer applies. As Einstein noted, the curvature of gravity around a collapsing star pulls other particles with it, and continues to do so even as acceleration reaches a constant state.

Types of Black Holes

There are four types of black holes, each derived from two components: charge and rotation. Electric charge influences the black hole near its singularity, while a massive spinning object, such as a pulsar, causes the rotation of a black hole. These types of black holes are listed in Table 1. In 1963, New Zealand mathematician Roy Kerr additionally suggested that these black holes may also be gateways to parallel universes. Kerr was the first mathematician to solve and apply Einstein's general relativity theory to a rotational star. Since then, additional theories suggest that the existence of an object opposite to a black hole must exist, as the matter pulled in must be pushed out. This is called a *white hole* and would then be connected to the black hole via a "wormhole." However, until many black holes are studied in closer detail, no concrete evidence exists to support the existence of white holes.



An artist's rendering of a super massive black hole at center of remote galaxy digesting the remnants of a star. The area around the black hole appears warped because the gravity of the black hole acts like a lens, twisting and distorting light.

Source: NASA Jet Propulsion Laboratory (NASA-JPL).

Table 1 Types of Black Holes

Type	*Rotation*	*Charge*
Schwarzchild	No	No
Reissner-Nordström	No	Yes
Kerr	Yes	No
Karr-Newmann	Yes	Yes

Several physicists have attempted to describe the many processes that lead up to the event horizon. Einstein's relativity theory states that as an observer approaches a black hole, the very warping of space itself will cause time to warp too and, in effect, slow down until it "freezes" at the event horizon. However, time at the vantage point of the observer's origin will remain constant, and if the observer never breaches the event horizon, the point of origin will have advanced into a much distant future.

Classic Paradox

If a probe were sent to investigate a black hole, clocks on board the probe would act as normal, even though the probe had begun to enter the region of the event horizon. If the probe were commanded to return, it would simply just turn around and eventually be away from the influence of the gravity well. After approximately 1 minute of clock time to the probe, the probe would be on its way again through the "normal" universe.

However, back at the International Space Station, the probe would appear to slow down and freeze as though no longer moving. The simple act of sending a reverse command would take very little time to transmit but would take much longer to execute as the probe experiences the warp. Although it never fully crossed the event horizon and managed to climb out of the black hole region, it will have taken thousands of years to do so. When the probe returns to "normal" space, it may be thousands of years later for Earth, but just mere moments for the probe. The two clocks would then be asynchronous.

Hawking determined that black holes emit radiation due to quantum effects and, as such, allow the black holes to lose mass. A loss of mass suggests that the black hole is capable of losing mass and therefore dissipating given time. Because time does not apply within the black hole, though, it is unknown how this effect would occur.

The First Findings

In 1971, Tom Bolton of the David Dunlap Observatory at the University of Toronto, Canada, noted a star in the constellation Cygnus whose binary companion was causing the main star (called HDE 226868) to exhibit anomalous behavior. Too massive to be a mere neutron star, this area, known as Cygnus X-1, became the first object named a black hole. Since then, many more stellar regions have been found exhibiting similar peculiarities. Even now, there is a controversy surrounding the definition of a black hole and what should and should not be included as aspects in defining a region as a black hole. Although Hawking originally denied that this particular region was a black hole, he has since conceded that there is now enough evidence to support the theory.

Recent Findings

In 1994, NASA scientists working with the Hubble Space Telescope suggested that a super massive black hole exists at the center of the elliptical galaxy M87. This was the first evidence that black holes may be at the center of all galaxies. On February 29, 2000, astronomers using the Chandra X-Ray Observatory (an orbiting X-ray telescope) discovered what appeared to be a massive object at the center of the Milky Way galaxy, which the Keck observatory confirmed shortly afterward. Scientists reduced the size of the accretion disk of the central black hole in 2004 to less than the distance between the earth and the sun using the Very Long Baseline Array of radio telescopes. Many universities and individual astronomers maintain several Internet sites devoted to lists of black holes, found by utilizing a search engine.

Boethius, Anicius (c. 480–c. 524)

Anicius Manlius Boethius was the most important Latin philosopher in late Antiquity. The Neoplatonist and Christian is traditionally called "the last Roman and the first scholastic." This is because his works conserved essential ideas of the ancient Neoplatonic philosophy in a Roman encyclopedic manner and became fundamental for the Christian scholastic education in the Middle Ages in Western Europe. His works on Aristotelian logic and mathematics, partly translations of Greek tractates on philosophy and theology, were standard school books in the Middle Ages.

Boethius was born circa 480 CE and received an excellent education in Latin and Greek literature and philosophy. He became extremely successful in his public career very early on. He was consul in Rome in 510 CE, and his two sons were consuls in 522 CE. According to his own statement, this was the high point of his life. However, his successful and happy life was cut short by a radical change: Boethius became involved in political intrigues, was fired by King Theodoric, imprisoned at Pavia, and finally executed around 524 CE. This catastrophe is the background of Boethius's most famous book, the *Consolation of Philosophy,* in which the Lady Philosophy consoles him with Neoplatonic arguments by showing him the true nature of happiness, with God as its highest source.

The final part of the *Consolation,* the famous Books IV and V, focuses on the problem of the reconciliation of human free will and God's providence. It aims at avoiding determinism. The discussion of this topic includes a theory of time, because God and humans have different ways of knowing distinguished by time and eternity. God knows all at once. His thinking is beyond time, because his eternity (*aeternitas*) is the source of time but not time itself. Eternity is defined as the total and perfect possession of endless life at once. Therefore in God's providence all the uncountable past and future happenings are present. Eternity is regarded as a "pure present" or a divine "now."

Contrasting eternity, Boethius mentioned the Aristotelian doctrine of the infinity of the created world (everlastingness—*sempiternitas, perpetuitas*) that has neither a beginning nor an end of time. In doing so Boethius touched on a cardinal philosophical and theological problem of his times. Christians believed in the creation of the world and of time by God as recorded in the Book of Genesis and as stated by Boethius in "About the Catholic Faith." Others thought that, according to Plato, the created world is coeternal to its creator. In the *Consolation,* Boethius explicitly rejected the latter interpretation and followed Plato's (and Aristotle's) view that the world is not eternal but perpetual.

Whereas the everlasting world imitates God's timeless eternity by being unlimited in duration, human beings are even more deficient. Humans think and act within the limits of time (*tempus*) that has a beginning and an end, a past and a future. Human knowledge, therefore, covers only particular aspects of the whole seen and unseen Creation but not the whole, neither one part of it after the other nor at once. Because of this restricted perspective, humans cannot adequately understand God's providence and their own fate evolving from providence.

The distinction between eternity, everlastingness, and time goes back to complex philosophical speculations of Neoplatonic and Christian thinkers—namely Plotinus and Saint Augustine of Hippo, mainly reflecting Plato's *Timaios*—and was fundamental for the scholastic theories of time in the Middle Ages and later on.

Bohm, David (1917–1992)

The American theoretical physicist David Bohm is widely regarded as one of the 20th century's most original thinkers. Over the course of a distinguished career that spanned more than 50 years of teaching and writing, Bohm participated vigorously in the international scientific debates surrounding the overthrow of classical physics by the twin but apparently irreconcilable theories of relativity and quantum mechanics. Along the way he made important contributions to the study of the basic properties of the physical world, such as the theory of the plasma, a fourth state of matter in addition to the solid, liquid, and gaseous states. Eventually the reach of Bohm's ideas went beyond the traditional boundaries of physics and cosmology and came to influence the fields of philosophy, language studies, psychology, and the arts. In his later years he became convinced that the phenomenal world, including time and space, is no more than the surface appearance of something much deeper, the ultimate ground of being in which even the distinction between mind and matter could be resolved. As Bohm observed, not only had Einstein's theory of relativity shown that a sharp distinction between space and time cannot be maintained, but also quantum theory implies that elements separated in space and moments separated in time are noncausally related projections of a higher-dimensional reality, a reality that is, moreover, enfolded in consciousness. The universe, according to Bohm, is an unbroken, flowing, unified whole.

Born in the coal-mining town of Wilkes-Barre, Pennsylvania, where his father owned a small furniture store, David Bohm later recalled his first encounter, at age 10, with a science fiction magazine, which fired his imagination with tales of space travel and distant planets. An absorbing interest in science led to his serious study of physics as an undergraduate at Pennsylvania State University. Following a year of graduate study at the California Institute of Technology (Caltech) in Pasadena, Bohm arranged to meet with J. Robert Oppenheimer, founder of a school of theoretical physics at the University of California, Berkeley, that was attracting many of the brightest young scholars in the nation. Evidently impressed, Oppenheimer invited Bohm to join his team of research students, and in 1941 Bohm moved to Berkeley and entered the vanguard of nuclear physics, where his creativity began to flourish. Against the background of World War II, however, the implications of basic research into the nature of the atom had taken an ominous turn. By the end of the 1930s scientists in both Europe and the United States had recognized the possibility of constructing a nuclear weapon, and in 1942 the U.S. government secretly enlisted Oppenheimer to head an international group of top physicists in developing an atomic bomb. The code name for their efforts was the Manhattan Project, and the extreme concern with security surrounding their work was to have a profound effect on the future of many of the scientists affiliated with the Radiation Laboratory at Berkeley.

Although Bohm was not directly involved with the Manhattan Project and in fact was ignorant of its very existence, his sympathy with socialism and his association with members of the American Communist Party placed him, and other scientists who held similar views, under a cloud of suspicion; Oppenheimer himself was under close surveillance. The fear that the Soviet Union, then a U.S. ally in the war against Germany, would succeed in developing a nuclear weapon before the United States generated an atmosphere of mistrust that lasted long after American warplanes had dropped atom bombs on the cities of Hiroshima and Nagasaki.

Awarded his Ph.D. in 1943, Bohm was invited after the war's end to join the faculty of Princeton University in New Jersey, where he became friends with Albert Einstein, at that time a Fellow of Princeton's Institute for Advanced Study. At Princeton, Bohm wrote his first major work, *Quantum Theory,* which upon publication became a widely adopted textbook for physics students. Although acceptance of quantum theory had become all but universal among physicists, Einstein maintained strong reservations about the theory's insistence that, at the smallest scale, chance and probability were absolute and irreducible properties of the physical world. Taking Einstein's objections seriously, Bohm began formulating his concept of the "quantum potential," which would allow even the more bizarre aspects of quantum reality to be explained causally and as manifestations of the holistic nature of the universe. The implications of this idea would occupy Bohm's imagination in various ways for the rest of his life.

Meanwhile, the cold war with the Soviet Union had given rise to near-hysterical fears of communist domestic subversion. The House Committee on Un-American Activities had launched investigations of scientists formerly associated with the Radiation Laboratory at Berkeley, and David Bohm, among others, was called to testify. Indicted but subsequently acquitted of all charges of wrongdoing, Bohm was nevertheless denied a renewal of his contract by Princeton, which had come under political pressure to "put its house in order." Now unsure of his prospects for academic employment in the United States, Bohm applied to the physics department of the university in São Paulo, Brazil, with recommendations from both Einstein and Oppenheimer, and in October 1951 he began a period of voluntary exile that lasted, except for periodic visits, until his death.

Later, Bohm taught at the Israel Institute of Technology (Technion) and then in England, first at the University of Bristol and then at Birkbeck College, London, where he remained until his retirement as professor emeritus. Throughout these years, he continued to develop, expand, refine, and publish his ideas, some of which deeply influenced others, such as John Bell, whose eponymous theorem established the essentially nonlocal character of the quantum world. Among those with whom Bohm maintained collegial and personal relationships were Einstein, Oppenheimer, Niels Bohr, Richard Feynman, and the philosopher of science Karl Popper; his many correspondents included Werner Heisenberg, Louis de Broglie, Wolfgang Pauli, Maurice Wilkins, and the historian of science Thomas Kuhn. He also maintained friendships with several notable figures outside the realm of science, such as the Dalai Lama and the philosopher Jidda Krishnamurti.

Near the end of his life, Bohm's growing conviction that the material world and consciousness together form an unbroken whole was given full expression in his theory of the implicate order; namely, that what we take to be reality (the *explicate order*), in which separate and distinct particles are observed to interact, is an abstraction derived from a deeper, *implicate order* in which time and space are no longer the dominant factors that determine relationships of dependence or independence of separate elements. Physicists' efforts to reveal the ultimate "building blocks" of the universe by analyzing it into ever-smaller constituents fail to address this issue. And yet, not only has the mechanistic view of reality already been superseded but, according to Bohm, both relativity and quantum mechanics are likely to be revealed in the future as abstractions from still more general laws. To illustrate how the implicate order may be enfolded within the explicate, Bohm uses various metaphors, including that of the hologram: Just as each point in a holographic image encodes information about the whole image, so is the entire universe enfolded within any given point in spacetime. As for consciousness, Bohm's intuition was that, far from being purely local, merely an epiphenomenon of electrochemical processes in the brain, mind is a universal quality and that, at the deepest level, matter and consciousness cannot be separated.

Bonaparte, Napoleon (1769–1821)

Napoleon I, born Napoleone di Buonaparte, is among the most renowned figures in modern European history. He rose to prominence during the French Revolution (1789–1799) to become first consul of the French Republic, and then emperor of France. He conquered much of Europe militarily and instituted a series of liberal political reforms, including the *Code Napoléon,* making him one of history's most contradictory rulers.

Napoleon's extraordinary military and political career was evident enough to his contemporaries, who often likened him to Alexander, Caesar, or Hannibal. The art and literature of the period are littered with such imagery. Napoleon was deeply conscious of his place in time and carefully cultivated his image as a "great man" of history. He embraced the French Revolution and became its foremost beneficiary. He consolidated many of the reforms of the revolution and spread them across Europe, coupled with much violence in doing so. Napoleon crowned himself emperor of the French before Pope Pius VII, in conscious imitation of Charlemagne a thousand years earlier. He made his son the king of Rome, linking his name to the legacy of the so-called Eternal City. Napoleon's epic battles, such as those at Austerlitz and Waterloo, are among the most consequential in history. Taken together, the French Revolution and Napoleonic period represent a transitional moment from the *ancien régime* to modern Europe.

Napoleon was born at Ajaccio, Corsica, soon after the island became a French possession. His parents, Carlo and Letizia Buonaparte, sent the young Napoleon to study in Paris where he graduated from the military academy in 1785. An admirer of Rousseau and Voltaire, Napoleon supported the French Revolution that erupted in 1789 and joined the revolutionary Jacobin Club. Patronage and prodigious service as an artillery commander won him promotion in the French army. Following highly publicized campaigns in Italy and Egypt, he returned to Paris and took part in the coup d'état of 18 Brumaire. He held the position of first consul until 1804, by which time he had consolidated enough power to declare himself emperor in a grand ceremony at the Notre Dame de Paris. Napoleon's insatiable appetite for power and glory brought France into conflict with the other states of Europe, which formed a series of alliances led by Great Britain. At its height, the Napoleonic Empire included nations across Europe, to which many reforms of the French Revolution were extended, as well as much exploitation.

Napoleon's disastrous invasion of Russia in 1812, immortalized in Leo Tolstoy's novel *War and Peace,* demonstrated that the emperor could be defeated. Napoleon abdicated in 1814 following additional defeats and was exiled by the Allies to the tiny island of Elba. He escaped the following year and marched on Paris, gaining followers along the way. The so-called Hundred Days of rule ended abruptly with Napoleon's legendary defeat at Waterloo on June 18, 1815. The Allies exiled Napoleon this time to the island of St. Helena off of the coast of West Africa, where he died on May 5, 1821, at the age of 51. Today, Napoleon I is entombed at Les Invalides in Paris.

The period denoting the rise and fall of Napoleon is often referred to as the Napoleonic period or the Age of Napoleon, a designation reserved for few figures in world history. Napoleon's legacy remains controversial; he has been both celebrated and vilified perhaps more than any other figure of his time. His self-destructive ambition drove Europe into years of brutal warfare that has been described as the first total war. Moreover, his sweeping changes to the political map of Europe gave impetus to national unification movements, such as in Italy and Germany.

Boscovich, Roger Joseph (1711–1787)

Roger Joseph Boscovich (Rudjer Josef Boşković, or Ruggiero Giuseppe Boscovich) was born on September 18, 1711, in Ragusa (Dubrovnik), Dalmatia, to a large Catholic family. He finished his principal work, *Theoria Philosophiæ Naturalis Redacta ad Unicam Legem Virium in Natura Existentium* (A Theory of Natural Philosophy Reduced to a Single Law of the Actions Existing in Nature), in Vienna in 1758, and a definitive edition in Latin and English appeared in 1763. Boscovich's scientific accomplishments were so extensive that they cannot be listed here. He published about 100 scientific treatises (most in Latin) and during his lifetime had an academic scientific reputation in France and Italy, England and the United States, as well as in the Slavic world.

Yet the rest of his exceptional life was eclipsed by the fact that Boscovich was the undisputed founder of one of the three families of atomic theory. Boscovich's considerable scientific reputation today is based largely on the theory of matter that he formulated in his *Theoria*. This work helped shape modern conceptions both of matter and of the force field. For example, Michael Faraday and James Clerk Maxwell adapted their theories of the electromagnetic field to ideas based on Boscovich's theory of natural philosophy.

His *Theoria* consists of a great many topics in physics, which may be skipped over by the reader interested primarily in his theory of time. Supplements I and II of the *Theoria* contain Boscovich's mature theory of time, space, and matter. Upon reading his entire magnum opus, though, the modern nature of Boscovich's system becomes apparent. His theory of point particles (*puncta*) includes kinematics, along with a relational and structural understanding of particles. In the case of high-speed particles, Boscovich foresaw the penetrability of matter.

Though his father was of purely Serbian lineage and his mother of Slavonic-Italian origins, Boscovich always insisted he was a Dalmatian nationalist. He died on February 13, 1787, of an extended lung ailment.

Boscovich's Relation to Zeno, Newton, and Leibniz

To understand Boscovich's notion of time, it is best to summarize his own place in the history of Western reflections on time. Even at the beginning of Boscovich's career, the paradoxes of motion posed by Zeno of Elea in the long-past Presocratic period still confounded science.

One paradox assumes two columns of soldiers marching past each other at the same speed and in front of columns of stationary soldiers. Zeno demonstrated that the soldiers would be moving at both half-speed and double-speed relative to the other marchers. He considered this absurd, dismissing, in a sort of reductio ad absurdum argument, the assumption of *real time*. His paradox of motion, then, was a conceptual problem for all serious thinkers.

In reply to Zeno, Aristotle had argued that instead of using multidimensional objects, such as columns of soldiers, unextended points should be employed. In agreement with Aristotle, Boscovich embraced zero-dimensional points as the basis of his notions of time and space.

But this led to another conundrum that still baffled thinkers at the time of Boscovich; using only such unextended points, it is impossible to construct continuous space. This is true because either the points touch, in which case they "compenetrate" and become one point, or they do not touch, in which case a *continuous* space or time cannot be constructed. Boscovich solved the remaining problem by rejecting the validity of the law of continuity as applied to space and time, whereas the law of continuity holds true (only) for motion. Thus he founded one of three primary families of atomic theory: point-particle atomism.

Though a great genius in his own right, Boscovich was eclipsed by two near contemporaries, Sir Isaac Newton and G. W. F. Leibniz. Independent of Newton, Leibniz had also discovered the calculus of infinitesimals, solving Zeno's paradox at a mathematical level. The latter had also adopted zero-dimensional points in his physics and metaphysics, which he called "monads." While Newton's "atoms" were extended and substantial, Leibniz's monads and Boscovich's "force-point particles" were without extension or substance. Unlike Leibniz, however, Boscovich did not attempt to build a continuum from such zero-dimensional points. Rather, he argued that a continuum is the motion of one point. He supposed that any two points never have direct contact, an event that the metaphysics of Leibniz allowed.

By modifying Leibniz's monadology, and by rejecting Newton's corpuscular theory, Boscovich forged his own path. In this way, Boscovich was able to "avoid a mighty rock, upon which both of these others [Zeno and Leibniz] have come to grief." Behind their misconceptions was the "imperfect idea of a sort of round globule having two surfaces distinct from one another, an idea they have acquired through the senses; although, if they were asked if they had made this supposition, they would deny that they had done so."

Perhaps the most striking and counterintuitive postulate of Boscovich's theory was that *there is no universal time, only local time*. At the level of force-points, there is only local time relative to two points. *Time in the context of a single force-point does not exist,* for Boscovich's theory. Time is a strictly relative feature of localities between at least two points, and in the case of sensory objects, great masses of points.

The same is true for space, which Boscovich considered highly analogous to time. Spatially, a solid rod, measuring two precise and distinct points, cannot be rotated in space to measure the same distance between two new points, as it cannot be proven, without circular reasoning, that the rod has not been bent during its rotation. Just as there is a space only relative to the rod, there can be no absolute measure of time, without circular reasoning.

There is no actual space or actual time but only "real local modes." While these force-points are objective and real, and are the only references of "time," they are not centers of time awareness (or sensation generally), at least not for the author of the *Theoria.* Above all, what Boscovich wanted to say about time is that it is not a *continuum consisting of many points;* rather, it is *a relation between two or more discrete force points.* Thus the smallest particle of time is not a time atom (an indivisible length of time) but instead a "tempescule," a "continuous progressive movement in which some intervals are parts of other intervals," since there is a potential to insert an infinite number of points between any two points, no matter how close the time points are together. Space extends in three directions between points of space, whereas time has but one direction. The apparently continuous line of time actually consists in the progressive movement of the present.

Without saying so directly, Boscovich accused his critics and fellows of a "fallacy of division." They had reasoned that what is true of macroscopic objects is true of their most basic constituents. Namely, because larger composite objects are extended, solid, impenetrable, and in contact with each other, elemental objects must also be extended, solid, impenetrable, and in contact with each other. This transfer of properties from whole to part, with only the senses (especially the tactile sensation of solidity) as evidence, was logically illicit.

Similarly, the elemental nature of time and space cannot be arrived at by the senses, according to Boscovich. The ultimate nature of the force-points can never be fully comprehended. The senses cannot be the ultimate jury of reality, as the case of Copernicus had shown. Likewise, the nature of the force-points cannot be deduced from properties of macroscopic objects. What seems certain to the senses may be overthrown by science.

Thus Boscovich founded the point-particle family of atomism. Even for readers in the 21st century, such relativity may be appreciated for its precociousness.

Boscovich and Spinoza's Metaphysics of Substance

Almost every intellectual pursuit during Boscovich's lifetime revolved around the perceived cultural twin threats of Spinoza and Newton (determinism and materialism, respectively). To Boscovich's disadvantage, it has been almost completely overlooked that Boscovich's theory of force-points rejected both Spinoza's concept of "substance" and Newton's corpuscular atomism, the roots of both being traceable to Descartes. At one fell swoop Boscovich rid the general literate public of its twin threats but did so by completely overturning the testimony of the five senses.

Ironically, among the reading public, a growing concern became Boscovich's own theory: Even though the author insisted that his force-points were not centers of spirit, conation, emotion, cognition, or any of the like, many among his readers and the general public worried that some future thinker would modify the theory in precisely that manner. Though Boscovich was an ardent and committed Christian and an outstanding member of the Society of Jesus, his theories were atheist–scientific in interpretation.

In the Appendix on Mind and God to the *Theoria,* Boscovich argued that force-points cannot be construed as *spirits* and that *time is linear, not circular.* First, spirits are immaterial and cannot be spatially or temporally locatable, as must be force-points. Second, because the number of force-points is infinite, there is no mathematical necessity for time to eternally recur. To avoid a version of the theory now called "eternal recurrence," Boscovich argued that there is no definite number of force-points, that instead their number is infinite.

For the reader of the *Theoria,* these rebuttals are unconvincing. In the first case, readers knew quite well that consciousness (and with it the soul) might easily become only another sort of wavelength in Boscovich's physics. This would reject the Cartesian dualism in concert with Christianity, to the advantage of a monism of a universal singular force in no way identifiable as the traditional God. Here Boscovich introduced something of a deus ex machina into his physics, as his theory of force accounted for all physical relations as properties of force-points at varying distances. In the second case, readers remembered that Boscovich's law of force postulated that *there are no actual infinities in nature*. By introducing an actual infinity of points, he violated his own theory. Further, Boscovich introduced another deus ex machina into his physics by arguing that an "infinite determinator" would choose against eternal recurrence, in any case, because an infinite determinator would want linear, not circular, time. To the careful reader of the *Theoria,* however, these rebuttals by Boscovich rang hollow before the specter of soul, time, and God being reduced to sets of force-points.

Boscovich in Relation to Kant and Schelling

The relation of Boscovich to Kant is exceptionally complex, and it must suffice here to remark that both Boscovich and Kant sought to occupy a position situated between Newton and Leibniz, but without repeating their mistakes. There the similarities largely end, though, for the paths of discovery followed by Boscovich and Kant diverged for decades.

The elder Boscovich knew of Kant's arguments against his point-particle atomism and was not convinced. In fact, Boscovich drew nothing from the young Kant into the original *Theoria* and mentioned the objection from Kant (not by name) in a later edition only to include a summary of arguments against his own position.

In his Supplements I and II, Boscovich drew a distinction between "space and time" and "space and time as we know them." Significantly, though, he did so adopting neither a cumbersome metaphysic of faculties nor a distinction between noumena and phenomena. Thus Boscovich's theory would have been a valuable asset to Johann Gottfried von Herder, an opponent of Kant's metaphysics, who did not know of the former. Moses Mendelssohn, another critic of Kant who knew of Boscovich's theory, found Boscovich's theory worthy of public endorsement.

Within the rather alien German Idealist tradition, oddly, Boscovich found another adherent. In his philosophy of nature, Friedrich W. J. Schelling employed Boscovich's *Theoria* precisely to avoid the metaphysics of both Spinoza and Newton (along with that of Leibniz). Almost certainly, Schelling would have come into contact with the ideas of the *Theoria* while Kant's student at Königsberg. At that time, the young Kant was working out a theory of force, which would occupy him off and on until his last works. In his dissertation, Kant had reviewed and modified the theories of force from a wide range of naturalists and physicists. The exclusion of Boscovich is remarkable; apparently Kant was not yet settled in his own mind about the *Theoria*.

Kant certainly knew of Boscovich and his cultural "danger": Moses Mendelssohn had made that obvious to the German literate public. In his last years, Kant still wrestled with Boscovich in *Metaphysics of the Groundwork of Natural Sciences* around the ancient questions of motion and direct contact. As was his wont in this case, Kant never explicitly mentioned Boscovich. But identifiable ideas in Kant's thinking were originally and uniquely from Boscovich. In *Metaphysics of the Groundwork of Natural Sciences,* Kant's final word was a theory of force based on force-points much closer to that of Boscovich than to the theory of Leibniz.

After Schelling, the overt influence of Boscovich on German thought would come primarily with Friedrich Nietzsche's *Beyond Good and Evil,* in which the author lauded Boscovich as another Copernicus in usurping the world of sense-driven appearances (by destroying the last remnant of solid, extended matter). Nietzsche employed the force-points of Boscovich not only as centers of physical force but also of conation and sensation, even of temporal registry. This evolved quickly into Nietzsche's own theory of will to power. An early and foundational note from 1873, the "time atomism fragment," sketched precisely these modifications of Boscovich's point-particle theory into Nietzsche's own theory of force-points. Yet the influence of the *Theoria* on Nietzsche's philosophy went unnoticed except for a crucial study (in German) by scholar Karl Schlechta and physicist Anni Anders in the 1960s. Since the 1990s, though, awareness of Boscovich's role in Nietzsche's work has become widespread. Although Boscovich was one of a large number of scientific influences on Nietzsche, his theory of force was by far more central than the others.

In any case, Boscovich will be remembered as a point-particle theorist and as a philosopher of nature.

Boucher de Perthes, Jacques (1788–1868)

Jacques Boucher de Perthes was a French archaeologist and writer who revolutionized archaeology by pioneering the notion of prehistory. He discovered evidence that humans had existed far earlier in time than had been previously thought.

Boucher de Perthes was a French customs official by profession and a geologist by hobby when he made his groundbreaking discovery. During the 1830s and 1840s he explored and excavated sites in the Somme Valley near Abbeville, France. At a site named Moulin-Quignon he found humanmade tools and pottery alongside extinct elephant and rhinoceros remains. He concluded that because the tools and bones lay together in the same layer of the earth, they were most likely from the same period of time. Perthes collected and studied the tools, which included bifaced "hand-axes." In 1847 he published the first volume of his three-volume work, *Celtic and Diluvian Antiquities,* in which he detailed his findings along with illustrations. Perthes claimed that the tools were made by Celts before the cataclysm of the biblical flood. Scientists did not take Boucher de Perthes's discoveries seriously at the time. It was not until the late 1850s that notable geologists, including Sir Charles Lyell and members of the Geological Society of London, visited his excavations and verified the discovery.

Jacques Boucher de Crèvecœur de Perthes was born into an aristocratic French family that claimed descent from the family of Joan of Arc on his mother's side. Born to wealth, he was able to devote much free time to study and writing on a variety of subjects, including literature and politics. He also wrote plays that never sold. Perthes traveled extensively and was a social activist for the poor throughout his life. In 1825 he was appointed director of the Abbeville customs office, a position formerly held by his father.

Boucher de Perthes's discovery had immense implications for humans' perception of time. He refuted the long-held notion that humanity was created only 6,000 years earlier, or 4004 BCE, a date notably argued by Archbishop Ussher. He established the concept that humanity, and the earth itself, dated far earlier in time than had been previously believed. Gradually he was acknowledged as the founder of prehistoric archaeology. Boucher de Perthes's assertions were largely reinforced with the publication of Charles Darwin's *On the Origins of Species* in 1859. Darwin famously established that organisms evolve over a very long period of time through the process of natural selection.

In 1863, a human jaw was found by a worker at the excavation site known as Moulin-Quignon in France. After careful examination by French and British anthropologists, the jaw was authenticated and appeared to further vindicate Boucher de Perthes. However the "Moulin-Quignon jaw" proved to be a fraud arranged by a worker who was motivated by a reward of 200 francs. The hoax did not damage Boucher de Perthes's reputation. In 1864 Napoleon III honored him with the medal of Officier de la Légion d' Honneur for his contributions to science. Boucher de Perthes died in Abbeville, France, in 1868.

Bradbury, Ray (1920–)

Ray Bradbury's published writings include a vast array of science fiction and fantasy short stories, some of which are inspired by his fascination with time machines and time travel. Bradbury has created lasting images of a futuristic world in which people visit the past. His stories often focus more on the concern with the moral aptitude of people who are given the opportunity to experience scientific advances, rather than on the scientific advances in and of themselves. Born in Waukegan, Illinois, Bradbury moved with his family to Los Angeles, where he graduated from high school in 1938. Bradbury first published his short story "Hollerbochen's Dilemma" (1938) in a Los Angeles Science Fiction League's fanzine *Imagination!* In 1941, he broke into the professional market when he published the short story "Pendulum" in *Super Science Stories.*

Bradbury began writing full time in 1943, emerging first as a science fiction author and later moving into fantasy, mystery, nonfiction essays, children's literature, and even comic books. Over the course of a long career he has written over 500 works, including short stories, poems, novels, and plays for theater and television.

Many of Bradbury's short stories depict time travel and time machines. In "A Sound of Thunder," first published in *Collier's* magazine in 1952 and reprinted in his collection *The Golden Apples of the Sun* (1953), Bradbury uses time travel to emphasize the profound effect actions occurring in the past can have on the future, when present-day Earth unravels after hunters inadvertently kill a prehistoric butterfly when on their safari expedition.

In "The Fox and The Forest" (*The Illustrated Man,* 1951) Bradbury wrote about a married couple living in a dismal and dehumanizing future overrun with war and bomb-building efforts. They attempt to flee their world by taking a time travel holiday in Mexico, circa 1938. In "Forever and the Earth" (*Long After Midnight,* 1976), Bradbury uses a time machine to transport Thomas Wolfe from his deathbed into the future. Concepts of time travel also exist in his children's book *The Halloween Tree* (1972). Another story that deals with time machines or concepts of time travel is "Last Rites" (*Quicker Than the Eye,* 1996).

In his novel *Dandelion Wine* (1946), he told of a human time-machine, Colonel Freeleigh, who could transport other people back in time by his ability to tell stories. Bradbury republished this story as "The Time Machine," in *Golden Apples of the Sun.*

"The Kilimanjaro Device," first published in *Life* magazine as "The Kilimanjaro Machine" and later reprinted in *I Sing the Body Electric* (1969), is about an encounter with Ernest Hemingway. *Ahmed and the Oblivion Machine* (1998) is a children's fable about a young boy gifted to travel through time and experience life's sorrows and joys.

It is not only his concepts of time travel that made for fantastic stories. Bradbury often tells tales with futuristic vision, not only of what life would be like but how humankind would take advantage of, or misuse, future technological advances because of moral lapses, greed, neglect, and corruption.

Bruno, Giordano (1548–1600)

During the Italian Renaissance, the self-unfrocked and controversial Dominican monk Giordano Bruno emerged as its most important philosopher. To a significant degree, this reputation is due to his daring conception of time within a bold cosmology. Bruno challenged all earlier models of our universe, from the geostatic and geocentric viewpoint of the Aristotelian perspective to the God-embraced and Christ-centered worldview of Nicholas of Cusa. As a result of his rejection of previous ideas in astronomy, philosophy, and theology, Bruno presented a new and astounding cosmology that foreshadowed, in a general way, our modern conception of time in terms of physical relativity and the present interpretation of this material universe in terms of ongoing evolution.

This bronze statue of Giordano Bruno on the Piazza Campo de Fiori, Rome was erected on the place where the Dominican friar and philosopher from Nola (southern Italy) died at the stake February 17,1600, after he was tried and condemned to death for heresy by the Inquisition's court.

Source: AFP/Getty Images.

Dissatisfied with empirical evidence and personal experience, Bruno used thought experiments, rational speculation, and his own powerful imagination to envision the essential characteristics of this dynamic universe. He rejected both Aristotelian philosophy and Thomistic theology. Likewise, he was not content with the models of reality that were presented by Nicolaus Copernicus, Johannes Kepler, and Galileo Galilei. Going beyond all earlier models of a finite and closed universe, Bruno argued that the cosmos is eternal in time, infinite in space, and endlessly changing. For him, time had no beginning and will have no end in the flux of nature; it stretches forever into the past and forever into the future. Consequently, in such a universe, there is no fixed or privileged point of reference.

Rejecting the biblical account of Creation as having taken place over 6 days, Bruno saw cosmic creation as an endless process throughout eternal time. For him, there is no static or absolute framework within which to judge the passing of events to be long or short compared with other events; the length of time is relative to an arbitrary temporal framework within the eternity of time. Throughout cosmic history, the universe has created an infinite number of stars, comets, planets, moons, galaxies, and island universes. In fact, there has even been time for life forms and intelligent beings to emerge on countless other planets strewn throughout the universe. Therefore, our own species occupies neither a special place nor a central position within cosmic reality. In Bruno's sweeping and liberating vision, our human species is merely a fleeting speck in the incomprehensible vastness of sidereal history.

For Bruno, God is nature. Therefore, God is eternal, infinite, and endlessly creating new objects, events, and relationships throughout cosmic history. Ultimately, the Brunian cosmology is grounded in a mysticism that unites, in a divine reality, eternal time and infinite space. In 1600, Bruno was a victim of both religious and political intolerance. Having been found guilty of infidelity and heresy, he was burned alive at the stake in the Campo dei Fiori of central Rome. Today, an impressive statue of this iconoclastic thinker stands on the very spot where he died. He is best remembered for his perspective on time and unorthodox insights into the composition of our universe.

Bruno and Nicholas of Cusa

Giordano Bruno (1548–1600) and Nicholas of Cusa (1401–1464) provided a unique interpretation of God and the universe within their conceptual framework of time. Although some influences of Nicholas of Cusa upon Bruno's ideas are often ignored or misconstrued, together they reflect both the theological and philosophical turmoil that faced the Catholic Church in the 15th and 16th centuries. Advancements in science, philosophy, and the desire for freedom from dogmatic thought had brought serious consequences to these dynamic thinkers. Accusations ranging from heresy, apostasies, blasphemy, to the critical responses from known scientists and their accepted theories had brought periodic censure to Nicholas of Cusa and condemned Bruno to death. The commonalities and differences that can be seen in the fate of these two philosopher-theologians are due to the ideas within their embodied views.

The influence of Platonic and Neoplatonic thought found throughout the views of both Nicholas of Cusa and Bruno are expressed in the shared commonalities regarding the spatiotemporal nature of God and the universe. Infinite and eternal, the cosmos emanates and is constituted from the One (Absolute) in a materialistic interpretation of God. Mysticism, mathematics, and the unity of contradictions provided a comprehensive account of the diversity or plurality found in nature and was associated with the very nature of God; albeit, humankind can never fully understand God. In their theological and philosophical perspectives, not only is God constituted in the material of the known universe (monistic and pantheistic), but also God is indivisible.

Although such views are intriguing, at least from a philosophical perspective, these postulations regarding God, the universe, and humankind's place in nature directly challenged the philosophical underpinnings of Catholic theology and other theological denominations. As for the Catholic Church, the Christian interpretation of Aristotle as presented by Saint Thomas Aquinas (1225–1274) was dogmatically pervasive during this time, as it is today. The postulated views of Nicholas of Cusa and Bruno proved to negate basic church doctrine, especially the conceptual framework of time as represented in the church's divine revelation by God. Further implications regarding holy scripture, Christology, the Holy Trinity, and salvation and redemption are apparent. In regarding these issues, the differences between Nicholas of Cusa and Bruno become evident.

In the intellectual timeline, Nicholas of Cusa was a link between Aristotle and Bruno. He held that humankind is in a state of "learned ignorance" and is incapable of understanding the unity and infinity of the Absolute Maximum and Absolute Minimum of the One or from Absolute Necessity, that is, God within the conceptual framework of the Trinity. Within this framework, the coincidence of contradictions and opposites are united and embodied as One, which humankind can only perceive as separate and distinct. Infinity regarding these concepts was represented by analogies drawn from the mathematical properties of lines, triangles, circles, and spheres, and even motion. It is these analogies of mathematics that allow humankind to arrive at and differentiate divine truth and the infinity of truth.

The cosmos (which includes humankind), by its very nature, is only a "contracted" maximum, a reflection or mere copy of the Absolute Maximum. In this regard, the cosmos had a distinct beginning. The infinity and the eternal nature of the cosmos become the only significant link with the Absolute Maximum. For Nicholas of Cusa, Christianity was unique and paramount within the unification of the Absolute Maximum and Absolute Minimum within the contracted universe, for Christ Incarnate became a focal point within unity as depicted in the Trinity. Just as God is constituted and contrasted with humankind, Christ embodied both perspectives simultaneously. Christ's nature was both Absolute Maximum and Absolute Minimum within the contracted nature of the cosmos. This allowed Christ to transcend death and enabled humankind to know God. The mysteries of faith steeped in mysticism seek to provide individuals the path, via Christian love, toward the Church. This union of individuals, such as is expressed by the congregation, becomes united with Jesus Christ on whose existence humankind depends.

Bruno provided a different view of the cosmos and humankind's place within it. For Bruno, the spatiotemporal universe—form and matter—not only had no beginning and is infinite in nature, but also is in a constant state of flux. In this manner, time becomes relative. This relativity confers upon it a sense of individuality, for example, as depicted by motion or life, and that which is juxtaposed as eternity. Individualistic concepts of time are not singular in nature; rather, the time of each individual is irrevocably linked to others within the universe. This dynamic and diverse plurality of the monadic universe is united and one within nature, ultimately equating God with nature. Bruno postulated that within this infinite universe there are numerous planets, stars, and galaxies, some of which contain life within their relative conceptual framework of time. Consequently, in a universe that is full of life and has no center or periphery, humankind's place in the cosmos is without a hierarchy. The life of our species is one among many within the inconceivable stretch of the cosmos.

Bruno speculated that, in the process of understanding humankind's nature, our species will discover the nature of divinity within ourselves. This divinity can be expressed throughout human cultures and their respective religious–mystical perspective. A combination of mysticism and rationality results in a sense of universalism, as depicted in ancient religions and magic, which is reflective of the divinity within the human species. If the Brunian idea of humankind's nature and relationship with the divine is taken seriously, differences among religious practitioners are negated. A sense of utopia, peace, and harmony would be an eternal goal that could be realized. Although human life is finite, perhaps in a Brunian sense our species' existence and "divine" nature are infinite and peace is possible when compared to humankind's history and life on other worlds.

Bruno's ideas of time, the universe, and the nature of divinity had resulted in severe repercussions. His anti-Aristotelian stance, rejection of Ptolemy and acceptance of Copernicus (based on mysticism), rejection of traditional religions, and critical judgment of orthodox Christianity had not endeared him to authorities. Bruno's view, considered more art than science, attempted to unify and expand the human perspective beyond the confines of many geocentric and anthropocentric lines of thought. In contrast to the philosophical and theological positions of Nicholas of Cusa, these contrary and conflicting views resulted in his trial and execution in 1600.

The concept of time, as with the universe, pushes the human intellect to the fringes of reality. The concepts as depicted by Giordano Bruno and Nicholas of Cusa are representative of many perspectives encountered within humankind's desire to understand itself in terms of nature and its relationship to the cosmos. Human evolution, as with speculations on the evolution of life on other planets, is intertwined within the fabric of time and space. Subjective and elusive, the infinity of time and space remain central to human existence, even though it is neither central nor critical to the universe or cosmos. For Nicholas of Cusa, learned ignorance aids humankind in the epistemological fulfillment of the universe and the understanding of our species' relation to the divine. Bruno, on the other hand, postulated a more humanistic approach. Ultimately, time is relative in a chaotic universe filled with life on planets throughout the cosmos. Together, Bruno and Nicholas of Cusa provide a unique perspective that still resonates today.

Buddhism, Mahayana

Buddhism was divided into two schools because of a schism that gained increasing momentum between the 1st century BCE and 2nd century CE. The new school of Buddhism called itself "the greater vehicle," or Mahayana, as it had reinterpreted the teachings of Siddhartha Gautama (563–483 BCE) to accommodate a greater number of people. The Mahayanists distinguished themselves from the old mainstream Buddhism by referring to it as "the lesser vehicle," or Hinayana. Because there is a derogatory connotation to the epithet *Hinayana*, contemporary scholars tend to shun the term in favor of *Theravada* or *Theravada Buddhism*. Among the philosophical differences between the two schools is a new conceptualization of temporality that defies the traditional division of past, present, and future and bridges the conceptualization of time in the realms of relative and absolute order.

Major Characteristics

Both schools of Buddhism subscribe to a common set of basic teachings attributed to Gautama Buddha (also known as Shakyamuni or Sakyamuni). Among these teachings are the Four Noble Truths, the Noble Eightfold Path, the theory of *karma,* and the cosmology of impermanence, or *dukkha*. Differences arose from the way that the two schools made sense of the teachings. Whereas the Theravadins insisted on a rigorous adherence to the Buddha's original teachings, the Mahayanists championed a more liberal, dynamic, and esoteric interpretation. As a result, Mahayana Buddhism developed a number of innovative shifts in emphasis.

The Bodhisattva Ideal

The most important Mahayana innovation was perhaps the *bodhisattva* ideal. Literally "awakened being," the bodhisattva is a Buddha-in-waiting, who vows to postpone entry into *nirvana* (freedom from desire or attachment) until all living beings are saved. This voluntary sacrifice for the sake of others presents a sharp contrast to the Theravada ideal of the *arahant,* or "worthy one." The latter is also enlightened, but attends to his or her own pursuit of sainthood and seeks nirvana just for him- or herself. What the bodhisattva wants is universal salvation. Much as the bodhisattva merits nirvana, he or she chooses to remain in the realm of *samsara* (endless cycle of birth and rebirth) to help people awaken to the impermanence of human existence, transcend the temptation of desires and wants, and be relieved of sufferings.

Central to the bodhisattva ideal are wisdom and compassion. In addition, the bodhisattva vow involves a pledge of commitment to the perfections of morality, patience, vigor, and meditation. The bodhisattva is the name for a group of celestial beings who perform acts of incredible generosity, bring hope to lay as well as monastic Buddhists, and are worshipped alongside the Buddha.

Trikaya, or Threefold Nature

Another Mahayana innovation was the notion that the Buddha had *trikaya,* or three bodies: a Manifest Body (*Nirmanakaya*), a Body of Bliss (*Sambhogakaya*), and a Body of Dharma (*Dharmakaya*). According to this doctrine, the historical Siddhartha Gautama was only the Manifest Body of a universal, spiritual being known as the Buddha. Underneath his external manifestation, the Buddha is at once eternal with his Body of Bliss and absolute with his Body of Dharma.

Out of the three-body doctrine grew the notion of a deity: The Buddha is divine and has transcendent power. His Body of Dharma is that which provides the universal ground of being and, therefore, constitutes the Absolute. His Body of Bliss is capable of assuming various transformations, including Maitreya (Buddha of Future) and the five cosmic Buddhas: Vairocana, Aksobhya, Ratnasambhava, Amitabha, and Amoghasiddhi. Indeed, Mahayana Buddhism embraces a pantheon of Buddhas, whereas Theravada Buddhism professes faith in the teachings of Gautama Buddha solely.

Sunyata, or Void

The Mahayana doctrine of *sunyata* (emptiness) stresses the void nature of all things, including their components. The whole external world is no more than an illusion projected by thought. All phenomena in the world are ultimately unreal, as are the sufferings of endless birth and rebirth. Furthermore, the ultimate void is true of the Absolute as well, which is empty in the sense that it is totally devoid of the distinctions, limitations, and delusion imposed by thought.

The concept of sunyata has its philosophical roots in the *Madhyamaka,* or Middle Path tradition founded by Acharya Nāgārjuna during the 2nd century. It employs dialectic oppositions to account for the relationship between the realms of samsara and nirvana. Ignorance of the ultimate void condemns one to the realm of samsara, whereas knowledge of the ultimate void elevates one into the realm of nirvana. The Mahayana goal, however, is to transcend these opposites in enlightenment. This is possible because nirvana can be found in the transience of ordinary life. Samsara is nirvana, and one does not have to follow a path of monastic withdrawal from the world in order to realize the bliss of nirvana. Ultimately, nirvana is samsara correctly understood.

Universalism of Buddha Nature

Mahayana Buddhism universalizes Buddha nature. Within the Theravada, there is a divide between samsara and nirvana. One can attain nirvana only through the dissolution of one's individuality, hence the doctrine of *anatman* or "no-self." In contrast, Mahayana Buddhism posits a connection between the two realms. All sentient beings are reflections of the Buddha, and Buddha nature is inherent in all living beings. Humans and animals alike have the seeds of Buddha nature within them, so any sentient being can gain Buddhahood.

In its spiritual quest, the Mahayana school advocates the transformation of one's relationship with the world rather than severing oneself from ordinary life. By stressing that spiritual assistance is possible from the Buddha, bodhisattva, and one's own Buddha nature, this school offers more hope of enlightenment in a single lifetime for both lay people and monastic Buddhists. Proceeding from a broader interpretation of the Buddhist tenets, Mahayana Buddhism not only incorporates the monastic principles and practices of the old school but also calls attention to the importance of faith, prayer, chanting, offering, and revelation through meditation in attaining enlightenment.

The Mahayanists did not see themselves as creating a new start for Buddhism. They claimed rather to have recovered the true spirit and message of the Buddha's teachings. In modern times, new research has led some scholars to suggest that Mahayana Buddhism does not hold closely to the teachings of Gautama because it may have evolved from a religious system that was ignored or opposed by the early Buddhists.

Mahayana Schools

Under the broad umbrella of Mahayana Buddhism, a number of different traditions came to flourish, including such schools or sects as Pure Land, Tiantai, Vijnanavada, Chan (Zen, in Japanese), and Tantric Buddhism.

Pure Land Buddhism

Pure Land Buddhism was introduced into China as a devotional society during the 4th century by a Chinese scholar, Huiyuan. Based on the first-century Sukhavativyuha Sutra (Pure Land Sutra), this school provided devotees with a simplified way to obtain salvation—repeating the name of the Buddha Amitabha (Buddha of Infinite Light) faithfully in order to be reborn in his heavenly Pure Land in the west. It was a paradise where everyone was enlightened and headed for the bliss of nirvana. Deliverance to this paradise depended on devoting oneself in chanting to Amitabha and reading the Pure Land Sutra. Not only did Amitabha (Amida in Japanese) hearken to prayers and respond to invocations, but the Buddha delighted in offerings. This Mahayana sect had a great appeal to the laity and spread far and wide in China, Korea, Japan, and Vietnam.

Tiantai Buddhism

Tiantai Buddhism represented the first Chinese attempt to found an eclectic school of Buddhism. It had a place for all the Buddhist scriptures, which were seen as the true words of the Buddha speaking to an audience who understood his message better and better over time. Founded in the 6th century CE by its first patriarch Zhiyi, the Tiantai (Tendai in Japanese) school assigned central importance to the Saddharmapundarika Sutra (Lotus Sutra). Its basic position is very much in the Madhyamika (Middle Path) tradition. Tiantai Buddhism teaches that because there is no noumenon besides phenomenon and phenomenon itself is noumenon, all things have no reality and, therefore, are void. Furthermore, all beings are of the same Buddha nature, and all are to attain Buddhahood eventually. Tiantai Buddhism became very influential in China, Korea, Japan, and Vietnam.

Vijnanavada Buddhism

Parallel to the Madhyamika (Middle Path) tradition is the Vijnanavada (Consciousness Only) tradition, which arose in India during the 4th century CE. According to this tradition, nothing exists outside of the mind, and only consciousness is real. Its works were taken to China two centuries later by Xuanzang, a Chinese monk who rendered the Vijnanavada compendium into Chinese and is remembered as the greatest of all pilgrim-scholars. His disciple Dosho introduced Vijnanavada Buddhism into Japan. The 7th century saw an indigenous Chinese school grow out of the Vijnanavada tradition in general and the *Avatamsaka Sutra* (Garland Sutra) in particular. Established by a master monk, Dushun, in the late 6th century CE, this Mahayana sect was known as Huayan (Flower Garland), and it primarily worshipped the Buddha Vairocana (Primordial Buddha; Rulai in Chinese and Dainichi in Japanese). Huayan Buddhism quickly found its way into Korea and Japan in the 7th century.

Chan Buddhism

Chan Buddhism was a form of Mahayana that underwent extensive cross-breeding with Daoism after it was brought to China in 520 CE by an Indian monk, Bodhidharma. Chan (Zen in Japanese) is the Chinese transliteration of *dhyana,* which is the Sanskrit word for "meditation." Indeed, meditation is a centerpiece of Chan Buddhism. It features an individual quest for spiritual insight, which is also typical of the approach of Theravada Buddhism. For Chan adepts, however, enlightenment is an awakening to the sunyata, or emptiness of reality. Chan apprenticeship is primarily informed by "wordless teaching," which is characteristically Daoist. This Mahayana school also has a rather "this-worldly" character. In addition to meditation, Chan adepts can be engaged in manual work (gardening, wood-chopping, etc.) as much as in cultural pursuits (e.g., calligraphy, painting, poetry writing). It is important that they look within ordinary life for inspirations, which, integrated into spiritual insights from meditation, can culminate in sudden enlightenment. Chan Buddhism spread to Vietnam in the 6th century CE, became dominant in Korea during the 10th century, and led to the rise of the Rinzai and Soto sects in Japan between the 12th and 13th centuries.

Tantric Buddhism

The earliest texts of Tantric Buddhism date back to the 4th century. Often known as Vajrayana Buddhism, this school teaches attainment of enlightenment by the bodhisattva path. Sutras important in Mahayana Buddhism are generally important in Tantric Buddhism as well. What makes Tantric Buddhism distinctive is its adoption of esoteric tantra techniques to expedite enlightenment. Such techniques usually employ mantras, mandalas, and even sexual activities as aids to meditation. Mantras are sacred words with mystic power, whereas mandalas are artworks of religious symbolism that depict deities, holy landscape, and other-worldly vision. Following a reformed Madhyamika tradition, Tantric Buddhism identifies knowledge on three levels of consciousness: the commonsense level that is illusory, the relative level that recognizes the temporary existence of components, and the true level that brings about an awareness of the ultimate void. Enlightenment comes with the realization of wisdom on the true level, and Tantric Buddhism claims to provide an accelerated path toward that goal. Tantra techniques are synonymous with Vajrayana practices or the Vajrayana. Sometimes called "the diamond vehicle," the

Vajrayana constitutes a dominant part of Buddhism in Tibet and Shingon Buddhism in Japan.

Today Buddhism is a thing of the past in its country of origin, and the most complete Mahayana canon exists in classical Chinese. Unlike the Pali canon, which was compiled by the Theravadins, the Mahayana scriptures were written in Sanskrit and, in some cases, classical Chinese. Because many of the Sanskrit texts are lost, they have to be recovered from the Chinese translations that have survived the vicissitudes of time.

Reality, Time, and Temporality

The Buddhist cosmology identifies samsara with the relative order of reality and nirvana with the absolute order of reality. The former is conditioned, whereas the latter is unconditioned. *The* Nirvana Sutra says, "Buddha (*Tathagāta*) is permanent with no change at all." In contrast, time is "becoming," namely, change. To stress the ever-changing nature of time, Mahayana Buddhism sees time as a flow of events and a process.

A process has an "arising," a "duration," and a "dissolution." Nothing lasts forever, but the process is due to happen all over again. In line with this view, emphasis is on time as "becoming" rather than "being." Moreover, time is cyclic in the sense that the process of birth and rebirth recurs endlessly. It sends one into the misery of an afterlife based on one's karma that is carried over from this life. The doctrine of karma dictates that whatever one does has an impact on one's reincarnation. The uninitiated, however, are ignorant of the karmic effects of time. Rather than redeeming themselves from false desire and attachment, they choose to seek moments of pleasure and live in momentariness, thus the cyclic return of samsara.

The absolute reality is timeless. Not only is it immutable and eternal, but, according to the Lotus Sutra, it comes from nowhere and goes to nowhere. Time as becoming belongs in the realm of samsara. Nonetheless, that time is ever-changing is unchanged, so there is room for an enlightened mental process that parallels the perception of temporality in its true nature.

The Mahayana sense of temporality is based on an awareness of relational organization, not the ontological past, present, and future. A case in point is the factors and conditions that shape the process when salt is poured into water. At the moment of pouring, saline water is a thing of the future but has its making in the present. Once the ingredient is being dissolved, both salt and water are becoming things of the past. What happens is an interlocking of stages ("arising," "duration," and "dissolution"). As the past and future are very much in the present, the tripartite ontology of time is of little use. Attention to relational organization will reveal how a coming-together of causative factors and conditions leads to their formation of a special relationship and interaction to produce a result. An understanding of the relational organization of processes is possible in the realms of samsara and nirvana.

Buddhism, Theravada

Theravada Buddhism is a school that grew out of the teachings attributed to Siddhartha Gautama (563–483 BCE) and was recorded in the Pali language around the 1st century BCE. Literally meaning the "school of the elders," Theravada Buddhism represents the old orthodoxy of Buddhism. At its core is a set of doctrines that are common to all Buddhist sects and designed to promote the deliverance of individual humans from the suffering of life. Featuring a monastic life of austerity, Theravada Buddhism is followed primarily in Sri Lanka, Burma, Thailand, Cambodia, Laos, and parts of Vietnam, Malaysia, China, and Bangladesh. Despite its asocial nature, this school has a sense of historical time, and it developed a conceptualization of temporality that is dualistic, pertaining to the phenomenal and ultimate reality respectively.

Theravada Buddhism is sometimes referred to as *Hinayana Buddhism*, a term that is no longer used in informed circles. Its problem lies in the derogatory meaning that *hina* assumes in Sanskrit texts when it appears in contrast to *good* or in juxtaposition with terms such as *ignoble* and *harmful*. Rather than denoting "lesser vehicle," *Hinayana* can be taken to mean "vehicle of despicable quality." Consequently the World Federation of Buddhists recommends that it be avoided.

Gautama, the Buddha

Siddhartha Gautama was born to King Suddhodana Gautama and Queen Maya in Lumbini (now in Nepal). The young prince applied himself assiduously to the ascetic practices of Hinduism and Jainism. In addition, he sought out some of the most famous spiritual and philosophical teachers of his time. Years later, however, it occurred to him that neither the traditional religions and philosophies nor asceticism had brought him closer to true wisdom.

The king was determined to do everything within his power to stop the prince from choosing a spiritual life over the throne. However, at the age of 29, Siddhartha renounced the world of luxury and embarked on a long journey to seek the true nature of reality through the eyes of a wanderer. On the night of his 35th birthday, he entered into the deepest of meditations under a tree in Gaya, India, and was able to attain enlightenment after persevering through the most excruciating temptations. It marked the birth of Gautama, the Buddha (Enlightened One). He spent the next 45 years traveling from place to place to preach and spread the doctrines of Buddhism. Parallel to his preaching was the way of life he led: Walking barefooted, he held an alms-bowl in one hand and a walking stick in the other, with his head shaven clean of hair and his body wrapped in a plain robe of saffron. The Buddha died at the age of 80 in Kusinara, India. Virtuous and wise, the Gautama Buddha was also known as *Sakyamuni* or *Shakyamuni* (sage of the Sakyas kingdom).

Fundamental Teachings of Buddhism

The essence of the Buddhist teachings is stated in the Four Noble Truths. This doctrine runs as follows: Human existence is suffering (*dukkha*); suffering is caused by desire and attachment (*trishna*); the cessation of suffering comes with the removal of desire and attachment (*nirvana*); and the way to the cessation of suffering is the Noble Eightfold Path, which serves to bring about the extinction of desire and attachment.

To pursue the Noble Eightfold Path is to cultivate right understanding, right thought, right speech, right action, right livelihood, right effort, right mindfulness, and right concentration. This model of spiritual cultivation has three prongs: *Sali,* or physical activities (right speech, action, livelihood); *Samadhi,* or mental cultivation (right effort, mindfulness, and concentration); and *Panna,* or development of wisdom (right understanding and thought). Together they define the Buddhist ideal of a virtuous and moral life.

Buddhism stresses the impermanence of life. According the Buddhist philosophy, what we call a "being" is no more than a combination of the Five Aggregates of Attachment: matter, sensations, perceptions, mental formations, and consciousness. Each of these aggregates is an ever-changing force that arises out of conditions and operates in a conditioned state. There is no unchanging substance in a "being" or "self" or "soul," all of which are false ideas. As our physical and mental being has no immutable and independent existence, life is transitory and impermanent. Moreover, Buddhism sees a parallel between impermanence and suffering, as was stated by the Gautama Buddha himself: "What is impermanent is *dukkha.*"

A major form of suffering is *samsara* (circle of continuity), in which living beings are trapped in a continual cycle of birth and rebirth. The momentum to rebirth is shaped by the volitional activities of one's previous life, which have karmic effects. The theory of karma is a theory of cause and effect. Moral intention and behavior yield good karma that impacts one's next life positively, whereas immoral intention and behavior yield bad karma that affects one's next life negatively, including condemnation to the misery of a nonhuman creature. The main spiritual goal of Buddhism, however, is to seek total liberation from samsara, the endless cycle of birth and rebirth. To this end, one must awaken to the true nature of reality and transcend false desire and attachment.

The Pali Canon

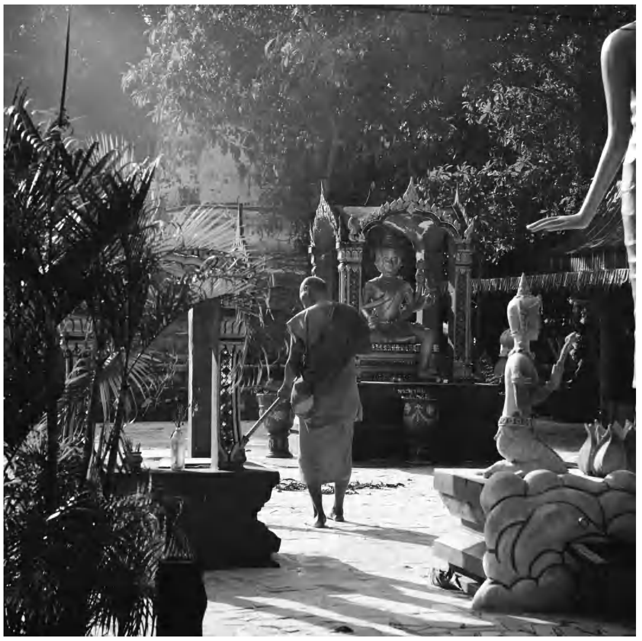
The earliest scriptures of Buddhism are represented by the Tripitaka (three baskets of law). Written in Pali and compiled from an oral tradition, the Tripitaka did not take shape until some 400 years after the death of Siddhartha Gautama. There were conflicting memories with regard to what Gautama Buddha had actually said and meant. As it is, the text tends to reflect the memories and views of those who were close to the Buddha, such as his prominent disciples Kayshapa and Ananda. As the most important of all Buddhist scriptures, the Pripitaka comprises three books: Rules of Conduct (*Vinaya Pitaka*), Discourse (*Sutta Pitaka*), and Analysis of Doctrine (*Abhidhamma*).

The various sects of early Buddhism were founded on a relatively literary interpretation of the Pali canonical tradition. One of these sects was named *Theravada* and is held to be representative of the orthodoxy of early Buddhism. The Theravadins were found mostly in Sri Lanka rather than India by the time Buddhism was bifurcated into two major schools of thought: old and new. The new one was named *Mahayana*, whereas the old one came to be known as *Theravada* or *Hinayana*, a coinage attributed to the Mahayanists.

The Theravada Tradition

Early Buddhism, as represented by the Theravada sect, arose in rejection of the Brahmanical tradition, vedic ritual, and caste theology of Hinduism. It maintained that all human beings were equal but vulnerable to the suffering of life. Only in Buddhism could one find an ultimate solution to such suffering and misery. In prescribing this "ultimate solution," Theravada Buddhism stresses the importance of following the original teachings of the Pali canon. More specifically, it professes devotion to taking refuge in the Buddha, the Dharma, and the Sangha (order of monks)—the Three Jewels of Buddhism.

The Theravada school of thought held that the Buddha was a human being, and that he owed his attainment of nirvana to human endeavors and intelligence rather than inspiration from any external power or god. There is a noticeable absence of metaphysical statements about the Buddha in Theravada Buddhism. For its followers, the Buddha is a teacher par excellence, who sees reality in its true form and achieves the perfect wisdom. To take refuge in the Buddha is to follow the teachings and example he left behind.



A Buddhist monk sweeps around a temple (Wat Pranang Sang) in Thailand. Buddhism stresses the impermanence of life. According to the Buddhist philosophy, what we call a "being" is no more than a combination of the Five Aggregates of Attachment: matter, sensations, perceptions, mental formations, and consciousness.

The teachings expounded by the Buddha are known as the Dharma. It sheds light on the true nature of reality and provides impersonal laws in place of God. Ignorance is the root cause of all evil, and it is to be overcome by taking refuge in the Dharma. Devotion to the Dharma is devotion to the Buddha Gautama. It means rigorous adherence to his original teachings and adamant opposition to reinterpreting them liberally.

Following the Buddha's example, Theravada practitioners see the attainment of nirvana as their immediate goal. It is their final exit from the world. But such liberation is entirely personal, and no assistance from outside is possible. Enlightenment can be achieved only through one's own effort—by leading a monastic life of austerity and taking refuge in the Sangha in addition to the Buddha and the Dharma. Literally meaning “group” or “community,” the Sangha serves to awaken human intelligence and initiate one into the quest of individual enlightenment.

Such is the attitude of Theravada Buddhism toward the Buddha, the Dharma, and the Sangha. Just as noteworthy is its interpretation of dukkha. While the Buddhist philosophy stresses the impermanence of entity (i.e., being), it emphasizes the persistence of processes (i.e., samsara). In the Theravada tradition, dukkha is very real, whether it denotes “impermanence” or “change” or “suffering.” As a process, it contrasts sharply with entities such as desire and attachment, which are illusory.

Historical Awareness and Time Concept

Legend has it that the historical Gautama started his spiritual journey after he had seen an old man, a sick man, a dead man, and a recluse. These four signs turned his mind away from the world into the wilderness. If this legend were any indicator, then the goal of Theravada Buddhism was to seek liberation from the grip of change and becoming by way of enlightenment. It appeared asocial and ahistorical of Theravada Buddhism to urge a complete severance from the phenomenal world in quest of enlightenment. Nonetheless, this school developed a historical awareness in order to relate the biography of Gautama, chronicle the events in his life, and discuss the intellectual heritage of its saints. The concept of historical time is necessary for learning hagiologies and convincing the faithful. Temporality, however, was perceived differently in relation to the two different orders of reality: relative and ultimate.

Theravada Buddhism does not subscribe to the theory of *sunyata,* or total emptiness of reality. Although time is only a successive flow of components and aggregates, it is not unreal. In the relative or phenomenal order of reality, the operations of time are characterized by momentariness and cyclicity. Human existence is like a fleeting bubble. Between birth and death, sentient beings live in moments, because nothing is free from change, and its long-lasting duration is merely illusory. Burdened with desires and wants, human existence is condemned to an endless cycle of birth and rebirth, which is the doing of karma.

Cyclic time, in turn, is the manifestation of *dhamantā,* which is the law of the universe. Literally “rule” or “norm,” dhamantā dictates an iron chain of causality. There is, however, more than simple recurrence in the workings of dhamantā, for the causation of recurrence is multilateral. It involves a concatenation of several causative factors activated together situationally. As a result, each living being is unique and different from what it was in a previous life. Theravada Buddhism denies that any sentient being exists or perishes eternally in the phenomenal world.

Cyclic time is to be measured in terms of cyclic becoming. Although there is no single cause in becoming, karmic effects are decisive. This makes sentient beings the arbitrator of their own becoming. By will and volition, one can choose to accumulate good karma in order to eventually rise above cyclic becoming.

In the ultimate or transcendental order of reality, historical time is irrelevant; so are the momentariness and cyclicity of time. There is no past or future. What is left is an eternal present, in which wisdom of eternal laws and rules prevails. Time is cumulative and no longer measured in terms of cyclic becoming. It is divided into great units called the *kappas* (eons), each represented by the appearance of a Buddha. Notably, the Buddha Gautama is said to have refused to speculate whether the world is eternal or not, probably because it contains more than one order of existence: animal, human, and divine.

Buddhism, Zen

Zen is a form of Japanese Buddhism that developed from the Chinese Mahayana school of

Buddhism known as Chan. The core of Zen practice involves using seated meditation to achieve enlightenment. In Zen, one sees and accepts the world just as it is and is aware of the impermanence of everything; one should fully focus on each moment, not what has been or what will be. The medieval Zen master Dogen developed a complex view of the stationary aspects of time to account for the apparently stable sequential order of the passage of moments. His theory substantiated his claim that the Buddhist ideal could be realized only through continuous practice. By focusing on and living fully in the moment, an individual can achieve *satori,* the intuitive understanding of the underlying unity of all existence.

History

Zen first emerged as a distinct school of Buddhism in China in the 7th century CE. From China, Zen spread southward to Vietnam and eastward to Korea and Japan by the 13th century. In the late 19th and early 20th centuries, Zen also established a distinct presence in North America and Europe. The two main sects of Zen were brought to Japan by Japanese monks who studied in China. The Buddhist monk Eisai (1141–1215) introduced Rinzai Zen in 1191, and the Buddhist monk Dogen (1200–1253) introduced Soto Zen in 1227. Both sects still flourish today, along with some smaller movements.

Because of a worldview that lives in the moment, Zen has had a strong influence on Far Eastern arts and crafts. Haiku poetry, ceremonial tea drinking, painting, calligraphy, gardening, and architecture were all influenced by the practice of Zen. Mountains, birds, plants, rocks, and other natural subjects were ideally suited to a point of view that reflects immediate direct vision (like a window) rather than an interpretation of a subject (like a mirror).

It is difficult to trace when the Western world became aware of Zen, but a Japanese Zen monk named Soyen Shaku did attend the World Parliament of Religions in Chicago in 1893. In Europe, Expressionist and Dada movements in the art world of the early 20th century shared many themes with Zen. The British-American philosopher Alan Watts took a close interest in Zen Buddhism and lectured on it extensively through the 1950s. Jack Kerouac published a book in 1959 titled *The Dharma Bums,* illustrating how a fascination with Buddhism, and Zen in particular, was being absorbed into bohemian lifestyles, especially along the western coast of the United States. In the decades since that time, schools in the mainstream forms of Zen have been established around the world.

Zen Practice

In other forms of Buddhism, an individual achieves enlightenment through a combination of training, meditation, and the study of religious texts. Zen, in contrast, focuses solely on seated meditation (*zazen*) as the means of gaining enlightenment. Meditation practices differ in Zen schools. Soto Zen teaches *shikantaza,* which is strictly sitting in a state of alert attention completely free of thought. In practicing shikantaza over time, insight is gradually achieved. Rinzai Zen uses koans during meditation to achieve enlightenment in a sudden flash. Koans are riddles with no solutions or paradoxical anecdotes or questions that demonstrate the uselessness of logical reasoning, such as "What is the sound of one hand clapping?" Zen tradition emphasizes direct communication over the study of scripture, so the Zen teacher plays an important role. The Zen teacher is a person ordained in any Zen school to teach the Dharma (teachings of the Buddha) and to guide students in meditation. Zen is a way of life that has paradoxically produced a large body of literature.

Time in Zen Buddhism

There have been many writings on time in the history of Buddhism, but Dogen of the Soto Zen school has gone farther than most in attempting to organize the experience of time into a system of thought. Dogen wrote an essay titled "Uji" in the year 1240 when he was 41 years old. *Uji* is the philosophy of time (U = existence, and ji = time). Basically, he wrote that time is existence and all existence is time. The word *Uji* refers to a specific time taken from an infinite continuity. Dogen says: "Uji arises, free from desire. It materializes now here, now there. Even the king of heaven and his retainers are not separated from uji manifested. Other beings on land and in water also arise from uji. All things in darkness and light arise from uji. These manifestations become the time process. Without time, nothing can arise." Dogen's view is that all existences are linked and ultimately become time. From one point of view, each moment of time is isolated and disconnected from the past and future. From another point of view, time manifests new time each moment, connecting the past and future. Dogen speaks both to the continuity and discontinuity of time.

Zen Buddhism emphasizes the transience of the phenomenal world. A great emphasis is placed on concrete events being intuitively understood through contemplation rather than the study of theory or scripture. Through meditation, one hopefully becomes enlightened, or achieves Buddhahood. Buddhahood is time. Dogen states that those who want to know Buddhahood may know it by knowing time as it is revealed to us. Because we are already immersed in time, Buddhahood is not something to achieve in the future but something that "is" now, and we just have to realize it.

C

Caesar, Gaius Julius (100–44 BCE)

Gaius Julius Caesar was a brilliant Roman general and statesmen whose actions truly changed history and altered its course. Had he never existed, the world today might be a very different one. He was born a patrician and claimed descent from the Trojan hero Aeneas and ultimately the goddess Venus—a distinguished, if fanciful, lineage that stretched back thousands of years.

Caesar became the head of his family at age 16, following the death of his father. He joined the army and served with distinction until his return to Rome in 78 BCE. He then pursued a legal career and thrived as an orator. He was on his way to Rhodes in 75 BCE to study under a respected master of oratory when his ship was seized by Silician pirates and he himself was captured and held for ransom. After it was paid he hunted down the pirates and had them all executed, which he had promised them while he was still in captivity.

Upon Caesar's return to Rome a number of promotions followed. He was elected first tribune, then quaestor, then successfully ran for the office of pontifex maximus (high priest of the state religion) in 63 BCE; this office permitted him the right to reform the Roman calendar to what we call the Julian calendar, a variation of which (the Gregorian) we now use today. Caesar thus influenced the way the Western world conceives the passage of time. Caesar was then appointed governor of Outer Iberia (in Spain), where he led troops to several victories. He returned to Rome and was elected consul (together with two other statesmen) in 59 BCE. He then formed a political alliance known as the First Triumvirate with the wealthy statesmen and generals Crassus and Pompey. Caesar was then appointed governor of northern Italy, the western Balkans, and then southern France. He proceeded to conquer and annex additional provinces of Gaul (France) that had previously been beyond Rome's scope. In 55 and 54 BCE he led two campaigns into Britain with reasonable success, and then returned to Gaul, where he continued to secure the unstable regions for the next few years. Caesar had thus succeeded in Romanizing a greater portion of Europe than had ever been done before.

In the meantime, Caesar's former ally, Pompey, who was head of the Senate (as Crassus had been killed in battle), ordered Caesar to return to Rome, as his proconsul term had expired. Caesar knew that he would have to enter the city as a private citizen and without his army, leaving him open to certain legal prosecution for his actions as proconsul. He decided to ignore this and effectively declared war on his former friend (and son-in-law, as Pompey had been married to Caesar's daughter until her untimely death). Caesar declared his intentions when he crossed the river Rubicon in 49 BCE. Civil war erupted, and Caesar spent around a year defeating his rival Pompey's legions across Europe, finally pursuing him as far as Alexandria in Egypt, where Pompey was murdered by the Egyptian court.

Caesar in the meantime was appointed dictator of Rome, and began to interfere in a civil war in Egypt between Ptolemy XIII and his sister Cleopatra VII. He began a love affair with the queen and defeated her brother in battle. He then traveled to the Near East for additional campaigns, and to Africa to defeat the last of Pompey's supporters. He returned to Rome in 45 BCE and named his grand-nephew Gaius Octavius (the future Emperor Augustus) his heir. The Senate named Caesar Dictator Perpetuus (dictator for life), and many feared that he would become king; this led to an assassination plot led by Caesar's friend, Marcus Junius Brutus and his brother-in-law, Cassius. On March 15 (the Ides of March) in 44 BCE the assassins struck, stabbing Caesar 23 times on his way to a Senate meeting. Unfortunately, what the assassins had tried to prevent was exactly what they precipitated: the end of the Republic and the beginning of a hereditary monarchy. Mark Antony and Octavian joined forces with Caesar's cavalry commander Lepidus (to form the Second Triumvirate) and waged war against the armies of Brutus and Cassius, defeating them at Philippi in Greece. Mark Antony and Octavian then came to blows, with Mark Antony forming a legal and amorous alliance with Cleopatra. Antony and Cleopatra were defeated and committed suicide, and Lepidus went into exile, leaving Octavian free to be declared the first Roman Emperor.

The Roman Empire, which Caesar had effectively created, continued to dominate the Western world for centuries; its influence is still felt in modern language, culture, science, technology, and religion. We can only speculate as to what our world might have become had Caesar himself never existed, or if his life had taken an alternate course.

Calendar, Astronomical

A human invention, the calendar was created to measure and record the passage of time. For our early ancestors, survival depended on observing changes in the sky. The moon's changing shape and position were easy to see, which is why most ancient calendars used the synodic period or lunation, the interval between successive full moons, as an intermediate measure between the solar day and the solar year. Herein lies one of the primary difficulties with calendar design.

Lunar months vary between 29 and 30 days, and the number of lunations fluctuates between 12 and 13, resulting in a calendar year of varying lengths. When to begin a new year was another concern. The oldest calendar, first used around 4236 BCE, is that of predynastic Egypt. The beginning of this 365-day calendar, divided into 12 months of 30 days and 5 extra days, was marked by the rising of the brightest star. Because the tropical year, the interval between successive equinoxes, is slightly longer, at approximately 365.25 days, this calendar gradually drifted into error.

The earliest Roman calendar, 735 BCE, began in March. Composed of 6 months of 30 days and 4 of 31, it resulted in a 304-day year. The remaining days, which fell in winter, were uncounted until Numa Pompilius, the second king of Rome, hoping to collect more taxes, added 2 months (Januarius and Febrarius), thereby lengthening the year to 354 days. With their names based on Latin numerals, the seventh, eighth, ninth, and tenth months became our September, October, November, and December.

Following the advice of the astronomer Sosigenes, Julius Caesar abandoned the republican calendar and began reforming the old Egyptian one, lengthening the year to 365.25 days, and arranging the months according to the solar year. Their lengths were either 30 or 31 days; February had 28, with an additional day inserted every 4 years. July, named after Julius Caesar, had 31 days. Augustus Caesar, unhappy that August had only 30, ordered that it be changed to 31, which would have meant three consecutive 31-day months. To avoid this, the rest of the months were rearranged, hence the rhyme, "Thirty days hath September. . . ." In order to realign the calendar with the seasons, Julius Caesar ruled that 46 BCE, known at the time as "the year of confusion," would have 445 days.

Although used widely for more than 1,500 years, the Julian calendar was about 11 minutes and 14 seconds too long, the tropical year being 365.24219879 days long, not 365.25. By 1580, the resurrection of Christ, tied as it is to the spring equinox, fell on March 11, which was 10 days too early. Pope Gregory XIII ordered that October 5, 1582, became October 15, 1582. He further decreed that February would have one extra day in years divisible by 400, resulting in an average year of 365.2425 days. By modern day calculations the Gregorian calendar, in use today, is about 26 seconds too long. Alternate calendaring systems continue to be proposed and their merits examined and debated. However accurate, none are really viable in the long run. As noted in 1878 by the American astronomer Simon Newcomb, the years are slowly decreasing by about a half a second each century. From time to time, future generations will find adjustments are necessary.

Calendar, Aztec

The Aztec calendar is a timekeeping system that was used in the Mesoamerican Aztec culture and by other peoples of the pre-Columbian era in Central America. The calendar is sometimes referred to as the Sun Stone, due to the imagery depicted on the carved basalt. The original name that was used historically by the Aztecs, however, is *cuauhxicalli* ("eagle bowl"). The original Aztec calendar was carved into a slab of basalt weighing more than 22 metric tons, and was found in 1790 in the main square in Mexico City. The carving is currently housed in the National Museum of Anthropology and History in Chapultepec Park in Mexico City.

The Aztec calendar was a complex counting of days and years that involved two cycles: one consisting of 365 days based on the solar year, and the other consisting of 260 days, which may be based upon the Aztecs' obsession with numerology. Together, when all the combinations of the cycles were exhausted and formed a 52-year "century," the combined cycle culminated with an elaborate ritual by the Aztecs known as the New Fire Ceremony, which helped stave off the end of the world.

The 365-day count (*xiuhpohualli* in Nahuatl) consisted of 18 months divided into 20-day periods, with the remaining 5 days known as *Nemontemi*. The days in *Nemontemi* were considered unlucky, and were filled by fasting, in the belief that nothing good would come by attempting anything productive. Whether the Aztecs placed these 5 days at the end of the calendar year, throughout the year, or at the beginning is unknown, but it is certain they were there.

Each month in the *xiuhpohualli* had a name and corresponded to a deity in Aztec mythology. Because human sacrifice and ritualized warfare were a religious necessity in Aztec culture, many of the months are characterized by the types of human sacrifices and actions performed. These sacrifices would be performed on the Sun Stone itself. For example, in the month of *Hueytozoztli* (great vigil), the patron deities Centeotl and Chicomecacoatl were appeased with virgin sacrifices. At this time of the year occurred the blessing of the maize, with which both Chicomecacoatl and Centeotl were associated.

The 260-day count (*tonalpohualli*) consisted of 20 periods of 13 days (*trecenas*), each given a particular sign. These included, in order: caiman, wind, house, lizard, serpent, death's head, deer, rabbit, water, dog, monkey, grass, reed, jaguar, eagle, vulture, motion, flint knife, rain, and flower. The periods would begin sequentially, assigning a number to each symbol (i.e., 1 caiman, 2 wind, etc.), until after the 13th day, when the beginning of a new trecena would be marked 1, with whatever symbol with which it was associated.

The *tonalpohualli* is very important for the Aztec mindset. Not only does it serve as a divinatory tool, but it also serves as a time division for a particular deity. The Aztecs believed in an equilibrium that pervaded the cosmos. It was their duty to maintain that equilibrium. Since the deities of the Aztecs are always battling for power, everything needs to be divided up among them (including time) to prevent the disruption of the equilibrium.

In order to prevent confusion of years, the Aztecs named a new year with the symbol of the last day of the last month of the year. These 4 days could be represented only by the glyphs for reed, flint knife, house, and rabbit. Subsequently, in the 52-year century, the numbers 1–13 would apply to each of these four glyphs, depending on the year count (i.e., if the previous year was 1 reed, the next would be 2 flint knife). This would continue until the 13th year, and then a new glyph would be assigned to the year as 1 (in the above cycle it would be 1 flint knife). In order to avoid confusion with days, the date would be written with the year boxed in. An Aztec day would be represented as its *tonalpohualli* counterpart (e.g., 1 caiman) in its year (e.g., 1 reed). At the end of the 52-year cycle, the process would begin anew, with the year reverting to 1 reed.

The Aztec calendar, as it has come to be known, remains significant to many scholars interested in mathematics, anthropology, archaeology, and cosmology. It offers insights into both the religious and the agricultural life of not only the Aztecs, but also other Nahuatl peoples who used a similar system. Though it remains under a museum's custody, the calendar still keeps its count, endlessly repeating its 52-year cycle.

Calendar, Egyptian

An old Arab proverb states that "man fears time, but time fears the pyramids." Indeed the pyramids of Giza are perhaps the most famous and recognizable structures to have ever existed, built beginning around 2500 BCE. The Egyptian civilization was not only concerned with grand projects like monumental architecture, or ethereal ones dealing with deities, mummification, and the afterlife, but also with more worldly matters such as mathematics, medicine, and keeping exact track of the day, month, and year. Until the end of the Old Kingdom (ca. 2181 BCE), the Egyptians numbered years according to a biennial census. By the end of the Old Kingdom a different system was employed that was very straightforward. Since the weather is largely unchanged throughout the year, the Egyptians reckoned time according to the inundation of the Nile, the most important event in their lives. The annual inundation renewed the fertility of the land, and it was an event for which the king himself was considered responsible in his capacity as the nearest living relation to the gods.

There were three seasons of 4 months each. The first began around mid-July, when the annual inundation began, and lasted until mid-November, when it ceased. This season was named *Akhet,* meaning "inundation." Following this was *Peret,* meaning "rowing," which lasted until mid-March, and finally *Shomu,* meaning "harvest," until mid-July and the next inundation. Each of the seasons was divided into 4 months, which also had names (rarely used), each with 30 days. Most monumental inscriptions begin with the date. This is written according to a standard formula. First comes the word for year (*hezbet* or *renpet-hezbet*), followed by a number. This signified in what year of the current king's reign it was written. Then comes the sign for month, followed by a number, then the season, then the sign for day followed by a number. Finally, a phrase that goes something like "under (the reign) of the King of Upper and Lower Egypt . . ." ends the formula.

A variation occurs when the month is the first of the four within a season; this can be written using only the word for "first." Another variation commonly occurs when it was the last (30th) day of the month, in which case the word for "last" replaced the sign for day and the following number 30. The Egyptian calendar also took into account the remaining 5 days left over after the 360 counted within the system, by adding 5 extra days after the end of the year (the last day of the harvest season). These are known as *epagomenal* (added) days, each representing the birthday of a different god: Osiris, Horus, Seth, Isis, and Nephthys. The first day of the year was called the "Birth of Re." As the Egyptians had no leap years, their calendar lost a day every 4 years.

The Coptic calendar, still in use today, is based on the ancient Egyptian one. Ptolemy III attempted to introduce a 6th epagomenal day every 4 years to avoid the loss, but the idea met opposition from the priests. This reformation was not put into use until Roman Emperor Augustus synchronized the Egyptian calendar to the Roman, Julian one in 25 BCE. This became known as the Coptic calendar, which is still in use today by the Coptic Church. Egyptian farmers still think in terms of the harvest season for obvious reasons.

Translating Egyptian dates into our calendar system is problematic for Egyptologists. We do not know how many years every king ruled, and sometimes there were two kings at once. However, scholars are helped a little by Egyptian astronomical calculations, most importantly the annual rising of Sirius at the start of the inundation season. Given the loss of 1 day every 4 years, if the rising of Sirius is recorded (only three such examples exist) the year (BCE) can be calculated to within a 4-year time frame, for example 1317–1320 BCE. Otherwise, there are different systems of establishing a margin of error; from the Middle Kingdom (c. 2050–1800 BCE) it is about 30 years, and accuracy increases with the passing centuries. By the 6th century BCE, the margin of error virtually vanishes.

The Egyptians also divided their days into 24 hours, with the day beginning at sunrise (about 6 a.m.). The day and night were composed of 12 hours each. In astronomical texts each hour has a name, but in ordinary accounts they are simply numbered.

The Egyptians regarded time as not only linear, as we do nowadays, but as cyclical as well. Each day, week, month, year, and reign was regarded as newly created, hence the reason they calculated years according to the current king. Egyptian has two words for *eternity: djet* and *neheh. Djet* represents linear time, which refers to an unchanging flow of existence. *Neheh* signifies cyclical time, viewed daily by the rising and setting of the sun, the seasons, the inundation of the Nile, birth, death, and the reign of a new king. In other words, the Egyptians saw themselves as passing through a single time continuum, albeit in a cyclical fashion. A typical Egyptian formula goes *djet neheh,* usually translated as "for ever and ever" or "for ever and eternity," used, for example, when wishing eternal life upon a king. The Egyptian calendar thus not only calculates the day, month, and year of a given event, but also summarizes a great deal about the Egyptian cosmology and how they viewed time itself—the very time that man fears, the time that fears the pyramids.

Calendar, Ethiopian

Ethiopia is located in the Horn of Africa, neighboring Sudan, Kenya, Somalia, and Djibouti. It is one of the oldest countries of the world, with diverse ethnicity, languages, cultures, religions, and traditions. Ethiopia was under the rule of monarchs for decades, if not centuries; from 1974 to 1991 it was under military rule. Beginning in

1991, Ethiopia instituted a federal system of government with some forms of democratization. Unlike most nations in Africa, Ethiopia maintained its independence from colonialism. This nation has its own calendar, and it recently celebrated the end of the second millennium on September 12, 2007. This date marks New Year's Day 2000 on the Ethiopian calendar.

The Ethiopian calendar divides the year into 13 months with 12 months of 30 days and one month of 5 or 6 days (see Table 1). The 13th month is an intercalary month called *Paguemain;* it has 5 days that become 6 days every 4 leap years on a leap year. Ethiopia is known for having a 13-month calendar; it has become part of a slogan to attract tourists: Ethiopia, 13 months of sunshine. The table, adapted from Aberra Molla, presents the names of the months in Amharic and English, and their starting dates in the Gregorian calendar, including the variations of the starting dates during leap years.

The Ethiopian New Year begins on September 11 of the Gregorian calendar and on September 12 in leap years. The New Year falls in September, right after the end of the rainy season. After 3 months of clouds, fog, cold, and rain, September brings a joyous season of sunshine and blossoming flowers. It also brings the start of the school year for children, with the big feast of the New Year holiday called *Enkutatash*—the mark of the beginning of the year. Another holiday, *Meskel,* follows a fortnight later and celebrates the discovery of the True Cross (*Meskel*). September brings the beauty of greenery and flowers, relief from the darkness of the rainy months, and a fresh start for another year.

The year 2007/2008 in the Gregorian calendar is the year 2000 in the Ethiopian calendar. It marks the end of the second millennium and the beginning of the third millennium. The Ethiopian calendar falls behind the Gregorian calendar by 7 or 8 years. The 7 years' difference ranges from September to December, and it becomes 8 years beginning from January up to August. For example, the 7-year difference between the two calendars in the month of December becomes a difference of 8 years in January after the New Year of the Gregorian calendar, whereas it comes back to 7 years in September again, right after the Ethiopian New Year. This is, as Aberra Molla notes, because of the difference between the Ethiopian Orthodox Church and the Roman Catholic Church regarding the determination of the date of the creation of the world. According to the Ethiopian Orthodox Church, the world was created 5,500 years before the birth of Jesus Christ. Accordingly, it is now 2,000 years since Jesus Christ was born while it is 7,500 years since the creation of the world.

The Ethiopian calendar is similar to the Coptic calendar. According to Molla, it has its origin in the Coptic Church of Egypt. The difference between the Ethiopian and Coptic calendars is the saints' days and their observance time. According to the Ethiopian calendar, Ethiopian Christmas and

Table 1 The Ethiopian calendar versus the Gregorian calendar

Epiphany are celebrated on January 7 and January 19, respectively.

The Ethiopian calendar has 4-year cycles. The years are named after the evangelists Matthew, Luke, Mark, and John. The year is divided into the four seasons of autumn, winter, spring, and summer. The week in the Ethiopic calendar has seven days with 24 hours in each day; 12 hours of day and 12 hours of night. The days are *Ehud* (Sunday), *Segno* (Monday), *Maksegno* (Tuesday), *Rebu* (Wednesday), *Hamus* (Thursday), *Arb* (Friday), and *Kidame* (Saturday).

According to the Ethiopic calendar, the day starts with the rising of the sun in the morning and ends at sunset, followed by the beginning of the night. In the morning, the day starts with the first hour as 1 o'clock (7 a.m. local time) and the day ends at 12 o'clock (6 p.m. local time). The night starts at 1 o'clock (7 p.m. local time) and ends at 12 o'clock at sunrise (6 a.m. local time). The Ethiopic calendar divides the 24 hour day into even equal hours of 12 hours of daytime and 12 hours of nighttime. The hour-count in the Ethiopian calendar indicates the number of hours since the beginning of daytime or nighttime. So, 5 o'clock (11 a.m. local time) is the fifth hour of daytime, whereas 5 o'clock at night (11 p.m.) is the fifth hour since the onset of nighttime. Ethiopia is located at 45 degrees longitude, thus midnight in London is 3 a.m. in Ethiopia or the ninth hour of nighttime. Traditionally, people have understood the day to start in the morning and end at the sunset, with the next day starting with sunrise. The 12 hours in between are nighttime. It appears people conceive of one day as being those 12 hours of daylight. This, however, is not the case with the official version of the day, which is in fact 24 hours of both daytime and nighttime taken together.

Government offices and businesses use both the Ethiopian and Gregorian calendars side by side. Some institutions, however, prefer the Gregorian to the Ethiopian calendar. The use of the two calendars simultaneously sometimes causes confusion and inconvenience. Confusing the dates, year, and hours of the day of one calendar with the other can have serious consequences. For instance, in higher education institutions where the Gregorian calendar is used for academic schedules, a freshman student may confuse the time for an 8 a.m. examination to mean 8 o'clock (2 p.m. local time) and miss the morning examination while waiting for 8 o'clock (2 p.m.) after lunchtime—a very serious problem for the poor freshman student who could receive a failing grade and dismissal from school. The Gregorian calendar is also used for Ethiopia's interactions with the outside world in commerce and other sectors. The growing trend toward global interdependence seems to mandate wider usage of the Gregorian calendar in Ethiopia. Ethiopia is proud of its traditional calendar and is determined to keep it, while it also attempts to communicate with the rest of the world by embracing the Western calendar.

The 2000 Ethiopian Millennium, which was launched officially on September 12, 2007, was a yearlong celebration. It was recognized by the United Nations and the African Union. The event was attended by signatories and heads of state, with speeches and music performances and a series of special events. Controversy surrounded the celebration, however. Some critics of the government oppose extravaganzas while millions of Ethiopians are still suffering from poverty. The government and its supporters, however, argued that the millennium celebration could be a renaissance to mobilize the people and generate commitment and momentum to eradicate poverty and attain development in Ethiopia.

Calendar, Gregorian

The Gregorian calendar is the world's most widely used calendar today. A calendar is a system of organizing units of time and of reckoning time in advance in order to satisfy the needs of a specific society. It serves practical purposes, providing the basis for recording and calculating dates over extended periods, and for planning and maintaining cycles of civil and religious events. Therefore, a calendar can provide a sense of understanding and controlling time, linking humankind and the cosmos. Because the principles on which a calendar is based are shared by the whole society that adopts it, it can be considered a specific form of social contract, a source of social order and cultural identity.

A calendar is constructed on astronomical cycles: The principal ones are the year (which is based on the revolution of the earth around the sun), the month (which is based on the revolution of the moon around the earth), and the day (which is based on the rotation of the earth on its axis). Yet these cycles do not synchronize perfectly: The average periods of sun and moon do not comprise an integral number of days, nor are they exactly commensurable with each other and with the length of a day. Moreover, the irrational ratios between the fundamental time units (year, month, day) are not constant in the long run.

Therefore, calendar years and months, which have an integral number of days, cannot be synchronized exactly with respect to the astronomical year and to the cycle of lunar phases. Thus, each calendar tries to surmount the problems that arise from this incommensurability through rational approximations. For instance, the Julian calendar, which reformed the Roman calendar in 45 BCE, added a leap day to February every 4 years. In this way the average length of the calendar year became quite congruous with the length of the astronomical year.

Furthermore, each calendar fixes a specific date for beginning the year, and most calendars choose an initial epoch for counting years: a historical or legendary event is adopted as starting point of the year count in order to maintain a consistent chronology. For instance, the foundation of Rome was adopted as the initial epoch of the ancient Roman calendar, the birth of Christ as the initial epoch of the Christian calendar.

History of the Gregorian Calendar

The Gregorian calendar was developed by the end of the 16th century by the astronomers Aloysius Lilius and Christophorus Clavius in order to resolve the problems arising from the desynchronization between the Julian calendar and the astronomical data. As the mean Julian calendar was slightly too long, the astronomical equinox, which should be on March 21, had regressed to a date earlier in the month. Consequently, the calendrical equinox drifted forward, causing difficulties in determining the correct date of Easter. Indeed, in 325 the Council of Nicaea had determined to celebrate Easter on the first Sunday after the ecclesiastical full moon, which falls on or shortly after March 21, the date calculated for the vernal equinox. Over the centuries, the shifting forward of the calendrical equinox caused Easter to drift away from its correct date, losing its position in springtime and its relation with the Jewish Passover.

As early as the 13th century, scholars had realized that the method of calculating the date of Easter had to be reformed. Several attempts were made to find a solution to this question, but no consensus was reached. By the 16th century the astronomical equinox was occurring 10 days before the calendrical equinox, and astronomical full moons were occurring 4 days before ecclesiastical full moons. Therefore, in 1563, the Council of Trent established that the date of the vernal equinox had to be restored to March 21 and required the outlining of a new calendar in order to correct present errors and prevent future ones. Consequently, Pope Pius V introduced corrections to the lunar tables and the leap-year system (1568–1570).

In 1572 Pope Gregory XIII succeeded Pope Pius V; aiming to optimize the measures taken by his predecessor, he commissioned a study for a general reform of the calendar. The astronomer Aloysius Lilius designed a project for calendar restoration; it was worked out in detail by his colleague Christophorus Clavius. The project was forwarded by Pope Gregory XIII to many Christian princes and university professors, gaining consensus and agreement.

On February 24, 1582, Pope Gregory XIII published the bull *Inter gravissimas,* whose specific aim was the reform of the calendar. This reform corrected the length of the solar year, changing the previous value of 365.25 days to the new value of 365.2425 days. In order to obtain this average length, the number of leap years was corrected from 100 in 400 years to 97 in 400 years. To achieve this result, the leap year system of the Julian calendar, which fixed every 4th year as leap year, was maintained, making corrections only at the turn of centuries: The bull determined that secular years divisible by 100 but not by 400 should be considered common years. Moreover, the error accumulated over the centuries since the Council of Nicaea was corrected by the removal of 10 days: the day after October 4, 1582, was designated October 15, 1582.

The order of the months and number of days per month of the Julian calendar were confirmed: January 31 days, February 28 (in leap years 29), March 31, April 30, May 31, June 30, July 31, August 31, September 30, October 31, November 30, and December 31.

Although Pope Gregory XIII recommended in his bull to defer by 10 days the expiration of any payment, many people strongly opposed the adoption of the new calendar, fearing it could conceal a deception. Nevertheless, the Gregorian calendar was adopted in 1582 in Spain, Portugal, and their colonies, in the Polish-Lithuanian Commonwealth, and by most of Italy, France, Holland, and Zeeland; in 1700 in Denmark, Norway, and the Protestant states of Germany; in 1753 in the British Empire; in 1918 in Russia and in 1923 in Greece; and by the end of the 19th century it had been adopted in Japan and Korea and at the beginning of the 20th century in China.

The Gregorian calendar is quite accurate, accumulating an error of one day in about 3,300 years. Yet it also shows some weaknesses: Because of its unequal units, it cannot be divided into equal halves or quarters, and years and months may begin on any day of the week, making it difficult to predict the date of movable feasts.

Calendar, Islamic

The Islamic or *Hijri* calendar has 354 days in a year, divided into 12 lunar months of either 29 or 30 days (29.5 days is the time taken by the moon to complete a full circle around the earth). This calendar is used in many Islamic countries as the primary way to date events, and by all devout Muslims to track the observance of Islamic holy days. The Hijri calendar is named for the year 622 CE, when the *Hijra* occurred—the emigration of the Prophet Muhammad and some of his followers from Mecca to Medina to escape their enemies. Islamic years are labeled as AH (from the Latin phrase *anno Hegirae,* or "in the year of the Hijra"); for example, the Gregorian year 2008 CE corresponds to 1429 AH in the Islamic calendar. The Hijri calendar first came into use in 638 CE, when it was introduced in Medina by Caliph Umar ibn al-Khattab, a close companion of Muhammad.

Because the lunar year is shorter than the solar year (the time taken by the earth to complete a full circle around the sun), fixed events or celebrations in the Islamic calendar fall 11 days earlier with each successive solar year, taking 33 years to move through the entire cycle of the solar calendar. The calendar used in Arabia prior to the introduction of the Islamic calendar was a lunisolar calendar that used lunar months, but that occasionally had an additional intercalary month inserted in order to keep the calendar in alignment with the natural seasons arising from the sun's annual peregrinations. The Qur'an forbids this practice in Surah 9, verses 36–37, which state that God has ordained a fixed number of months (12) each year, and that transposing of additional months is arbitrary and is an act of Unbelief.

The first day of each Hijri year is called Ras as-Sana ("head of the year"), and the names of the 12 months of the year reflect their origins in more ancient systems for marking the solar seasons. The months are *Muharram* (the sacred month), *Safar* (the month that is void), *Rabi' al-awwal* (the first spring), *Rabi' al-than* (the second spring), *Jumada al-awwa* (the first month of dryness), *Jumada al-thani* (the second month of dryness), *Rajab* (the revered month), *Sha'aban* (the month of division), *Ramadan* (the month of great heat), *Shawwal* (the month of hunting), *Dhu al-Qi'dah* (the month of rest), and *Dhu-al-Hijjah* (the month of pilgrimage). Four of these months (*Dhu al-Qi'dah, Dhu-al-Hijjah, Muharram,* and *Rajab*) are considered sacred, because fighting was traditionally forbidden during them, and sins and good deeds carried more weight at these times than during the rest of the year. Ramadan is the month when Muslims focus on the moral and spiritual elements of life, fulfilling the fourth pillar of Islam (*sawm* or fasting) by practicing abstinence and fasting each day from sunrise until sunset, and by engaging in self-reflection and acts of kindness and generosity. During the month of Dhu-al-Hijjah, devout Muslims fulfill the fifth pillar of Islamic religious obligation (*hajj*) by making a pilgrimage to Mecca in Saudi Arabia. Two major festivals are universally celebrated by all Muslims; these are *Id al-Adha* (the Festival of Sacrifice), and *Id al-Fatir* (the Festival of Breaking of the Fast). Id al-Adha occurs on the tenth day of the month of Dhu-al-Hijjah, signaling the official end of the hajj pilgrimage with communal prayer and the sacrifice of animals. Id al-Fatir is celebrated for 3 days at the end of Ramadan; it marks the end of a full month of fasting with acts that honor God's benevolence, including feasting, gift-giving, visiting friends and family, and helping the poor.

The Islamic weekly calendar is derived from the Jewish Abrahamic tradition, with each day beginning at sunset. The days of the week are called *yaum al-ahad* (meaning "first day," and corresponding to Sunday in the Christian calendar), *yaum al-ithnayn* (second day), *yaum ath-thulaathaa'* (third day), *yaum al-arbia'aa'* (fourth day), *yaum al-khamis* (fifth day), *yaum-al-jumu'a* (gathering day), and *yaum as-sabt* (Sabbath day). At noon on *yaum-al-jumu'a* (Friday), Muslims gather at a mosque or *masjid* for worship.

Islamic months begin at sunset of the day when the *hilāl* or lunar crescent is first visually sighted. Although this method is still followed in India, Pakistan, and Jordan, visual observations can be inaccurate because of atmospheric conditions or because of the differences in the timing of moonrise across international time zones. Arithmetical astronomical calculations are therefore often used instead to set the calendar and to designate important holy days. In Saudi Arabia and most of the Gulf states, however, the *Umm al-Qura* calendar (based on precise observations of the new crescent moon in Riyadh) is used, causing holy days to be celebrated in that country several days in advance of other Muslim countries. To solve this problem, several prominent Islamic governance councils have since 1419 AH (1998–1999 CE) adopted an updated methodology for calculating the Umm al-Qura calendar that results in a uniform standard for determining Islamic days of observance. Another variant of the Islamic calendar, developed by early Muslim astronomers, is the *Fatamid* or tabular Islamic calendar, which uses arithmetic rules to set out a predictable 30-year cycle of years that has 19 years of 354 days and 11 leap years of 355 days. This calendar is accurate to within 1 day over a 2,500 year period, and is most often used as a way to date historical events or to convert dates between the Hegira and Gregorian calendars.

Calendar, Julian

According to legend, the Roman calendar began with Romulus, cofounder of Rome, who had a calendar of 10 months, or 304 days. His successor, King Numa, added 2 months for a total of 354 days and then added another day to avoid the Roman superstition against even numbers. Still, this did not meet the accurate tropical year of 365.242 days.

To fix the inaccuracy, priests added an extra month every 2 years, which came to a total of 366.25 days a year. They also tried to add an intercalary month every 8 years, as a Greek version of the calendar did. This added up to roughly 365 days, but priests often forgot to add extra months when needed. The priests and aristocrats kept the calendar a secret so they could use it to their advantage, adding days or subtracting days to hasten or stall elections. In 304 BCE, Creius Flavius posted the codes to force the priests to publish the calendar as a public document, although the priests still held the power to add extra months.

Julius Caesar became pontifex maximus in 63 BCE, and undertook to reform the Roman calendar. While on campaign in Egypt, Caesar had seen the Egyptians' effective and simple calendar system. By the time he came to power, the republican calendar had drifted more than 3 months out of line. When elected, Caesar recruited Sosigenes and Alexandrian astronomers, along with many other philosophers and mathematicians, to aid in the task of calendar reform.

The first stage of reform began in 46 BCE by adding 2 extra months to bring the calendar back into alignment with the vernal equinox on March 25. In total, the year 46 BCE had 445 days, becoming known by some as the year of confusion, and by Caesar as the last year of confusion. The year 45 BCE then became the first year of the new system, and the date for the beginning of the year moved from March 1st to January 1st.

The length of the new calendar year included an extra 10 days, totaling 365 days instead of 355. The lengths of months were organized starting with January having 31 days and February having 29 days (except every 4th year, or leap year, when February had 30). From February on, months alternated between 31 and 30 days, beginning with March having 31 days. The dates of festivals and holidays stayed the same along with the old system of numbering days according to calends (1st day of the month), nones (5th/7th day), and ides (13th/15th day). Although most of the months kept their traditional names, the senate renamed the month *Quinctilis* as Julius (July) in Caesar's honor.

The calendar helped foster a middle class of traders, bureaucrats, soldiers, lawyers, money lenders, and craftsmen who now could measure time in the civic world of the empire. Because the new calendar was based on science, none could tamper with it for politics. With the new idea of a leap year, the calendar held 365.25 days compared with the actual tropical year of 365.242. This new calendar became the most accurate in the world and lasted until the Gregorian reform in 1582.

Alexandrian astronomers such as Hipparchus and Ptolemy later noticed that the calendar ran 6 hours slow. Roger Bacon also noted this at a later date. The Romans had no concept of a minute, so they could divide the day only into simple fractions for astronomical purposes. But for Caesar, a calendar year's being off by a few minutes or hours meant nothing compared with the former calendar's being off by days and months for the previous 2 centuries. After the death of Caesar, pontiffs began to confuse the leap year rule. Since Romans counted inclusively, they began adding a leap year every 3rd year instead of every 4th year.

To correct the leap year error in the calendar, Augustus Caesar left out all leap years between 8 BCE and 8 CE. To honor him, the senate renamed Sextilis as Augustus and took a day from February to add to his month so his would not be shorter than Julius Caesar's. They then adjusted the lengths of the remaining months by switching the lengths of September through December to maintain a constant alternation. As amended by Augustus, the calendar continued in use until the Gregorian reform.

Calendar, Mayan

The Mayan calendar, which originated as early as the 6th century BCE, was based in part on the traditions of earlier Central American cultures, including that of the Olmecs. The Mayans made careful observations of the moon, sun, and stars. From their astronomical studies they developed a complex calendar system that allowed them to perform calculations to determine what day of the week a future date would land on.

Despite lacking reliable instruments to establish accurate lengths of time, the Mayans used fixed reference points and matched multiples of lunations, calendar cycles, and eclipse intervals to discover the length of the tropical year and the lunar synodic month. Lacking a system for expressing fractions, they used multiples to express that the length of the tropical year as 365.242 days and the length of the lunar synodic month as 29.530864 days. Whereas the solar calendar used by Western nations such as Rome or Egypt disregarded the phases of the moon, the Mayan calendars included them. With the correlation of two different cycles, the Mayans determined dates of solstices and equinoxes to an accuracy of within one day.

The Mayan calendar system employed a complex correlation of two cycles, the *Haab* and *Tzolkin,* to make the Calendar Round. Each day and month had a name or number and a god associated with it to give the day fortune or misfortune. Mayan priests would weigh gods against one another, and their activities depended on whether or not the day would hold fortune or misfortune.

Haab

The Haab calendar, based on solar observation, structured the planting of agricultural crops. It consisted of 365 days, organized in 18 named months (*Pop, Uo, Zip, Zotz [Zodz], Zec [Tzec], Xul, Yaxkin, Mol, Chen [Ch'en], Yax, Zac, Ceh, Mac, Kankin, Muan, Pax, Kayab, Cumku*) with 20 days each plus *Uayeb,* a 5-day period. The name of each day began with a number from 1 through 20, followed by the name of the month. For example, the calendar would begin with 1 Pop, 2 Pop, 3 Pop, and continue until 20 Pop at which the next month would begin with 1 Uo, 2 Uo, 3 Uo, and continue on through the 18 month names. During the 5 days of Uayeb, considered phantom days or days of misfortune, all activity was avoided while the people waited for them to pass.

Although the Mayans knew the year was 364.25 days long, this calendar ignored that fact and drifted off 6 hours per year. Due to this, the New Year occurred at different times with different points recognized as the beginning. The Haab calendar consists of a circular view of time in which history repeats itself. In the case of the Haab, history repeated itself every 20 years. According to this, the past, present, and future blend together since all will eventually repeat.

Tzolkin

Mayans used the Tzolkin calendar ceremonially, setting the dates for feasts, when to wage war, and when to offer sacrifices. The Tzolkin consisted of 260 days, or 20 periods of 13 days. Days were labeled by using 20 named days and 13 numbers. The 20 named days consisted of *Imix, Ik, Akbal, Kan, Chicchan, Cimi, Manik, Lamat, Muluc, Oc, Chuen, Eb, Ben, Ix, Men, Lib, Caban, Ezznab (Adznab), Cauac, Ahau.* Each of the 260 days had its own unique name through keeping the named days in the same order and counting them off from 1 to 13. After 13, the numbers restart at 1 and the names later restart after Ahau, creating a cycle of new combinations. For example, the calendar would start with 1 Imix, 2 Ik, 3 Akbal, continue to 13 Ben, then the numbers would start over with 1 Ix, 2 Men, 3 Lib, and continue until the names repeated with 7 Ahau, 8 Imix, then continue until the numbers repeated again with 13 Cimi, 1 Manik, and 2 Lamat. This allowed for the calendar to have no official beginning or end until the end of the 260 days, following a cyclical view like the Haab.

The combination of the Tzolkin and the Haab was called the Calendar Round and consisted of 52 years. The day the year began was the year bearer and gave fortune or misfortune to the year. Only 4 days could be the year bearer: Kan the maize god and Muluc the rain god both predicted good years while Ix and Cauac both predicted bad years. Neither the Tzolkin nor the Haab counted the years, since a date in the combined Haab and

Tzolkin would not be repeated for 52 years (beyond the average life expectancy).

Long Count

The Long Count calendar held a linear view of time and allowed for the Mayans to record the time and events. This allowed for the recording of time and events every 20 years on carved stelae by using pictorial inscriptions that included dots and bars. The earliest stele known is correct up to a few hours (date 292 CE, stele no. 29). The calendar measured from the mythological beginning of time (in the Gregorian calendar, 3114 or 3113 BCE) to a then-distant point in the future (Gregorian calendar 2011 or 2012 CE). The 1-year difference in the Gregorian calendar is related to the question of the year 0 between 1 BCE and 1 CE.

Each day in the Long Count calendar is named in terms of two smaller cycles, a cycle of numbers from 1 through 13 and a cycle of 20 names used in a fixed order. The cycle's number system, based on 20, consists of 360 days (a *tun,* or a year). A *katun* equals 20 tun, and because of the layout, a katun could end only on the day of Ahau. Each katun had a ruling god that yielded the same powers each time a katun returned, but only three katuns held good prophecies.

A *baktun* consists of 20 katuns (400 years), and a complete cycle consists of 13 baktuns (5,200 years). The name of this cycle is based on Ahau, the date on which the katun ends. The cycle begins with 13 Ahau and drops 2 with every Katun until the cycle repeats itself (13–11–9–7–5–3–1–12–10–8–6–4–2–13). What is considered a Great Cycle is completed at the end of all 13 cycles; it's said that all things will then cease to exist (2011 or 2012 CE) and a new world will be ushered in with the next Great Cycle.

Calendar, Roman

The Roman calendar was a dating system purportedly enacted by Romulus, the cofounder of Rome, in the year 738 BCE. Originally, the calendar had 10 months and 304 total days. Six calendar months contained 30 days and 4 calendar months contained 31 days. The remaining 61 days that make up our current tropical calendar of 365 days were at that time ignored, falling into an uncounted winter season.

The 10 months of the Roman calendar were called Martinus, Aprilis, Maius, Janius, Quintilis, Sextiles, September, October, November, and December. Numa Pompilius, the second king of Rome, inserted the month of January at the beginning of the year and the month of February at the end of the year. In 452 BCE, February was relocated to its current calendar position between January and March.

Despite the addition of January and February, the calendar was still a full 10.25 days short of the current 365-day calendar year. This shortage caused confusion in seasons and lunar cycles, and time became endlessly out of sync. In an attempt to prevent further misalignment of the calendar and the seasons, an occasional intercalation was performed, allowing for the addition of a 27–28 day month every 2 years. This created an average of 366 days per year when extrapolated every 4 years, and it kept the seasons on track. This practice, also called Mercedonius, comes from the term *merces,* meaning wages, because workers were paid at this time of the year.

This intercalation method continued to cause confusion. Intercalation was an official duty of pontifices, and their reasons for timing of the intercalations often remained secret. Calendars were not public documents, and political tactics to lengthen or elongate the ruling terms of magistrates and other public officials confounded the problems.

In an effort to construct a more sound and incorruptible calendar system, Julius Caesar initiated a calendar reform. In 46 BCE, the Julian calendar was established; it was later modified into the Gregorian calendar now in general use.

Calendars, Asian

In addition to the Gregorian calendar, the solar, or sun-based, standard international calendar of today, a variety of traditional calendars are in common use throughout Asia, depending on the country as well as the religion of the users. The lunar calendar is used mainly for cultural and astrological purposes. Characteristic of lunar calendars generally, the date that marks the beginning of a new year can vary. For those who live in an agricultural society, a solar-based calendar is best suited so that events occur at the same time each year according to planting/harvesting. Yet most calendars were based on the lunar year, which follows the cycles of the moon. The Chinese calendar, and subsequently others in use on the Asian continent, became a lunisolar calendar, one that follows both the sun and the moon, so that, for example, the solar calendar would number the months, while the lunar calendar would be useful for marking dates such as holidays.

Differences among Asian calendars also reflect how cyclical dating and chronology were tied historically to the reign of an emperor or ruling dynasty in that country. Thus, the numbering of a year meant different things in different traditions. Another difference is that the lunar calendar is based on where the moon rises and the time when it rises, leading to different starts of the month in various latitudes. Again, this can cause confusion when using the moon to determine the start of a day, a month, or even a year.

Some of the more common, or well-known, Asian calendars are the Chinese, Japanese, and Singaporean, as well as specific ones such as the Kali Yoga and Parasurama calendars used in Southeast Asia. Today, however, while cultures continue to use their traditional calendars for marking holidays and cultural events, the day-to-day dating of events is based on the Gregorian calendar to ensure that time is observed consistently across cultures.

The Chinese calendar has survived intact for nearly 5 millennia, partially because until the mid-1900s the calendar was considered sacred and thus one needed imperial authority to change it.

Over its long history, India has used many calendars and dating systems that can be split into two basic types—civil, which changed with each regime, and religious, as in the case of those maintained by the Hindus. Although each region had its own Hindu calendar (over 30 different ones), there are some common components. The earliest calendars in India began with a solar year of 360 days split into 12 lunar months, corrected by an intercalating month every 60 months. In 1200 CE, the Muslim calendar came into use for administrative purposes; it was replaced in 1757 with the Gregorian calendar by the British. Yet, throughout this time, each state maintained its own calendar used in daily interactions. Even when an Indigenous government took control in 1947, the difficulties of date interpretation throughout the country continued. Two general Hindu calendars remain in use: the Northern or the Vishnu calendar, which is based on the lunar month beginning with the full moon, while in the Southern calendar the lunar month begins with the new moon. In northern India, the lunar month begins with the full or waning moon, while Hindus in the south of India, the Siva, measure the month from the new or waxing moon. To help avoid some of the date interpretation problems, the two halves of the month are numbered separately, with each half being called a *paksha*.

The Jain calendar has many similarities to the version of the Hindu calendar observed in Northern India. The month begins at the full moon, and month names are the same, although spelling varies. The Jain concept of how time cycles through progressive and regressive eras also differs from that of the Hindus. Jains believe that a complete cycle of time consists of 12 separate units. Of these, 6 represent deteriorating conditions and 6 represent improving conditions. The 3rd and 4th units of both half-cycles represent times when neither extreme predominates.

The Sikh calendar is a lunar calendar that is based on the moon's movement from one zodiac sign into the next, rather than on the phase of the moon, though the dates of some festivals are based on the phase of the moon. The beginning of a new moon is called the *Sangrand.* Sikh festivals are marked on a special calendar called the Sikh Gurupurab Calendar, which begins in March or April. This intercalates an extra lunar month whenever 2 new moons occur within the same solar month. The Sikh lunar calendar is called *Birami* and is 12 months long, with each month averaging 29.25 days.

Buddhism originated from within Hinduism in much the same way that Christianity was derived from Judaism. Similarities between the two include lunar and astrological aspects. Buddhists and Hindus hold similar views on the cyclical character of time. Buddhists view time as an extension of the ever-repeating sequence in nature. Because Buddhist calendars are not associated with a specific civil calendar, the variances among geographical locations are even more pronounced than in Hindu calendars. For example, the method for determining the new year is not uniform; some begin with the full moon of Taurus, while the Tibetan Buddhists, whose calendar has been heavily influenced by the Chinese, begin their calendar at the full moon nearest the midpoint of Aquarius. In Vietnam, they begin at the new moon in Capricorn. As Buddhism spread outside of India, the two dominant traditions, Mahayana (in the West of India) and Theravada (in the East of India), became prominent in separate regions.

The structure of certain traditional calendars can also vary according to the needs of the culture, such as fishing or traveling for trade. The fishermen of Botel-Tobago Island (near Taiwan) had failed to observe the expected rising of the flying fish during a particular season. To solve the problem of keeping a calendar in step with both the moon and the seasons, they inserted an intercalary month when their own lunisolar calendar fell too far behind. Their fishing season was then postponed during this extra month.

Calendars, Megalithic

Calendrical devices of a megalithic nature are found in many areas where early civilizations took root. These are exemplified by the huge stelae produced by the Mayan people of Mexico and Central America on which were recorded astronomical and mathematical data, such as the Long Count, that covered more than 4,000 years. Indeed, it appears that Mayan buildings even had astronomical orientations directed at celestial risings or settings on the horizon. Others were aligned so that shadows would cast images, such as the serpent on the Castillo at Chichen Itza. This pyramid also has four staircases of 91 steps that, with the top platform, combine to make 365—the number of days in the year. The Egyptian pyramids have remarkably accurate north/south—east/west alignments. Although these may not have been calendrical, they do seem to have been based upon either the rising and setting or vertical alignments of polar stars, and "star clocks" appear to have been painted upon the ceilings of some Egyptian tombs. Star paintings with astronomical alignments also have been found in megalithic tomb mounds in Japan. In China the Imperial Forbidden City is oriented on a north/south axis with the Temple of Heaven. The Emperor would follow this path on the winter solstice to perform rituals to guarantee the return of longer days. In Kenya a series of stone pillars called *Namoratunga* and bearing Sudanese Kushite engravings line up with conjunctions of the moon with various stars around 300 BCE. There are many other examples of archeoastronomy to be found, but not all are megalithic in nature. In recent decades, however, research has come to indicate that much more ancient megaliths found in western Europe, long believed by local peasantry to be petrified giants, giants' tables, beds of legendary heroes, or just ancient curiosities of unknown use to others, may have served as solar or lunar calendars to the prehistoric farming peoples of the Late Stone Age and Early Bronze Age.

In the most literal sense, *megalith* means very large stone (μεγα λιθος) in Ancient Greek. In the archeological sense, megalith refers to massive block-like stones that have been arranged into simple or complex architectural constructions, most often referent to the Neolithic (or "New Stone") and Bronze Ages of western Europe (although megalithic architecture is known from later periods, also, and is a worldwide phenomenon, as described above). The simplest type of megalith is the upright standing stone, or *menhir.* The name comes from the Welsh *maen,* meaning "stone," and *hir,* meaning "long," thus menhir means "long stone," and it is synonymous with the Breton *peulvan* (related to *pol* in Gaeilge, as in *Pol na Brone,* the Dolman of the Sorrows in the Burren of County Clare, Ireland). Sometimes menhirs are solitary objects; sometimes menhirs are arranged in groupings, or alignments, that range from just a few stones to more than a thousand, set in long rows, as at Carnac in Brittany and Callanish on the island of Lewis in the Scottish Hebrides, which are parts of gigantic alignments that may be calendrical in nature.

Ogham Stones

Ogham stones, found in Ireland, are megalithic menhirs that were incised in the Late Iron Age with horizontal or diagonal grooves on the corners in precise patterns that represent letters and numbers. It is believed possible that they also were done in (now decayed) wood, as the names preserved for the "letters" are those of tree species: The Ogham letter ├ corresponds to 'B' and is called *beith* in Irish, meaning 'birch,' ╞ corresponds to 'L' and is named for rowan (mountain ash); ┤ corresponds to H and is called after 'hawthorn;' ╡ corresponds to 'D' and is named after 'oak;' † stands for 'A' and represents 'pines/firs;' ǂ is 'O' and refers to gorse; and " corresponds to 'EA' and is called after 'aspens,' to give a few examples (the vertical line down the center of each symbol is the corner of the stone). The stones are believed to have been carved to commemorate people or events, mainly because most of the inscriptions are chiefs' names and dates. It is likely that the dates carved into these stones are not the dates of erection, however, as that would be anachronistic: the Late Iron Age dates are several millennia after the probably Neolithic times of construction.

Dolmans

A more complex type of structure is the *dolman,* or stone table (sometime called *cromlech*). These were burial chambers that consisted of upright megaliths covered by flat capstones, most likely sheltered within earthen mounds (*tumuli*) in antiquity, although most mounds have eroded away after 4 to 7 thousand years of weathering. Sometimes the chambers

Legananny Dolman in Ireland: Dolmans were burial chambers that consisted of upright megaliths covered by flat capstones, most likely sheltered within earthen mounds in antiquity, although most mounds have eroded away after 4 to 7 thousand years of weathering.

are elongated into galleries, and they may have small entry courtyards and transected internal vaults with corbelled ceilings as at Newgrange.

Druid Temples?

In 1648 English antiquarian John Aubrey (1626–1697) saw the megaliths around the British countryside as components of a massive prehistoric temple. He proceeded to conduct research at Avebury, Stonehenge, Wayland's Smithy, and other ancient sites that led him to describe them as *Templa Druidum,* or Druid temples. This view was seconded in the 18th century by fellow antiquarian William Stukeley (1687–1765) in two books, one about Avebury, the other about Stonehenge, published in the 1740s.

Despite Aubrey's and Stukeley's druidic provenance for megalithic constructions, and notwithstanding the popular French cartoon strip *Asterix,* in which an ancient Gaulish character, Obelix, frequently is shown to be transporting and erecting megaliths, the Celts were not responsible for the creation of the Western European megaliths. Celtic culture is archeologically accepted to have arisen in the first millennium BCE, and the megaliths of Western Europe are considerably older than that—some on the order of 4,000 to 5,000 years. Although the Celts and their priests, the Druids, did not build megalithic structures, according to some classical sources they did worship and sacrifice at them, just as do some modern people, who did not build the megaliths either. Although the people that we call the Celts did not build them, their ancestors may have, as modern DNA analysis has shown a continuous link between the peoples of Western Europe from the Stone Age to today.

Calendrical Hypothesis

In 1955 an engineer and amateur astronomer, Alexander Thom, presented a paper on his statistical analysis of 250 megalithic monuments, most of them in Scotland and Wales, that he believed showed considerable astronomical and geometric understanding on the part of their Neolithic builders. In addition to a celestial map that aligned the monuments with the horizon, Thom found what he believed to be a Middle Bronze Age solar calendar that was divided into 16 parts, or "months," that included four 22-day months, eleven 23-day months, and one 24-day month. This would divide the four annual quarters between the solstices and equinoxes into four yet smaller quarters per season. These four smaller quarters, or sixteenths, are Thom's "months." Although this idea was rubbished by archeologist V. Gordon Childe, it formed a springboard for further inquiry into the calendrical hypothesis.

Stonehenge

Perhaps the best-known megalithic site is also the one that best demonstrates the calendrical hypothesis: Stonehenge. Stonehenge is a truly impressive example of Late Neolithic/Early Bronze Age megalithic architecture. Although it began as a simple circular banked ditch in the late 4th millennium BCE when the entrance and the Heel Stone were erected, the bulk of what today is visible at Stonehenge was constructed from approximately 2000 BCE to 1500 BCE. Because Stonehenge was built by an agricultural society, knowledge of solar and lunar aspects is believed to have been considered vital to survival because it provided more or less reliable indicators of when to plow, plant, sow, and reap. The latitude on which Stonehenge rests is the one where the sun and moon form perpendicular aspects, a phenomenon reflected in the shape of the monuments and their surrounding fixtures. The Avenue from the great circle lines up with the 6-meter–high Heel Stone like the sites on a gun barrel, the target being the rising sun on the summer solstice.

During the second phase of construction a series of 56 holes ranging in size from 0.8 to 1.8 meters, called Aubrey Holes after John Aubrey's mention of them in his *Monumenta Britannica,* were cut in the chalk bordering the embankment to hold vertical timbers. In the third phase the bluestones, weighing between 1 and 1.5 tons, were brought to the site from the Prescelly Mountains of Wales 225 kilometers distant and raised in the center of the circle. The gigantic sarsen trilithons (sets of three stones estimated at about 30 tons each, forming huge upside down U's) were raised in the fourth phase of construction in the Early Bronze Age. The solar connection associated with Stonehenge is significant here in that it is in the Bronze Age that Welsh Celtic specialist Miranda Green sees the rise of a sun cult based upon solar symbols found on art and artifacts from this time.

In 1961, astronomy professor Gerald Hawkins used an IBM 704 computer to plot 120 pair of points against celestial positions to investigate what he believed to be the purpose of the monument: an astronomical computer to calculate, among other things, the solstices and lunar eclipses. Hawkins had expected to find solar alignments at Stonehenge, but the lunar alignments came as a surprise to him. Hawkins concluded that Stonehenge formed an astronomical observatory designed to predict lunar eclipses in a 56-year cycle that included two segments of 19 years and one of 18 years, based on the original Stonehenge's 56 Aubrey holes and the 19 bluestones of the horseshoe. The two smaller circles of holes, the Y and Z holes within the ring of Aubrey Holes, add up to 59 holes, or two lunar months of 29.5 days each. Continuing the 29.5-day lunar month theme, the ring of 30 Sarsen stones contains one that is quite a bit smaller than the rest, making the number essentially 29.5—once again a lunar month, and this pattern is repeated in the Bluestone Circle. Although some archeologists, notably Richard Atkinson, who was known for his work at Stonehenge, strongly disagreed with Hawkins, it is ironic that astronomers such as Fred Hoyle found his work to be the impetus for even further calculations. Brian M. Fagan argues that Stonehenge never was a device for calculating eclipses, but that it only *implies* the idea of time as reflected in the celestial cycles observable to its builders. To put it somewhat simplistically, following the publication of Hawkins's *Stonehenge Decoded,* the archeologists tended to side against him, while the astronomers tended to side with him.

Although it usually is the summer solstice sunrise above the Heel Stone that gets much of the commentary when discussing the astronomical nature of Stonehenge, Julian Richards argued on his BBC television archeology series, *Meet the Ancestors,* that it was the winter solstice, *not* the summer solstice, that may have been more important to the builders. According to Richards, the Avenue is just that—an avenue to the site from which to view the winter solstice, not a sight down which one would view the summer solstice sunrise. Rather than looking down the avenue to the Heel Stone, we should be looking in the opposite direction, through the largest trilithon, at the winter solstice sunrise when the image between the uprights is split like a window, and the sun rises through the upper part of the image as in the window, or Roof Box, at Newgrange in Ireland.

Newgrange

Newgrange, Knowth, and Dowth are the three megalithic passage tombs, or fairy mounds *(sidh),* found on Newgrange Farm in the Boyne valley, or *Brú na Bóinne* (Palace or Mansion of the Boyne), north of Dublin and about 8 kilometers west of the town of Drogheda, near Slane, in County Louth. At Knowth, one of the slabs is carved with an intricate scalloped design resembling a zodiac and is known as a "sundial." The best known of the three megalithic monuments is Newgrange, built in the late 4th millennium BCE. The massive mound covers an area of over one acre and is surrounded by 97 carved curb stones. The mound had eroded badly until it was reconstructed forensically through trial and error by its excavator, Michael J. O'Kelly, between 1962 and 1975. Surrounding the mound were a series of white quartz stones that were believed by some to have been a ceremonial road. O'Kelly noted their locations and, suspecting that they formed part of a wall, reconstructed the wall repeatedly, tearing it down each time until the stones fell into the positions where they were found to begin with. This, he decided, was the original design, which he then reconstructed.

Germane to the subject being discussed here, the great entry stone at Newgrange is carved with a number of spirals reminiscent of Vincent Van Gogh's painting *Starry Night,* and indeed this is known as a "celestial motif," although the spirals may represent the sun's passage across the heavens, not stars. Behind the stone is an entrance surmounted by a window, or "Roof Box." Normally the corbelled, cruciform vault at the end of the upward-sloping 19-meter–long passage is completely dark. However, for 2 days on either side of the winter solstice the interior is illuminated just before nine a.m. for about 17 minutes by a shaft of sunlight that enters the Roof Box and travels up the passage as far as the basin stone in the corbelled vault (a parallel phenomenon can be observed in the Sun Dagger at Chaco Canyon, New Mexico). Designs similar to Newgrange, complete with carved upright stones, can be observed at Loughcrew in County Meath, Ireland, and at Gavrinis in Brittany, France, built nearly a millennium earlier. Not far from Gavrinis is Carnac, an immense site in Brittany consisting of row upon parallel row of menhirs that seem to be aligned to both the sun and the moon, although whether or not they represent anything of a calendrical nature is unclear.

Calendars, Tribal

The advancement of tribal peoples from rudimentary to scientific calendars reveals their intent to live a harmonious existence with the celestial bodies, and demonstrates the significance of stellar movements for tribal societies in forecasting seasons of harvesting, hunting, and fishing times, and ritual observances. These dedicated prehistoric observers of the sky were the precursors of modern astronomers.

Throughout the world, prehistoric astronomers reverently observed "the sacred sky"; their legends were affiliated with the stellar movements in concurrence with the changing seasons. Their attentive tracking guaranteed the precise timings of rituals and times of the year, which not only helped advance their societies toward the institution of accurate calendars but also gave rise to distinct cultures and customs, tribal lifestyles, and worldviews. In the beginning, oral tradition transmitted this knowledge from one generation to the next; the employment of simple measures progressed and diversified into complex and concrete means such as alignment fixtures and symbolic petroglyph recordings. A prestigious position was to monitor these devices and interpret their significance; this responsibility was accorded to a skilled and sanctioned authority, the shamans and priests. Among the Lakota, this was the Keeper of the Counts; among the Zuni, the Sun and Bow Priests; and in the Cherokee tribe, the Day Keeper.

Other planetary cycles were also observed: The Evenks of Siberia tracked the season of the Cosmic Hunt of Ursa Major, or the Great Bear; the Dogon tribe of West Africa kept observations of Sirius; the Pawnee monitored the "White Star Woman" or Venus; the Kahuna Priests of Hawai'i tracked the 223-month eclipse cycle. Daily measurements of time were overseen according to the available location: The Chacoans calculated the day's passing via shadow castings upon the pueblo terraces, while the Salish tribes gauged daily time by observing the ebb and flow of tidal fluctuations. The counting of winters appears to be the universal standard for yearly calculations, though some circumpolar peoples counted a winter year and a summer year.

Seasonal Documentation

Tribal astronomers have created artistic engravings and paintings as reminders of seasonal occurrences, such as the carved baton remnant discovered at Lorthet (Hautes-Pyrenees) bearing reindeer, jumping salmon, and two triangles that scholars theorize as seasonal indications; in Alaska, the season of salmon arriving in a thick blanket of fog is represented upon Tlingit totems and longhouses with "Fog Woman"; the Yakutia rock drawings of Siberia illustrate the Cosmic Elk constellation, which appears in March, foretelling the return of the sun. The Lakota used painted buffalo hides to record extraordinary astronomical occurrences. Also, star maps on cave ceilings from the Old and New Worlds depict stellar illustrations, circles within circles for the sun, or animals such as elk to represent constellations.

Knotted cords were frequently implemented to chronicle time; the Peruvians created the *quipu,* an intricate system consisting of a rope and attached cords with elaborate knot arrangements. In addition, methodical engravings of notches or drilled holes were universally employed for tallying days, months, and even years; such as the notches upon certain kiva walls in Chaco Canyon for lunar and equinox observances, allowing a sunbeam or moonbeam to glide over the markings to record significant days. Scored trees, for instance, were used by Papua New Guinea tribesmen to calculate lunar months; and the scoring of sticks was utilized by tribes like the Pawnee for makeshift calendars to record days, months, and years. Engraved bone artifacts from the European Upper Paleolithic cultures have been decoded by Alexander Marshack, who posits these markings to be lunar-phasing notations. The Indigenous tribes of the Nicobar Islands utilized chevron hatches and crosshatches for lunar calculations; while on Easter Island the Mamari illustrated tablet represents lunar phases. Winnebago calendar sticks have been used to calculate important dates, such as for planting and for ceremonies.

Cycles

The tribal concept of time concerning lunar phases can be seen in two devices: a 12-moon/month calendar that adds an intercalary moon when appropriate to balance the year; and a 13-moon calendar that removes a month when required. With continued observation of the sun and various constellations, a standard developed to track a more linear concept for a 365-day year. The Mayans' and the Chacoans' celestial concepts envisaged numerous cycles operating simultaneously; for example:

Moon's phase: 29.53 days

Tzolkin (Mayan): the sacred year (nine 28-day months of gestation) or 260 days

Calendar Round (Mayan): 18,980 days or 52 years

Lunar declination (Chacoan): 18.6 years

Months and Years

The nomenclatures of months (or moonths) tend to be epithets of natural occurrences. For the Tlingits, "when the black bear cubs are born"; for the Sioux, "Moon of Strawberries." Months were also named for activities: for example, among the Aleuts, "dried skins being eaten due to lack of food," and the "month of months" when their potlatch celebrations took place. The months were also named for the seasons: (Japanese) "Harmony—Happy Spring," or "Autumn Long Month"; the Japanese year also contained 24 *ki* or "solar terms." Many times, months or seasons overlapped one another.

The New Year was celebrated at various times by tribal people; many observed this occasion at spring. For the Tlingit, the initiation of the summer salmon run indicated a new year had begun; the New-Fire celebration in November hailed the new year for the Pueblo people; and the setting of the constellation Pleiades signified the new year for the Cherokee, with celebrations on the following new moon, near the beginning of November.

Archaeoastronomy and Megalithic Calendars

Mountains have been known to represent the cosmic womb for certain cultures. Some tribal homes were fashioned to look like a womb, with their doors facing eastward for the arrival of the sun. The Lakota tipi itself symbolizes the sun. Creating permanent structures to calculate time became the logical progression in astronomy. Rocks appear to be the first astronomical calendars, such as the Sahara Stonehenge of the Nabta culture, which anthropologist J. McKim Malville posits to be the oldest astronomical megalithic alignment. Megalithic circles such as the Lakota Medicine Wheels and the

British megalithic sites are known to have solar and lunar orientations; in addition, the numerous mounds and "earthworks" of Mesoamerica are also documented with solar and lunar alignments. Many of the archaeoastronomy pueblos or "Great Houses" at Chaco Canyon were constructed with solar, lunar, and planetary alignments; the geographical placement of each Great House is also postulated to have stellar relationships. A unique megalithic calendar in the state of Washington, named "Skystone" by astronomer Jerry Hedlund, utilizes grooves and indentations on the massive boulder to observe the solstices and the winter and summer rising of Sirius.

Calvin, John (1504–1564)

The French-Swiss Christian theologian John Calvin was, like Martin Luther and Huldrych Zwingli, a major Protestant reformer. He was the founder of the so-called Calvinist mode of Protestantism, a precursor of modern Protestant Christianity not only in France but in the entire Western world. As ecclesiastical leader in Geneva for several decades, he shaped a very pious and stringent way of civic living. His theology of predestination strongly influenced religious conceptions of time in terms of human salvation.

Life and Works

Calvin was born as Jean Cauvin on July 10, 1509, in Noyon, in the Picardie region of France, as the son of an influential legal assistant to the bishop of Noyon. At the age of 14 he enrolled in the colleges De la Marche and Montaigu, both parts of the University of Paris. Though initially he intended to study theology after he had acquired basic knowledge in Latin and the liberal arts, he prevailed in his decision to study law in the central humanistic law schools Bourges and Orléans, from 1528 to 1531. In Orléans, he attained a doctoral degree. But after the death of his father, Calvin decided to give up jurisprudence and to attend the Royal College in Paris to study Greek and Hebrew languages and the history of antiquity. Here he authored his first published work, a comment on Seneca's *De clementia.*

After a Lutheran speech by a friend of his whom he was said to have influenced, Calvin was forced to flee from Paris in 1533. As a matter of principle he renounced the benefices of the Catholic Church in Noyon, arranged by his father. He had to escape a second time when the king authorized the prosecution of (Zwinglian) Protestants.

Upon his arrival in Basel in 1535, the highly intellectual Calvin began to study theology, already influenced by the spirit of Renaissance humanism as embodied in the work of Desiderius Erasmus and other leaders of the Reformation: Luther, Zwingli, and Philipp Melanchthon. Calvin began to write about theology, starting with a preamble to a translation of the Bible into French by his cousin Pierre R. Olivétan. The next year, Calvin himself set out to influence the whole Protestant movement by the release of a first version of his *Institutio Christianae Religionis* (Institutes of the Christian Religion) that, although somewhat immature, nonetheless attracted considerable attention. Within his *Institutes,* Calvin developed his ideas about predestination.

During 1536, the Protestant Reformer Guillaume Farel insistently asked and finally convinced Calvin to join his enterprise to encourage the Reformation in Geneva. After several months of religious teaching in the Cathedral, he became a priest and soon published a first *Catechism.* Because they proved to be too restrictive in their postulations in face of the governing council and in their parochial obligations to the citizens, Farel and Calvin were ejected from Geneva in 1538.

Until 1541, Calvin stayed in Strasbourg where the Reformist Martin Bucer had persuaded him to act as lecturer and preacher in a French fold. In 1540, he married the widow Idelette de Bure in defiance of the celibate habits of the clergy and published his *Comment on the Letter of Paul to the Romans*. In Strasbourg, he met Melanchthon.

Also in 1540, the town council invited Calvin to return to Geneva. Boosted by his meanwhile European-wide role as a major Reformist, Calvin did not accept until the council granted broad rights to him, in particular to impose his reforming but very strict constitution *Ecclesiastical Ordinances of the Church of Geneva* in 1541. A powerful Consistory was established and soon evoked the citizens' resistance. In the period until 1554, in which he released a second version of his *Catechism,* Calvin several times feared being banned again from Geneva because of his rigorously religious order. The constitution of the almighty clerical Consistory reflected Calvin's conviction of the prior authority of the clergy over any secular governance.

Calvin left a lastingly negative impression on many admirers of the Reformation by his betrayal of the Spanish preacher Michael Servetus when he passed through Geneva on his flight from Catholic persecution. Calvin paved the way for Servetus's conviction to death. This happened to occur in the turbulent year of 1553 when Geneva was struggling with masses of incoming religious refugees. After his election to the town council, Calvin's predominance was stabilized definitively, leading to and in turn strengthened by a massacre under the leaders of the opposition against his theocratic regime.

During the following years, Calvin concentrated on writing comments to nearly the entire New Testament and on corresponding with the other leading Reformists. Furthermore, he founded the Genevan Academy with the intention to teach young Protestant theologians according to Calvin's humanism and exegesis of the Bible. The Academy is considered very important in the success of the spread of the Reformation across Europe.

John Calvin died on May 27, 1564, in Geneva, after grave and chronic illness and was buried according to his own wish anonymously and without any ceremony.

Theology

The undoubted sovereignty of God and the authority of the Bible are central in Calvin's theology. Human existence arises solely from obedient belief, and humankind is ordained to live in devotion and modesty; with these principles Calvin shaped a source of Puritanism. By his appraisal of modesty and effort and in the belief that economic success shows the goodwill of God, Calvin influenced the economic motivation of Western societies to this day.

Calvin's doctrine of predestination maintains that some people are destined for salvation whereas others are not, and there is no way to interfere with this predestination. Humility, piety, expiation, and preparation for a spiritual rebirth for the sake of achieving a good future life should dominate the present pursuit of happiness. A sober abnegation of man's present estate is a consequence of Calvin's theology.

Campanella, Tommaso (1568–1639)

Born in 1568, in Stilo, Calabria (Southern Italy), Giovanni Domenico Campanella attracted attention and caused controversy as a Dominican monk, natural philosopher, political theorist, and utopian writer. Some of Campanella's most popular works include *Philosophy Proven by the Senses* (1591), *Selections* (poetry, 1622), *A Defense for Galileo* (1622), *The City of the Sun* (1623), *The Great Epilogue* (1623), and *Metaphysica* (1638). Showing a great fascination with natural science, astronomy, astrology, mathematics, and "natural" magic, Campanella worked these subjects into his writings on philosophy and theology. Campanella's concept of time is interwoven with his understanding of creation and eternity and their connection with God as creator.

Campanella entered the Dominican order in 1583 and adopted the name Tommaso in honor of Thomas Aquinas. In his studies, the young monk quickly disagreed with the traditionally accepted Aristotelian philosophy and began following the work of Bernardino Telesio (*On the Nature of Things*). Campanella wanted to strip away the writings of the popular Greek philosophers and examine the natural world through the human senses. The empiricism and beliefs that Campanella embraced, however, contained weaknesses and contradictions.

For Campanella, every human being, animal, and plant consists of three "primalities." As created beings, humans reflect the three-part nature of God, as Father, Son, and Holy Spirit, and consist of body, mind, and soul, as opposed to the Aristotelian dualist nature of body and soul. Therefore, Campanella's writings reflect the emerging Renaissance philosophy and contain themes of occultism, "natural" magic, animism, and pantheism. These philosophies and beliefs raised suspicions within the Roman Catholic Church about this Dominican monk's writings. Suspected of heresy and treason, Campanella underwent several Inquisition trials and periods of imprisonment from 1592 to 1626. Between his imprisonments, Campanella traveled throughout France and Italy and wrote voluminously. In 1597, authorities arrested Campanella for his association with and leadership of a political conspiracy to establish a new political order, following his utopian ideas (laid out in *The City of the Sun*), of a theocratic monarchy. Although Campanella spent 8 years in Rome following his imprisonments, he fled to Paris, France, in 1634, for safety and gained acceptance in the scholarly community until his death in 1639.

Although *Philosophy Proven by the Senses* and *City of the Sun* express and describe Campanella's philosophical and political framework, Campanella's *Great Epilogue* and *Compendium* provide the most in-depth look at time and eternity. In these works, Campanella defines time as "the successive duration of things." The Eternal God created time when he created the temporal universe, and the changes and mutations that occur in the world, such as the young becoming old, prove the succession of time. Campanella defines eternity as "the permanent duration of the Maker, without a before or after" (or a past or future). These two concepts contrast with Aristotelian thought, which says that time relates only to human activity and that the world exists as an eternal universe. Therefore, Campanella understood time as created with the world and representing the continual movement and flow of nature.

Campanella's literary contributions reflect the philosophy and ideas of the Renaissance and the Scientific Revolution, promote intellectual freedom, and support a political utopia of equality and ideal living conditions. The Dominican monk's works pertaining to time and eternity also presented challenges to traditional worldviews and incorporated theology and empiricism.

Carroll, Lewis (1832–1898)

Lewis Carroll is the pseudonym of the Reverend Charles Lutwidge Dodson, an English writer and mathematician who is perhaps most famous for his much acclaimed books, *Alice's Adventures in Wonderland* and *Through the Looking Glass.* One of the most intriguing aspects of his writing is the relative suspension of time that occurs as is evident in how Alice and other characters continue to react to one another without consequence. In other words, there appears to be little attention to the temporal dimension of a cause-and-effect relationship. This is further evident in that little time actually passes in the time from when Alice begins her adventure to when she returns home.

From the beginning of *Alice's Adventures in Wonderland*, Carroll introduces a dimension of time. As Alice falls asleep and enters her dream, she observes an extraordinary white rabbit that she follows in part because she is curious about a rabbit who keeps time, especially with an oversized pocket watch. As she enters the rabbit hole and begins falling, she begins to question how long and how far she has fallen. She finally gives in and claims she will just see where she lands. Carroll's oblique commentary on Victorian society, and to some degree our own, is based on a cultural tendency to become preoccupied with how long a task takes instead of with the task itself and the end result.

Dream-induced stories offer us a fantasy and with that a suspension of how ordinal time is kept. Although Alice appears concerned with having to get back—her cat Dinah may miss her—she enters Wonderland by falling asleep with little awareness of how much time has passed. The timekeepers become integrated into the story in a way that offers the possibilities of traversing the time-space barrier. In the case of Alice, she is in a world where un-birthdays are celebrated, where tea time is any time, and where rabbits—creatures we would normally think of as devoid of time-related concerns—are timekeepers. The White Rabbit, as he is known, even carries a large pocket watch to continually remind him of his lateness.

Carroll recalls the afternoon that inspired this writing as one that spun on forever—as if he had lost track of time—"all in a golden afternoon." He continues, "the why of this book cannot and need not be put into words." It is arguable that Carroll wrote *Alice* to suspend his mind from his everyday work in mathematics. He kept these two worlds separate and reacted harshly whenever asked to comment on the other aspect of his life when not in that context.

Carroll dismissed many of the interpretations of his work, calling for children's minds and dreams to be the true interpreters of his work. Children have very little sense of time and rely on an innate sense of enjoyment to engage in their pastimes and activities. Yet elements of time are evident in how his characters come to life and often perform a satirical narrative of contemporary society. Culturally, we become socialized by the clock and rely on it as an instrument that ends up determining our pleasures and pastime activities. Carroll's readers enter a world where the opposite of what is expected occurs. For example, in *Through the*

Looking-Glass, Humpty Dumpty explains the idea of un-birthdays on 364 days of the year—allowing individuals not to have to wait a year between celebrations. Instead, time is not relevant for when celebrations can occur, opening up the option for celebrations to occur without anticipation of or waiting for a specific calendar event.

Given that Carroll neglected to embrace interpretations of his work, his writing remains a topic of interpretation among literary, political, cultural, social, and philosophical scholars. He opened up a world of intrigue by offering a realistic environment that exists in Alice's dreamlike state. As past and present generations have, future generations will continue to look on his work as wondrous literature that offers much for contemporary culture to interpret.

Cartan, Élie Joseph (1869–1951)

Élie Joseph Cartan was a French mathematician and physicist, outstanding especially in the area of differential geometry and group theory. He worked in various French universities, including in the period 1912–1942 as professor at the Sorbonne in Paris. He is among the principal architects of the modern rebuilding of differential geometry, which allows the expression of its concepts and laws without the use of coordinates. Among others, he introduced the general notion of differential form in the manner used up to the present day.

A significant contribution of Cartan to the theory of time is his geometric formulation of the Newtonian theory of gravity (1923). The Cartan theory is based on four-dimensional spacetime with Newtonian absolute time (see entries on Relativity) and with Euclidean geometry in the three-dimensional sections connecting simultaneous events in spacetime. Space—in contrast to time—is here not absolute, and the principle of relativity is extended to the arbitrary translatory motions of systems of reference. In Cartan's formulation, the functioning of gravity is expressed by help of some connection with the curvature of spacetime. Consequently, spacetime with gravity is curved by course of connection, and not by course of metrics.

The Cartan connection is bound to mass density in such a way that the validity of Newton's law of gravity is assured, and it is bound to space metrics and time metrics in such a way that the validity of Euclidean geometry of space and the existence of absolute time are assured. The necessary axioms form a somewhat complicated system (discussed in detail in the first volume of Charles W. Misner, Kip S. Thorne, and John A. Wheeler's monograph *Gravitation*). They make it possible to compare the essential features of Newton's and Einstein's gravity theories directly. Whereas Newton's theory is much simpler than that of Einstein in the mathematical language of the 19th century, the situation is quite opposite in modern geometric language.

The other contribution of Cartan to physics is presented by the *Einstein–Cartan theory.* It is a generalization of Einstein's general theory of relativity including in its equations not only the *curvature* but also the *torsion* of spacetime related to the *spin* (the inner angular momentum) of matter. It cannot be excluded that the ideas of this theory will find their use in anticipated unifying theories.

Catacombs

Catacombs are a series of connected subterranean rooms, tunnels, or galleries created for the interment of the dead. These burial places are most extensive in Rome, but can be found throughout the Mediterranean world, in Paris, France, other areas of Italy, Asia Minor, Egypt, Tunisia, and Malta. Individual rooms or recesses were dedicated to a single family, so relatives could return on important anniversaries to remember loved ones. They were places to gather for family worship and reflection over generations. Inscriptions and paintings in the catacombs provide historical information on an important time period, enabling us to see the evolution of religious thought during the earliest centuries of Christianity in Europe.

The term *catacomb* today is virtually synonymous with the Christian cemeteries established in Rome during the time of the Roman Empire, but catacombs actually originated in the Middle East about 6,000 years ago. These earliest burials were usually secondary burials—the bones of the dead were recovered, placed in ossuary containers, and interred in a cave or burial chamber. Over the following millennia, burials increased in complexity. By 1500 BCE, far more elaborate underground chambers were connected by galleries.

After the Roman Empire conquered Palestine, or Judea, many Jews migrated to Rome, bringing their burial practices with them. Romans cremated their dead, but the Jews continued to dig their resting places underground. Jewish catacombs were used strictly for burial and can be identified by simple inscriptions of the menorah, a seven-branched candelabrum.

Roman catacombs were carved into the soft volcanic tufa. The law did not allow for burial within the city limits, so the 60 or more catacombs lie in the immediate suburban area of that age, with entrances along the main roads leading into the city.

Early Christians in Rome were considered a Jewish sect, and their catacombs were modeled after those of the Jews. As the Christian community grew, new catacombs were created and existing ones expanded, though Christian catacombs were more than simply burial places. Religious and funeral services were held in them, and they provided temporary refuge for celebrating the Eucharist in times of persecution.

Structurally, the Christian catacombs of Rome form a labyrinth. Tunnels wind through the rock for miles. These galleries are lined with rectangular niches, called *loculi,* that hold the remains of one or more individuals. The earliest Christians were typically very poor. In imitation of Christ's simple burial, bodies were simply wrapped in a shroud and placed in a loculus. The opening was then sealed with mortar and tiles or a slab of marble. The name of the individual and a simple religious symbol were then inscribed on the tombstone.

As burials became more complex, other types of tombs developed. *Cubicula* were small rooms off a gallery that served as a family tomb. *Arcosolia,* large niches with an arch over the opening, were also used to inter families. Both cubicula and arcosolia were embellished with religious frescos and murals. *Forma* were individual tombs dug into the floor of a cubiculum or gallery. Forma were frequently dug near the tombs of the martyrs.

The catacombs were dug exclusively by a specialized guild of workers called *fossores*. They dug gallery after gallery by hand, carrying the debris out in baskets or bags. Periodically, shafts to the surface were created to provide light and air.

Roman law protected all burial sites and rendered them sacrosanct. Even slaves were entitled to a dignified burial. The Christian catacombs of Rome were used most heavily from the third century through the early 5th century when the Goths invaded. Repeated invasions in the succeeding centuries put an end to catacomb burial, as the invaders did not share the Roman restraint about plundering these sacred places. The remains of interred saints and martyrs were removed and housed more securely in churches around the city, and by the 12th century catacombs were completely forgotten.

In 1578, workers accidentally uncovered a catacomb under the Via Salaria while mining for stone, rekindling interest in these ancient burials. Catacombs have remained a curiosity and tourist attraction until the present day, though scientific excavation and analysis of the catacombs did not occur until the mid-1800s.

Catacombs were vital to early Christians. Serving primarily as resting places for the remains of the faithful, they provided a place for the living to spend time with their dead, recognize important anniversaries together, and wait with their loved ones for resurrection. The burial places of saints and martyrs provided the faithful with a physical location for pilgrimage.

Catastrophism

Catastrophism, an idea that emerged at the beginning of the 18th century, holds that the earth has been affected by a series of sudden, short-lived, violent events (such as land upheavals and floods that may have been worldwide in scope). These catastrophes, or "revolutions," shaped the earth's surface, forming mountains and valleys, and at the same time destroyed whole species of organisms, some specimens of which were preserved as fossils. After each catastrophe, entirely different life forms repopulated the earth, either by migration or because life emerged again, which would explain the differences in fossil forms encountered in successive stratigraphic levels. Initially, this could be a way to rationalize first field observations with an assumed short history of the earth and the decisively established organic origin of fossils as vestiges of ancient beings. However, a dynamics of paroxysm did not require catastrophists to hold to a limited geological time for the age of the earth. Many catastrophists believed that the earth was millions of years old and still concentrating its major changes on brief ruptures. The earth today was viewed as the result of an accumulation of catastrophic events, which articulate a directional history of the earth and life. Many scientists and historians regard directionalism more as a central theme than the dynamics of paroxysm and, consequently, some scholars redesignate catastrophism as a "directionalist synthesis."

Origins of Catastrophism

The Swiss naturalist Charles Bonnet (1720–1793) was the precursor of catastrophism. In his work *Principles of Catastrophism,* he suggested that all living things have been destroyed by catastrophes at periodic intervals throughout the earth's history and they themselves accounted for fossils. Bonnet was the first to use the term *evolution* in a biological sense. He believed that a new creation follows a catastrophic event in which new life forms could elevate one level in the Great Chain of Being (the influential concept that all of nature, from nonliving matter to sophisticated organisms to spiritual beings, is arranged in an unbroken physical and metaphysical series or hierarchy).

Catastrophism, however, is generally associated with the great French anatomist and paleontologist Baron Georges Cuvier (1769–1832). Cuvier is credited with applying his anatomical principle of the "correlation of parts" in the systematic study of fossil vertebrates to arrive at his most memorable discovery: that species of animals have indeed become extinct. Cuvier reconstructs the skeleton of fossil tetrapods (mainly large mammals) from isolated bones by gathering together and re-creating lost skeletal elements, given that the anatomical structure of every organ is functionally related to all other organs in the body of an animal because animals interact with their environment, resulting in the functional and structural characteristics of their organs. He concluded that these large terrestrial vertebrates had become extinct, based on the fact that their skeletons are very different from those of present-day species, which were very well known on all continents; and given the unlikelihood of discovering new ones. To explain the patterns of extinction and faunal succession in the fossil record and the alternations of marine and continental sedimentary strata that he himself had registered, Cuvier argued that sudden land upheavals and inundation of low-lying areas by the sea might have been responsible for the most recent extinctions in Eurasia. He viewed these revolutions as naturally recurring events, subsequent to long intervals of stability during the history of life on Earth, and this led him to enumerate successive ages down into the sequence of strata indicated by the fossil animals that they contain. Timewise, the history of the earth had been indefinitely long. At the same time, Cuvier expresses the directionality of geological history. Following the Wernerian system, he argues in favor of systematically changing mineralogy throughout time, and for a pattern of decreasing effect or intensity of catastrophes, as an original universal ocean gets smaller. Thus catastrophic dynamics and directionality are interconnected in a distinctive and comprehensive view.

Cuvier also affirms directionality when he remarks that fossils from successively older strata become increasingly more different from modern species, and thus ever more "primitive" by the conventional definition of progress. However, in Cuvier's view, species were immutable (fixed). Faced with bitter opposition to the evolutionary ideas of Jean-Baptiste Lamarck (1744–1829), his major argument was that mummified cats and ibises (brought to Paris by Napoleon's expedition to Egypt) showed that no transformations had taken place in 3,000 years. Cuvier also argued that each species is so well coordinated, both functionally and structurally, that it could not have survived significant change. Ironically, Cuvier's lifework is considered as marking a transition between the 18th-century view of nature and the view that emerged in the second half of the 19th century as a result of the doctrine of evolution. By rejecting the Chain of Being in favor of classifying animals in four separate groups (vertebrates, mollusks, articulates, and radiates), each of which had a special type of anatomical organization, he raised the key question of why animals were anatomically different.

Catastrophism Versus Uniformitarianism

Catastrophism was the dominant paradigm of geology until uniformitarianism became commonly accepted. Because catastrophism was more easily associated with religious doctrines, it greatly overshadowed the opposing uniformitarian ideas of James Hutton (1726–1797) that slow changes over long periods of time could explain the features of the earth. The dominant belief in many cultures about the creation and development of the world was essentially catastrophist. The finest example of these beliefs is the biblical account of the Great Flood, whose influence on scientific thinking persisted up to the threshold of the 19th century. Cuvier gave credence to his concept of catastrophism in 1812 in the essay "*Discours préliminaire*" (which he included in his "*Recherches sur les ossements fossiles de quadrupeds"*) as well as in the expansion of this essay into book form in 1825, "*Discours sur les révolutions de la surface du globe,*" the most important of all catastrophist texts. Cuvier's essay was very influential in England, where natural theology was dominant during the early 19th century. A group of geologists that included William Buckland (1784–1856) and Robert Jameson (1774–1854) misinterpreted Cuvier's ideas and explained catastrophism in a very different way. Jameson translated Cuvier's essay and published it under the title "Essay on the Theory of the Earth." He added extensive editorial notes to the translation that explicitly linked the latest of Cuvier's revolutions with the biblical flood, and the resulting text was extremely influential in the English-speaking world. Buckland spent much of his early career trying to demonstrate the reality of the Noachian flood with geological evidence, and he frequently cited Cuvier but misinterpreted his work. As a result of the influence of these and other advocates of natural theology, the 19th-century debate over catastrophism took on religious connotations in Britain that were not nearly as prominent elsewhere. Catastrophism became a bastion of ecclesiastical reactionaries in a vain effort to stem the inexorable advance of the natural sciences.

From around 1850 to 1980 most geologists endorsed uniformitarianism, thanks to the fact that it was clearly and concisely explained by Charles Lyell (1797–1875) but also because Lyell, a lawyer by profession, discredited catastrophism as a viable explanation of geological phenomena. Cuvier's catastrophism, which was widely spread by means of the distorted views of natural theology, was placed beyond the pale of scientific respectability by Lyell's rhetoric that falsely attributed to him two major charges that he had not made (and that still persist in recent textbooks). For Lyell, catastrophist geology became "a boundless field for speculation" that could "never rise to the rank of an exact science." Cuvier's essay, however, exposes all characteristic features of catastrophism as a science. It is an irony of history that Cuvier, one of the greatest intellectuals of 19th-century science and a champion of rationality, as well as other catastrophists, should become an object of ridicule without being read.

The Enlightenment and the intellectual climate of the Revolution influenced French thinkers and scientists, who, after a long period in which science was dominated by tradition, irrationality, and superstition believed that systematic thinking applied to all areas of knowledge could lead to the progress of ideas. Influenced by these ideas, Cuvier avoided religious or metaphysical speculation in his scientific writings, but he was also habituated to processes of dramatic and discontinuous upheaval by life experiences of The Reign of Terror (during the French Revolution). He made no reference to divine creation as the mechanism by which repopulation occurred following the extinction event. By contrast, he appointed the migration of surviving animals in isolated areas as the plausible mechanism. Nor did he make any explicit reference that the most recent revolution corresponded to the biblical flood. It is true that Cuvier paid special attention to the last revolution, concluding that it cannot be dated much farther back than 5 or 6 thousand years. He actually noted that no human fossils existed at all in the countries where the vertebrate fossil bones are discovered; however, as it is assumed that the last catastrophe occurred within human memory, he scanned the oldest records of all cultures and thus coordinated two sources of evidence, natural history for estimating the effect of ordinary causes since the last paroxysm and civil history. Since Western cultures recorded this event as Noah's Flood, and since Cuvier used the Bible as one source of legitimate historical information among many, posterity charged him with distorting geological facts to support religious traditionalism. However, his empirical hope was to understand catastrophes through a detailed study of the most recent event, the most suitable for this goal given the fragmentary nature of geological evidence and the tendency for such evidence to become more and more inadequate as we penetrated deeper into time.

Some textbooks have erroneously regarded Lyell as an empiricist who, by fieldwork and close attention to objective information, drove the dogmatism of catastrophists out of science. On the contrary, the catastrophists advocated empirical literalism as a fundamental approach to science. They interpreted what they observed as a true and accurate record of actual events and interpolated nothing. Early geologists and paleontologists noted that breaks or ruptures appeared frequently in the geological record when they studied the structure of the mountains. For instance, it is usually observed that deformed layers containing marine fossils may be truncated and overlain by other horizontal beds also containing marine fossils but that are entirely different from the previous ones. Applying the law of superposition and the principle of original horizontality, the defining principles of stratigraphy already established during the 17th century, these were interpreted by geologists as two rock masses or strata of different ages that appear separated by a surface indicating that sediment deposition was not continuous, the strata above the surface being younger than the strata below (unless the sequence has been overturned), and that folding and/or faulting of older strata occurred prior to deposition under the sea of the younger strata. This discontinuity evidences an event that catastrophists interpreted as paroxysmal to deform the original horizontal strata and eradicate the older fauna. Uniformitarian geology, however, interpreted the folding and/or faulting of older strata and their elevation above the sea as associated processes that occur so slowly that we cannot appreciate the changes within a human perspective. Equally, the surface between both rock masses was formed through subaerial exposure and erosion over a very long time, representing a gap in the record that could cover several millions of years. According to Lyell, catastrophists misinterpreted the massive lacunae as evidence for rapid change. Geological unconformities and local extinction look paroxysmal, but only because slow, daily changes rarely leave any evidentiary trace at all. In his view, the geological record must be treated as imperfect to an extreme degree. Proper procedure in geology requires interpolating into a systematically impoverished record the unpreserved events implied by our best theoretical understanding.

Recent Theories

In the last decades of the 20th century a revival of Cuvier's catastrophism, a neo-catastrophic school, gained wide acceptance with regard to certain events (such as the mass extinctions) in the distant past. One stimulus for this change was the work of Walter and Luis Alvarez who in 1980 suggested that an asteroid struck Earth 65 million years ago, at the end of the Cretaceous period, and caused a mass extinction in which 70% of all species, including the dinosaurs, disappeared. In 1990, a 180-kilometer candidate crater marking such an impact was identified at Chicxulub in the Yucatán Peninsula of Mexico. The improbability of such an event is no argument against such a hypothesis, because the improbable, even with odds of once every billion years, must have taken place a few times in geological history. The sedimentological importance of rare events is difficult to assess because the record of such events may be very subtle. This is especially true if a deposit has been thoroughly bioturbated or if the record of an event is simply an erosional surface. Moreover, we know now that catastrophic events occur as natural events, as was illustrated by the observation of the Shoemaker–Levy 9 cometary collision with Jupiter. Since then, most of the mechanisms suggested to explain mass extinction events have been catastrophic in nature.

Thus, new theories such as *actualistic catastrophism* or *episodic sedimentation,* and disciplines like *Event Stratigraphy* and *Cyclostratigraphy,* developed in the geoscience community, represent a synthesis of Lyell's uniformitarianism combined with Cuvier's catastrophism. They are founded on the assumption that the earth as we know it today has been shaped by slow natural processes, but that most of the stratigraphic record was produced during cyclic and episodic astronomically forced events that were disturbed by other occasional natural catastrophic events such as bolide impacts or cataclysmic volcanic activity, which have produced abrupt environmental changes that have greatly affected the evolution of life on Earth. The immensity of geological time is important not only because of the immensity of the cumulative effects, but also because the long duration provides a chance for the improbable to take place.

This conceptual change in evolutionary biology during the last third of the 20th century also produced new theories, such as *punctuated equilibrium* and a revival of *saltationism,* that posit that evolution among the species takes place in rapid bursts separated by long periods in which little change occurs. These ideas contrast with Darwin's gradualism that, influenced by Lyell's uniformitarianism, requires that the fossil record be imperfect to interpolate the intermediate forms that, as Cuvier explicitly noted, have never been found.

Causality

The belief concerning the causal characteristics of the material world is one of the basic ones. It is possible to adopt a standpoint like the philosopher David Hume (1711–1776), and to assume that causal relationships are only a product of our mind because they cannot be derived from empirical data. Hume believes it is impossible to discover empirically in the world any relation between phenomena that could be called causality. Causality is but a name for a human custom that connects phenomena frequently succeeding each other. According to Hume, cause and effect are considered as mere successions, not as inner causal connections. In this case, science in the modern sense is possible only as a simple description.

The second option is to suppose the objective character of causal relations without being able to present an unambiguous argument; we remain at the level of metaphysical assumption, supported if not by arguments, then by the experience not only of individuals, but also historical experience and the results of science as well as individual practice. The discussion concerning the topic then has meaning only in relation to this; in other cases it will always lead to a situation where there are two opposing claims without the possibility of one decisive argument. We have selected the latter option and we consider it useful to restate the fact here, particularly because there is a rather widespread fallacy in definitions of causality and determinism that quite precludes the understanding of what is going on in contemporary science in this field. This fallacy, briefly expressed, consists in the identification of causality with determinism in a naive assumption that if there is a cause for something, it must be deterministic. The speculation then usually quickly proceeds on the presumption that there is some cause for everything; the whole universe and everything in the world are thus deterministic. To those who turn to etymology and refuse to give up the predetermination of everything that has its cause, we can offer what might seem to be a play on words, but one that is in this case very useful. The point is that we can distinguish between the expressions *determined* and *deterministic.*

Cause and Effect

Let us start step by step, however, from causality. What we understand by *causality* is the relation of material elements or systems, when the change of a state in one of the systems—the *cause*—necessarily elicits the change of a state in the other system—the *effect.* The *elementary causal relation* cause–effect is a certain abstraction that cannot be found in such isolated form in nature. What is closer to reality is the idea of a *concatenation of causes and effects* with which a range of philosophers work—from Aristotle (the hierarchical model of the world from the first cause to the purpose of all purposes) up to the mechanical materialists who aim to trace in the initial causes through their effects all the states the universe gradually acquires. Even this is, however, to a certain extent, a simplified notion counting on the presumption that one and the same cause always elicits an identical effect and that it will never be different. Another approach can thus be a combination of these causal chains in a *causal web* along which the changes from the initial causes gradually spread. In the following step this—so far two-dimensional—web can acquire a third dimension and stretch thus from area into *space,* and when we add a *retrospective effect* to the systems in the form of original causes, we can obtain a more complex picture of causal relations in the structure of material systems.

We can call the perfect knowledge of the initial state of a system in the causal relation *the complete cause;* that is, a cause that always elicits an identical effect. In reality, however, such perfect knowledge often remains an ideal and we have to take into account *conditions* that take part in the effect. The conditions themselves cannot elicit the effect, but they can influence the progress of the process or the very initiation through which the causal relation is fulfilled.

The problems with causality, explicitly expressed in the history of philosophy by Hume, led many natural scientists and philosophers to an effort to replace such a relation in our descriptions with functionality. This particularly concerns those who were close to positivist-oriented philosophy, because the function describes the concurrent interdependence of variables, but not their history. In such a description, some or all of what is called the asymmetries of the causal relation, which in their own way reflect the history of the system, are missing—it is *existential asymmetry* (which expresses the current character of cause and the potentiality of effect—the nonexisting cannot be the cause of the existing), *genetic asymmetry* (which is the expression of the ability to elicit changes, creative activities), and *temporal asymmetry* (which emphasizes the fact that whatever transformation—of matter, energy, and information—is fulfilled at the maximum speed of light, which is final, and that there is thus always a nonzero interval between cause and effect, whose extent depends on the distance in which the causal relation is fulfilled and the speed at which it happens).

Determinacy and Determinism

After a brief review of causality we can define the concepts of determinacy and determinism. *Determinacy* is the dependence of the system on causes; that is, everything that has some cause is determined directly by these causes. *Determinism* is the opinion that we are able to predict all the effects of determined systems if we know all their causes. That is, to emphasize this difference, causality and determinacy are the *objective* characteristics of material structures; determinism is *the view, the belief* that it is possible, with sufficiently exact knowledge of the state of a system, to count and predict all its subsequent states in relation to both the past and the future. The differentiation of determinacy and determinism, however, entails significant difficulties, the basis of which is an onto-epistemological problem. The point is that it implies the idea that we can speculate on the behavior of a system in terms of its "really" happening, independently of the observer (determinacy), and of the behavior of a system in terms of how we can calculate it (determinism). A given problem nonetheless cannot be disposed of by such a claim. It is evident (if only from a brief glimpse at the sky and the movement of celestial bodies) that systems always behave in a certain way, entirely independently of whether we are able to find solutions for their behavior in equations or not. The question of the *full* and *partial* determinacy of a system then arises. A fully determined system would be such that its every state in the arbitrarily distant future would be unambiguously dependent on (regardless of whether we would be able to calculate it or not, if anyone bothered to calculate it at all) the initial conditions or the "first cause" of the given system; that is, the whole chain of causes and effects being in progress in the system would be determined in advance by the initial state. A partially determined system would then once more stabilize after each change of the state and the subsequent state would correct itself according to the changed conditions. The first cause would then "dissolve" in the succeeding generations of causes and effects until it would lose influence on the subsequent states of the system. We can decide between these possibilities either on the basis of our philosophical (or other) belief, by which we at the same time dispose of the obligation to argue, or on the basis of some data, but in that case measurements (physics) must be performed, they must be somehow processed (mathematics), and the result must be interpreted. Through this, however, we step into the field of opinion and our belief; that is, we return to determinism and the additional differentiation of the determined, so that the deterministic loses its sense and what remains is again only causality and determinism. This determinism itself then acquires various forms in history that in fact mimic the route from the full determinacy of the universe (consistent determinism) to indeterministic systems.

A typical example of consistent determinism is *mechanical determinism,* based on the successes of classical physics and the idea of the universe as a mechanism (a big and complex mechanism, but still a mechanism) that is fully, at least fundamentally, quantifiable. This view of the deterministic universe, represented most often by Pierre-Simon Laplace (1749–1827), utterly excludes coincidence from the world, or rather considers it merely a subjective fact or a result of our ignorance of the causes. It is sufficient to discover causes, and coincidences will disappear from this world.

Twentieth-Century Interrogations of Causality

The picture reveals the first lacunae at the turn of the 20th century when Henri Poincaré (1854–1912) distinguished stable and unstable systems; he introduced the term *dynamic non-integrable system* and showed that most dynamic systems are of this kind. In simplified terms, the integrability of a system means that in a dynamic system, which can always be fully characterized by kinetic energy (which is dependent only on the speed of the bodies in the system) and potential energy (the mutual position of bodies, their interaction), transformations can be found such as to allow a perspective within which the potential energy can be eliminated and mutual trajectories thus neglected. It is therefore comparatively easy to find the trajectory of bodies and to define the future states of the system. Poincaré shows that such variables cannot be found and that dynamic systems are non-integrable. This means that in the field of classical physics a difficulty with determinism appears. The problem has been long understood as a mathematical one and it has been expected that the problem of such systems would be solved after the device was refined. This neglect lasted until the second half of the 20th century when chaotic systems, which revived the question, started to be talked about more frequently.

In the meantime, other problems appear. Mechanical determinism, entirely in line with classical physics, does not question the possibility of obtaining information about the state of the system, because it presumes an immediate impact from a distance. This view is, however, disturbed by Albert Einstein's (1879–1955) theory of relativity, which introduces the principle that the speed of light, which is final, is the maximum possible speed attainable in our universe. No signal can travel faster and we therefore find ourselves enclosed in the area of what is called the horizon of particles or—if we intend to place emphasis on mutual interaction—in the area of the causal horizon.

Quantum mechanics means another questioning of determinism, namely in its more moderate form. It shatters the idea of classical physics that it is possible to assume the standpoint of the observer of the system who measures required data without influencing the system itself. Werner Heisenberg's (1901–1976) uncertainty principle in its consequences means that it is not possible to obtain simultaneously with sufficient exactitude all the decisive information (typically the energy and position of the particle) regarding the quantum system. Even though quantum mechanics thwarted deterministic ideas and for many meant a definitive rift with the mathematical predictions of the future and was also understood as the confirmation of freedom from the side of physics, there still remained numerous scientists and philosophers who believed, like Einstein, that "God does not play dice." They were convinced, and some still are, that the impossibility of obtaining at the same time all the required data about the system is just a technical problem or that it is a question of those characteristics of reality that have so far escaped us and that the situation will improve with the development of technology and physics and that determinism will be preserved and the world will not be ruled by accident, out of which the notion of objective fact would emerge in indeterministic conceptions of some quantum physics interpretations. However, all the experiments that so far have been performed with the aim of deciding the situation, including attempts that were inspired by the thought experiments of significant followers of determinism, have proved that most probably it is not a technical problem, but that reality itself is such. So the notions *determined* and *deterministic* blend here again and it seems that the systems really are not the predetermined "first cause" once and for all. The followers of determinism can still argue through the ambiguity of the transition from the world of subatomic particles to our macroworld and rely on the fact that somewhere the rescue of the deterministic world would once again appear. This hope, however, is slowly beginning to fade with regard to the works that do not need to proceed on the basis of quantum mechanics and the uncertainty principle; they do not even require relativist physics, but they are based on the very core of classical physics, namely on dynamics in the form as experienced at the very end of the 19th century (H. Poincaré). It had been presumed for a long time that this was just a problem of technical insufficiency, but since the middle of the 20th century theories have been gradually conceived that prove that even dynamic unstable systems, as defined by Poincaré, show equally indeterministic behavior as, for instance, quantum systems.

The probability description, characteristic of chaotic (and quantum) systems, becomes part of science much earlier, that is, in relation to thermodynamic theory in the second half of the 19th century. It was applicable wherever it was used with systems containing a very large number of elements, so it was not possible (and as a result, as it turned out, not even necessary) to take into consideration the exact characteristics of each of them; but to determine the behavior of a system with a sufficient degree of probability it was enough to know their probable configuration. Yet because it was supposed that it would be enough to have sufficient capacity for finding all the data about each element in order to replace the probability description with an unambiguous (dynamic) one, this *stochastic chaos* did not disrupt the belief in determinism. The incidental behavior of such a system is influenced by external conditions, unlike *dynamic chaos* where the unpredictable behavior is brought about by the impossibility of estimating the initial conditions.

Similar to classical and relativistic physics when the classical model remained a good device for the description of bodies of the macroworld moving at low speeds and became a special case of relativist physics, everything gradually indicates that history will be repeated with new protagonists, and the deterministic description will remain reserved for the relatively narrow circle of simple systems and will become a special case in a more general description, which will be probabilistic.

Chaco Canyon

Situated within the "House Made of Dawn" (the San Juan Basin) of the Four Corners area (where the boundaries of New Mexico, Arizona, Utah, and Colorado meet), a remarkable culture evolved. The hunter/gatherer nomadic Archaics were the first to populate the area, around 8,000 BCE. This early culture left cosmographic pictographs upon the canyon walls, revealing an ancient knowledge of the seasons and celestial movements. Approximately 700 CE, near the end of the Basket Weaver Period, the Chacoan ancestors, who had inhabited pit houses, began building complex communal architecture, monumental stone edifices now called "Great Houses," that required the engineering of a sophisticated astrological comprehension. One wonders what the temporary means of calculating these alignments might have been, prior to these constructions. These Great Houses were not only planned, but built in stages. Assembled data from tree rings on lumber revealed that construction of some could require decades to complete, while others took centuries. This technology gathered calculations of the equinoxes, solstices, and other cycles of time; these data assisted in planting, harvesting, celebrations, and, possibly, dates for trade fairs. The villages appear to be unsustainable and were low in population on those high desert plateaus; archeologists posit the Chaco Canyon Great Houses, and other cosmological structures, to be evidence of the Chacoan worldview. Chaco Canyon appeared to be a political and cultural center, with Pueblo Bonito the nucleus, as roads of 30 foot (10 m) width, bordered with beams, lead out of Bonito to the remaining major Great Houses in Chaco Canyon. In addition, roads lead out of the canyon to the surrounding 150 communities. The canyon's major distinct architectures were then speculated to be public structures utilized for traditional ceremonial occasions, in addition to trade and commerce. Artifacts divulge evidence of an extensive trade economy. For example, discovered samples of jewelry reveal manufacture from elements originating in Mexico and California.

Scholars such as Anna Sofaer have postulated that the Chacoans demonstrated a "cosmographic expression" with the construction of their habitations, with precisely calculated roads leading out of Pueblo Bonito, in addition to each community's placement. The Solstice Project ascertained that of the 12 major Chacoan villages, 4 have cardinal bearings, one is aligned to the solstice, 5 to the lunar minor, and 2 to the lunar major. In addition, there are Great Houses that illustrate a relationship in bearings; there are North–South and East–West connections, and a three-community relationship with the southern lunar minor standstill. Furthermore, examination of the Great Houses themselves has disclosed more alignments, of which the following is a sample: the sun sets in alignment with a south wall prior to an equinoctial full moon; calculations of terrace umbrae can be observed from East to West for daily reckoning, and seasonal from North to South; there is a kiva window forming a beam of light recording summer solstices on a wall, and an area tracking the 28-day lunar cycle; a doorway frames the rising lunar minor standstill. Other astronomical markers include the stone pillars at Chimney Rock, which frames the rising northern lunar major standstill; and an "observatory" of three sandstone slabs at Fajada Butte, which forms a glissading streak of light that records the solar solstices, lunar equinoxes, and the 18.6 lunar declinations on a petroglyph spiral.

Unequivocally, such precise calculations, constructions, and accompanied celebrations would have a significant influence upon the mindset of the Great House inhabitants and the Chacoan culture as a whole. The estimated zenith of their society peaked near 1020 to 1130 CE. Around 1250 CE, the migration from Chaco Canyon began. The House Made of Dawn stands as a testament to the sophistication of Mesoamerican cosmographic knowledge and the magnificent artistic expression it generated.

Chambers, Robert (1802–1871)

Robert Chambers, British publisher and amateur geologist, was most noted for his contributions as depicted in the book titled *Vestiges of Natural History* (1844). This controversial work, first published anonymously then later credited to Chambers, directly challenged both theological circles and the scientific community during the Victorian era (1837–1901). Chambers's unique interpretation and synthesis of religion and science promoted several controversial issues. Among these issues, Chambers questioned the barrier between science and the general population—professional versus amateur—and more importantly, the use of science to discredit the literal interpretation of scripture found in the Holy Bible. Although Chambers received a hail of criticism from all directions, his iconoclastic work did provide the possibility for future scientists and "unorthodox" theories to be offered for serious consideration, particularly in the case of Charles Darwin and the publication of his *On the Origin of Species* (1859).

Chambers held that, contrary to scripture, the universe, stars, and planets are beyond humankind's conception of time. Utilizing the nebula hypothesis, Chambers stated that our planet and solar system are but one part within common and innumerable systems contained within the vastness of the cosmos. Each planet, of which there are infinite variations, is subject to the same stages of development and is governed by infinite laws as established by Divine Providence. As for Earth and humankind, science and rational speculation could unravel the divine mystery of our planet's history, its relation to the solar system, and the processes of the divine creator. Geology, not theology, would be essential in uncovering this dynamic concept of time and history.

Chambers speculated, correctly to varying degrees, that geology and fossil remains could expose and explain the history of Earth that had been lost to the sands of time. As the earth proceeded from one stage of development to another, life gradually developed, as depicted by the fossil record within geological strata. Plants, fishes, reptiles, birds, and mammals conformed to the principles of development established by providence; arranged in perfect unity within a hierarchal framework from lowest to highest. This process toward greater complexity set forth by Divine Providence was preordained for the arrival of humankind.

Humankind is regarded by Chambers as the apex of temporal creation. Influenced by the laws of nature, established and governed by God, the mental capabilities of humankind are distinct, by degree, from other animals. Thus, this unity of humankind as depicted by mental capabilities is dependent upon the creation of the human brain. Unlike the rest of life, which is defined and finite, the human animal mind progresses from finite to infinite and gives a sense of consciousness within terms of individuality. Consciousness, intellect, and memory (conception and imagination) are the driving force not only for reproduction but also for creative contemplation of God and eternity. During this act of contemplation, humankind can understand moral laws established by God and that can be found within nature itself. Humankind has autonomy within these natural parameters, for example, design, from which the "good" can be derived and developed. This moral nature of humankind is eternal and fixed. Essentially, our species is depicted as a natural creation, driven by design to discover its natural morality, the divine, and to know God on a personal level.

In assessing Chambers's interpretation of then-known scientific principles, scientists of his era were understandably critical. Today it is Chambers's concept of time that appears most valuable. The age of the universe, as well as of the planets, must be taken beyond the traditional anthropocentric concepts of time. His conceptual framework for the gradual and distinct appearance, in geological terms, of plants and animals, which ultimately culminated in the sudden appearance of our species, denoted the slow and progressive natural state of designed life. Built upon natural geological and atmospheric conditions, the design set forth by the designer or creator resulted in the plethora of life on this planet. Although Chambers believed in the "vestiges of creation" while denying their actual philosophical implications, his synthesis of time directly challenged the traditional interpretation of scripture and some assumptions made by some scientists of his day.

Change

Change takes time and does not happen instantaneously. A rock chip from a mountain, slowly, over centuries of rolling down a river, becomes a smooth, round pebble. A tiny egg and sperm become a breathing, living human in 9 months. A drop of water held at 31 degrees Fahrenheit becomes ice. Whether slow or fast, change is never immediate. Even in the split second between the last swipe of the axe and the tree hitting the ground, turning from a living tree to a dying piece of wood, time elapses. As the seconds tick by, the numbers on the clock and the calendar change, ages grow older. Time is the medium of change, but change occurs only in one direction. Where there is change, there is before and after. The interval between before and after is understood as the passage of time. Time enables change to happen, and at the same time, time is constituted by the observation of change, whether in a cyclic or noncyclic manner.

Although humans have determined ways to measure the distance between the start and end of change, some thinkers have observed that it is not time itself that passes, but rather our senses informing us that change has occurred. Parmenides of Elea and his teacher, Xenophanes, felt change was mere appearance. Paramenides' student, Zeno of Elea, proved that time as change is unreal. Accordingly, time is not seen as a change, but with passage of time, change occurs. Change is also related to time in that the measuring and observing of time changes, yet this same event, despite different numbers measuring it, is still the same span of time, despite man's resistance to changing his method of measure. The definition of time is the same the world over—the passage of life; it is the method used for measuring the time that changes. Whether by using a predetermined method or by how it feels to have passed, time is measured. The shared concept among all measurements of time is the counting of a regularly recurring identical change, sometimes the recurrences and sometimes equal increments between occurrences. Thus, it is this counting of changes that allows time to happen. And it is time that enables us to observe the changes occurring all around us. Yet time appears to change when we observe it without the benefit of counting regular occurrences. An hour can appear to change in length, between the hour waiting for an athletic event to start and the hour an exciting game lasts. An hour can change by how it is measured—a sundial hour can vary from a clock hour. In any case, time cannot be detected without change occurring, whether we observe the change or not. Time is only the measurement at regular intervals of a continuous occurrence. Whether the heartbeat used by Galileo when timing the motions of the pendulum, or the seconds passing as a minute hand goes around a clock face, these are all changes that are occurring and thus are measured to indicate the passage of time. Time cannot be altered; it is the changes in other things that occur as time passes that constitute the change, not the passage of time itself.

In the 19th century, change was often equated with progress. Since then, events have demonstrated that this is not always the case. Change can be progressive, or it can be regressive and destructive. Change can occur in any direction, can end or be open-ended. No matter the direction of change, this alteration is measured, in part, by the time that has passed between start and end, or between one point and another on the continuum of time. In order to measure change over time, one must examine not only the start and end but also intervals along the continuum of the change over time. In some areas of research, such as the social sciences, assessing change over time is often explicitly the focus of the study. In other disciplines of study, such as organizational research, this is often more implicit, but still fundamental to making inferences and deductions from the data gathered. When measuring change over time, the more observations of the occurrences, the more frequent the observations, the more accurate the final outcomes will be. Change occurs over time, and it is because of this that the notions of time-specific and time-related errors need to be considered in any evaluation of change.

It was said by Lothar I, Holy Roman Emperor (840–855), that times change and that we must change with them. It can also be noted, however, that not only do the times change, but so does time itself. We can never return to the time that has passed, nor can we return to the person we were at an earlier time. As time passes, changes occur, whether realized or not. Moreover, as time passes, the ability to observe change alters. Impairments in a person, whether caused by age or improved by age, affect the perceptions of time passage. These differences cause a change to be observed differently, based in part on the perceptions of time's passage. Change, in this instance, can be defined as a variation in a property of a thing. Thus, the change occurs as the time passes and the property thus shifts in the item. Even an event that occurs never occurs in an instant, and thus change occurs throughout the event as the event progresses.

Charlemagne (742–814)

Charlemagne, or Charles the Great, was king of the Franks and Lombards and first Emperor of the Holy Roman Empire. He is often referred to as the "father of Europe," as his reign witnessed the consolidation of much of Western Europe following centuries of disunity. For this reason, Charlemagne is considered among the most important rulers of all time. His long reign represents a watershed period in human history; during it he expanded the Frankish Kingdom into a vast empire that included much of Western and Central Europe. He oversaw a revival of learning and culture referred to by historians as the Carolingian Renaissance, so named after his family dynasty. During this period, may of the peoples of Northern and Eastern Europe were converted to Christianity. In acknowledgment of these achievements, Charlemagne was crowned *Imperator Augustus,* emperor of the Romans, by Pope Leo III on Christmas Day, 800. This action was deemed provocative by the Byzantine emperor in the east, confirming the schism between the two churches. The famous coronation of Charlemagne gave birth to the Holy Roman Empire, which survived until 1806, when it was dissolved by Napoleon Bonaparte.

Charlemagne was the oldest son of Pepin III and grandson of Charles Martel. At the death of his brother Carloman in 771, with whom he had shared rule, Charlemagne took control of the entire Frankish Kingdom. In 773 he allied with Pope Adrian I, who was in a conflict with the Lombard ruler Desiderius. Charlemagne defeated Desiderius and in 774 became king of the Lombards. He continued the close relationship with the Christian church that had been pursued by his father. Charlemagne greatly expanded his realm in a series of military campaigns in Saxony, in Bavaria, and in Italy, but was checked in Spain in 778. He compelled the Saxons to convert to Christianity. His close friendship with Pope Leo III and coronation as Holy Roman Emperor in 800 incurred the jealousy of Constantinople, which still claimed to rule the Roman Empire. Charlemagne's rule legitimized the old split between East and West and yet also renewed the precedent set by Imperial Rome of uniting the various nations of Europe under one rule. The coronation of Napoleon I in 1804 was done in implicit imitation of Charlemagne's, testament to his influence on history, although with a different role for the Pope.

The Carolingian Renaissance, a resurgence of learning and culture during Charlemagne's reign, was centered at his imperial court at what is now Aachen in modern-day Germany. There he oversaw the creation of the palace school and invited intellectuals from across Europe, including Alcuin and Einhard, to instruct and to promote scholarship. Charlemagne encouraged commerce throughout his empire and dispatched administrators, *missi dominici,* to the most remote quarters of the realm so that he could supervise affairs. His efforts promoted the preservation of classical literature.

Charlemagne has been depicted as a legendary figure in much art and literature since his death in 814, notably in the medieval tale *Chanson de Roland,* and during the 19th century's Romantic period. In modern times he has been referred to as a forerunner for the idea of European unity. Charlemagne is buried in the imposing Byzantine-Romanesque cathedral he commissioned to be built at Aachen.

Chaucer, Geoffrey (c. 1343–1400)

Geoffrey Chaucer was among the foremost poets of late-medieval England. Having been, among other things, a soldier, ambassador, and customs agent, he was also a man of letters who found time to keep abreast of literary developments at home and abroad. Appreciated by 15th-century readers as a moralist, Chaucer appeals to modern audiences largely because of his lively storytelling and judicious insights about human nature.

Chaucer's poetry reveals his acute interest in time, evident even in his choice of poetic genres. Although they focus primarily on love relationships in the manner of the medieval historical romance, Chaucer's *Troilus and Criseyde* and the *Knight's Tale* from the *Canterbury Tales* are clearly indebted to the epic, set as they are in the remote eras of the Trojan War and the siege of Thebes. Time is no mere abstraction in Chaucer; nor is it simply a feature of the background of his narratives. His antique settings in the aforementioned two works complement the aristocratic status and the idealized, heroic behavior of his characters as well. Very different are the *Miller's Tale* and *Reeve's Tale:* as examples of the fabliau, these stories feature coarse characters, scatological humor and frequent deception, and unfold in the narrator's present, a world apart from the epic past. Their peculiar form of entertainment depends on immediacy of action and fast-paced storytelling in the here and now.

Partial or complete sources or analogues can be found for many of Chaucer's works, originality not having been as prized in the Middle Ages as it is in our own day. Despite his frequent debts to earlier and near-contemporary works of literature, however, the poet also saw a good deal of life itself. Born in London in the early 1340s, Geoffrey Chaucer may have attended one of the schools in the district near the River Thames where his father would have plied his trade as a vintner. He also served, possibly as a page, in the court of Elizabeth de Burgh, Countess of Ulster, an opportunity likely brought about by his father's influence as a wealthy wine merchant. Before he was 20 years old he gained firsthand experience, while in the army of King Edward III under Prince Lionel, Elizabeth's husband, of what historians call the Hundred Years' War between France and England (1337–1453). His military years marked the beginning of a varied career as a civil servant. Indeed, it was his service in three royal administrations, not his brilliance as a poet, that led to his being buried in Westminster Abbey in 1400. He was married to Philippa (de) Roet, and one of his children, Thomas, enjoyed an even more brilliant public career than his own.

It is tempting to assume that his political connections and involvement in matters of state must have spurred Chaucer to make overt references to his times. This assumption would be incorrect, however, as the poet seldom mentions significant contemporary events. Whether in his short lyrics or in his longer works, explicit "timeliness" is rare, though his avoidance of topicality also makes it relatively easy for modern readers to enjoy his poetry for its lyrical or narrative qualities.

Although it did not lead him to write social criticism or protest literature in the manner of William Langland, author of *The Vision of Piers Ploughman,* Chaucer's interest in time did find expression in the way he crafted meaning. It appears subtly, for example, in his use of timing in the development of his own fictional personae within his poems. *The Book of the Duchess,* for example, is early work (dating probably to the late 1360s) whose speaker, apparently an unsophisticated, naïve version of the poet himself, recounts a dream of his in which he encountered a grieving knight in a meadow. The farther we read in the account of this dream, the more obvious it becomes to us that the Black Knight is mourning the death of his beloved, the Lady White. Chaucer, however, deliberately portrays his narrator as one who offers consolation and counsel without fully understanding the reason for the grief-stricken knight's suffering until very late in their conversation—until nearly the end of the dream, in fact. After many hundreds of lines, the knight is finally compelled to do away with elaborate, poetic mourning and simply tell the uncomprehending Chaucerian persona that White has died. The bluntness of the revelation leaves the narrator almost speechless, and it is the poet's deliberate strategy to contrast the knight's despair with the narrator's shallowness, prolonging the sense of failed conversation to an extent that makes us aware of the oddly comic quality of the situation.

Although Chaucer wrote short lyrical poems, he is best remembered for longer works like *The Book of the Duchess, The Parliament of Fowls, The House of Fame, Troilus and Criseyde, The Legend of Good Women,* and of course *The Canterbury Tales*. Their length makes it necessary to understand in premodern terms what was said above about Chaucer's sense of timing. Like other writers of his age, Chaucer was fond of long, detailed descriptions and digressions recounted at a leisurely pace. Although modern students occasionally complain that these are distracting features of his work that bog down their progress through it, medieval writers and readers who aspired to literary sophistication (as their culture conceived it) enjoyed them as hallmarks of good verse.

Apart from Chaucer's conscious ideas about narrative time and historical periodization, the poet's place *within* time, specifically literary history, has aroused much scholarly debate over the past decade and a half. Conventionally labeled a "medieval" poet, Chaucer is often placed within surveys of Western European literature before the Italian poet Francesco Petrarca or Petrarch (1303–1374), who lived roughly two generations earlier than the Englishman. This anachronism is related to the modern scholar's sense that Petrarch, having been fascinated with the classical Roman past, was more "modern" than Chaucer: The remnants of that past abounded in 14th-century Italy, and thus a "Renaissance" poet could arise much more naturally there than in contemporary England. Also of relevance is Petrarch's personal distaste for the Scholastic philosophy of his own day, articulated in a Latin that he condemned as barbarous. For his part, Chaucer had a real interest in historical and cultural change, but he had none of Petrarch's despondent yearning to rebuild antiquity on the ashes of his own time or to cleanse the Latin language of its alleged postclassical impurities. Important work in the field of Chaucer studies by David Wallace and others has challenged the knee-jerk temptation to label Chaucer a product of the "Middle Ages" and Petrarch the herald of the "Renaissance."

Chauvet Cave

Both accident and scientific surveys have led to discoveries of caves throughout Europe that contain artifacts and artwork created by Paleolithic populations. Temporally speaking, these caves provide information on early European populations for whom little other evidence exists. Chauvet Cave, a relatively recent discovery, is one of the more noted such caves.

Discovered in 1994 by Jean-Marie Chauvet, Eliette Brunel, and Christian Hillaire, Chauvet Cave is located among the Cirque d' Estre Cliffs in southern France. As evidenced by skeletal remains, the cave was visited by a number of animal species including bears, deer, birds, and wolves. As for human populations, it is the presence of wall paintings and engravings that clearly marks human intrusion into the cave. Spanning hundreds of meters in length, the cave itself is the product of nature's ceaseless attention, particularly in the form of water erosion. Ultimately, after millions of years of alterations due these natural processes working on the cave's walls, ceilings and floors, Chauvet became a multichambered cavern that was augmented by stalactites, stalagmites, collapsed walls, and other geological phenomena. Structurally, the cave's several chambers vary in size from a few meters in width and height to a chamber that is upwards of 30 meters wide. Collectively, the geological phenomena associated with Chauvet Cave provide details about the effects of natural processes on subterranean dwellings while simultaneously providing researchers with an idea of times during which the cave's changes occurred. The remains Chauvet Cave's human occupants left behind give an entirely different picture and temporal understanding.

Remnants of human occupation of Chauvet Cave comprise a variety of artifacts including flint scrapers and blades, the remains of fire pits, and human footprints. Of course, the most evident indications of human occupations are the murals painted and engraved on the walls of the cave. Using charcoal and other miscellaneous matter as a medium, Chauvet's human occupants generated abstract images of animals, humans, and miscellaneous objects upon the walls much in the way other peoples adorned the walls of caves throughout the region during Paleolithic times. Specifically, animal images found were bison, mammoths, bears, rhinoceroses, and horses. As for the detail of the images created, while some images were roughly designed, others were quite detailed in their outline and overall attributes.

Why were the paintings and engravings created? What purpose did they serve? These questions, which have been debated since the first cave paintings surfaced, remain unanswered. What has been determined, however, are the times when Chauvet Cave was visited. With a large sample of carbon-14 dates determined through the analysis of bone and wood charcoal fragments, researchers discovered two main periods of occupation or rather visitation of Chauvet Cave, the first centered around 31,000 years before the present era (BPE) and the second centered around 26,500 BPE.

Chauvet Cave itself has provided researchers with a large sample of carbon-14 dates and breathtaking examples of wall art that clarify the variety of techniques utilized by prehistoric populations to generate their paintings and engravings. With its discovery being so recent, Chauvet Cave will undoubtedly continue to enlighten researchers for quite some time.

Chemical Reactions

The International Union of Pure and Applied Chemistry's (IUPAC) definition of a chemical reaction is "a process that results in the interconversion of chemical species." A chemical species is "an ensemble of the chemical elements which is identifiable as a separately distinguishable entity."

The transformation of reacting species into a new chemical product can be likened conceptually to events that occur in everyday life—it involves the interaction of objects (molecules, atoms, ions) with each other, and the outcome of the process is governed by their relative sizes, positions, and energies. A key has to be inserted correctly into a lock for it to be opened, and an egg's shell can be broken only by the application of sufficient force. The relation of these ideas will become clearer as the fundamental processes governing a chemical reaction are examined.

A discussion of *chemical reactions* in the context of time is highly appropriate: They have occurred since the dawn of time, they are both controlled by time, and, given the huge range of timescales on which reactions can take place, for example, the rusting of an iron nail compared to dynamite exploding, they exert an influence over the course of time. The history of chemical reactions in time is discussed in a manner complementary to the discovery of the chemical elements, although the two are very closely linked. This entry gives detailed consideration to the timescale on which chemical reactions occur: the very fast; those that are easier for human beings to contemplate; and the very slow. This highlights the technical ingenuity of scientists who have developed many sophisticated techniques to study ultrafast reactions.

History of Chemical Reactions

The world as we know it, indeed the entire universe, is composed of the chemical elements. The 94 known chemical elements (there are more in the periodic table, but they do not occur naturally) were formed shortly after the start of time as we know it—the *big bang*—and have been combining with each other ever since. Shortly after the big bang, extreme temperatures are believed to have favored the fusion of the separate neutrons and protons present, forming helium and deuterium nuclei, in a process termed *big bang nucleosynthesis*. These positively charged nuclei subsequently combined with the negatively charged primordial particles present, electrons, to produce the first atoms, of which most were hydrogen. The extreme conditions generated by the production of the first stars are believed to have created heavier elements through the processes of *stellar and supernova nucleosynthesis,* and *cosmic ray spallation.* The first chemical reactions would have now occurred, with simple chemical entities based on light atoms such as carbon, nitrogen, and oxygen produced in abundance.

The formation of the earth (c. 4.6 billion years ago) was followed by the Hadean eon, where the earth began to take shape. Changes in the chemical composition of the atmosphere, afforded by volcanic eruptions, the cooling of the earth's surface, and asteroid bombardment, have been proposed to have been instrumental in the development of life. The generation of small organic molecules, known to be monomeric constituents of living organisms from the most basic chemical species, is propounded as one of the most widely accepted theories of the origin of life. The combination of α-amino acid molecules to form polypeptide chains; the similar production of nucleotides, phosphates, and sugars could, theoretically, react together in such a way as to give the double-helix of life, DNA. The classic Miller-Urey experiment exposed a mixture of simple gases and water vapor to an electrical discharge (to mimic lightning), and the ensuing chemical reactions were indeed found to produce simple biomolecules that are essential to life. An early earth atmosphere rich in ammonia, methane, water, carbon dioxide, and nitrogen could have been transformed chemically to give a so-called primordial soup.

The suggested transformation of simple biomolecules into the polymeric constituents of life, and their organization to give a living cell, remains a controversial theory. Such an event would mark the cornerstone of evolution and of the history of the earth. The first simple single-celled organisms were all likely to have been heterotrophic, requiring relatively complex organic substrates, for example, simple sugars, to be sustained and to reproduce. It has been proposed that such organisms diverged as a process of evolution to produce autotrophic species, which were able to use an alternative source of energy and were subsequently able to transform the most basic chemical precursors into much more complex ones. The most important example of autotrophic chemical reactions is photosynthesis: the conversion of water and carbon dioxide driven by sunlight into carbohydrates. Photosynthesis is one of the most important natural chemical reactions known to humankind, and the challenge of reproducing it satisfactorily within the laboratory has still not been met.

Profound environmental changes occurred as a result of the production of oxygen. Initially, oxygen dissolved in the oceans and combined with oxophilic elements to produce numerous oxides such as those of the common metals, iron in particular. Over time, its concentration in the atmosphere gradually increased, with far-reaching consequences for the diversity of the living organisms that, until then, existed in anaerobic conditions. Concomitantly, the conversion of oxygen (O_2) to ozone (O_3) in the upper atmosphere by ultraviolet light formed a protective layer around the earth that actually reduced the amount of damaging ultraviolet radiation reaching the earth's surface. A popular notion is that this could have safeguarded the development of simple organisms that were then given the chance to evolve in an increasingly aerobic environment. Moreover, those organisms that did not evolve to be able to assimilate oxygen were largely wiped out by the increasingly toxic environment. Today, the earth is finely balanced by cycles of respiration (effectively the production of energy by oxidation of relatively complex carbon-rich organic molecules producing carbon dioxide and water) and the reverse of this process, photosynthesis. The energy produced by respiration provides the driving force for the conversion of very unreactive nitrogen gas into soluble nitrogen compounds. The combination of photosynthesis, respiration, and the fixation of nitrogen forms the basis of life itself.

The discovery and exploitation of fossil fuels as an energy source by humankind was almost certainly the next most significant way chemical reactions would alter the environment of the planet. Reserves of coal, gas, and oil were formed from decaying organic matter by very slow chemical reactions, but comparatively recently given the estimated age of the planet. Combustion of fossil fuels for heating, driving industrial processes, and travel has been held responsible for the rising levels of carbon dioxide in the atmosphere and is claimed to be a major contributor to global warming.

The commercialization of chemical reactions occurred as an inevitable part of the Industrial Revolution. New raw materials such as sulfuric acid (the production of which is thought to be the first chemical process to be performed on an industrial scale), soda (sodium carbonate), and caustic (sodium hydroxide) were required to support many thriving industries including glassmaking, soap production, and cotton bleaching in the 19th century. It is appropriate to mention that many of these chemicals now being produced on a grand scale had their origins in the alchemical era. The accidental discovery of mauvine (an intensely colored purple dye) during an attempted synthesis of the antimalarial quinine by William Perkin in 1856 was the catalyst for the generation of the modern-day chemical industry. Existing chemical companies such as Imperial Chemical Industries (ICI) and Bayer began to diversify into photography, food, pharmaceuticals, and explosives. The improvements in scientific understanding during this period drove the desire to better understand chemical reactions and the structures of molecules; both academic and industrial chemical research have since flourished. Our current level of understanding means we are able to design and control chemical reactions to provide us with food, health, fashion, and entertainment.

The Timescale and Study of Chemical Reactions

The rate at which a chemical reaction proceeds is studied by *reaction kinetics*. The timescale on which a chemical reaction can occur ranges from the very slow, taking days or years to complete, to the ultrafast, of the order 10^{-15} seconds (one quadrillionth of a second). The majority of chemical reactions require a millisecond (one thousandth of a second) or less. For a chemical reaction to take place, the reacting molecules must collide with one another in a favorable orientation to overcome the energetic barrier to reaction: the activation energy to form the activated complex (or transition state). This represents the highest energy point on the reaction pathway (rather like the top of a mountain); it will then rapidly collapse, with the products of the reaction tumbling downhill, to either the unchanged starting species or the new product(s).

A catalyst lowers the activation energy in forming the activated complex, meaning more of the reacting entities will have the energy required to react on collision. The presence of a catalyst therefore increases the overall rate of reaction. Enzymes are nature's catalysts, and numerous manmade materials are employed in industrial processes in an attempt to compromise between making the speed of a reaction reasonable without making the process economically unfeasible.

In a kinetic study, it is conceptually useful to imagine the whole reaction process being photographed from start to finish. Each "snapshot" represents a different stage in the reaction pathway, and, depending on the rate of reaction, it may be possible to view the discrete stages of the reaction.

The scientific investigation of reaction kinetics has always presented a challenge to chemists. Classical investigations (which predate 1900) of reaction kinetics could be performed only on very slow reactions, as the progress of the reaction had to be followed by some physically variable property that was perceptible to human beings, such as a color change or the evolution of a gas. The change in such a property was monitored over time, producing a relationship between the progression of the reaction and the time elapsed, which could then be used to determine the reaction rate. The shortest observable reactions were of the order of seconds. The development of rapid mixing techniques early in the 20th century allowed so-called stopped flow methods to probe reactions of the order of milliseconds. A significant problem encountered using this technique was that, for very fast reactions, efficient mixing takes an infinitely long time compared to the speed of the reaction itself. Therefore, the reactions would have already taken place before the reacting species had mixed properly, giving inaccurate results. Recent improvements in instrumentation have meant that reactions on the microsecond timescale can now be studied.

Scientists recognized early on that new techniques would have to be developed for the study of faster reactions. Manfred Eigen, Ronald Norrish, and George Porter were co-recipients of the 1967 Nobel Prize in Chemistry for their development of flash photolysis in 1949: a pump-probe technique that could interrogate reactions of the order of microseconds. A chemical sample was irradiated using a very short burst of intense light (from a very powerful flashlight) to produce a reactive (and most often short lived) intermediate, the subsequent decay of which by, for example, chemical decomposition or the reemission of light, was monitored spectroscopically.

With the advent of lasers in the 1960s, the shutter speeds of our notional "camera" could be increased substantially, and the pico- (one millionth of one millionth of a second) followed by the femtosecond regimes were now accessible.

Chemical reactions are also concerned with reaction *dynamics:* changes to the molecular architecture, such as the perturbations in bond lengths and angles that occur as a reaction is taking place. As understanding of chemical reactions improved over the 20th century, scientists became much more ambitious and began to explore the possibility of probing extremely fast reactions, or, more specifically, the direct observation of the shortest lived species known in chemistry: the activated complex. The reorganization of electrons in chemical bonds and the nuclei of the constituent atoms over atomic dimensions (a vibration of a chemical bond) is of the order of femtoseconds (10^{-15} seconds). Thus, to achieve resolution of the activated complex, the shutter speed of our "camera" would have to be around 10 to 100 femtoseconds. Ahmed Zewail pioneered the experimental techniques for the exploration of chemical reactions into the femtosecond regime (with the main technological requirement being sufficiently short exciting laser pulses) for which he was awarded the Nobel Prize for Chemistry in 1999. Femtochemistry has now diversified and been rebranded in many branches of science. Femtobiology has been applied to fundamental biochemical processes such as vision, protein dynamics, photosynthesis, and proton and electron transfer. The understanding of early femtosecond events in a protein environment is important for understanding the function of these systems.

Additional spectroscopic techniques have been developed during the 21st century, not with the aim of studying kinetics of chemical reactions, but to exploit the different timescales of molecular processes that do not necessarily lead to chemical reactions but are more suited to probe reaction dynamics. The Heisenberg uncertainty principle stipulates that, in measuring the position and momentum of an object, the more accurately one property is determined, it follows that the other becomes less accurately determined. Therefore, as a molecule of a particular energy is less well defined, its lifetime will be increased.

Since different molecular architectures have different energies, improvements in spectroscopic techniques that have allowed the changes in energy between molecular states to be very accurately measured can be used to determine how molecular properties such as the distance between two nuclei change over the course of a chemical reaction. A large difference in energy between two different molecules allows them to be distinguished even if they interchange very quickly. High-frequency techniques such as ultraviolet visible (10^{-15} s) and infrared spectroscopy (10^{-14} s) are easily able to distinguish between molecular states that are blurred to electron- (10^{-4}–10^{-8} s) and nuclear-spin resonance (10^{-1}–10^{-9} s) probes.

There is much speculation as to how the earth and even the universe will come to an end, if indeed they will. Humankind's negative influence upon the environment as a result of chemical reactions is only too apparent. The depletion of ozone in the stratosphere caused by the photochemical degradation of CFCs (chlorofluorocarbons); the emission of greenhouse gases; and the poisoning of terrestrial land and water systems promises a bleak future for the earth. It is possible that an increasingly toxic and humid environment will make life on the planet unsustainable.

Looking even farther into the future, in a climax of destruction, all objects created by chemical reactions could disintegrate under the influence of the continually expanding universe into radiation and elementary particles that will move away from each other—an awesome contradiction to the formation of the first elements and their ensuing chemical reactions at the dawn of time.

Chemistry

A modern, albeit superficial, definition of chemistry is that it is the science dealing with the composition of substances, their properties and reactivity. All matter in the universe is composed of the *chemical elements;* their systematic study, and that of the *compounds* they form, is chemistry. Chemistry has earned itself the title of the central science, as the study of matter is fundamental to all other sciences, including physics, materials science, biology, and pharmacology to name just a few. Typical applications of chemistry in modern life include the discovery and development of new drugs; the discovery and production of fuels, plastics, fertilizers, pesticides, vaccines, and foods; the use of chemical techniques by forensic scientists to solve crimes; and the production of new materials and pigments for the clothes we wear and the many functional items in our homes. It is certain that chemistry has occurred since time began and will prevail until time ceases, and this makes the discussion of chemistry in time both fascinating and hugely important. The impact that the science of chemistry has had on humanity is huge. The ill-defined and semi-empirical beginnings of what we now know as the highly advanced, organized, and multidisciplinary science of chemistry lends well to a general overview of the subject being discussed within the framework of time.

Initially, the development of chemistry as a widely accepted scientific discipline from its rather chaotic foundation in alchemy and philosophy is discussed from a historical perspective, with particular emphasis on the scientific, technological, global, and economic impact from its initial establishment in the 16th century to the present day. Next, the position and influence of chemistry in the 21st century is introduced by a retrospective exposition of the effect of chemistry on humanity and the environment. The subsequent expansion alludes to the challenges within chemistry itself as both the source of, and solution to, many fundamental problems that currently face humanity, and that will most certainly become more pressing and severe in the near future.

Chemistry in the Past

Around the 7th century BCE, Thales of Miletus is credited as the first of the Greek philosophers who endeavored to explain the natural world around him without invoking any supernatural phenomena. Indeed, he is arguably the first *scientist.* The Greeks explained many natural occurrences, such as lightning and earthquakes, as the direct intervention of anthropomorphic gods and heroes. Such mythological reasoning was sidelined by Thales and he instead proposed, for example, that the earth floats on water, and hence the occurrence of earthquakes can be explained by the striking of the earth by waves of water. Thales held the view that all matter was ultimately derived from water, although this hypothesis was certainly tainted with the supernatural. Thales' Miletian philosophical descendants were more coy: Anaximander ascribed to all substances being made from *apeiron,* a single, unknown substance. Subsequently, air (Anaximines) and fire (Heraclitus) were separately proposed to be the basic constituent of all matter.

The quest by philosophers to produce a simple explanation of the natural world, combined with the observation that one substance could be converted into another, meant the idea that all substances were ultimately composed of the same basic building block was attractive and persisted for some time.

Aristotle (c. 4th century BCE) agreed with the notion that ultimately there was only a single primal substance, but argued that it was incomprehensible to humankind. Somewhat contradictorily, he believed that Empedocles' four elements—earth, air, fire, and water—were the constituents of all matter. He was also sympathetic to Anaximander's view that the phenomena of heat, cold, wetness, and dryness were influential in the interconversion of different substances; a view not alien to our modern-day understanding of the transformations between states of matter with, for example, water converting from a solid to a liquid to a gas by heating; the process being reversed by cooling.

Leucippus is believed to have formulated the idea that all matter is made of many small particles, or *atomos* (a term coined by Democritus, meaning "indivisible"), all of which are made of the same primal substance, but are observed differently depending upon the material. These ideas were made to be compatible with Aristotle's "quartet of elements." There was disagreement between proponents of atomism and those of the older theories. Opponents of Leucippus wanted to know what he claimed might separate these small particles if they were really indivisible?

Empedoclean views of the four elements constituting matter, which was supported by the credible figure of Aristotle, eventually led to the suppression of atomism as a credible explanation for the composition of the natural world. Its perceived blasphemous stance was condemned in the Middle Ages, though it did not disappear completely. It was the experimental input from *alchemy,* rather than conjecture, that progressed our understanding to what we know and accept today.

Although alchemy has long been regarded as pseudoscientific, that is, a practice that claims to be scientific but does not adhere to the scientific method (the proposition of a hypothesis based on a natural phenomenon that is then tested experimentally in an objective and transparent manner), it is the forerunner of chemistry as we know it today.

Closely related to the ancient traditions of Hermeticism, Western alchemy is often viewed as a practice akin to black magic, with practitioners intent on producing gold from a variety of tenuous, mystically based recipes and incantations. This view is somewhat dispelled, however, when it is considered that many of those who practiced alchemy went on to influence much of what is now called modern science, Isaac Newton and Robert Boyle being two examples. In fact, over the course of the early modern period, mainstream alchemy developed into a discipline now recognizable as the precursor to modern chemistry.

A cursory examination of alchemy and its metamorphosis into a rigorous scientific discipline follows. It is significant that it predates the philosophical musings of the ancient Greeks by a considerable margin.

It is believed that "Western alchemy" originated in Egypt (5000–400 BCE) and subsequently became established in Greek and Arabian civilizations, and in Europe from 1300 onwards. Chinese and Indian alchemy were developed independently and remain culturally isolated.

The proliferation of alchemy was motivated by spiritual beliefs that were connected to unexplained and enchanting physical phenomena, such as fire: a mystical force that could transform one substance into another. In the same way compounds are broken down and recombined by the alchemist, it was believed that the immortal spirit was separated from the mortal body upon death, and recombination with matter meant immortality. The search for an *elixir of life* was closely linked to the ongoing challenge of being able to transmute poorer base metals into gold. By the same token, the alchemist sought the perfection of the self, with death not seen as the end.

During the Renaissance, the ideas of René Descartes and Roger Bacon provided the foundations for developing the scientific method. Around this time, Western alchemy began to split into two separate strands. Initially, it was Paracelsus who directed alchemy away from the underlying mystical and spiritual influences and applied a more scientific approach, giving rise to *iatrochemistry.* However, there remained those who held firm to the spiritual foundations of alchemy and continued the search for immortality and metal transmutation.

It has been said that the development of metallurgy (which is inextricably linked with alchemy) was the turning point in history that marked a departure from the Aristotelian elements. The metals, of which a significant number had been discovered by the 17th century, were regarded as "earth," an extrapolation of the notion that the known states of matter corresponded to the physical form of a substance: "air" was gas, "water" was liquid, and "earth" was solid. The cultural importance of gold was increasing, and its obvious difference from the other metals was of great interest, therefore the notion of them being "the same" was unacceptable.

The vague and esoteric language of alchemy, the irreproducibility of experiments, and the exposure of fraudulent practice began to frustrate eminent writers such as Geoffrey Chaucer and Dante Alighieri. Alchemists were accused of deliberately trying to conceal their methods from the uninitiated, and their opponents argued that they were in fact self-deceived; skepticism and distrust toward alchemy became popular opinion.

The publication of *The Sceptical Chymist* by Robert Boyle in 1661 became a cornerstone in the development of chemistry away from its alchemical roots. Boyle refuted the concept of Aristotle's quartet of elements, instead contending that all substances were made of irreducible particles of some shape or form. An important point is that he argued that a proposed theory must be proved by experimentation before it could be accepted as true. Subsequent work in the 18th century by Antoine Lavoisier paved the way for the chemistry we know today. He concluded, rightly so, that water and air were composed of distinct entities, and thus they were not elements at all. Lavoisier also took the significant step of quantitatively measuring his experiments, allowing him to demonstrate mass changes during combustion. Crucially, the identification of oxygen was achieved, though it is certainly debatable whether Lavoisier was the first to discover this element. Joseph Priestley was instrumental in corroborating the work of Lavoisier.

At the turn of the 19th century John Dalton is to be credited with the revival of a modern atomist theory: Elements are made of small particles called atoms; all the atoms of a given element are identical to each other but different from those of another element; atoms from one element can combine with those of another in a fixed proportion; and they cannot be created or divided into simpler particles. He implemented a system for depicting the known chemical elements of that time (though some were erroneous as, in fact, they were chemical compounds) and, most important, gave them a measurable quantity: atomic weight. Jöns Jakob Berzelius proposed the designation of simple symbols for the chemical elements, for example, F for fluorine and Mg for magnesium. This is the modern-day language of chemistry.

Many were now to attempt the tabulation and systematic ordering of the known chemical elements. It was Dmitri Mendeleev who studied the behavior of individual elements, grouped them together by virtue of similar chemical properties, and successfully predicted the existence of elements that were discovered during his lifetime. This culminated in the much-vaunted periodic table of elements, today's chemist's "road map" to all the known chemical elements.

It now remained for the conclusive identification of atoms themselves as being the true "primal matter." In 1909, Ernest Rutherford chose gold with which to perform his experiments to determine to composition of the atom. Being malleable, it could be beaten into very thin sheets, which made it almost transparent. Firing α-particles (positively charged helium nuclei) at thin gold foil afforded some very surprising observations. The refinement of Rutherford's results by Niels Bohr, coupled with Joseph John Thomson's earlier discovery of the electron, and the subsequent discovery of the neutron by James Chadwick in 1932, led to the establishment of the currently accepted view of the atom. It consists of a dense, positively charged nucleus of two distinct subatomic particles, protons and neutrons, surrounded by a cloud of negatively charged electrons, with the two separated only by empty space (an idea intolerable to most early Greek philosophers).

Chemistry in the Present and Looking to the Future

The development of chemistry from the early attempts by philosophers to understand their surroundings to the well-established and undisputedly vital scientific discipline it is today has been key to the development of civilization across the globe. However, the influence of chemistry has been both positive and negative. While people are able to live longer and more comfortably thanks to improvements in agriculture (fertilizers and pesticides), pharmaceuticals, and energy derived from crude oil, the improvement in our quality of life has impacted negatively upon the environment through, for example, global warming, the depletion of the ozone layer, and pollution of terrestrial water systems. Numerous human tragedies have arisen through the irresponsible or malicious use of chemicals: the Bhopal disaster; the deployment of nerve and blister agents during warfare; and the prescription of thalidomide to pregnant women to name but a few. Chemistry and the chemical industry are certainly sometimes viewed with suspicion, and the dogma that "natural" substances are "good" and those produced by man are "bad" persists. Certainly a prominent challenge for the future is to educate the general public; ignorance is perhaps the fault of chemists and other scientific disciplines for allowing themselves to be viewed as impenetrable.

Chemistry today is very much at the forefront of technological development and it is studied intently in academic and industrial institutions. Research efforts are directed toward both blue-sky exploration and the addressing of specific scientific problems. The discovery and development of new chemical reactions and techniques have elements of both, whereas the preparation of new chemical elements by nuclear chemistry and the development of sustainable energy alternatives are restricted to each category, respectively.

Perhaps surprisingly, alchemy, the transmutation of elements, is still an actively pursued area of research. The prospects for the isolation of the heavier nuclei of elements with an atomic number greater than 118 appear to be very challenging.

Humankind's desire to understand and predict the properties of molecules has been unrelenting. The application of quantum mechanical methods to the study of a chemical system has made the most of the improvements in computing power. Chemists are still currently limited to the study of comparatively simple systems under artificial conditions. For example, most density functional calculations on molecules to probe their stability and geometry are performed in the gas phase, with interaction between other molecules unaccounted for. As computers become more powerful, chemists will be able to study the structure of more complex molecules (invariably those that play a key role in biochemistry) and probe their interaction with one another.

Nature has remained far superior in its elegance and efficiency in producing useful chemicals. Humankind has marveled at the complexity of photosynthesis, respiration, and the fixation of atmospheric nitrogen for decades. Attempts to model these systems in the laboratory using a much more basic repertoire of chemicals have met with only limited success. Such attempts have, however, broadened our understanding of these natural processes considerably. The industrial production of bulk chemicals is costly both in terms of energy and its impact on the environment. The development of a process to produce ammonia with the comparable mildness and efficacy of the nitrogenase family of enzymes would make a welcome replacement for the Haber process. Similarly, the cheap and environmentally benign production of hydrogen to be used as an energy source is highly sought after. The increasing levels of carbon dioxide in the atmosphere, generated from the combustion of fossil fuels, are largely responsible for global warming. The sequestration, or ideally, utilization of CO_2 as a feedstock itself is highly desirable.

Similarly, some the most efficacious medicinal compounds are those isolated from natural sources, but they tend to be highly complex structures and very difficult to make in the laboratory. The ingenuity of synthetic chemists means that, given enough time and resources, any molecule can be made in the laboratory. But this process is inefficient and expensive, and largely serves to showcase what chemists can achieve rather than resulting in a useful product. Given the dwindling success of the pharmaceutical industry in generating new medicines, the future will see a renaissance of drugs being developed from natural products. Instrumental in this process will be the crafting of genetic engineering, rendering bacteria, rather than chemists and glassware, the far better choice for producing potential new drugs on the scale likely to be required.

Astrochemistry, the application of chemical techniques to the study of the chemistry in outer space, has afforded interesting insights into the universe itself and its influence on the formation and the development of planet Earth. Many hypotheses have been put forward to suggest that life as we know it, or at least its simple organic precursors, could have developed in space and then subsequently been transferred to Earth by meteorites. Chemistry will continue to be of immense value to space exploration, and it is hoped that it will provide more clues as to our origin, and maybe even our subsequent fate.

Chicxulub Crater

The Chicxulub crater is an approximately 180-kilometer–diameter structure, which is now buried by a nearly 1-kilometer–thick sequence of carbonate sediments, on the northern edge of the Yucatan Peninsula (southeastern Mexico). The name Chicxulub was selected because a small town, Puerto Chicxulub, is located above the center of the structure. The best-known surface expression of the crater is a concentric pattern of karst sinkholes called the Ring of Cenotes (*cenote* is the local Maya word for sinkhole). The Ring of Cenotes is generated by progressive subsidence of the crater's wall and is visible in satellite images of the region. The formation of the Chicxulub crater represents a significant event in the Phanerozoic's history: it was made about 65 million years ago when an approximately 10-kilometer–diameter extraterrestrial body hit the earth, causing the great mass extinction at the end of the Cretaceous period.

The Chicxulub structure was described initially in the late 1940s as a set of nearly circular geophysical anomalies discovered during oil surveys. In the next decades, three exploratory wells drilled into the structure by Petróleos Mexicanos (PEMEX, the Mexican state-owned oil company) penetrated late Cretaceous rocks (andesite). This andesite was originally interpreted as having a volcanic origin, and the Chicxulub structure was considered a giant end-Cretaceous volcano.

This interpretation changed at the beginning of the 1990s, when certain evidence confirmed an impact origin for the Chicxulub structure: impact melt rock in the crater, an extensive field of tektites around the Gulf of Mexico, and a millimeter-thick layer worldwide that contains material of the meteoritic impact (iridium anomaly, microdiamonds, nickel-rich spinels, microtektites, and shocked quartz grains). This millimetric key-bed represents the dust and fine ejecta that covered the atmosphere after the Chicxulub impact and deposited slowly, probably over months or a few years after the impact.

The environmental perturbations of the Chicxulub impact event included a temporary absence of sunlight caused by dust and aerosols ejected into the atmosphere, impact winter (similar to nuclear winter), acid rain production, worldwide wildfires, and the largest tsunamis and earthquakes of Earth's most recent history. These disruptions caused the second, more severe biological crisis of the Phanerozoic: the Cretaceous–Tertiary mass extinction event. About 75% of all uppermost Cretaceous species were rendered extinct in this event, including the popular nonavian dinosaurs.

Chicxulub crater is the youngest and best-preserved large impact crater on Earth and is relatively untouched by the forces of erosion or tectonic deformation. For these reasons, it is of great interest for the study of impact cratering, including environmental and climatic effects and their biological consequences. The images obtained by the seismic reflection survey will be used to construct models of crater formation that can be applied throughout the solar system.

Christianity

A monotheistic religion that originated in the Near East during the first century CE, and whose essence is the belief in Jesus Christ, Christianity is a theocentric faith proclaiming the existence of a personal God, one in the Holy Trinity. The God of Christianity is an autonomous, indivisible, immaterial being, an absolute unity possessed of infinite life and totally distinct from the world. Each of God's persons has only one and the same divine nature and remains in a reciprocal personal relation with the others on the basis of its origin. God the Father is the principle that originates the Son and the Holy Spirit (*Filioque*). As the Almighty Father, God is the creator of the entire universe, which he sustains in existence and upholds in its activities, guiding both the lives of individuals and the history of human communities (divine providence). Having elected humankind from all earthly creatures, both as spiritual creatures (human soul) and material beings (human body), God has granted humans immortality. He created humans in his own image and likeness, and bestowed on humans his grace and friendship (God's children). Human disobedience against God's decrees (original sin) is understood not as having caused God's revenge, but as having brought about the promise of salvation already outlined in the Hebrew Bible, or Old Testament. Thus, Christianity has its source in Judaism and is considered a revealed religion. This entry provides a detailed overview of the history of Christianity from its sources in Judaism and development through the Roman period, through the Middle Ages and into the modern era, an outline of Christian doctrine, and an explanation of Christianity's understanding of, and relationship to, time.

Source of Christianity

The Hebrew Bible shows the eternal covenant between the Israelites and Yahweh (Jehovah). In its oldest confessions of faith, Israel proclaimed God to be the redeemer of the nation, the Lord of the holy history, the one who has chosen the fathers, granted them his promises, and then realized these promises. Such formulas, defined as Historical Creed, for example included in Deuteronomy (Deut. 6:20nn and 26:5b–9), were designed for public recitation in prescribed ritual practices. Through such recitation, Israelites experienced their own selves before God. It was thus acknowledged that the nation responded to God and fulfilled the terms of the covenant not only as a group, but also through individuals. Individuals, however, were not always correct in their responses to God's initiatives and not always righteous toward their neighbors. In monarchic times, the faith and deeds of the kings could either secure the well-being of the nation or cause misfortune. This made the Hebrews reflect on the sinful condition of humanity and on the fact that humanity was constrained by sin, subject to suffering and death. Such a reflection gave rise to thoughts about the need for redemption and led to emergence of the Messianic idea. The life and teaching of Jesus of Nazareth, which were directed against institutionalizing and legalizing faith, confirm his awareness of being the Messiah awaited by the people of Israel. The Gospels show Jesus of Nazareth as the Messiah acting in the name of God and fulfilling the prophecies articulated in the Hebrew Bible (in Christianity, the Old Testament).

History of Christianity

The term *Christians* comes from the word Christ (gr. *Christos*), which refers to the real historical person considered as someone anointed by God and the Son of God, according to Saint Peter's confession of faith: "Thou art the Christ, the Son of the living God" (Matt. 16:16). The life and teaching of Jesus Christ was conveyed from the Pentecost onward in the form of the oral proclamation of God's message of salvation. Later it was written down in books that were considered holy and inspired. These are known as the New Testament and are part of the Holy Scriptures. In terms of chronology, the earliest texts of the New Testament were the Letters of Saint Paul to Thessalonians, written in 50/51 CE. The first gospel was the Gospel of Saint Mark, while the writings of Saint John, comprising three letters, the Gospel, and the Revelation, are the last pieces of the New Testament in the chronological order of composition. The books of the New Testament are the confession of faith of the first Christians. They were not intended as Christ's biography or a history of the first Church, but they nevertheless provide a reliable source for establishing many historical events. The historical existence of the founder of Christianity is also confirmed by a few non-Christian sources. His activity in Galilee and his death on the cross, which was not a major event in political terms, could not have been the center of attention for Jewish or Roman chroniclers. Josephus Flavius, a Romanized Jewish historian, includes in his work *Iudaike archaiologia—Ancient History of Israel,* known also as *Antiquities of the Jews,* reliable information about the person of Jesus Christ ("then there appeared Jesus, a wise man, if he was man at all, because he performed many outstanding things; he was a teacher of the people . . . and many people followed him. On the basis of the accusation formed by our chief men Pilate sentenced him to death on the cross but his former friends did not stop loving him, because on the third day he appeared to them alive, just as God's prophets had foretold" (Matt.–18.3, 3). To the skeptics the text seems too positive, so they consider it to be at least partially interpolated by Christians. But even if this were the case, the interpolation itself is evidence of the historical existence of Christ. Two Roman historians, Tacitus (55–120 CE) and Suetonius (65–135 CE), mention Christ in connection with their accounts of other historical events. Tacitus describes the great fire in Rome (64 CE) and the fact that Emperor Nero blamed it on the Christians.

Suetonius gives an account of the expulsion of the Jews from Rome by Emperor Claudius (50 CE). Both texts prove that the existence of Christ was known in Rome and that his figure was associated with the Christians.

The First Church

A lack of definitive historical documents complicates the study of the origins of Christianity and causes serious controversies. It is generally considered that the first Christian community was formed in Jerusalem around the year 30 CE. It consisted of Jews who had embraced Jesus' teachings during his life on Earth and under the influence of the first catechesis of Saint Peter (the so-called primary catecheses, which include the speech given on the descent of the Holy Spirit, Acts 2:14–36), which proclaimed the resurrection of crucified Jesus. Many other such communities were created by Jews living in the Diaspora and converted from Hellenism. Only some Jews inhabited Jerusalem and Palestine; others were dispersed all over the region. This resulted in cultural as well as political, and even religious diversification of the Jewish nation, although it shared a single cultural background and preserved the faith in one God—Jehovah. In general, Jews in the Diaspora were able to exercise religious and political autonomy. They used the Greek language (*koine*), sometimes even for the liturgy. Because the use of Greek led to the appropriation of other Hellenic influences, people from Jerusalem treated their Hellenizing neighbors from the Diaspora with reserve. Through its connections with Greek culture, the Diaspora was more open to Christian teaching than the Judeans were. In order to facilitate apostolic work with the rapidly growing numbers of Christians, seven deacons were nominated (Stephen, Philip, Prochorus, Nicanor, Timon, Parmenas, and Nicolas of Antioch), probably from the group of Hellenists. They were appointed for the purposes of religious service and works of charity (Acts 6:1–7).

The term Christianity appeared as late as 43 CE in Syrian Antiochia, where the believers in Jesus were called *christianoi* for the first time (Acts 11:26). The term most probably derives from pagan circles and was originally pejorative. The same word can be found in some early Christian writings, for instance in the texts of Ignatius of Antioch, Tertullian, or Eusebius of Caesarea. Before that, the believers in Christ called themselves the commune, the community, or the church (Acts 5, 11), while the Jews treated them as a sect of the Nazarenes, Galileans, or Ebonites (hebr. *Ebionim,* the poor).

Christianity spread thanks to the missionary activities of the apostles and their associates as a result of the first persecution. This started with the bringing of the Apostles Peter and John before the Sanhedrin because the Jewish priests and the Sadducees were aggrieved at the apostles teaching to the people about the resurrection of Jesus. Their first hearing finished with threats and was soon followed by a second arrest and imprisonment from which, according to the Acts, they were delivered by an angel of God (Acts 5:17–19). Both arrests took place on the orders of the high priest and his kin, who rejected the teaching about Christ and feared social unrest in Jerusalem. The following persecution affected not only the apostles, but also the church in Jerusalem and even spread to other Christian communities in Palestine. It started in 32 CE with the charges raised by a group called the Libertines, Cyrenians and Alexandrians against deacon Stephen, whom they accused of blasphemy (Acts 7:54–60). The persecutions that followed his death resulted in a dispersal of Christians over Judaea, Samaria, Galilee, and beyond Palestine, reaching Damascus, Joppa, Philippia, and Antioch in Syria.

When visiting the dispersed Christian communities, Peter and John attracted new believers. Their numbers grew, and new communities were formed. Deacon Philip baptized a courtier of Ethiopian Queen Candace (Acts 8:25–40). Apostle Peter baptized pagan centurion Cornelius together with his household (Acts 10:1n). However, the model in which a Christian was to be strongly linked with the Jewish culture proved incompatible with Christianity as a universal religion.

The dispersal of the apostles was the result of the persecution of the church in Jerusalem instigated by Herod Agrippa I in 43 CE. This was initiated by the king following his appointment by Emperor Claudius as the ruler of all of Palestine. In this way, Herod Agrippa tried to curry the favor of the high priest Ananias after deposing his son Teophilus. The king's sudden death in 44 CE restored peace to the Christian church in Jerusalem.

The next wave of persecution was linked with the destruction of Jerusalem in 70 CE, which followed the Jewish uprising against Roman rule. Started 4 years earlier, the Jewish uprising turned into a bloody war; the Roman response left the nation in ruins. The war also caused serious damage to the church in Jerusalem, although its members left the city before the siege, seeking refuge on the east bank of the river Jordan. Most of them settled in the small town of Pella and created a local church led by Bishop Simon, a relative of Jesus.

Faced with an influx of numerous converts from paganism, some communities began to abandon various Judaic religious traditions, such as circumcision and other Mosaic rituals. The resulting schisms, which caused problems for the new converts, were officially conciliated by the so-called Jerusalem Council (Acts 15:1–35).

The Missionary Journeys

The growth of Christian communities gained particular impetus thanks to the missionary journeys of Saint Paul. In the years 46–48 CE, he visited together with Barnabas and his cousin John Mark such locations as Cyprus, Pisidian Antioch, Iconium, Lystra, and Derbe. The second journey, dated 50–52 CE, took Paul to Troas, Philippi, Thessaloniki, Beroea, Athens, and Corinth. On this journey Paul was accompanied by Silvanus, and they were joined at a later point by Timothy and Luke. With the exception of Ephesus, this missionary journey was intended as a visitation to the local churches as some of them were adversely influenced by groups of Judeo-Christians or the followers of Apollos, a Jew who taught the philosophy of Plato. Through the efforts of Paul and Barnabas, a Christian community was also founded in the capital of the empire, Rome. The activities of the other apostles after leaving Jerusalem went unrecorded until the turn of the 2nd century, and those accounts are doubtful, modeled as they often were on ancient tales of fictitious heroes. Also, it is possible that they were written by Gnostics, who tended to attribute their writings to the apostles. Nevertheless, it is possible to find out from them about the geographic reach of Christianity at the end of the apostolic period. According to these sources, Andrew (brother of Peter) continued his missionary activity in Scythia, Thrace, Epirus, Greece, and the Crimea. James the Elder did not work outside of Jerusalem; he was killed in the city and became the first martyr among the apostles. Apostle Philip (frequently confused with Philip the Deacon) was reported as working in Asia Minor and among the Parthians. Bartholomew went in all likelihood to South Arabia, erroneously identified in the sources as "India." Thomas is mentioned as a missionary to the peoples inhabiting the regions between Syria, Persia, and India (Malabar Christians consider him as the founder of their religion). Matthew the Evangelist, son of Alphaeus, conducted a mission to Palestine and allegedly also to the Aramaic-speaking peoples; Aramaic was his mother tongue and the language in which he originally wrote his Gospel. James the Younger, son of Alphaeus, probably never left Jerusalem, where he was head of the local church. Jude Thaddeus, brother of James, preached the gospel first in Palestine and then in Arabia, Mesopotamia, and Syria. Simon, known as the Canaanite, was a missionary in the regions around the Black Sea, perhaps also in Africa and Persia. Finally, Matthias, who was elected a member of the Apostolic College after the death of Judas (Acts 1:23–26), was reported to have conducted missionary work in Ethiopia and Colchis.

Structure of Local Churches

In order to make the ministry to new communities more efficient, the apostles appointed superiors for local churches known as *episkopoi* (literally, "overseers"), while smaller individual congregations were headed by the elders or presbyters (*presbiteroi*). James was appointed head of the community in Jerusalem, Titus in Corinth, and Timothy in Ephesus, giving rise to the church hierarchy. This fact was obliterated, however, by the still unsettled terminology, because in Paul's descriptions of church structures we find more emphasis on posts rather than on offices. It is certain that the posts of bishops and presbyters, like those of deacons, have always been connected with one local church. *The Pastor* (Ποιμή́υ) *of Hermas*—dated the last decade before the year 150—uses these terms interchangeably; *Didache,* known also as *De doctrina apostolorium,* has only one term, *episkopoi;* Polycarp in his *Letter to Philippians* mentions only *presbiteroi* and *diakonos;* while Ignatius of Antioch makes a clear distinction of three groups in a local church: *episkopoi* (bishops), *presbiteroi* (priests), and *diakonos* (deacons). According to him, the college of presbyters and deacons is subject to the bishop. Such a structure, called monarchic episcopacy, is widely mentioned after 140 CE. Apart from institutional structures, there also existed some charismatic faculties of the members of the communities. These faculties were temporary and served the completion of certain tasks, for instance the gift of prophecy or glossolalia, that is, the gift of tongues (1 Cor. 12:8–11).

The apostolic letters indicate that there occurred tensions and divisions among Christian communities (1 Cor 1:10–12). In theology, it is considered that the inviolable principle of unity is founded in the deposit of faith called the symbol of faith (the doctrine that all converts belong to the Mystic Body of Christ—1 Cor 12:12–13). The institutional element is considered the other fundamental principle (the fact that the church is subject to the College of Twelve, with Peter as its head—1 Cor 12:28). The first Councils already showed the spiritual and honorary primacy of the Roman community and its bishop. At first, however, the bishops of Rome themselves did not claim the right to the title of pope, that is, head of the whole church. It was only in 451 that Leon I, Bishop of Rome, formulated his thesis, which stated that all Christian communities derive their authority from the Roman Church and that local bishops are the delegates of the bishop of Rome. These opinions influenced the future growth of Christianity as both a doctrinal and institutional monolith.

Persecutions of Christianity

In the first century, Christianity existed in Asia Minor, Syria, Greece, Egypt, and Italy. In the 2nd century, it spread to Gaul and North Africa. The hostility of the Roman authorities resulted in the fact that Christianity was persecuted by many emperors: Nero (54–68), Domitian (81–96), Trajan (98–117), Marcus Aurelius (161–180), Decius (249–251), and Diocletian (284–306). The first official pronouncement of the imperial authorities directed against Christianity was connected with the burning of Rome on July 16, 64. Rumors were spread that the city was burned at the emperor's order, because he wanted to see it in flames and compose poems about it, the way Homer described the destruction of Troy. Anxious about the consequences, the emperor, following Tigellinus' advice, accused the Christians of arson. Tacitus had no doubts that this was a false accusation, although he shared the opinion that the Christians deserved severe punishment for their "hatred of humankind." The persecution instigated on private motives could not have been designed to exterminate Christians in the whole empire, although some later apologists described Nero as a tyrant who aimed at the total extermination of Christians. Lactantius in the 4th century argued that the emperor's decree (*Institutum Nerinianum*) did not introduce any legal act against Christians but was meant to spread the conviction among all the officials that being a Christian was a crime if the emperor persecuted it in Rome. A series of further persecutions started in the times of Emperor Domitian. Like Nero before him, he instigated terror because of private motives. This weak and suspicious man lived in constant fear of being deposed, therefore he ordered the killing of Jude Thaddeus, who was a simple man but descended from the family of King David. Having learned about the prophesy about David's offspring who would rule the world, the emperor interpreted it as a direct threat to his rule. Roman historian Dio Cassio mentions "many others" who fell victim to Domitian's orders, although Tertullian estimates this was but a small fraction of what happened as a result of Nero's cruelty. In the time of Domitian, the majority of losses suffered by the church occurred in the East, where the emperor's cult was most widespread, and since Domitian assumed the title *Dominus ac Deus* (Lord and God), all those who refused to use this title were severely punished. The persecutions ordered by Nero and Domitian confirmed the conviction of the pagans that Christians were untrustworthy and wicked people. They were often charged with the same crimes as the Jews, since, in the beginning, the former were identified with the latter, but even when the difference was finally acknowledged, not only were the old charges not withdrawn, but at the turn of the first century new accusations were added. Asia Minor became the first arena of local persecutions under the next emperor, Trajan. This is confirmed by a letter from the governor of Bithynia, Plinius the Younger, to the emperor. The governor writes that the Christians are abundant in the cities and villages. Pagan citizens bring them before the judges who question them and often sentence them to death. Plinius asks the emperor how to treat the Christians because he noticed that the investigations revealed no real offenses against the law, and some denunciations were clearly motivated by a craving for revenge. The letter proves that until then there were no special regulations against the church except for a general rule from the time of Nero that it was forbidden to be a Christian. Marcus Aurelius, an adherent of Stoicism, claimed that the ruler should seek happiness in service of his subjects, but did not prevent many dangerous outbursts of pagan hatred of Christians. The persecutors wanted to make the Christians guilty of the wrath of gods, which they believed was the reason behind the misfortunes brought about by the invasion of the Parthians in the eastern and southern provinces of the empire, the disastrous floods caused by overrunning rivers, as well as the attack of the barbaric peoples on the western borders of the empire, which had been safe until then. The Christians were not always sentenced to death. Some were banished or forced to work in the mines and quarries. Decius, the first emperor of Illyrian origin, wanted to strengthen imperial authority after the period of military anarchy. This desire caused him to imprison many Christians in the first weeks of his rule. The edict proclaimed after 250 CE ordered all inhabitants of the empire to take part in public propitiatory sacrifice to placate the gods and avert misfortune to the empire. Whoever refused to obey this order was cast in prison, where torture was used to break their resistance. Although the Christians were not explicitly mentioned in the edict, it was directed mainly against them. Many did not withstand the trial, becoming apostates who were called *lapsis* (the fallen). Some tried to escape or buy official documents confirming that they had participated in the sacrifice. Who was imprisoned and managed to survive was called a confessor, and those who died were given the honorable name of a witness—*martyr.* The death of Decius in 251 on the marshes in Abrittos for a short time put an end to the persecution, though it was instigated again by Diocletian. The reason for this new outburst of hatred after nearly 20 years of peace and tolerance is not known. Undoubtedly, some Neoplatonists, like Hirecles and Galerius, could have had some share in it; it also might have been connected with the emperor's drive for strong and divine-like power, which gradually transformed *Imperium Romanum* into a totalitarian state. After Diocletian had secured the borders, strengthened his rule, and removed economic difficulties, he finally undertook the task of reviving the old Roman religion: the Christians were the main obstacle. He started his struggle against Christianity by cleansing the army, issuing in 299 an edict in which he demanded that all soldiers and officials should make sacrifice to the gods. In the next edict, in 303, he ordered the destruction of all Christian temples and the burning of the holy books.

Hostility against the Christians was apparent not only in persecutions but was also articulated in virulent writings and satires. Marcus Cornelius Fronton (c. 100–175), a Roman orator, teacher, and friend of Emperor Marcus Aurelius, delivered a public speech against the new religion, although he confused the Christians with the Gnostics and repeated commonplace accusations formed by the pagans; his speech was later disseminated in written form. Celus, a learned representative of Platonic philosophy in the 2nd century, criticized the new religion on philosophical grounds and became a serious intellectual adversary. In his anti-Christian treatise *The True Word* (Ἀληζής λόγος) from the year 178, which he wrote after studying the scriptures and debating with the Christians, he rejected the existence of a personal god and the doctrine about the creation of the world. His work confirmed the learned pagans in their appreciation of Greek literature and contempt for Christianity.

Development of Christianity

Despite adverse historical circumstances until the 4th century, Christianity spread to nearly half of the provinces of *Imperium Romanum.* From the 3rd century onward it reached the neighboring countries: Armenia, Georgia, and Persia. In 313, Constantine the Great issued the Edict of Milan, which officially recognized the existence of Christianity and included it among the religions tolerated by the state. After 324 he increased the privileges of Christianity, granted it almost unlimited missionary possibilities and freedom of building temples, making it also possible to replace apology, which was no longer necessary, with theology. The next ruler, Theodosius I the Great, issued in 380 an edict, *On the Catholic Faith,* in which he proclaimed that he wished all the peoples of the empire to accept the religion conveyed by Apostle Peter. In this manner, Christianity was recognized as a state religion. On the basis of this law, heresy became an offense punished by the state, and heretics had drastically limited civic rights. The next regulations forbade public debates on doctrinal issues. Historians consider Theodosius the real founder of the "state Church," which does not entail approval of every decision made by the authorities, but rather points to the public acknowledgment of strict cooperation between the church and the state. Theodosius zealously supported the position of the orthodox church through his legislative initiatives, but he did not openly interfere in its policy.

Although Origen and Hippolytus describe the practices of baptizing children, in the first centuries the converts were mainly adults whose consciousness and knowledge was shaped either by the Mosaic religion and the Jewish culture, or polytheism and the Hellenic culture. The introduction of a long period of preparation before baptism, which included the explication of the symbol of faith, did not, however, remove the risk of individual interpretation of the Christian dogmas. The earliest occurrences of doctrinal difficulty are recorded among the converts from Judaism, for whom the main problem was the relationship of Mosaic law with the Gospels and the relationship of Jesus to Jehovah. Different interpretations of the principles of faith led to the errors called heresies, while differences in the sphere of law, religious practices, and life of the church resulted in divisions into factions, or schisms. The first schism took place in the Jerusalem Church after the death of James the Younger when a group of Christian Jews observing rigorously all the precepts of Mosaic law refused to obey Simeon, the legitimate bishop, and elected their own superior, Tebutis. It is worth stressing that while schisms destroyed the original unity of the church, heresies rather stimulated the shaping of the Christian doctrine. As early as ancient times, Western theology was manifestly different from what was believed in Eastern theology. The West was mainly concerned with the problems of soteriology, especially with regard to the objective sanctity of the church (on this ground arose Donatism, which was concerned with the legitimacy of the sacrament dispensed by a presbyter-traitor, and Priscillianism, which preached dualism and extremely radical asceticism), the original state of humanity, and the results of original sin (the Pelagian heresy held that the sin of Adam was not the original sin of all people because everyone had free will and could therefore avoid sin since they could distinguish between good and evil; Pelagianism maintained that baptism removes only sins of individual people, and that children, who have no sins, do not need it for their salvation), and finally the relation of the effects of God's grace to human freewill (the semi-Pelagian heresy, originated by John Cassian and Bishop Faustus from Riez, according to whom God's grace helps only those who have begun to desire salvation, but does not influence the desire itself). The multicultural East was more concerned with Trinitarianism and Christology. On their basis arose such heresies as Arianism (which held that the Son of God, *Logos,* is not coexistent with God the father, only the first and most perfect creature, but is as far removed from the being of the Father as finitude is removed from eternity), heresy against the Holy Spirit (i.e., the opinion that the Holy Spirit is a creature and differs from the angels only through a higher degree of perfection), Nestorianism (i.e., a dissenting conception of the Incarnation, according to which *Logos* was not born together with the body of Jesus of the Virgin Mary: the "Word" dwelt in Jesus only as another person but was connected with him), Monophysitism (a heresy that held that Jesus had only one nature, which was primarily divine with human attributes), and Monothelitism (a heresy recognizing the existence of one will in Jesus). Due to lack of cultural unity, the crystallization of the dogmas of faiths resulted in the East in the creation of many national churches, such as the Nestorian Church in Persia; the Coptic Church, which accepted monophysitism, in Egypt; the Ethiopian Church; the Armenian Church; and the Jacobite Church as well as the Maronite Church, which upheld monotheletism in Syria.

The Middle Ages

In the early Middle Ages, Christianity spread mainly in the Mediterranean and in Western Europe. The areas of Africa and Asia Minor were then under Arabic rule, which in 711 took hold also of the Iberian Peninsula. Consequent to the Turkish expansion between the 11th and 15th centuries, Islam spread all over Asia Minor, and in Europe held sway in the Balkans. At the same time, Christianity was introduced in Spain, France, England, Germany, and Lombardy. The Gaelic and Germanic tribes, with the exception of Romania, were under the influence of Western Christianity. The conversion of the Slavonic tribes started in the 7th century and continued until the 11th century. It occurred successively in Croatia, Slovenia, Bohemia, Slovakia, Poland, and among the Polabian Slavs (i.e., the Slavs who lived along the Elbe). The areas inhabited by the Hungarians, Finns, or the peoples of the Baltic region were Christianized even later, at the turn of the 9th century. In the 8th through the 10th centuries the missions in the East reached Bulgaria, Serbia, Russia, and finally Romania. The missionary obligation imposed on the apostles by Jesus resulted in the Christanization of such remote areas as the East Indies (5th century) and parts of China (7th–10th centuries). It was only the persecutions, which became particularly severe in the 12th through the 15th centuries, that forced the church to reduce and then abandon altogether the Christianization of the Chinese people.

With regard to institutional dependence, Western Christianity was closely connected with the Apostolic See, especially after the missions of Saint Willibrod and Saint Boniface (org. Wynfrith). All the attempts at creating autonomous local churches in the Merovingian period failed not so much because of the unity of government that was connected with the reestablishment of the western empire by Charlemagne the Great in 800, but rather thanks to the supremacy of the empire that was made possible by the Georgian Reform. This reform consolidated the centralization of church government, with the pope as its head. Other important unifying factors included the common Latin language, canonical law, and scholastic teaching. Attempts at creating patriarchates in Arles, Aquilea, and Hamburg were unsuccessful. Eastern Christianity was completely different; despite one common Byzantine culture, church law, and liturgy, the ancient patriarchates were the agents of decentralization and finally led to factual division. An important step in this process was taken at the Second Trulan Council in 692, when the equality of Constantinople and Rome was officially recognized. From among all the general councils, only the first seven (including the Council of Nicea in 787) were officially approved by Byzantine Christianity, although the bishops from the East were still present at the three following councils: the Eighth Council of Constantinople in 869, the Second Council of Lyon in 1274, as well as the Council of Basel and Rome in 1439. The following councils were attended only by bishops of the Western church. The distance between Western and Byzantine Christianity (including the church in Georgia) was becoming more and more apparent. A combination of political, cultural, ethnographic, social, and religious events (e.g., the problem of iconoclasm in the 8th century and the Focius affair in the 9th century) led to the ultimate separation, which took place in the year 1054 and is known in history as the Great Schism. Efforts to restore unity yielded no positive results. A formula of unification was worked out at the Florentine Council (1439), but some political factors prevented it from being effective (in Russia the problem was the Tartar bondage, while Byzantium and the Balkans were troubled by the Turkish invasion, which ended with the total destruction of the Byzantine Empire). The only exception was the union with the Maronite Church, which was achieved in the 17th century and exists until present times. The Middle Ages were also marked by violent reactions against the accumulation of material goods by the church. In France and Italy the movement of apostolic poverty called Catharism appeared; in Bohemia the Hussites criticized the abuses of the church.

Modern History

The geographic discoveries in the 15th and 16th centuries provided a stimulus for missionary activity first in Central, then South and North America. The missions were, however, associated with Portuguese, Spanish, and French colonialism, due to which they often failed to bring the desired evangelical results. Having recovered from the turmoil of the Great Schism and after the period of concilliarism, which postulated the transfer of power from the pope to the general councils, Western Christianity retained its hierarchical structure. The turning point in the history of the Western church occurred in the year 1517, which marks the beginning of the Reformation and Protestantism. It eventually resulted in the formation of the Augsburg Evangelical Church in Germany, the Reformed Evangelical Church in Switzerland and France, and the Anglican Church in England. Later on, other reformed groups separated from these larger communities; the Baptists and Congregationalists separated from the Anglican Church in the 17th century; the same time saw the birth of the Quakers; the Methodists appeared in the 18th century, and the Salvation Army was founded in the 19th century. All the European churches had their missions in Africa, Asia, and Australia, and they became particularly intense in the 19th and the beginning of the 20th century. The Eastern church, struggling for survival under the rule of Islam, did not undertake any major missionary activities. Only the Orthodox Church in Russia organized missions from the 16th up to the beginning of the 20th century in territory that was the former Tartaric khanates of Kazan, Astrakhan, and Crimea; among the native inhabitants of the areas beyond the Urals; in Siberia, Alaska, and in the Far East. Thanks to the missions, in the 19th century Christianity reached the farthest ends of the world. The 20th century brought other evangelical works that were mainly addressed to the followers of non-Christian religions.

The centralization of the Catholic Church was strengthened by the Council of Trent (1545–1563), which emphasized the principal role of the Apostolic See, and was consolidated by Catholic reform; in effect, the history of papacy came to be identified with the history of the church. Papal control was challenged by such claims for local independence as state control in Spain (etatism), Jansenism and Gallicanism in France, episcopalism in Germany, and Josephinism in Austria. Further development of these tendencies was curbed by the First Vatican Council in 1870, which declared the dogma about the primacy of the pope and the infallibility of the teaching authority of the Roman Catholic Church. Those in disagreement with both dogmas formed the Old Catholic Church. The effect of centralization was that many former local prerogatives, for instance those that belonged to the Primate or the Metropoly, were lost. Such close unity was unknown in the Protestant churches and communities, which mostly relied on the authority of the state. The lack of juridical unity resulted, however, in the lack of agreement in doctrinal matters.

In the East, meanwhile, the Turkish conquest contributed to the growing authority of the ecumenical patriarch in Constantinople, the centralization of church government, and the assumption of the Greek form of liturgy and church offices. The national patriarchates in Bulgaria and Serbia, which had been established in the Middle Ages, ceased to exist while the Melkite patriarchates in the Middle East were being gradually subjected to Constantinople. The only exception was the Orthodox Church in Russia, which had received autonomy in 1448 and began to play a significant role in Orthodox Christianity. In 1589, a patriarchate was established in Moscow, but its significance decreased in the 17th century under Patriarch Nicon, and it was finally abolished in 1720 by Czar Peter I. The revival of the national consciousness of the Balkan peoples and the political division of the Turkish Empire in the 19th century led to the decentralization of the church and the growing autonomy of the national autocefalic churches in Greece, Serbia, Bulgaria, and Romania. The continuous efforts at reestablishing unity among the Christians in the East resulted in partial unions of these churches with Rome. In effect, the particular churches were divided into Catholic Unites, on the one hand, and the pre-Chalcedonian or Oriental Christians, on the other. (In Poland, the Union of Brest established the Unite Church called, since the 18th century, the Greek Catholic Church.)

The infiltration of Byzantine Christianity by Protestantism led to internal crisis. The liturgical reform undertaken in Russia at the turn of the 17th century resulted in a schism and the establishment of the sect of Raskolnikovs. The pre-Chalcedonian Church, threatened by extermination or Islamization, struggled for existence. In the Protestant churches and communities, which in the Enlightenment, dominated by rationalism, went through a deep crisis up to the point of doctrinal negation of Christianity and suffered the loss of many believers who accepted deism or atheism, followed a period of revival of orthodoxy. Widespread movement of pietism was conducive to the deepening of spiritual life and stimulated social engagement.

The split of Christianity resulted in violent religious wars that seriously eroded doctrinal authority and made for the development of deistic and atheistic trends. The Christianity of the 18th century was frequently perceived as residual, an anachronistic legacy of the Dark Ages, and was blamed for the regress of religious life. The 19th century brought the restoration of religiosity as well as the reawakening of Christian philosophy and theology, which to some extent could be linked with the influence of Romantic thought. The same period witnessed also the process of growing independence of the church from the state, thanks to individuals engaged in social activity. Christian trade unions, which were established in France and quickly spread to other European countries, began to defend the working class in agreement with the Christian social doctrine. From the pontificate of Leon XIII, who formulated a program of social activities of Christianity in his encyclical *Rerum novarum,* published in 1891, started a process of re-Christianization of society, which affirmed the employment of scientific discoveries, technological progress, and the development of modern culture in the service of humanity.

The Christian Concept of Time

In all religious systems worldwide, including Christianity, time is conceived of as the dimension where hierophany, the manifestation of the sacred, takes place. Sacred time is contrasted with secular time. The former entails the works and the manifestation of the sacred, whereas the latter denotes the time of human actions, which are identified with history. Many tensions between sacred and secular time can be listed, the most important of which concerns the passing of time. Sacred time can be personified as a deity (e.g., Cronus or Aion) or may be referred to as the eternal.

The Christian notion of time is rooted in a linear conception, with a marked beginning and the end toward which everything is destined. The initial moment is placed in real history rather than in the mythical *illud tempus.* The linear conception determines the logic of history, which precludes the possibility of repetition. Its nature is theocentric; on its terms, time and space become antagonized also as modes of human existence. This conception can be juxtaposed with the cyclic (cosmo-centric) notion of time, according to which human actions take place only in space, not in time. In the linear notion of time, typical for monotheistic religions, God is not limited by a definite space, but instead is a lord of time, which is the sum of his acts.

The Christian notion of time no doubt refers to the Hebrew religion, in which God is shown by the prophets as the one who intervenes in human history, which has become his epiphany. On the basis of the linear notion of the sacred time, Judaism developed a linear understanding of secular time; the 7 days of creation became prototypes of the 7 days of the week. Both times find their culmination in the moment of the Apocalypse. Through theophany, which takes place in sacred time, God reveals his acting in history. Thus historical events have become a continuum of interconnected episodes, without the possibility of their cyclic repetition. On the basis of the Hebrew concepts, Christianity has worked out the system of universalism. Christ is perceived as *Kairos,* that is, time of salvation. *Illud tempus* is treated as always accessible for humans desirous of mending their ways. It is possible, thanks to the figure of the Messiah (Christ), who separates the present moment from the past, identified with the result of the First Parent's sin. The second coming of the Messiah denotes merely the closure of the present, while eternity lies beyond this point. Thus Christianity stresses the fact that we live in last times, although the second coming will take place in the unpredictable and divine *kairos,* not *chronos,* which can be derived from experience and knowledge about the cyclicity of some events.

In the first centuries Christianity was marked by millenarianism, probably derived from Persian tradition (the best-known proponent of this idea was Papias, the bishop of Hierapolis in Phrygia). The millenarianists prophesized a 6,000–year history (through an analogy to cosmogony) followed by a 1,000-year–reign of the just after the imprisonment of Satan. The end of time was to come at the turn of the 8th millennium, when the world would become the arena for the battle against released Satan.

The linear concept of time was strongly confirmed by the patristic tradition (e.g., Ireneus of Lyon and Augustine of Hippo), although some cyclical trends were not totally absent from Christian thought. This is why Gnosis, Arianism, and Docetism were opposed by the church, because by challenging the linear conception of time they also contested the temporal and historical nature of the Incarnation. On their terms, it ceased to be a historical fact, a temporal point of reference, and the moment when the sacred entered historical time. On the other hand, up until the present day Christianity has kept the notion of the liturgical year, which is a cyclical remembrance of Christ's biography, from his incarnation to ascension. The Holy Mass is a peculiar form of periodicity, since it reenacts the sacrifice of Christ.

According to the Christian conception of time, human life is once given and unique. Hence the fear of wasting the indivertible. The uniqueness of earthly life endows Christian eschatology with special significance. The medieval memento mori—"Remember that Thou Shalt Die" rings until the present day the note of anxiety and urges everyone to do good in order to save one's soul, for even the slightest delay in this matter may have fatal consequences.

Doctrine

Viewed against other religions, Christianity, being focused on resurrection, has an eschatological and integral character, by which is meant that it is held to be the supreme and ultimate religion and not a stage in the development of civilization, and also that it embraces the whole of earthly reality, including all people and all aspects of human existence.

The conditions for becoming a Christian (belonging to the church) are faith in the word of God and baptism. By observing the norms of behavior prescribed in the Ten Commandments (the Decalogue), interpreted in the spirit of the New Testament formula of the love of God and one's neighbor, humans realize their salvation in the moral sense. Because of the universality of God's saving will, also toward people who are non-Christians, believers can achieve salvation also in non-Christian communities, even those whose activity is restricted to earthly existence, because salvation comes only through Christ, in Christ, and with Christ (*anakefalaiosis*). Doctrinal truths, which belong to the deposit of faith, are preached and infallibly interpreted by the magisterial authority of the church. In Roman Catholic Christianity, infallibility in the matters of faith and morality belongs to the pope and the bishops who are united with him; it concerns both the official teaching (*ex cathedra*) and regular teaching. In Orthodox Christianity, which has adopted the principle of concilliarism, this infallibility belongs to the bishops and all believers; in the Anglican Church it is the prerogative of the entire ecclesiastical community and it is called the ultimate criterion of the infallibility of truths defined at the council by human authority. The particular doctrinal issues have often received a new form of expression due to theological reflection, influenced by different philosophical and cultural conditions. Although there exists a considerable agreement among different Christian groups in the matters of trinitology and anthropology, much wider dissent can be observed in the interpretation of the origin of humankind, the concepts of grace (charitology), and the teaching about last things (eschatology). The most significant differences occur in the sphere of Christology (knowledge of Christ), soteriology (knowledge of Christ the Savior), knowledge of Saint Mary, eclesiology (teaching about the church), as well as sacramentology (teaching about the sacraments).

Because of its ability to develop outside its native cultural environment, Christianity belongs to the family of universal religions, along with Buddhism and Islam. In this group it retains the leading position, with 37% of the believers of all religions; the most numerous groups in this number are Catholics (c. 1.1 billion), Protestants (570 million), Orthodox Christians and members of Oriental churches (178 million), as well as Anglicans (70 million).

Chronology

The term *chronology* is derived from Greek *XpovoXoyia,* or computation of time. In contemporary science, chronology is understood simultaneously as a consequence of historical events in time and as a discipline dealing with regularities of these events as arrangements in time, as well as with general principles and scientific methods of time measurement. In this context, chronology could be viewed in at least three main dimensions: astronomic, historical, and general chronology.

Astronomic Chronology

Astronomic chronology is a branch of chronology that studies regularities of repeated celestial phenomena, establishes precise astronomic time, and often is understood as one of the basic methods of historical chronology. In this dimension it is very close to timekeeping, or chronometry.

Small-scale observations of astronomic chronology are based on the earth's spinning motion (the so-called sidereal day) and the earth's revolution around the sun (true solar day), while longer periods usually involve observations of the visual localization of the moon and sun among stars of the celestial sphere (sidereal and synodic month, sidereal and tropic year). On this basis, different systems of solar, lunar, and lunisolar calendars were developed, and their earliest forms can be traced back to late prehistoric times. The history of the invention and implementation of different calendar forms of timekeeping are the subject of the other branch of chronology—historical or technical chronology.

Historical (or Technical) Chronology

This type of chronology traditionally is regarded as a special subdiscipline of history, occupied with the study of calendars and calendar systems as these existed in the historical past in different regions of the world. Among the important tasks of this branch of chronology are the assignment of precise dates to events and phenomena, defining the time of historical narratives (chronicles), and specification on this basis of the true dates of particular facts. In such a context, historical chronology is deeply connected with other historical subdisciplines—historiography and the study of historical sources.

Studies of Calendars and Calendar Systems

The alteration of day to night was already obvious to early prehistoric hunter–gatherers and probably was reflected in the peculiar Magdalenian notched bones that are often regarded as the earliest archaeological records of primitive notational systems. The origin of land cultivation and agriculture required more complicated chronometry where warm/cold and dry/wet seasons' alternation and repeated climatic events such as inundations were taken into consideration. Such observations could be recorded in the ornamentation of special forms of ceramic vessels and clay figurines used in celebration of fertility rites and traditional ceremonies supposed to exert an influence over the weather. Most such systems were correlated with the vernal and autumnal equinoxes, which were marked by special ceremonies involving thousands of people. Probably the original megalithic constructions, such as Stonehenge in Britain, were specially built to make these events easy to observe for shamans and pagan priests and illustrative for local populations.

According to oral tradition, Druid priests were highly skilled in the organization of such calendar ceremonies.

The first complex calendar systems based on observation of lunar and solar phases appeared during the period of the formation of early civilizations in the Near East and were connected with the necessity of rational organization of the early state economy as well as appropriate celebration of basic cults of the community. Traditionally, it is thought that the earliest forms of the solar calendar were invented in ancient Egypt, and, with slight modifications caused by the need to correlate the solar calendar with the true astronomic year, reflected in the introduction of the leap year, it remains widely used in contemporary Western civilization. Early forms of the lunar calendar were developed by the Arabs, and today this calendar remains the basic form of timekeeping in the Muslim world. The ancient Hebrews are regarded as inventors of the lunisolar calendar, which continues to be applied in traditional Jewish chronometry up to the present day. Other ancient civilizations created their own particular systems of timekeeping, among which are included the Babylonian, Persian, Chinese, Indian, and Vietnamese calendars.

Rapid development of mathematics and astronomy in ancient Greece contributed greatly to the comprehension of discrepancies between the rough division of time into years and the real recurrence of celestial events. In order to correlate the solar calendar with astronomic reality, an 8-year system based on the addition of a supplementary month every 3rd, 5th, and 8th year of the cycle and the so-called Methon cycle was introduced.

The Roman calendar in its early stage was less than precise, consisting of only 10 solar months. Its principal revision, undertaken in 46 BCE under the initiative of Julius Caesar on the basis of advice from Sozigen (an astronomer from Egyptian Alexandria), resulted in the expanded Julian calendar, the basic cycle of which consists of 3 years of 365 days each and 1 leap year of 366 days. This calendar, introduced on January 1, 45 BCE, and in regular use since the 8th year of the common era, was the basic frame of timekeeping in Europe and its colonies until the end of the 16th century.

The reason for a new revision of the calendar was a discrepancy between the astronomic and the calendar vernal equinox, which was noticed for the first time at the end of the 13th century and became more and more apparent during subsequent ages. Pope Gregory XIII, by his decree of February 24, 1582, introduced amendments to the Julian calendar. His new version was called the Gregorian calendar. It was immediately applied in the Catholic countries, while most of the Protestant nations adopted it only in the 18th century. The transition of the civil states of Russia, Bulgaria, Serbia, Romania, and Greece (countries with predominantly Orthodox Christian populations) to the Gregorian calendar at the beginning of the 20th century made it the most widespread form of timekeeping in the world. Nevertheless, the Orthodox Church officially rejects the Gregorian calendar and still maintains its own system of timekeeping, based on the Julian calendar, to the present day.

Apart from these widely disseminated and well-studied calendar systems in the historical past, many other forms of systematic timekeeping based on solar, lunar, and combined lunisolar time observations were used. Some of them still remain in use, mostly in vast areas of Eastern Asia (in the traditional Chinese and Japanese calendars) and in Muslim communities all over the world that observe the traditional Islamic calendar; others are used only in the context of traditional rituals and ceremonies of native cultures (e.g., calendars of the ancient Maya) or have become an integral part of Western civilization's spiritual life (e.g., the zodiacal calendar). Calendars have also been introduced in the wake of epoch-making events in modern times (e.g., the calendar of the French Republic, and the Soviet revolutionary calendar); these soon became obsolete. In the contemporary world community, the Gregorian system of timekeeping is recognized internationally by official bodies; the other calendars can be applied locally, ethnically, or occasionally.

Historical Events and Phenomena Dating

Specification of the true dates of historical events is another important task of historical chronology. This procedure is based on two kinds of primary data: one originated from historical sources (chronicles, narratives, etc.) and the other obtained with the help of natural sciences.

In the case of historical sources, determining their true dates, authenticity, and reliability is a cornerstone of the dating process. In most cases, the problem of historical source verification is solved through multilevel comparisons of different sources and their correlation with data from the natural sciences, if available.

Usually a distinction is made between absolute and relative dating. Relative dating is aimed at defining the strict order of certain events or delineating the period of time when they could have happened. Relative dating is most widely applied in archaeology, based on typological and stratigraphic methods. Relative dating is important in many social sciences when determining the actual date of an event or phenomenon is not possible. In these cases, cross-dating based on matching known dates for events and phenomena can be used. Glottochronology, which attempts to determine when certain languages separated based on the percentage of words remaining from their primary basic vocabularies, is another example of relative dating methods.

The goal of absolute dating is to identify actual dates of specific events. In history this is usually expressed as a day, month, year, or century; in archaeology it might be in thousands or even millions of years. Absolute dates are established with the help of the scientific methods of the natural sciences or by correlation with established actual dates of other events.

Physical methods of absolute dating have been considered to be most reliable since radiocarbon dating was invented in 1946 and rapidly introduced into scientific methodology all over the world. This method is currently widely used for the dating of organic artifacts (objects made mostly of bone and wood). Later, thermoluminescence and uranium–thorium balance dating methods were added to absolute dating methods and helped to cover intervals of up to several million years. Chemical methods of absolute dating, such as the obsidian hydration technique, are also used to determine ages of relatively "old" objects as precisely as possible. Biological dating, such as dendrochronology, which dates objects based on the annual growth rings of trees, is used to examine artifacts like buildings. It is useful for relatively "young" artifacts that are no older than several centuries.

When it became possible to derive absolute dates by comparing a variety of sources, the problem of correlating, for example, references referring to "years ago" versus "years before Christ" became especially critical. During the past decade this problem was often considered more serious than deriving the correct date.

General (or Scientific) Chronology

The main task of general chronology is the reconstruction of the exact order of historical events and phenomena as well as establishing the duration of historical processes. General chronology (as well as dating) can be precise only when an event or phenomenon can be dated with absolute numbers, or relative if ascertaining the order of events or by determining a time period in which they could have taken place. Ancient chronologies, often referred to in most of the important events and phenomena in the histories of specific populations (nation, country, etc.), were regarded by their creators as the best way to satisfy the needs of both versions of general chronology.

In Ancient Egypt, events usually were dated consecutively based on the year of a specific pharaoh's rule. Every new pharaoh established his own "era" of timekeeping. A crucial task in Egyptian chronology is determining the details and specifics of each pharaoh's rule.

Ancient Greek history offers a more complicated version of event correlation with the comparison of information about specific facts and events obtained from various historical narratives that were created in different periods. Even so, ancient Greece has no unified general chronology, and historians have to date an event simultaneously in several year-keeping systems, the most widespread of which are correlated with the reigns of Persian rulers and the governments of Ephorus of Sparta and Archonts of Athens. In the 4th century BCE, historian Timaeus proposed introducing a general chronology based on lists of Olympiad winners, which had been kept since 776 BCE. This system was widely used by historians but not by official administrations. The first general scientific chronology of ancient Greece was created by Eratosthenes in the 3rd century BCE; he established the absolute date of several basic events (e.g., Xerxes' invasion, the beginning of the Peloponnesian War, etc.) and on this basis calculated the dates of other events.

A general chronology of Roman history was based primarily on lists of Roman consuls, which are easily integrated with ancient Greek chronological systems. Also, a dating system originating from the foundation of Rome (753 BCE) was introduced by Varro in the 1st century CE.

In the late Roman period, the Diocletian influence became most widespread in 284 CE because of its connection with calculating the dates for Easter, but soon it was replaced by the "Christian era" introduced in 532 by Dionysius Minor as the *ab incriptione* era. During the Renaissance, historical event dating based on the Christian era developed into the modern chronology system, the basics of which were formulated by Joseph Scaliger (1540–1609). He managed to transfer all existing dates into a unique system of dating originating with the Julian period (started in 4713 BCE) and reintroduced the process of historical date verification by reference to astronomic events mentioned in historical sources. Later, Petavius proposed a system of back-keeping years before the Christian era; this scheme has been widely recognized since the 18th century.

Critique of General Chronology

The problem of the reliability and authenticity of dates is regarded as critical in both genres of general chronology, and it inevitably implies a process of exhaustive critique of various dates and their sources. So, for example, the Diocletian era was recognized as reliable when the starting date of Diocletian's reign was established independently by three scientists using three different methods. This and a series of other coincidences established a background that allows scientists to believe that Roman general chronology is rather reliable. Greek chronology could easily be synchronized with Roman since there many dates known in both traditions. Synchronization of Egyptian, Persian, and some other chronologies widespread in the ancient Middle East is based on lists of rulers made by the Egyptian historian Manetho. Chinese general chronology also is regarded as rather reliable since even today it is based on the same 60-year cycles; in ancient times, moreover, it is reinforced by a highly developed historiographic tradition with a detailed chronology. The decree by India's king Ashoka, in which names of Hellenistic rulers are mentioned, is regarded as the cornerstone for verification of ancient Indian general chronology.

Another branch of general chronology critique—the so-called New Chronology invented by the Russian academician Nikolay Fomenko in the late 1990s—makes the radical claim that all dates established in ancient times and studied today should be regarded as invalid. This concept is based on the assumption that all historical narratives in fact were created recently in attempts to prove the great antiquity of human history and culture, whereas the true duration of human history does not exceed a thousand years.

Fomenko's hypothesis has provoked a new phase of discussion about the reliability and authenticity of general chronology that, it is hoped, will enable obtaining new details to enhance our knowledge of the human past.

Chronometry

According to Saint Augustine, we measure time by mind. The sense of a length of time is indeed a basic human experience, but it depends on the person and his or her momentary state; consequently it cannot serve as an objective and reproducible indicator of duration of time. Therefore, periodical processes have been used for time measurement from time immemorial. It was on these processes that *clocks* were based. The oldest clocks were based on astronomical phenomena—the movement of sun, Earth, and stars in the heavens. Mechanical clocks were already in use in antiquity—water or sand, later on spinning balance wheels and vibrating springs. Galileo counted the beats of his heart in order to verify the regularity of swings of the pendulum.

Although originally time periods were only counted, the idea of their in principle unlimited divisibility was developed in antiquity. According to Aristotle (*Physics*), past and future time is separated by the moment "now," which in itself has no length. Nevertheless, time is in some sense compounded from moments. Later on, this idea was made precise by mathematics, which represented time's moments as elements of the set of real numbers. The lengths of time sections between pairs of events—the beginnings and ends of occurrences—is then ideally determined by a real number, although measurement allows us to determine this rate with only limited precision.

Of course, thinkers in antiquity were already aware of the problem that whereas motion is measured by time, and time is measured by motion, why are there not as many times as motions? It appeared essential for the measurement of time that various clocks exhibit a more or less common rhythm. The concept of *ideal clock,* measuring the time *solidary,* follows from it. The data t^* and t of solidary clocks can differ only by the choice of unit of measurement and the choice of beginning of reading of time, and thus they are connected by the relation

$$t^* = K\,t + C$$

where $K > 0$, C are constants. After deciding on a common unit of time, we *calibrate* all the clocks in the same way and then we are able to measure time intervals between events in the same units. The theoretical background for the existence of ideal clocks is based on the validity of universal physical laws, which are, expressed in ideal time, nonvariable; therefore a given periodical process subjected to these laws lasts—in the case where equal inner and outer conditions are the same length of time. We call this the *homogeneity of time.*

For 2 centuries, the role of ideal time was played by the *absolute time* of Newtonian physics. This time is not only the time of a specific clock or of a definite object but also determines the time difference among the simultaneous states of all the world. It makes it possible not only to determine the lengths of time intervals for the given object (or clock connected with it) as its *proper time,* but it also integrates all events into the time course of the world as a *coordinate time.*

The theory of relativity cancels this connection between proper time and coordinate time. According to the *special theory of relativity* (STR), clocks in different places can still be synchronized (best by the exchange of light signals) in the *inertial systems of reference* (mutually uniformly and rectilinearly moving systems, where the law of inertia is valid), but this synchronization gives different results in different reference systems. An even more radical change is connected with the *general theory of relativity* (GR), according to which it is impossible to introduce global inertial systems in curved spacetime. Consequently, coordinate time loses its immediate metrical meaning and only proper time τ, defined as a length (integrated interval) of the section of world line $x^i(s)$ in four-dimensional spacetime, remains absolute. Thus

$$\tau = \int_P^Q \frac{ds}{c} = \frac{1}{c}\int_0^\sigma \sqrt{g_{ik}(x^j)dx^i dx^k}$$

where g_{ik} are the components of metrics, and c is speed of light serving as a coefficient of conversion between the spacetime interval and the proper time.

Thus it is possible to say that the clock (even a wristwatch) is an instrument capable of measuring the lengths of sections of world lines. [A world line is the path in spacetime traveled by an elementary particle for the time and distance that it retains its identity.] Then the solidarity of clocks follows from the fact that they determine the fundamental geometric properties of spacetime. The data of ideal clocks directly depend only on the length of world line and are not influenced by the curvature of spacetime (tidal forces) or by the curvature of the world line in spacetime (acceleration). A practical question arises: Which clock is closer to the ideal?

Throughout most of human history, time as defined by the motions of astronomical bodies has played a crucial role. Observation alone taught people to experience and explain the variances from the ideal. The contemporary unit of time—*second*—was originally derived from the threefold partition of the solar day (the interval between middays) into *hours* (based on the partition of the circle described by the sun on the sky), *minutes* (the "diminution" of the hour) and *seconds* (the "second" diminution). But the length of a solar day changes seasonally by minutes as a consequence of the inclination of Earth's axis and the variability of the velocity of the passage of Earth around the sun.

A more precise standard of time is provided by the rotation of Earth with respect to the fixed stars. But this period is also influenced by the season, accidental and systematic changes of the shape of Earth, and of the distribution of its mass. Moreover, as it was shown by the philosopher Immanuel Kant in the 18th century, a permanent deceleration of Earth's rotation is taking place due to the action of tidal forces. Although it slows by only 1.5 milliseconds in a century, its influence accumulates with time and leads, for example, to shifts in location for eclipses observed in antiquity. Consequently, the best standard of time in astronomy is *ephemeris time,* based on complex observations and calculations of motions in the solar system. Since 1956 the definition of a second has been based not on the day (1/86,400 of the solar day), but on the year (1/31,556,925,9747 of the tropical year from the beginning of the 20th century). Currently, three times are used for the purposes of astronomy—terrestrial, barycentrical, and geocentrical—in order to account for the effects of relativity.

A new type of astronomical clock with small, precise, and stable periods over the long term is based on *pulsars,* discovered in the 1960s and explained as rotating neutron stars whose directionally concentrated radiation strikes the earth with reliable regularity.

Timekeeping based on astronomical observations found its way into the manufacture of clocks produced in factories and laboratories. The turning point was the introduction of pendulum clocks in the 17th century, owing chiefly to the work of Christiaan Huygens. Further improvements were made to the clock with piezoelectric crystals, and in 1946 with the atomic clock based on the regular vibrations of atoms.

The basic advantage of atomic clocks follows from the principle of identicalness of objects of the microworld. It is impossible to produce perfect copies of macroscopic objects, and their aging leads to irreversible changes, but the states of atoms are ideally reproducible and unchanged by the flow of time. Since 1967 the second has been defined as a time with the duration of 1,922,631,770 periods of oscillation between two precise levels of a hyperfine structure of certain basic states of the atom of cesium-133. The best cesium clocks are correct to within hundredths of a microsecond per day (compare with 100 milliseconds per day for the best mechanical clocks in the 18th century). *International atomic time* (TAI; the acronym is based on the French: Temps Atomique International) is based on readings of the most precise atomic clocks over the world. The times used in present-day astronomy are derived from atomic time. The next essential improvement in measuring time will no doubt involve the methods of quantum optics and laser spectroscopy, which were honored with the Nobel Prize in physics in 2005 (R. Glauber, J. Hall, and T. Hänsch). According to Hall's Nobel lecture, "time is the most powerful metrological variable." The effort to increase the precision of the measurement of time is by no means purposeless. It will result not only in many-sided development of techniques, but it will also lead to new discoveries. Observations of the periods of pulsars measured by atomic clocks give support to the existence of gravitational radiation; the measuring of frequencies of radiation of objects at cosmological distances can inspire new cosmological and microphysical theories; and so on.

From a theoretical point of view, it is important that the ideal clock can be defined on the basis of the simplest physical phenomena: motions of free particles and light signals, and thus, geometric properties of spacetime, as stated by R. Martzke and John. A. Wheeler in 1964. The ticks of the *light clock* arise from the permanent exchange of light signals between mirrors with a constant distance; it is possible to check and keep this constancy with the help of the motion of other free particles and light signals, even allowing for curved spacetime.

Hence, the continuous timeline of physics can be determined with a conceptual and technical precision that far transcends the possibilities of its perception and experience by humans, because its physical foundation remains a psychological and philosophical mystery to us. It is supposed that the natural limit of the continuous concept of time is *Planck time:*

$$t_P = \sqrt{\hbar G/c^5} \approx 5 \times 10^{-44}\text{seconds}$$

This limit for continuous time is built up from fundamental physical constants ($\hbar$ is the Planck constant, G the Newtonian gravitational constant, c is the speed of light). However, the theory of discontinuous time could manifest its necessity in efforts to unify physics with an understanding of the earliest stages of cosmological evolution.

Chronostratigraphy

Chronostratigraphy is a discipline of stratigraphy that studies the relative time relations and ages of stratified rocks. The aim of Chronostratigraphy is to organize stratified rocks into units on the basis of their age or time of origin. A chronostratigraphic unit is a stratified body that includes all rocks formed during a specific interval of geologic time, and only those rocks formed during that time span. There is a hierarchy of formal chronostratigraphic unit terms that correspond with equivalent geochronologic unit terms. The first are stratigraphic units, whereas the second are time units. The chronostratigraphic units, according to their ranking, are the following: chronozone, stage, series, system, erathem, and eonothem; they correspond in rank to the following geochronologic units: chron, age, epoch, period, era, and eon. The position within a chronostratigraphic unit is expressed by adjectives such as *basal, lower, middle, upper,* and so forth. The position within a geochronologic unit is expressed by temporal adjectives such as *earliest, early, middle,* and *late.*

The boundaries of chronostratigraphic units are synchronous horizons by definition. There are several geologic methods of time correlation and dating, although their resolving power usually is greater than 20,000 years in most cases. The methodology used for the chronocorrelation is derived from Steno's law of superposition, which states that in an undisturbed sequence of sedimentary strata the uppermost strata are younger than those on which they rest. The determination of the order of superposition provides unequivocal evidence for relative age relations. The bedding plane is the best indicator of synchroneity, but such a method usually has only local validity. The identification of lithostratigraphic units always has some chronostratigraphic connotation, since their boundaries eventually cut across synchronous surfaces, but this lithostratigraphic method also has local validity.

The paleontological methods have greater utility because they are based on the orderly and progressive course of biological evolution.

The fossil record is an important source of chronostratigraphic information. Several calibrated biochronological scales have been established from biostratigraphic data and integrated correlation. In order to attain a better biochronocorrelation, the identification of index taxa is necessary. Index taxa are fossils useful to define and identify geologic periods. The best index taxa belong to the following paleontological groups: foraminifera, calcareous nanofossils, dinoflagellate cysts, acritarchs, ostracods, ammonites, trilobites, bracheopods, graptolites, and conodonts in Phanerozoic marine environments, and pollen and spores, vertebrate microfossils, charophytes, and ostracods in Phanerozoic terrestrial environments. However, the paleontological methods do not provide unequivocal data, since the strata and the fossils they contain are not necessarily synchronous.

Periodic reversals of the polarity of the earth's magnetic field are utilized in chronostratigraphy, particularly in upper Mesozoic and Cenozoic rocks, where a magnetochronological scale has been developed. Polarity reversals are binary, however, and specific ones cannot be identified without assistance from some other method of dating, mainly paleontological (biostratigraphic) methods. Biomagnetostratigraphic correlation, calibration, and dating is the best method known to date.

Radioisotopic dating methods are unique in providing numeric age values, expressed in years. They are based on the radioactive decay of certain parent nuclides at a rate that is constant and suitable for measuring geologic time data with high precision with analytical errors in the range of 0.1% to 2%. Radioisotopic dating provides the best hope for working out the ages and age relationships of Precambrian rocks. However, not all rock types and minerals are amenable to radioisotopic age determination, so it can be used only on sporadic occasions.

Today, two new methods have been added for chronocorrelation and dating: cyclostratigraphy/astrochronology and eventstratigraphy. The cyclostratigraphic methods try to identify evidence of the earth's orbital fluctuations in the stratigraphic record. These fluctuations have caused climate cycles in the past, such as the quaternary glaciations, that may be recognized in the stratigraphic record from lithological, paleomagnetic, isotopic, and paleontological data. The best-known orbital periodicities are the precession (cycles of 21,000 years), obliquity (cycles of 41,000 years), and eccentricity (cycles of 100,000 and 410,000 years). Their recognition provides an impressive chronocorrelation and dating method (astrochronologic scale), although it needs assistance from other methods of correlation.

Chronostratigraphic units, mainly the stages, must be defined by boundary stratotypes. The boundaries of a chronostratigraphic unit of any rank are defined by two designated reference points in the rock sequence. The selected point must be a marker horizon favorable for long-distance chronocorrelation; thus it must represent a global event. The identification of global events in the stratigraphic record is the aim of a new discipline called *eventstratigraphy.* In geological history, the most frequent globally occurring events are: paleoclimatic changes (e.g., glacial deposits, evaporites, red beds, coal deposits, faunal changes), tectonic and eustatic changes in sea level, volcanic events, meteoritic impacts, and mass extinctions. The identification of these events and their calibration with paleontological, isotopic, paleomagnetic, and astrochronologic methods are the best tools for establishing the chronostratigraphic and geochronologic scales.

Three eonothems are recognized, from older to younger: Archean (3,900–2,500 million years ago [mya]), Proterozoic (2,500–542 mya), and Phanerozoic (540–0 mya), although a fourth eon is generally considered, the Hadean (4,550–3,900 mya). The informal Precambrian terms include Hadean, Archean, and Proterozoic (i.e., all time before the Cambrian). Subdivisions of the global geologic record are formally defined by their lower boundaries from a basal Global Standard Section and Point (GSSP), except for Precambrian units, which are formally subdivided by absolute age (Global Standard Stratigraphic Age, or GSSA). GSSP and GSSA are approved by the International Commission on Stratigraphy (ICS) and ratified by the International Union of Geological Sciences (IUGS).

The Hadean spans the time period between the earth's formation and the age of earliest-known rocks. It has no geological record known to date, except for some zircon crystals of Hadean age. The Archean, also called Archeozoic, is defined geochronometrically (GSSA) and not stratigraphically. It is subdivided formally in four erathems or eras: Eoarchaean (3,900–3,600 mya), Paleoarchean (3,600–3,200 mya), Mesoarchean (3,200–2,800 mya), and Neoarchean (2,500–2,800 mya). The Proterozoic represents an eon before the first abundant complex life on Earth; that is, before the first period of the Phanerozoic, the Cambrian. Its geologic record is much better than that from the preceding eonothem. The Proterozoic includes three erathems or eras: Paleoproterozoic (2,500–1,600 mya), Mesoproterozoic (1,600–1,000 mya), and Neoproterozoic (1,000–542 mya). Finally, the Phanerozoic spans the period of geologic time during which an abundant fossil record has existed. It subdivides into three erathems: Paleozoic (542–251 mya), Mesozoic (251–65 mya), and Cenozoic (65–0 mya) whose boundaries coincide with major mass extinction events: the Permian/Triassic boundary mass extinction event occurred between the Paleozoic and Mesozoic eras, and the Cretaceous/Paleogene or K-T boundary mass extinction event between the Mesozoic and Cenozoic eras. The Phanerozoic erathems are subdivided into systems or periods that are widely known popularly: Cambrian, Ordovician, Silurian, Devonian, Carboniferous, and Permian for the Paleozoic; Triassic, Jurassic, and Cretaceous for the Mesozoic; and Paleogene and Neogene for the Cenozoic. Moreover, the Paleogene is subdivided into three well-known series or epochs called Paleocene, Eocene, and Oligocene; whereas the Neogene is subdivided into Miocene, Pliocene, Pleistocene, and Holocene. Historically, the Cenozoic has been divided into Tertiary (Paleocene to Pliocene) and Quaternary (Pleistocene and Holocene), although most geologists no longer recognize these.

CHRONOTOPES

Chronotope is a term of literary theory that designates the spatiotemporal matrix of narrative texts. It was used for the first time by the Russian philologist and literary theoretician Mikhail Mikhailovich Bakhtin (1895–1975). The definition as well as the application of the concept of chronotope is Bakhtin's primary aim in his essay *Forms of Time and of the Chronotope in the Novel* (written 1937–1938). It is part of *The Dialogic Imagination,* a work that was not translated into English until 1981.

Bakhtin defines chronotope as the inseparable connection of spatial and temporal relations in literary texts. The word *chronotope* can literally be translated as "time-space" (from the Greek nouns *chronos,* time, and *topos,* place). "Time" is the first component of this neologism: this shall indicate that it is the dominating category in the chronotope.

Literary–artistic chronotopes share three basic features. First, they have generic significance, which means that a particular conception of spatiotemporal relations determines a literary genre. For Bakhtin, the history of literary–artistic chronotopes parallels the history of literary genres. Second, literary–artistic chronotopes determine to a large degree the image of individuals. The conception of characters in narrative texts is marked considerably by the spatiotemporal conditions surrounding them. The third basic feature of literary–artistic chronotopes is their representational significance. By locating narrative events and characters in a certain place at a certain time, the flow of time becomes visible. Thus, the novelist's design of a literary–artistic chronotope makes time and space concrete.

Bakhtin points out the existence of six types of literary–artistic chronotopes that emerged during the course of literary history from the Greek romance to the Rabelaisian novel. The first type of these chronotopes is the "adventure novel or ordeal." It is typical for the Greek romance (e.g., Heliodorus's *Aethiopica,* Chariton's *Chareas and Callirhoë,* and Xenophon's *Ephesiaca*) and dominated by "adventure-time," an immobile, reversible, mythological kind of time that is structured by extra-temporal gaps between moments in time. Adventure-time also determines the image of literary characters: as a nonbiographical time it turns them into unchanging, passive individuals, the irresolute objects of fate. The Greek romance is thus devoid of character development. On account of its mythological immobility, adventure-time leaves no trace in the characters.

The second type of literary–artistic chronotope is, according to Bakhtin, the "adventure novel of everyday life." It is characterized by a mixture of adventure-time and "everyday-time." To illustrate the significant features of this type of chronotope, Bakhtin refers to Petronius's *Satyricon* and Apuleius's *The Golden Ass,* two Roman novels that were written in the 1st and 2nd centuries CE. The chronotope of these narratives resembles to some extent the chronotope of the Greek romance: in accordance with adventure-time, the works of both authors describe exceptional moments in a person's life. They present no temporal progression in a strict sense. Yet, time in the adventure novel of everyday life differs to a significant degree from time as it is presented in the Greek romance. In contrast to the latter, it is not a reversible but an irreversible kind of time that leaves profound traces in the characters. The different conception of chronotope in the adventure novel of everyday life leads therefore to a different conception of character. In Apuleian and Petronian narratives the characters are no longer unchangeable objects of fate. Instead, their description is structured by the idea of metamorphosis. Metamorphosis is a method for portraying the whole of an individual's life in its most important moments of crisis. It shows how persons become other than they were before (e.g., the protagonist of *The Golden Ass,* Lucius, is presented before his transformation into an ass, he is presented as an ass, and he is presented as a mysteriously rehumanized character). According to Bakhtin, the metamorphosis of characters—that is, their development in time—is possible only because they are immediately confronted with everyday life. It is Lucius's punishment to participate as an ass in everyday life for a certain period of time. Yet, being vis-à-vis everyday life is exactly what distinguishes the Apuleian and Petronian chronotope from the chronotope of the Greek romance.

The remaining types of the literary-artistic chronotope are explained exclusively with respect to their temporal structure. The "life course of one seeking true knowledge" is the third type of literary-artistic chronotope discussed by Bakhtin. It is typical for ancient biography and autobiography. Time in these literary genres has a biographical character; that is, it presents an individual's temporal development. The fourth type of literary-artistic chronotope is the "miraculous world in adventure-time." It occurs predominantly in the chivalric romances of the Middle Ages (e.g., in Wolfram's *Parzival* and Hartmann's *Erec*). The chronotope of the miraculous world is characterized by a subjective playing with time: hours are compressed into moments, moments are stretched into days. The "Rabelaisian chronotope" is the fifth type of literary-artistic chronotope. It is marked significantly by an expansion of time and space, which means that the spatial and temporal dimensions are exaggerated as much as possible, creating an impression of grotesque unreality. The "idyllic chronotope" is the last type of literary-artistic chronotope described in Bakhtin's essay. It is characterized primarily by a cyclic rhythm of time in which the life of a character is just a repetition of the life of the generations before.

The description of the different chronotopes makes clear that Bakhtin regards spatiotemporal relations in narrative texts as the fundamental coordinates that determine to a large degree the literary parameters of a narrative piece of writing.

Clarke, Arthur C. (1917–2008)

Sir Arthur Charles Clarke is considered one of the preeminent futurists, science popularizers, and space visionaries, as well as being one of the most recognizable names in science fiction today. He was able to predict many aspects of space travel accurately, and may have even actually influenced those aspects. His writings deal with time, particularly his best-known novel, *2001: A Space Odyssey* (which spans human evolution from apelike protohumans, through our own species, to a conjectured future "star child").

Clarke was born on December 16, 1917, in Somerset, England. He grew up quickly, working on the family farm and helping the family, especially after his father died when Arthur was 13 years old. At this early age, Clarke was already showing interest in both science fiction and astronomy, which included the construction of his own rockets and telescopes. He also joined the British Interplanetary Society in 1934, and was later its chairperson.

After a brief career as an auditor, Clarke joined the Royal Air Force and eventually became a radar specialist. During the final days of his war duties, he published an article titled "Extra-Terrestrial Relays" in the October 1945 edition of *Wireless World*. This article showed the importance of, and laid the groundwork for, geostationary satellite communications. His idea to synchronize satellites (so they appeared to be stationary from the earth) made possible all forms of global communication throughout the world, including television, radio, and (now) cellular phone technology.

Due to the cost involved, Clarke was not able to attend college until after his stint in the RAF. He earned degrees in mathematics and physics from King's College after World War II and worked briefly as an assistant editor for *Physics Abstracts* before turning to writing full-time. Many of his early, nonfiction published works were on space travel, such as *Interplanetary Flight* (1950), *The Exploration of Space* (1951), and *The Exploration of the Moon* (1954). However, Clarke also continued to write fiction. During his college years, he wrote *The Sentinel,* a story that some readers have identified as the core of the idea for his most famous work, *2001: A Space Odyssey.* He was also contributing to the major science fiction magazines of the time, including *Fantasy, Astounding Stories,* and *New Worlds*.

During the 1960s, Clarke began his collaboration with director Stanley Kubrick on *2001: A Space Odyssey.* The screenplay for the movie was actually being written while the novel was being written, so there are differences between the two. The success of this masterpiece of science fiction led to several other works, most notably *2010: Odyssey Two,* which was adapted for the film *2010: The Year We Made Contact.* Again, Clarke showed his prowess for predicting space travel and future events.

Clarke became increasingly well known for his knowledge of space through his television appearances with reporter Walter Cronkite for the coverage of the *Apollo 11* moon landing, as well as some of the other Apollo missions. His expert analysis regarding the future of space travel during these events was astonishing in its accuracy. Clarke moved to Ceylon (now Sri Lanka) in 1956 and maintained dual citizenship in the United Kingdom and Sri Lanka. Toward the end of his life he became almost completely wheelchair-bound due to post-polio syndrome.

Clarke's published works include numerous science-fiction short stories and novels, as well as nonfiction books (including works about the ocean: scuba diving was another passion). His fiction mirrors his nonfiction in that he wrote from a strong background in the sciences; in addition, it demonstrates his uncanny ability to predict the course of scientific advancement and space travel.

Clock, Doomsday

The doomsday clock, which now reflects international security status, is one of the best-known symbols of nuclear danger. Originally referred to as the *Bulletin* Clock or the Clock of Doom, it debuted in the June 1947 issue of *Bulletin of the Atomic Scientists,* a publication founded in 1945 by Chicago-area scientists who were part of the Manhattan Project, which developed the first atomic bomb. The *Bulletin* was designed as a forum to explore the implications of the new power these scientists and their colleagues had unleashed.

Originally in a newsletter format, the publication developed into a magazine. At the request of cofounder Dr. Hyman H. Goldsmith, artist Martyl Langsdorf, the wife of physicist Alexander Langsdorf, created the design. Better known for her landscapes, the artist hit upon "the idea of using a clock to symbolize urgency." Langsdorf had planned on repeating the image of the upper-left quadrant of a clock face, with the minute hand approaching midnight, every month with a different background color. She drew her first sketch on the back of a bound volume of Beethoven sonatas. She credited "good design" as the deciding factor to start the clock at 7 minutes to midnight. The idea of moving the minute hand came later, in 1949, as a way to dramatize the *Bulletin's* response to world events. The clock dominated most *Bulletin* covers until 1964. Langsdorf updated the clock's design once more in 1989 by placing its hands on the globe.

Between 1947 and 2007, the minute hand has been moved back and forth 18 times. The first movement was to 3 minutes to midnight to acknowledge the Soviet Union's explosion of its first atomic bomb. In 1953, the doomsday clock read 2 minutes to midnight to emphasize the Soviet Union's and the United States' testing of thermonuclear devices within 9 months of each other. The most peaceful movement occurred in 1991 when the doomsday clock was set back to 17 minutes to midnight. The United States and the Soviet Union had signed the long-stalled Strategic Arms Reduction Treaty (START) and announced further unilateral reductions in tactical and strategic nuclear weapons. In 2007, the minute hand moved for the 18th time. Five minutes to midnight was based on the United States' and Soviet Union's continued ability to stage a nuclear attack within minutes. North Korea had conducted a nuclear test, and many were worried that Iran had plans to acquire the bomb. The challenge of climate change and its toll on ecosystems was also factored in.

Clocks, Atomic

With advances in science and technology, traditional mechanical clocks have been supplemented with atomic clocks, which give far more accurate time measurements. Further progress in atomic clocks will enhance practical uses ranging from medical research applications to outer space travel.

Origin

In 1945, Isidor Rabi, professor of physics at Columbia University, proposed the idea that an exceptionally accurate form of timekeeping could be procured from a process known as Atomic Beam Magnetic Resonance (ABMR), a process developed by Rabi during the mid to late 1930s. In essence, ABMR is composed of a harmonized magnetic field with an oscillating magnetic field being applied to it at right angles. This forces a transition between the nuclei of atoms with varying states of magnetic quantum numbers. The transition occurs only each time the frequency of the oscillating magnetic field possesses parallel and precise qualities. Given the closed environment in which this process occurs, the interval between one nucleus and the next obtaining the specific characteristic values is nearly flawlessly precise, thus making ABMR an excellent platform from which to launch a method of logging time. Mechanical clocks also use oscillating motion, with tuning forks, pendulums, and balance wheels. But the rate of movement for an ammonia atom in this type of motion is much higher—23,870 vibrations per second, as opposed to the average of 5 to 10 vibrations per second on a mechanical watch—with the elevated oscillations correlating to a greater degree of accuracy.

Prototype

Given the allure of a method of time recording and reporting more true than astronomical time (itself accurate to within only 3 minutes, 55.9095 seconds per 24-hour cycle), the United States National Bureau of Standards (NBS, now referred to as the National Institute of Standards and Technology, NIST) unveiled the world's first atomic clock in 1949, with nuclei of ammonia molecules providing the movement, or vibrations, as a result of the interaction between constant and oscillating magnetic fields. The mean accuracy of ammonia-based atomic clocks, as dispersed throughout the globe, is approximately 1 second every 3,000 years (with even the best mechanical watches being off a handful of seconds each day). By necessity, the device—and all future atomic catalysts used for the gauging of time—is connected to a time recording device; without the registering device being affixed, the near-perfect oscillation cycle would have no way of presenting itself to the outside world, thus rendering it useless as a measurement of time.

Progression

In 1955, the National Physical Laboratory (NPL) based in Teddington, United Kingdom, constructed the first cesium beam clock, utilizing atoms of cesium rather than ammonia. The clock's very precise frequency of 9,192,631,770 vibrations per second has been correlated to a margin of error equaling plus or minus 2 seconds every 3 million years. Throughout the following years, cesium-based clocks began to undergo various modifications and advancements, and during the 13th General Conference on Weights and Measures it was determined the SI second—or cesium-based 9,192,631,770 vibrations per second—would define 1/60 of 1 minute. Because of the acute accuracy of such a measurement, there is little reason to question the motives of this conference when, in 1967, it was determined world time would forever be based on an atomic and not an astronomical basis.

Despite the nearly flawless regularity of cesium vibrations and the subsequent recording of said vibrations, slight discrepancies still exist from one clock—most of which are housed in various research institutions throughout the world—to the next. As such, all "official" clocks (commercially produced cesium-based clocks are available, but their accuracy is at best dismal when compared to that of the laboratory-based models) are recorded and then averaged to produce the global standard, International Atomic Time (TAI, an acronym for the French: Temps Atomique International).

Points of Interest

Usage for so accurate an instrument is vast; time signals broadcast via shortwave radio stations and artificial satellite make it possible for "true time" to be had anywhere upon the globe. This highly accurate and standardized time format is then used in a variety of applications, from synchronization of the Internet to space shuttle launches, to the opening and closing of stock markets, and everything in between.

Contrary to the belief held by many, atomic clocks are in no way radioactive. The clocks are not a result of, related to, or bound in any way by atomic decay, the precursor to radioactivity. Without a working relationship with the catalyst to radioactivity, the chance of accidental radiation is nil. Instead of using the potentially hazardous energy or decay of an atom, the clocks rely on an oscillating part and "springs," not dissimilar to commonplace mechanical clocks. In lieu of the conventional metal coil spring and balance wheel used in mechanical movements, an atomic clock uses gravity, the mass of the nucleus, and an "electrostatic spring" caused by the positive charge of the nucleus and negative charge of its surrounding electron assemblage.

Of distinct interest is the direction that the advancement of atomic clocks has taken during the past decade. As of 1999, NIST began using the world's most precise and stable cesium clock, it being accurate to within 1 second over 20 million years. This instrument is composed of a 3-feet–long vertical tube that is encased within a larger unit. Lasers are incorporated to cool the cesium atoms so that ideal conditions are maintained, helping to ensure greater accuracy in the replication of vibrations per second, thus accuracy. Simultaneously, other lasers are incorporated to "toss" the cooled ball of atoms, thus creating a fountain effect within the 3-foot tube, allowing greater opportunity for the observation of oscillating atoms, much more so than previously allowed within enclosed housing units.

Outlook

The future of atomic clocks seems full of promise when considering ever-diminishing margins of error for replicability of motion, that is, identical units of time. First with ammonia and now cesium, researchers have begun construction of clocks based on hydrogen, beryllium, and mercury atoms, with good indications that these prototypes, once refined into fully operable units, could be up to 1,000 times more accurate than the atomic clocks of today.

Clocks, Biological

Biological clocks are internal mechanisms that help humans, animals, and other living organisms measure time and regulate the rhythms of their bodies and activities. Most commonly, these clocks tell us when to eat, sleep, rest, become active, and mate. Biological clocks allow organisms to determine internally, at any given moment, the actual time of day, month, or year. The internal mechanisms are triggered by fluctuations in environmental variables like changes in daylight or temperature. These internal timekeeping devices have evolved to interrelate with the daily, lunar, and seasonal changes. Environmental rhythms are predictable and set their course on planetary cycles. For example, as the earth spins on its axis, we experience day and night patterns. When the moon orbits the earth, we experience lunar phases and daily tidal changes. The predictable seasonal changes occur during the yearlong travels of the earth around the sun. Even absent human-made calendars and clocks, living organisms detect these environmental variables and naturally modify their behavior consistent to these variables.

Body time is controlled by the suprachiasmatic nucleus, or SCN. This cluster of cells resides within the hypothalamus, which is a tiny portion of the brain that forms on the bottom of the left ventricle and regulates many basic bodily functions, such as body temperature. The ability to synchronize biorhythms to the day and night cycles of the earth's 24-hour–long rotation around its axis provides evidence that this internal mechanism exists and responds to environmental change. The most common examples of biological rhythms for humans include sleeping, waking, eating, urination, and physical and mental performance and alertness. These patterns of behavior show that organisms behave as if they are independently capable of determining time.

The scientists who study biological clocks are called chronobiologists; they believe the biological clock begins functioning even before humans are born and that it develops as they grow. At 7 months of age, human babies have developed sleep patterns that are free-running, meaning that their sleep cycles are not regulated by external cues such as the rising or setting of the sun. Chronobiologists have also discovered that biological rhythms send messages to the brain, telling people what activities to perform. Because the urinary biological rhythms take longer to develop in babies, they wear diapers until they have mastered the rhythm, sometimes until they are 3 or 4 years old. As children grow, the biological clock matures and begins to slow urinary frequency during sleep hours, freeing older children from the urge to urinate and allowing them nights of uninterrupted sleep. The circadian or daily rhythms of 10-year-olds are disrupted by their high energy levels. Concomitantly, adolescents hit growth spurts and require more sleep than they did when they were younger. When they reach their 20s, they generally settle into a routine 24-hour day cycle. As energy levels fall for the elderly, their sleep cycles and circadian patterns are again disrupted.

Biological rhythmicity has also been seen in research studies involving groups of plants, animals, and microorganisms. In the late 19th century, plant physiologists researching circadian rhythm found that if a plant was removed from its natural habitat and was confined to a laboratory and subjected to disturbances in its daily cycles of day and night, the plant would maintain its primary biorhythms. Many plants that exhibit daily rhythms in which they raise and lower their leaves to correlate to the time of day or night will continue to exhibit similar patterns even after the source of light is disrupted. For example, if a plant normally lifts is leaves upward during daylight hours, it will continue to do so even if placed in a laboratory and removed from its light source. These plants slowly adapt to the new environment provided in the controlled study and can eventually reverse their normal daytime/nighttime routines. They can later even revert successfully to their natural habitat and primary biorhythms when returned to their native habitat. Laboratory experiments have consistently shown this extraordinary stability of biological rhythms. Daily rhythms for a wide variety of single-cell organisms, mammals, and plants also remain unchanged when they confront constant light or dark.

A strong sense of time enables organisms to most fully explore and participate in the portions of the day in which their activities will be most productive (eating, mating, sleeping, hunting, migrating, etc.). When an animal is relocated to a geographic area where the environmental cycle is greatly different, the animal's clock maintains synchronicity with its original environment. Similarly, if humans are rapidly translocated a great distance and experience significant time zone disruptions, they will also maintain synchronicity. Most humans and animals will slowly readjust after this period of initial disruption. This reaction to loss of time is a phenomenon commonly called jet lag, and many people describe physical effects of fatigue, lowered productivity, and decreased alertness until their internal mechanisms readjust.

Fluctuations occur at every level, from cellular to complete physiological activities, in which chemical, behavioral, and physiological responses are evidently correlated to the environment. Many biological rhythms correlate to periodic planetary changes, also referred to as geophysical correlates (ocean tides, amount of sunlight in a day, the changing months and years, and the seasonal differences). Some fluctuations or biorhythms do not have geophysical or external correlates, such as the biological rhythm of a heartbeat or a respiratory rate.

Clocks, Mechanical

The first mechanical clocks appeared about 1250 CE and employed weight-driven gears to keep time. Their invention represented an important step in the quest to discover a way to keep time accurately. The inventor of the first mechanical clock is unknown, but records indicate the timepiece originated in Europe. In all likelihood, the devices were invented in monasteries, where they were used to call the monks to prayer.

Mechanical clocks represented a vast improvement over previous timekeeping mechanisms of the day, including hourglasses and water clocks, which proved to be unreliable for accurate timekeeping.

The mechanical clock is composed of a few necessary parts, including a suspended weight that provides a driving force; a train of gear wheels that transmit power and turn a dial to indicate time; a time-controlling device that regulates the falling weight; and a mechanism known as an escapement. The escapement is a key component of the clock and is that which distinguishes it from its predecessors. This device takes energy from the power source, transmits it through gears, and releases it in beats, generally one per second. Early escapements were quite primitive and were unable to keep a regular beat. Later escapements were designed to fit on the top of the gears and were stimulated by the pendulum's motion. Rocking back and forth on the wheel, the escapement allowed the gear to advance one notch but blocked advancement to the next notch. When the pendulum returned, the escapement released another notch. In this way the escapement controlled the rate at which the clock beat.

Clocks relied on the pull of gravity as a power source. A weight was attached to a cord that was tightly wound around a toothed spool known as a capstan. As the cord unwound, the capstan turned a set of gears that then caused the hands on the clock's face to move. Although the early "modern" clocks represented a great leap forward, the devices were inaccurate at best, losing or gaining 15 minutes per day, and often much more than that. Such clocks often had to be reset daily at solar noon. Furthermore, their mechanical parts required a great deal of upkeep.

The next major advancement was the application of the pendulum to the clock in 1657, which provided a more reliable power source and hence represented a much more precise way to keep time. Clockmakers immediately began to employ the pendulum as a new type of "regulator," and timekeeping errors were reduced even further. The pendulum allowed clockmakers to add a minute hand to the clock, which previously had sported only an hour hand. Furthermore, continued refinements to the shapes of clocks added to the increased accuracy of the devices because they could house and protect long pendulums. Thus were longcase clocks born, later known as grandfather clocks. Mechanical clocks continued in use for more than 400 years before the advent of the electric and, ultimately, the atomic clock in modern times.

Patricia J. West

The Orloj is a famous astronomical clock in Prague, Czech Republic. It was one of a number of complex astronomical clocks designed and constructed during the 14th and 15th centuries, soon after the invention of the mechanical clock.

Coelacanths

The term *coelacanth* refers to fish that are members of the order Coelacanthiformes, renowned for their multiple limb-like lobed fins and extensive fossil history. Prior to the 20th century, they were thought to have been extinct for approximately 70 million years, but the fish catapulted to worldwide fame when several living populations were discovered.

The ancient lineage of coelacanths is part of the order of lobefin fishes and currently represented by two living species, *Latimeria chalumnae* and *Latimeria menadoensi*. They display a remarkable combination of morphological features that are unique or rare among all living fish, among which the most obvious are their seven fleshy fins. These include several pairs of muscular lobed pectoral and pelvic fins that are quite dexterous, being able to rotate and serve as multidirectional paddles for greater control in currents.

The shape and placement of the bones in these lobed fins show a clear similarity to amphibians' forelimbs, and at times it was thought that the colloquially named "four-legged fish" might be the direct ancient relative of all land-dwelling vertebrates. However, the molecular and paleontological evidence suggests that Coelacanthiformes are at most a side branch of an earlier ancestor that would later give rise to limbed animals capable of terrestrial domination.

Adult coelacanths can weigh up to 90 kilograms and grow as long as 2 meters, although they are often smaller. Specimens of *L. chalumnae* have thick scales of a pale mauve to blue color, while *L. menadoensi* is brown; both have flecks of iridescent white or silver. These markings provide excellent camouflage within their preferred habitat of encrusted rocky marine caverns, where they shelter at depths between 100 and 700 meters during the day, before foraging in shallower zones at night for fish, eels, skate, octopus, squid, and crustaceans. They are relatively sluggish, seen feeding by drifting head down in currents, aligning their gape with crevices in which to find food and swallow it whole.

The fossil record shows coelacanths emerged during the Devonian period, approximately 400 million years ago (mya). The group diversified into both marine and fresh water, becoming most abundant in the Triassic before suffering a slow decline terminating during the Cretaceous period 70 mya, after which no more fossils are known. Thus, the world was shocked when in 1938 a live specimen, dubbed *Latimeria chalumnae,* was caught off the coast of South Africa. Sixty years later, a new population of coelacanths (*Latimeria menadoensis*) was discovered north of Sulawesi in the Indonesian archipelago. Genetic analysis indicates that the two populations diverged about 5 mya.

The coelacanths have been an icon of evolution to both scientists and the public, thanks to their renown as a "living fossil," seemingly surviving extinction and appearing entirely unchanged over time. Both terms are somewhat misapplied. Coelacanths have always been present in the world's oceans. Humans were just unaware or ignorant of their presence—as we surely remain for much marine life. And far from remaining unchanged over time, there are periods of rapid morphological evolution in their history. One of the oldest specimens from this group, for example, has an eel-like morphology (*Holopterygius,* from 385 mya, found near Cologne, Germany). Other relatives from the same epoch had round, disk-like bodies or a range of disparate morphologies. This indicates the group went through an early period of anatomical experimentation before settling on the distinctive features of present-day coelacanths.

Coelacanths play an important role in our understanding of vertebrate evolution, and serve as a significant symbol of life's diversity and adaptive nature. Although humans do not eat coelacanths for food, some have been harvested for nonsensical medicinal purposes. In addition, they suffer byproduct mortality from other fishing activities. Their rarity indicates their future survival is in doubt, to the point that one species is listed as critically endangered and the other is unclassified until further evidence of their population can be found.

Cognition

Cognition has multiple meanings and is often used as a general term for all mental thought processes. More specifically, it often refers to the use and acquisition of both language and knowledge (including self-knowledge). Other mental processes frequently associated with cognition are judgment, perception, reasoning, awareness, intuition, and memory. Time is a fluid idea in relation to cognition, interweaving with it; the idea of time is shaped by cognitive processes, yet also shapes those same processes. Metacognition, mental representation, attention, and perception seem to be the primary areas where time and cognition most overlap.

Present mental states are formed and grounded in past interactions and ideas; these past interactions are then imposed on future possibilities. Nonetheless, thought about thought, often called metacognition, can invert this process and view it in an opposite manner from what is normally considered. Although time usually is thought of as flowing from the past to the present and then into the future, metacognition will often begin by forming a plan (projecting a course of action into the future), carrying out what is planned in the present, and then considering what has been accomplished (by looking at actions that are now past).

This process of reflecting on one's own mental state can be regarded as a form of mental time travel. It is also possible to contemplate times not personally experienced, such as the remote past or the distant future. A related idea is the mental representation of self as both a past memory and also as imagined in the future. Indeed, the Bischof–Kohler hypothesis, which claims that nonhuman animals are unable to consider future needs, holds that it is this ability that distinguishes humans from other animals. Others believe humans are not the only species to manifest this ability; research on the matter continues. Thus far, however, a conclusive case has not been made either way.

This flexibility in relation to views of time may be further demonstrated by the preference of English speakers (who consider time sequences as before/after) in contrast to Mandarin Chinese speakers (who often prefer to regard time sequences as up/down). Neither of these spatial metaphors is misplaced; time is often viewed as an object, more as a physical entity than a mental construct. Nonetheless, whether time is actually a physically existent entity or not can be debated. What is certain is that people often talk about time in terms of space but rarely about space in terms of time. It has also been determined that when the hippocampus (a part of the brain) is damaged, not only spatial memory but also episodic memory (the memory of particular events) is impaired. This suggests the two are intertwined in thought.

Humans have developed multiple gradations with which to consider time: minutes, hours, days, weeks, months, years. It has been suggested that both verbal and image-based processes are used. Perhaps this is why one often might recall exactly where and what time of day something happened . . . but not exactly the month or year.

Time can also seem to expand and contract depending on how intently one is paying attention to it. "Attention" is generally regarded as a cognitive function that allows a person to notice some aspects of a situation or object but not others. Exactly which aspects are noticed may to some extent be culturally dependent. What matters for this discussion is the fact that while one is noticing them, the nature of one's concentration is impacted. When a person is concentrating intensely, the passage of time may not be noticed at all; consequently it may seem as if time passes very quickly. When waiting for something to happen, however, it may seem as though time passes ever so slowly. Indeed, in such a situation it may be there is nothing else to pay attention to except the passage of time.

Coins, Ancient

Our knowledge of earlier civilizations has been greatly improved by direct examination of those artifacts that have survived the ravages of time. Unlike most animal and plant tissues, which undergo rapid or gradual decay, metal objects, particularly of the less reactive or precious metals, can remain preserved intact underground or underwater for centuries, even millennia. Included among such objects are the earliest examples of ancient coins. Coins themselves are actually a relatively recent historical development; the first specimens date back to the 7th century BCE. Most such coins were metal tokens, usually in the shape of a disc, that represented a specific value based upon metal composition, weight, or assigned value. On at least one side, coins had an image—and later an inscription—representing the authority that issued the coin.

History of Development

Trading based upon a bartering system using objects, such as shells, skins, salt, grain, cattle, and precious metals such as silver and gold, predates the first coins by millennia. When people began using metal for bartering, value was based upon the weight and purity of the metal, not the form or shape of the metal. An early standard of value was based on the price of cattle, such as an ox. Over time, people came to prefer to exchange metal because it did not wear out as easily as other materials and generally remained stable in value.

The first coins were struck in the 7th century BCE in the kingdom of Lydia, a region corresponding to modern western Turkey. These coins were made of electrum, a naturally occurring alloy of gold and silver; however, electrum quickly ceased to be used in preference to gold and silver. These coins were of an oval shape and had a lion figure stamped on one side and one or more punch marks on the other (what historians call punch-mark coinage). Due to close ties with and influence from Greece, coin usage speedily spread throughout the Greek colonies and into the larger Mediterranean world by the mid-6th century BCE.

Greece quickly developed a preference for silver coins and issued few gold coins. Although Athens and Corinth had the first mints, silver coins became so popular that they began to be minted in areas all around the Mediterranean Sea. By 500 BCE, these mints were using dies—striking a blank disc between two die—to stamp out coins rather than using single punches. The obverse die was seated in the anvil and the reverse die was on the base of the punch. The craftsman placed a blank piece of metal and struck the punch several times, thus making a coin.

Because of the existence of many mints, a custom developed that a particular mint would stamp its own design on a coin to identify the location where the coin was made; hence, the first mint marks. In the 200s CE, Roman mints began using standardized mint marks for their coins; these were located at the bottom of the reverse side.

The Romans began producing coins early in the 3rd century BCE, being highly influenced by Greek coins. About this same time (289 BCE), coins began being used for the first time as money, that is, having an exchange value not based on metal or weight. Initially, the Romans minted only coins of silver but by the late 3rd century BCE had begun issuing large quantities of bronze coins. After the unprecedented financial demands of the wars with Carthage (264–241, 218–201 BCE), Rome standardized its coin values based upon the *denarius* for silver coins and the *as* for bronze. Because Rome took booty and tribute from the people it conquered, silver and gold became scarce in the provinces, and coins made of those metals petered out by the middle of the first century BCE except in Rome. Throughout the first centuries CE, coin usage vastly expanded throughout the empire,

These Roman, silver-coated coins date to 240–244 CE. Obverse: The inscription says IMP GORDIANUS PIUS AUG, meaning "Emperor Gordian III, Augustus." The radiant crown indicates that the denomination of the coin is an Antoninianus. Reverse: the inscription says SECURIT PERP, meaning "eternal security."

mainly via the army. This trend continued to the end of the empire. Roman coins had become so common in usage for purchasing goods or paying laborers that their impact continued to influence the coins of European groups well into the Middle Ages.

Just as the Greeks spread coin usage in the Mediterranean basin, the Persians spread its usage in the East (as far east as modern Afghanistan and Pakistan). Cyrus the Great (550–530 BCE) introduced coins to the Persian Empire after he conquered Lydia in 546 BCE. His grandson Darius I (521–486 BCE) introduced a thick gold coin he named after himself, the *daric,* which weighed 8.4 grams. He is pictured on the *daric* holding a bow and arrow. Because of Persian influence in the Far East, coins began to be used in northern India by 400 BCE. These early coins, made of silver, seem to have been an adaptation of Greek prototypes, with an image on one side and up to five punch marks on the other.

China developed coins independently of Greek and Persian influence. The first coins date to the Zhou kings (late 7th or early 6th century BCE) and were in the shape of a knife or spade. These bronze coins contained an inscription of the clan name, place name, or weight. In the late 3rd century BCE, Qin Shi Huangdi unified the Chinese states and issued round coins with a square hole in the center. These coins contained a two-character inscription indicating their weight. This coin continued until the Tang Empire, when the emperor Gaozu redesigned the coin, adding a four-character inscription that gave the weight and the period of issue and designated the coin as money. Coins of the Tang Empire spread throughout the Far East, with similar designs being adopted in other nations. The Japanese introduced coins in 708 CE, the Vietnamese in 970 CE, and the Koreans in 996 CE. Eastern Asian coins followed the Chinese design until influenced by European nations in the 18th century.

Values

Early bartering in Mesopotamia placed a value on precious metals based upon their weight in shekels (11.5 grams). The first coins in Lydia had value based upon their weight—the *stater* (a word meaning "standard") weighing about 14.1 grams. The smallest Lydian coins were as tiny as 1/96 of a stater (0.147 grams). The largest weight was one *mina,* equaling 50 staters.

Within a century of their introduction, coins became standardized by one of three standards: Athenian, Persian, or Phoenician. Greece (the Athenian standard) used the stater early and then the *tetradrachma,* which weighed 17.5 grams, as its standard. These were divided into the smaller *drachma* coins of 4.2 grams. The Persians used the 8.4 gram gold daric and 5.6 gram silver *siglos* (Persian variant of the shekel) as their standard for coins. One daric equaled 20 *sigloi.* The Phoenicians used a silver stater coin of 13.9 grams as their standard, which they subdivided into 24 parts. However, the main coin they used was the half-stater of 6.5 grams. By the 5th century BCE, coins began to have a designated value assigned by the issuing authority, apart from the net worth of the material of which they were made.

The Romans' standardized silver coin was the *denarius,* which was the equivalent of one Greek drachma. The standard for bronze coins was the *as,* which equaled a fraction of a denarius (one denarius equaled 10 *asses* before 140 BCE and 16 asses after 140 BCE). In the first century BCE, the Romans introduced the gold *aureus,* equal to 25 *denarii.* This coin became fairly common, an indication of the wealth of the early Roman Empire. In the 3rd century CE, corruption and inflation plagued the empire. The value of gold coins reverted to being based solely upon their weight in order to correct the problem; however, this did not work. As inflation grew, silver coins were made containing a lower percentage of pure silver until they contained almost no silver (less than 1%).

Before the invention of coins, some merchants used dishonest scales to cheat people out of their valuables. Evidently, the invention of coins did not solve the problem. Some ancient coins have chisel cuts in them where someone sliced the coin to check its purity. Furthermore, Rome had problems with coin forgery at times when there were shortages of official coins (the 40s, 270s, and 340–350s CE).

Designs

From the first coins, designs varied by mints and included images of animals, plants, persons, mythic beings, deities, city symbols, and so on. Later scenes depicted rulers, significant events, patron deities, and the like. Each mint designed its own coins. However, in the 3rd and 4th centuries CE, the Romans made all of their coins uniform so that all their mints made coins of the same designs, metallic quality, and size—a first in history. The only variant was the mint mark, which remained unique for each mint.

Coleridge, Samuel Taylor (1772–1834)

Samuel Taylor Coleridge was one of the most influential poets and critics of the 19th century. Considered one of the founders of the Romantic movement in England, he is best known for his poems *The Rime of the Ancient Mariner* and *Kubla Khan.* He also wrote a voluminous amount of literary criticism and philosophy that still resonates in contemporary discussions of the imagination. Most of Coleridge's major poems and prose writings wrestle with the poetic imagination and with the poet's ability to create independent states of reality. The nature of poetic genius—and more specifically the way in which this faculty transcends both literary convention and the laws of time and space—becomes the central theme of *The Rime of the Ancient Mariner* and *Kubla Khan.* It is also the dominant concern of Coleridge's important critical work, the *Biographia Literaria.*

Coleridge was born in Devon in 1772 into a large family. His early life was marked by loss; his father died in 1781, and Coleridge was sent away to study at Christ's Hospital School in London. Here he developed a lifelong appetite for reading and for philosophy in particular. He entered Cambridge but never took a degree. Coleridge came of age in the turbulent years surrounding the French Revolution, and the volatile sociopolitical climate of the late 18th century is reflected in his life: He dropped out of Cambridge, enlisted in the dragoons, made an early and unhappy marriage, and eventually aborted a fantastic dream for a utopian community in the United States. Coleridge struggled with illness, poverty, and instability through most of his adult life.

It was not until 1798 and the publication of *Lyrical Ballads* that Coleridge really came into his voice as a poet. This joint collection of poems by him and his close friend William Wordsworth was a seminal text for the Romantic movement. Although it was not especially well received, in retrospect we can see in it the seeds of a new poetic vision that views the human imagination and its intersection with nature as the fertile nexus for a poetry that can release humanity from the restraints of rational thinking, including the conventional boundaries of time. Coleridge's output steadily diminished over the years as he struggled with poor health and opium addiction. His final years in Highgate, outside London, were relatively peaceful; he enjoyed there the status of a wise seer as he received visits from the leading poets and thinkers of his day.

Major Poems

Two poems invite special consideration of Coleridge's poetic concern with the nature of time. In *Kubla Khan,* published in 1816, the poet conjures a remarkably sensual and otherworldly landscape situated in a remote but not strictly historical past. Kubla Khan has ordered the construction of a "pleasure dome" by the sacred river Alf, and the poem then paints a remarkably detailed and mysterious vision of gardens, river, and sea that suggests the poet's penetration of an alternate reality, one that suspends time. Coleridge stated that he composed the poem while he slept through an opium-induced dream. Upon waking he simply wrote down what he remembered of it before being interrupted by a visitor. Whether true, embellished, or completely invented, both the poem and its purported composition express Coleridge's abiding belief that the poet's imagination had extraordinary creative power to stretch our understanding and experience of time.

In *The Rime of the Ancient Mariner* we see Coleridge using a ballad style to explore the nature of guilt, redemption, and spiritual love, but this long poem also challenges our conception of time. A sailor, or mariner, embarks on a long voyage that takes him with his fellow mariners to the South Pole. The mariner inexplicably shoots an albatross whose earlier appearance had freed the ship from dangerous ice. Wearing the albatross as sign of his guilt, the mariner endures a series of symbolic experiences that culminate in his release from abject desolation and his embrace of a restored sense of the sacred beauty of creation. Coleridge subtly contrasts the experience of time-based reality with the supernatural reality of the mariner's voyage. The result is one of the most symbolically complex poems in English literature, one that continues to compel critical questions about human perception of experience and time.

Columbus, Christopher (c. 1451–1506)

A navigator and cartographer, Christopher Columbus is presumed to have been born in Genoa, Italy, in 1451, son of Giovanni Colombo and Susana Fontanarossa. During his adolescence, he worked in his father's weaving shop. In the busy port of Genoa, Columbus learned the rudiments of navigation and cartography. During his youth, he traveled as a sailor to various countries such as Iceland, Flanders, and Portugal, where he was shipwrecked in 1476. In Lisbon he married Felipa Moñiz de Perestrello, a lady of the Portuguese court, whose connections permitted him not only to further his readings about navigation but also to present King João II with his project to travel to India by sailing westward. His project would later be approved, but more important, he received the title of Captain, which would grant him greater prestige and credibility when presenting his project to the Catholic Monarchs of Spain, Ferdinand and Isabella, in 1486. Undoubtedly a very important figure of modern history, Columbus helped to transform the knowledge and the history of his time.

Columbus set sail from the port of Palos in Frontera, Huelva, Spain, on August 3, 1492, and arrived on the island of Guananí on October 12 of that same year. In all, Columbus embarked on four voyages that circumscribed the Caribbean Sea and the Panamanian Isthmus. Although the Capitulations of Santa Fe stipulated that Columbus would receive the titles of Admiral of the Seas, Viceroy, and Governor, his failed experience in Hispaniola demonstrated that, although an excellent navigator, he was a terrible military officer, a disastrous politician, and a failure as an entrepreneur. Of his *Onboard Diary,* only the abstract compiled by Fray Bartolomé de las Casas has survived; in this fragment Columbus details the exploits of his four expeditions and makes an inventory of the newly discovered lands in rhetorical flourishes designed to convince the Catholic monarchs of the viability of his enterprise.

Myths and legends have sprung up around Christopher Columbus's name. Elevated to the stature of a Romantic genius by leaders who have wanted to see the mythical origins of their nations in his heroic deeds, Columbus has been represented in multiple novels and movies, exalted to the point of paroxysm in poetry, and lauded in extensive biographies and studies. That which is known for sure is that Columbus's arrival on the American continent heralded the genocide of millions of Indigenous people and the annihilation of important civilizations such as the Aztec and the Incan, as well as opened one of the most shameful chapters of human history: African slavery. Christopher Columbus died in Valladolid, Spain, in 1506. There is a controversy regarding his remains. While some scholars assure that his remains rest in the Cathedral of Seville, others claim that his remains are buried in the Columbus Lighthouse, in Santo Domingo, Dominican Republic.

Comets

Many comets have regular orbits and appear at predictable time intervals. In 1705, Edmund Halley hypothesized that four comets previously assumed to be individual entities were actually one comet with a regular orbit, based on his awareness that all items in space were affected by Newton's law of gravity. Halley successfully predicted that the comet would appear again in 1758.

Comets are normally equally distributed between those that have direct orbits and revolve around the sun in the same manner as planets, and those that have retrograde orbits and revolve in a manner opposite to the planets. Orbits are measured in Earth years.

Comets are categorized by their orbits and fall into three categories. More than 1,000 comets have fairly well defined orbits. The most widely studied comets are short-period, or periodic, comets that orbit around the sun every 200 years or less. Popular short-period comets include Encke: 3.3 years; Halley: 76.1 years; Kopf: 6.5 years; Temple: 5.3 years; and Wolf: 8.4 years. Long-period comets are those whose orbits are longer than 200 years but are still influenced by the gravitational forces of the sun. The Hale–Bopp comet has an orbital period of 2,400 years, and the orbital period of Hyakutake is 31,000 years. Some comets appear once and do not find an orbit but pass around the sun and get lost in space. These are referred to as single-apparition comets.

Although generally regular, orbits of comets are not always consistent. While there are more than 100 short-period comets whose orbits are mapped, astronomers occasionally lose track of one of them. Likewise, although infrequently, a comet that is thought to be "new" turns out to be a formerly "lost" comet. An example of this is Comet 11P/Tempel–Swift–LINEAR, which was discovered in 1869, lost after 1908 due to disturbances caused by Jupiter, and rediscovered in 2001.

Comets do not last forever. Each time they pass around the sun, comets lose some of their matter. Eventually, the comet will be reduced to a meteor. Comets can also collide with the sun or a planet and be destroyed. Some comets also develop parabolic or hyperbolic orbits that shoot them out of the solar system.

Comets are sometimes referred to as "dirty snowballs" due to their makeup of 50% gas and dust and 50% ice that is primarily frozen gas. They are believed to be ejected from either the Kuiper belt or the Oort cloud. Most originate from the Oort cloud, an outlying area of the solar system hypothesized by the Dutch astronomer Jan Hendrik Oort. Some of the short-period comets develop from the Kuiper belt, also known as the transneptunian region, a theoretical collection area of celestial debris beyond the orbit of Neptune described by

Comet Hale–Bopp was photographed in the constellation Andromeda by George Shelton, photographer for The Bionetics Corp., at 8:14 p.m. on March 31, 1997, from Merritt Island, Florida, close to the Kennedy Space Center. During this 24-hour period, Comet Hale–Bopp was making its closest approach to the Sun.

Source: NASA Kennedy Space Center.

K. E. Gerard Kuiper in 1951. Following ejection, the comet becomes caught in the sun's gravitation field and develops an orbit around the sun.

As comets get closer to the sun, the ice begins to melt, forming a gaseous cloud tail called a coma. There is also a second tail of dust and gas, though the two are generally perceived as one tail. Sometimes the tail of the comet will be seen in front of the comet since the dust and gas tails are lighter than rest of comet, and the solar winds can push the tail out in front of the comet when the comet is close to the sun. When the earth passes through the orbit of a comet, meteor showers are created. For example, in May and October every year, the earth encounters the meteor stream from Halley's comet.

Comte, Auguste (1798–1857)

Auguste Comte is known as the founder of sociology and the father of the paradigm of positivism. He was born Isidore Marie Auguste Francois Xavier Comte on January 17, 1798, at Montpellier, in southwestern France, at the culmination of the French Enlightenment. As a scholar, Comte wrote about the historical development of the special sciences in general, and the historical development of the interpreting human mind in particular. He saw each science and each explanation of it unfolding through time, passing from a religious stage (theology), through a metaphysical stage (philosophy), to an ever more empirical stage (science).

As a young man, Comte excelled in his studies. In August 1814 he entered competition for the entrance exams and was admitted to the École Polytechnique in Paris, an elite school that espoused the French Enlightenment ideals of republicanism and progress. Although he found Napoleonic tyranny distasteful, he preferred it to the restoration of the monarchy, and thus supported Napoleon during his years at the school. However, in April 1816 his studies were halted when the school closed owing to conflict between students and administration over the school's outmoded methods of examination. Comte did not reapply for admission when the school reopened and instead supported himself by tutoring in Paris.

In the summer of 1817, Comte made a social connection invaluable to his career as a scholar. He met Henri Saint-Simon, the 60-year-old director of the periodical *L'Industrie,* whom he then began to work for, in his own mind as a collaborator but apparently in the mind of Saint-Simon as a protégé and disciple. By 1824 this difference of perspectives erupted into a disagreement about whether or not one of Comte's essays ought to be published in his own name or under the name of Saint-Simon. They also disagreed about the importance of activism and theory, Saint-Simon favoring the former and Comte favoring the latter, and Comte disagreed with the tinge of religiosity that Saint-Simon gave his thought and writing. The differences were irreconcilable, and the two parted ways.

After some tumultuous years following the split with Saint-Simon, Comte became ever more ambitious in his thought. This is the point at which he began to develop his conceptions of positivism, the "law of three stages," and social science as the dominant unifier of all other sciences, all of which he discussed in his masterpiece, *Cours de philosophie positive,* written from 1830 to 1842.

Comte's positivism can be seen as a paradigm commensurate with the values and ideals developed during the Age of Enlightenment. One premise of the paradigm is that knowledge comes from the positive affirmation of theories through scientific methods such as observation. However, it is important to note that he felt it was necessary for theory to precede any type of observation so as to inform the observer what to look for.

For Comte, scientific positivism was the capstone of human social evolution. It is the third stage in his law of three stages, being preceded by the metaphysical stage, which is preceded by the theological stage. The theological stage itself was divided into three phases those being fetishism (object worshipping), polytheism, and monotheism. The theological stage, Comte argued, embodied man's earliest social existence. It is during this stage that humankind uses God or supernatural forces as an explanation for things and as an apex from which societal order descended. Thus, nature was mythically conceived and humans made no accurate causal connections between phenomena in nature. Comte thought that humanity had been in this stage until the French Enlightenment, and thus that this stage comprised the bulk of human history up to 1750 CE.

The second stage Comte discussed is the metaphysical stage, in which God, or supernatural beings, as an explanation for phenomena is replaced by rational explanations, and during which society is ordered according to rational principles rather than assumptions of divine intention. Philosophers began to theorize about the way the world works and to formulate postulations about the relationships of phenomena to each other. It was during this stage that humans began to have a conception of universal human rights existing on a higher plane than the whims of a monarchical ruler, and during which philosophers began to design forms of society in which the state would serve the people rather than vice versa.

Comte's third stage was positivism, which was characterized by the proliferation of science, especially morally charged science meant to restructure and perfect society as a whole. Thus positivism marked a development beyond the metaphysical stage because rational explanations themselves were no longer sufficient unless supported by empirical observations. Essentially, positivism meant the development of science, and then science leading humankind into a better future. He also believed that this stage would be characterized by the abandonment of the human rights developed during the metaphysical stage in order to serve society in the best way possible. He coined the word *altruism* to describe the responsibility of the individual to put the interest of the many above the one. He believed society at the positivist stage would function more as a single unified body than a collection of individuals.

Mirroring Comte's hierarchical view of stages in human social evolution was the hierarchy he ascribed to the sciences, which he termed the "encyclopedic law." According to this law, the sciences developed in a linear order and were necessarily built upon one another. Comte viewed inorganic physics such as astronomy, earth science, and chemistry as the crudest of the sciences, and thus the base of what one might envision as a scientific pyramid. Built upon these sciences was organic physics or biology, which marked the second stage in the development of scientific thinking. Finally, Comte felt that social science, which he first named social physics and then sociology, would be the apex of this scientific pyramid, encompassing all previous sciences to make for the superior science of society that would guide human action toward perfecting society.

By the end of his life, Comte had attached more than just a tinge of religiosity to his thought and to his vision of human history and future. By 1846 he had begun believing himself to be a sort of prophet of the religion of humanity that he believed positivism to be. By the end of his life he began declaring himself the Pope of Positivism. While in retrospect this may seem like folly, it is important to note that his contributions to human thought were invaluable. His focus on the interconnectedness of social elements was a precursor to functionalist theory, and his bold ambition laid the groundwork for the discipline of sociology within academia today.

Confucianism

Confucianism is a system of belief based on the ideologies of the 6th-century BCE Chinese scholar Confucius (Kong Fuzi). Living in a time of great social turmoil, Confucius devoted his life to the goal of restoring social harmony, which, he argued, was to be achieved by following the social order established by the sage kings and cultural heroes of antiquity. By creating citizens and rulers who were as virtuous as the sage kings, a perfect society would result.

Fully understanding Confucian doctrine requires that time be examined along several dimensions. First, the time period during which Confucius lived, known as the Eastern Zhou Dynasty (771–256 BCE), provides the context for his goal of social restoration. Second, the means for obtaining this goal are derived from elements of ancient Chinese culture extending to a legendary golden age of the past. Third, setting Confucianism along a historical timeline demonstrates its profound influence on Asian culture in the centuries following Confucius's death, an influence that continues now more than 2 millennia since its inception.

Confucius

The English name Confucius is derived from the Latinized name Kong Fuzi, meaning Master Kong. His birth name was Qiu of the family Kong. While he is credited as the founder of Confucianism, it really was not until several centuries after his death, through the work of scholars such as Mencius (c. 371–289 BCE) and Xunzi (c. 298–238 BCE), that Confucian principles were developed into a unified, established system. Confucius was born in 551 BCE in the state of Lu in northeastern China in what is today Shantung province. His father was a distinguished soldier who died when Confucius was a young child. His mother had little money, but worked hard to raise Confucius as an educated gentleman. Growing up he worked at menial tasks and lived a life of poverty, but also enjoyed opportunities such as hunting, archery, art, and a good education.

As an adult, Confucius desired a government post that would allow him the opportunity to persuade rulers to adopt his strategies for restoring order to society. However, he was unable to pass the qualifying examinations required for such a post. For a while he served as a clerk in the Memorial Temple of the Duke Zhou performing sacred, ancient ceremonies. He then turned his focus to teaching. Unlike other teachers of his time, Confucius accepted students based solely upon their intelligence and willingness to learn rather than on their social class. In his early 50s, Confucius finally passed the civil service examinations and obtained a government position as a magistrate, but soon resigned in frustration over his failure to influence the corrupt rulers. For the next 15 years he journeyed to various states in an unsuccessful quest to locate rulers who would implement his social policies. At the age of 68 he returned home to Lu where he spent his final years teaching and editing the ancient writings known today as the Five Classics.

Confucius died at the age of 72 in 479 BCE, thinking that his ideas would never be taken seriously by those in power. However, scholars of later centuries transformed Confucius's ideologies into a well-defined philosophical system that would shape and be shaped by Chinese culture and society, and eventually other Asian cultures as well, for more than 2 millennia.

Goals of Confucianism

Confucius lived during the second half of the Zhou Dynasty, known as the Eastern Zhou period (771–256 BCE). China was not yet a unified empire but rather consisted of numerous small, semi-independent kingdoms ruled by relatives of the hereditary king. These, in turn, were divided into districts ruled by governors. In the 8th century BCE, an invasion by non-Chinese tribes from the west forced the Zhou king to move his capital to the east. The weakened power of the Zhou rulers resulted in a historical time period characterized by civil war and social turmoil.

Numerous schools of thought arose in response to these changes, with each proposing a distinct solution to the crisis. Many blamed traditional values and sought contemporary solutions. Confucius looked instead to the traditions of an ancient past. His main goal was to restore the social harmony that existed during the golden age of the virtuous sage kings of antiquity who ruled by the Mandate of Heaven. This was a two-part goal. First, ordinary people would be transformed into *junzi,* which is often translated as "noble person" or "superior person." For Confucius, however, this term did not refer to nobility ascribed at birth. Rather, anyone could become junzi by cultivating the moral virtues of the sage kings. The junzi is a person who puts the needs of others before his or her own. Such a person sincerely refrains from self-interest in order to act in the best interest of society. Second, Confucius desired to create a perfect society. These two goals reinforce one another as superior people will naturally create a perfect, harmonious society and a perfect society will produce virtuous people.

The Golden Age of the Sage Kings

The foundation of Confucian doctrine is based on the virtues of the mythical culture heroes and sage kings of an ancient time. This is a time that predates the first historical dynasty. Confucian culture heroes are credited with the perfection of human social order. Therefore, many, such as Fu Xi and Shen Nong, later became canonized as deities. Fu Xi, the serpent-bodied emperor, is attributed, among other things, with teaching humans how to domesticate animals. Shen Nong is credited with the invention of agricultural tools and discovering the medicinal properties of plants. All of the culture heroes offered equally momentous gifts to humanity.

After the period of the culture heroes followed the golden age of antiquity of the sage kings who ruled during the legendary Xia Dynasty (ca. 2200–1750 BCE). Bestowed with the Mandate of Heaven, they ruled by virtuous example rather than by force. Exhibiting great altruism, their only concern was the welfare of their subjects. For this reason, they were junzi. The result of such ethical ruling was a perfect social order and harmony between heaven and humanity. However, the last Xia emperor lost the Mandate of Heaven due to his corruption and so was overthrown by the ruler of the first historical dynasty: the Shang Dynasty (c. 1750–1100 BCE).

Ancient Chinese Culture

The roots of many of the principal tenets of Confucianism can be located in ancient Chinese culture and religion. A few of the more central concepts that have shaped Confucianism include heaven, filial loyalty, and the emphasis on social relations.

During the Shang Dynasty (c. 1750–1100 BCE) there was a belief in the high god Shang Di (the Lord on High) who was conceived as a personal god. By the time of the Zhou Dynasty (1100–256 BCE) the Shang belief had been replaced with the notion of Tian (heaven). Tian was viewed as an impersonal sacred force that regulates human affairs and establishes moral order. Rulers were considered to be the Sons of Heaven, bestowed with the Mandate of Heaven. However, if a ruler became corrupt, Tian would remove the mandate and punish the ruler by sending disasters such as floods and wars. Confucius claimed that heaven had given him the mandate to reform the world.

Filial loyalty and respect for elders in Chinese culture is evident in numerous ways. The family has long been the basic unit of Chinese society and, according to Chinese legend, is what separates humans from animals. In fact, the family name (surname) precedes the individual name in China. Elders, far from being considered unproductive or outdated, are venerated for their wisdom. Children are to honor their parents as instructed in the Five Great Relations. Ancestor worship, dating back to at least the Shang Dynasty (c. 1750–1100 BCE), demonstrates that people not only are to be obedient and respectful to the living elders, but also to those who have died. Ancestor worship is particularly important insofar as deceased ancestors continue to exist in the realm of heaven and can even be elevated to the status of deity in the celestial hierarchy. If deceased ancestors are not appropriately honored, the living family may suffer negative consequences.

Finally, Chinese culture historically has emphasized group interdependence over rugged individualism. Rather than being viewed as autonomous, independent agents, the Chinese notion of personhood stresses the interconnectedness of individuals forming social networks. As our actions will influence others who share a single web of social relationships, we must think and behave unselfishly.

Obtaining the Goal: The Five Great Relationships

There are numerous virtues people must acquire in order to achieve social harmony. According to Confucius, humans are inherently good, but require training in virtue. The primary way in which to provide this training is through education that fosters the values of the golden age of the sage kings.

The Confucian emphasis on proper social relationships as a basis of a harmonious society is evident in the Five Great Relationships. Asian cultures have traditionally stressed the role of a person's social ties to others. The only way a perfect society may be achieved is if all people behave appropriately in their interactions with others. The ancients enjoyed social harmony because people knew their social roles and behaved appropriately. To know what is expected of any given individual in a particular social interaction, that person need only consider his or her social role and title. This has been referred to as the Rectification of Names. The required behaviors for each social role are outlined in the Five Great Relationships.

The first relationship, which forms the very foundation of society, is the Father–Son relationship (sometimes referred to as the Parent–Child relationship). The father is responsible for the education and moral values of his children and they, in return, are to be respectful, loyal, and obedient. The father is to have unquestioned authority in making decisions for his children. Eventually the children will take care of the father in his old age. This relationship does not cease upon the father's death. Rather, sons are expected to have their own children who will continue to worship their ancestors long after the death of those ancestors.

The second great relationship is that between Elder Brother–Younger Brother (or, Older Sibling–Younger Sibling). Many Asian languages have distinct words for siblings based on their age-position relative to other siblings. Older siblings are meant to help guide and protect younger siblings, and younger siblings are expected to comply obediently.

The Husband–Wife relationship, like the previous two relationships, is based on one person, here the husband, having authority and responsibility over the other person, in this case the wife. The husband is expected to be the breadwinner and to meet his wife's material needs in addition to serving as her protector. The wife, in turn, is to serve as a devoted housewife, acting in a motherly way, attentive to her husband's needs.

The fourth relationship is that of Senior Friend–Junior Friend. The friend with senior status helps shape the moral character of the junior friend. This may entail the senior friend acting as a mentor or offering advice to the junior friend. The junior friend is expected to be respectful and amenable to the advice of the senior friend. Examples of this relationship may be found between teachers and students, bosses and their employees, or even between coworkers of the same age but who differ in rank.

The final relationship is the Ruler–Subject relationship. Subjects should loyally and obediently follow their rulers, but rulers must place the interests of their subjects above their own. While it may seem that the Ruler–Subject relationship should be the first of the Five Great Relationships, scholars often place it last insofar as Confucius viewed the Father–Son relationship as a model for rulers' behavior. Confucius claimed that social order must originate at home.

Obtaining the Goal: The Five Virtues

When social interactions are guided by the precepts outlined in the Five Great Relationships, harmonious relations result. Similarly, on an individual level, for a person to work toward the goal of becoming junzi, it is necessary to adopt the Five Virtues. The Five Great Relationships and the Five Virtues are clearly interrelated.

Ren is the most fundamental of the Five Virtues. The Chinese character for this word blends the characters for person and for the number 2, stressing the importance of considering others. This word can be translated as "benevolence," "consideration," or "sympathy." It is respecting the interest of others in all that we do. When we truly care about the well-being of others, then social strife and petty competition are eliminated. Confucius explained how rulers, especially, must place the welfare of their subjects above that of themselves. The second virtue, *li,* which is often translated as "propriety," requires that we speak and behave properly in social life. As dictated in the Five Great Relationships, what is considered appropriate will vary according to a person's specific age, gender, social status, and the given social situation. A third virtue is *shu*. Some have translated this as "reciprocity" in that it instructs us to think of the impact of our actions on others. This has often been termed the Silver Rule, which states that we should not force upon other people that which we do not want done to ourselves. *Xiao* refers to family devotion. Not only does this entail that children respect their parents and that parents care for their young, but that everyone also honor the dead ancestors through appropriate sacrificial rituals. Finally, Confucius stressed the value of *wen,* or of cultural arts. Confucius maintained that education was required to instill proper virtues and so must include an appreciation for, and even some ability to participate in, such fine arts as poetry, literature, painting, music, and calligraphy.

Obtaining the Goal: The Confucian Classics

The most fundamental of the Confucian literature extant today consists of The Five Classics, which predate or were contemporaneous with Confucius, and the Four Books, which postdate him but are based largely on his teachings. Confucius did not write the majority of this literature, but is credited with editing and transmitting earlier works and adding his insight in the form of commentary.

For Confucius these texts were an important means of conveying the ancient traditions necessary for the restoration of social harmony that had existed during the time of the ancient sage kings. In fact, the earliest of the texts are thought to be the teachings of the sage kings themselves. The Confucian texts discuss the virtues of the ancient sages, providing examples in the forms of maxims and anecdotes of how we are to achieve virtuous government and citizens. For example, the Doctrine of the Mean contends that people must avoid excess and seek moderation. Whenever people exhibit too much pride or indulgence, for example, social strife and competition result.

The influence of Confucian literature on the worldview of the Chinese cannot be overstated as it served as the core curriculum of the state educational system for more than 600 years and formed the basis for the civil service exams required of all government workers.

Historical Influence of Confucianism on Asian Culture

In addition to considering the time period of the ancient sage kings and the role of social upheaval of the Eastern Zhou Dynasty, it is also necessary to outline the historical time periods following Confucius' death in order to demonstrate the profound effect of Confucianism on Chinese culture—an influence that has persisted for more than 2,000 years.

Even though the rulers of the Eastern Zhou Dynasty (771–256 BCE) failed to recognize the value of Confucius's ideas during his lifetime, the established doctrine of Confucianism was developed later in this dynasty by scholars such as Mencius (c. 371–289 BCE) and Xunzi (c. 298–238 BCE) who desired social reform based on a Confucian model. Rulers of the following dynasty

(Qin Dynasty, 221–206 BCE) forcibly suppressed Confucianism, but this dynasty was short lived. The longer period of the Han Dynasty (206 BCE–220 CE) was favorable for the advancement of Confucian ideals. It was during this dynasty that Confucianism was made official state policy, and elaborate temples were erected in Confucius's honor. Confucian influence was particularly strong by 126 BCE when the state adopted the writings of Confucius and Confucian scholars as the foundation for the state system of education.

The Han Dynasty fell in 220 CE, ushering in a period of political instability known as the Six Dynasties Period (220–589 CE). During this time Buddhism was introduced to China from India and Daoism was growing in importance. Confucianism was now relegated to a more peripheral role in Chinese culture than had been the case during the Han Dynasty. By the time of the Tang Dynasty (619–907 CE), Confucianism regained some of its former importance with a state mandate that every province in China erect a Confucian temple and conduct regular ceremonies and sacrifices.

By the beginning of the Song Dynasty (960–1279 CE), rulers were desperate to restore the social order lost in the turmoil of the preceding five dynasties. This coincided with the rise of neo-Confucianism developed by scholars such as Zhu Xi (1130–1200 CE), who aimed to bring about social order using Confucian models.

By 1313, in the Yuan Dynasty, Confucian literature formed the core curriculum of the civil service examinations that were required of anyone who wanted to enter a government post. During the Ming Dynasty (1368–1644 CE) neo-Confucianism continued to gain strength with the work of scholars such as Wang Yangming (1472–1529 CE). Even in 1644, when the foreign Manchus overtook the capital and ruled during the final imperial dynasty (Qing Dynasty, 1644–1911 CE), Confucianism continued to thrive.

Confucianism in the 20th and 21st Centuries

In 1911, as a result of Sun Yat-sen's revolution, China witnessed the collapse of the last imperial dynasty and the subsequent establishment of the Republic of China. Since that time, Confucianism has not held the state support or central role in education imparted by former dynasties. By 1916 the New Culture Movement had destroyed vestiges of the past deemed traditional and, therefore, as impediments to progress.

The Communist takeover in 1949 and the formation of the People's Republic of China only increased the aversion to Confucianism. During the Cultural Revolution (1966–1976), Mao Zedong (1893–1976) ordered his Red Guards to destroy all of those things considered traditional and backward, such as temples, sacred images, and sacred texts. All outward forms of religious expression, including Confucianism, were forbidden.

After the death of Mao, many ancient traditions began to resurface, and since the 1980s China has eased many of the restrictions against religion. It has been many years since Confucianism has enjoyed the vast state support of the dynastic periods. It nonetheless continues to form a central core of Chinese culture while increasingly spreading in influence to the island of Taiwan, as well as to other Asian countries such as South Korea, Japan, and Singapore.

CONSCIOUSNESS

Ideas and theories of consciousness have changed over time, from the early ideas presented by the ancient Greeks to modern 20th- and 21st-century philosophy. These ideas and theories have been profoundly influenced over the years by philosophy, metaphysics, naturalism, and more recently by psychoanalytic psychology, neuroscience, and quantum mechanics. Presently there is no uniformly accepted definition of consciousness; rather it has become more of an integrated theory consisting of several schools of thought. As science and technology evolve and humankind begins to develop a better understanding of the primate brain and how it works and the apparently subjective reality surrounding it, more is beginning to be understood about consciousness.

Ancient Greeks

The ancient Greeks provided early speculations on the human mind. Plato was one of the first thinkers to attempt to formulate the definition of what would become known as consciousness. Of course at that time there was no word equivalent that had the wide range in meaning that the word *consciousness* has in 20th- and 21st-century thought. Therefore the ancient Greeks speculated on what was known as mind.

Plato was one of the first to develop the idea of the mind. He proposed that the mind is something in the head and that objects existed as impressions in the material world. However, he maintained that these impressions were visible forms that are conveyed through what he called "the mind's eye" by a third nature: light. Plato further elaborated that these visible forms were observed by the mind's eye as mental content arranged as geometrical forms. Plato proposed that these geometrical forms were provided by the soul.

Another ancient Greek philosopher who expanded on the early ideas of consciousness was Aristotle, who was a physicalist, meaning that he believed that all things, including human beings, are intrinsically incorporated in a material universe. This is why he thought that the study of the soul (or psyche and to an extent consciousness) would fall within the confines of the science of nature. Aristotle made note of the concept of signals (sight and sound), the transmission of information (those signals reaching the human mind), and in many ways the notion of perception (the mind's realization of those signals).

Aristotle's idea of the mind, in general, supported Plato's idea that mind was something in the head (the brain), and that an object in the material world existed as an extension of time. However, Aristotle proposed that an impression of these objects was received by the sense organs (eyes and ears), and that the impressions received were relayed in a changed state to the mind and were extended throughout time and space.

Early Theories of Consciousness

René Descartes (1596–1650) was another influential thinker on the topic of consciousness. He was also responsible for coining the very famous Latin phrase *cogito ergo sum,* which in English means, "I think, therefore I am." While Plato and Aristotle maintained that faculties of the mind and soul could not be outlined or represented by mere terms of physiology, Descartes expanded their ideas into what is know as dualism (or Cartesian dualism). Descartes proposed that the physical world occurs in an extended form in the brain (which is material), but through a particular process it is then condensed into a nonextended form in the mind where thought occurs (which is nonmaterial). He also believed (much like Plato) that thoughts were produced by the soul, which is also nonmaterial. Therefore, according to Descartes' theory of dualism, the actual process of consciousness involves a material and a nonmaterial component.

In theory, Descartes' philosophical idea of consciousness was similar to that of Plato's idea of mind. In addition, the concept of consciousness being partly a product of an immaterial soul was maintained and undoubtedly a by-product of popular Christian thinking at that time. Also due to the indoctrinating influence of Christianity, which upheld that only our species has a soul, Cartesian dualism would imply that consciousness is exclusive to humans. The idea that only humans possess consciousness is also known as the *anthropistic theory.*

The Neurological and Evolutionary Perspectives of Consciousness

The *neurological* theory or *Darwinian* theory insists that consciousness is a direct result of the centralization of the nervous system, which was brought forth by progressive evolution. This theory implies that only humans and higher mammals with this anatomic tendency can possess consciousness. In addition, because the centralization of the nervous system has evolved over time, consciousness itself would implicitly have had to evolve over time. This would mean that the type of consciousness that *Homo sapiens sapiens* experiences now would have to be different to some degree compared to the consciousness that was experienced by our early hominid ancestors.

The idea that our current form of consciousness is not immutable, that it has changed over time and may be subject to change in the future, would seem to refute the dogmatic notion that consciousness is exclusive to our species, and that in fact animals (this is known as the "animal theory") or at the least higher mammals (such as chimpanzees) may experience different forms of consciousness similar to our own.

It is worth noticing that toward the end of the 19th century the influence of naturalism, due primarily to the writings of Charles Darwin, was influencing philosophical opinions about consciousness and causing them to change. The theme of consciousness was beginning to be viewed as a natural and biological process rather than a spiritual phenomenon. This would later motivate neuroscientists to explore and propose neurological bases of consciousness.

Psychoanalytical Ideas of Consciousness

Sigmund Freud (1856–1939), the founder of psychoanalysis, was influenced by Charles Darwin's concept that our species is part of the animal kingdom (not separate from it as previously believed) and his mentor Ernst Brucke's concept of "dynamic physiology," which applied the laws of thermodynamics (in particular the law of conservation) to living systems, in particular humans. These concepts compelled Freud to form his psychoanalytical theory, which he applied to the understanding of human consciousness.

Freud proposed that in human consciousness there is a conflict in place between pleasure-seeking behavior (known as the pleasure principle) and the rules or laws of the environment and society (known as the reality principle). He illustrated that this conflict is internalized by three properties. First is the *Id,* which operates in co-ordinance with the pleasure principle (known as the primary process). Second is the *Ego,* which attempts to enforce the reality principle (known as the secondary process); Freud considers the ego to be a human's consciousness. Third is the *Superego,* which according to Freud represents society and cultural restraints.

Freud's psychoanalytic contribution to the study of consciousness is that it allowed investigators to investigate further the consciousness of humans scientifically and opened up the doors to explore it psychologically. Freud's approach was novel because it superseded the conflict of the material versus nonmaterial basis of consciousness. His approach also focused on the individual experience and how it is internalized, interpreted, and expressed psychologically by the mind.

Freud also paved the way for consciousness to be viewed later in terms of introspectionism and individual psychotherapy. *Introspectionism* is a school of thought that maintains that consciousness is best understood in first-person accounts. Therefore it upholds that the conscious experience can be explained only in terms of data acquired from introspection. *Individual psychotherapy* is a school of thought that maintains that consciousness is a result of an organism's (or person's) adaptive capacity. Psychotherapy typically involves scheduled discussions between a patient and a mental health professional.

The psychoanalytical approach to explaining consciousness was different from previous philosophical approaches to consciousness in that it did not merely propose ideas, but rather attempted to make definitions based on psychological observations. It is important to note that during the early 20th century, consciousness was beginning to develop several different subdefinitions and new schools of thought. These opinions involved solely an individual's account of the conscious experience in order to define what consciousness was.

Twentieth-Century Philosophies of Consciousness

During the 20th century, metaphysics began to play a more critical role in engaging the problems of understanding consciousness. Implicitly, metaphysical thinkers were beginning to question the underlying theoretical principles of the already established theories of consciousness.

An important figure in the early 20th century was Alfred North Whitehead, who was a mathematician and a philosopher. He pointed out that there were limitations to our understanding of consciousness because the descriptions of our conscious experience were based in 19th-century ideas of space and time. According to Whitehead, 19th-century materialist views of time and space were not grounded in observation and scientific reality. He also believed that mind and nature are part of the same process, and in order to understand them scientifically one must understand relations within nature and the simultaneity of events.

Another important 20th-century thinker was Gilbert Ryle, a professor of metaphysical philosophy. He was most notable for his deliberately abusive declaration that the "official doctrine," which hails from Descartes, is absurd. The Cartesian doctrine was that human bodies are in space and are therefore subject to the mechanical laws that govern all bodies in space, yet human minds are not in space and are therefore not subject to those same mechanical laws. Ryle proposes that the human body is a complex unit and therefore the human mind is another complex unit; however, the mind is a complex unit composed of a different form (or forms) of material than the human body.

During Ryle's time psychological schools of thought known as "cognitism" were addressing the issue of consciousness. Cognitivists maintained that in understanding the mind, one must understand the "internal" rule-bound manipulation of symbols. Ryle opposed this school of thought vehemently with his famous "Ryle's Regress," which is essentially an argument discrediting the cognitivist theories of consciousness, claiming that they do not explain what they propose to explain.

More recently Daniel C. Dennett, a former student of Gilbert Ryle, has become well known for his multiple drafts model of consciousness, which is the theory that consciousness is based upon the premise that the brain acts as an information processor. According to Dennett, there exist a variety of sensory inputs from a given event; therefore there are a variety of possible interpretations of these inputs that arrive in the brain. Once these sensory inputs arrive in the brain they are interpreted at different times, which gives rise to a succession of discriminations. These discriminations then become available for eliciting behavior to that event.

It can be clearly seen that views of consciousness have changed over time, especially in the 20th century. Theories of consciousness have obviously become more complex, as seen in Dennett's multiple drafts model compared with the generalizations constituting the ancient Greeks' idea of the mind. This is mostly due to advances in understanding biology and humankind's place in nature (naturalism); the maturation of metaphysics; and the ensuing rigorous reevaluation of previous philosophical thought. Another common theme in 20th-century philosophy regarding consciousness is the rejection of previous dogmas, as illustrated by thinkers such as Whitehead and Ryle.

Twenty-First Century Explanations of Consciousness

As has been illustrated, the ancient ideas and early philosophies of consciousness have not only changed over time, but in some cases, as shown, were discredited and replaced in the 20th century. New thoughts in the 21st century may do the same to the views established in the 20th century.

Sir Roger Penrose originally proposed (actually in the late 20th century) the theory of the quantum mind, which asserts that consciousness is a quantum mechanical phenomenon. Quantum mechanics are scientific laws that are not seen on the macroscopic level; rather they become apparent at the atomic and subatomic levels. According to quantum mind theory, classical physics is inadequate to fully explain consciousness; the quantum model, which is associated with a number of intractable paradoxes, must be invoked. A major difficulty surrounding quantum mind theory is that many of its hypotheses require investigation for which no adequate technology capable of providing scientific proof yet exists. For now it remains only a theoretical explanation.

The Future of Consciousness

Eventually theories and models of consciousness will reach a limit in their attempt to explain consciousness. In the future, a more comprehensive study of neurophysiology, neurochemistry, and quantum mechanics (to rule in or rule out its validity) should begin to stabilize scientific thinking on what consciousness actually is as a process, and how it is able to occur in the brain or elsewhere. In addition, advances in technology may give rise to penetrating insights that in turn could give credibility to the idea that human consciousness perhaps is composed of different type(s) of matter, which is why we currently are having difficulty understanding it entirely.

As we continue to struggle to understand our own consciousness, an intriguing concept has emerged: that perhaps different forms of consciousness may exist among animals, cells, molecules (in particular DNA), and even atoms. These different forms of consciousness would be unobservable to humans, who do not completely understand their own consciousness. There is also the possibility that with the advent of artificial intelligence, forms of artificial consciousness or silicon-based consciousness may be created. No less intriguing is the question of what types of exobiological (alien) life forms may exist elsewhere in the universe and what types of conscious experience they may possess.

Copernicus, Nicolaus (1473–1543)

Nicolaus Copernicus (in Polish, Mikotaj Kopernik) was a Polish mathematician and astronomer, best known for his heliocentric theory of the solar system. The heliocentric theory, also known as the Copernican system, holds that the sun is at the center of the universe, and that the earth rotates on an axis and revolves around the sun. Copernicus published his theory in *De Revolutionibus Orbium Coelestium,* often considered to be the starting point of the scientific revolution.

In Copernicus's lifetime, the Ptolemaic theory of the solar system was accepted as accurate. Ptolemy had reasoned that the earth was motionless and was situated at the center of the universe. Copernicus challenged Ptolemy's theory by formulating his own system, the heliocentric, or "sun-centered," theory. The heliocentric theory transferred to the sun functions previously given to the earth. The major principles of Copernicus's theory are that the earth revolves around the sun yearly while rotating daily on its own axis. The movement of the earth is not apparent because we travel with it. Copernicus based his system on careful mathematical calculations, as well as by drawing on the ideas of ancient Greek and Arabic astronomers. His major work, *De Revolutionibus Orbium Coelestium,* or *Concerning the Revolutions of the Celestial Spheres* (1543), changed the existing notions of time and the universe. Copernicus did not publish his major work until the year of his death because he feared opposition from the religious establishment.

Background and Education

Nicolaus Copernicus was born into a successful family of merchants in Torun, Poland, on February 19, 1473. Debate over his nationality arises from the fact that West Prussia, including Torun, was ceded to the Kingdom of Poland following a conflict with the Teutonic Knights that ended in 1466. Though Copernicus was from a German family, he was born a Polish subject. He was taken into the care of his uncle, Bishop Lucas Watzenrode, after the early deaths of his parents. In 1491, Copernicus enrolled at the Jagiellonian University of Krakow where he studied astronomy and the liberal arts. Through the influence of his uncle, Copernicus was appointed a church canon in Frombork, Poland. This administrative position guaranteed his financial security as he pursued his work in astronomy. Copernicus obtained a leave of absence in 1496 in order to continue his studies. He spent several years in Italy studying law and medicine at the universities of Bologna and Padua, and received a doctorate in canon law at Ferrara in 1503. Copernicus returned to Poland in 1503 and assisted his uncle in the administration of the diocese, and in the defenses against the invading Teutonic Knights. Sometime around 1510 he wrote an essay known as the *Commentariolus,* in which he first articulated the principles of his heliocentric theory.

Copernicus was a skilled administrator, physician, scholar, diplomat, and mathematician in addition to his work in astronomy. He was invited to take part in the Fifth Lateran Council's commission on calendar reform in 1515. In 1517 he published his theory on monetary reform. During this time he also observed the heavenly bodies and began his major work, *De Revolutionibus,* publication of which was delayed by the author for many years due to its implications. Copernicus has been compared to Charles Darwin in this regard. In 1539, Copernicus began to study with a young mathematician named Georg Joachim Rheticus. Rheticus published a short introduction to the Copernican system, *Narratio Primo,* and then finally convinced Copernicus to publish his theory in detail. It is said that Copernicus held a copy of *De Revolutionibus* in his deathbed on May 24, 1543.

The Copernican Revolution

Copernicus's theory is often seen as a decisive moment in time. In replacing the earth with the sun as the center of the universe, he revolutionized humankind's understanding of science and religion. The heliocentric theory was a fundamental part of the transition of Western thought from the medieval to the modern period, as it transformed humankind's position in the universe and relationship to God. Like Darwin's theory centuries later, the Copernican system ignited controversies in religion, philosophy, and the social sciences. Its implications extend far beyond astronomy. Critics of Copernicus argued that his theory diminished humanity's place in the universal order and removed humankind as the center of God's creation. Copernicus anticipated a negative reaction to his work because of its disagreements with the Bible. He included a dedication to Pope Paul III (1534–1549), most likely as an attempt to circumvent criticism. Management of the printing of *De Revolutionibus* was given to a Lutheran minister named Andrew Osiander. Osiander added his own anonymous preface in which he claimed that Copernicus was merely suggesting a hypothesis rather than a factual description of the heavenly bodies. *De Revolutionibus* circulated widely throughout Europe, and a second edition was released in 1566. Though Copernicus can be seen as the heir of Ptolemy, the elapse of nearly 2 millennia makes his contribution all the more significant. Copernicus's work, therefore, has been deemed a revolution.

Influence

During the 16th century, most people still found it difficult to believe that the earth was in motion. Even other astronomers could not accept Copernicus's theory in whole. In 1588, the Danish astronomer Tycho Brahe developed a compromise position in which the earth remained motionless. Others, such as Johannes Kepler and Galileo, accepted the basis of the heliocentric theory and supported parts of it with their own work. Galileo was forced by church authorities to renounce the Copernican system. The English scientist Sir Isaac Newton used the Copernican system as the basis for his laws of gravity. Newton sought to confirm the Copernican system with his own complex calculations on the motion of objects. In time, many people came to accept as accurate the heliocentric model of the universe proposed by Copernicus.

Cosmogony

Cosmogony is the scientific discipline that explores the formation of the universe and the celestial bodies. There is agreement within cosmology that the universe came into being about 13–14 billion years ago with the so-called big bang. The nature of this event is beyond any physical interpretation due to the presumably immense temperatures close to the big bang, canceling any contemporary physical theory.

In the course of a symmetry break immediately after the big bang (BB) a very short-time explosive cosmic expansion occurred. One assumes this epoch of *inflation* to last for about 10^{-35} to 10^{-33} seconds after the BB. During this short phase the universe was undergoing expansion by a factor of 10^{30} to 10^{50}; the amount posited depends on the mathematical description.

Inflation is of fundamental meaning for the formation of cosmological structure. Prior to inflation, the universe as a whole was subject to the laws of quantum mechanics. In particular these say that some uncertainty underlies the position and momentum of a particle; this must not be understood as a limitation of our perception and information, but rather as a natural, inherent property of matter and energy. As a consequence, the quantum fields during pre-inflation *cannot* be distributed over space in a perfectly homogenous manner. The very early universe is, rather, infused with *quantum fluctuations*. While the universe expands exponentially during inflation, these quantum fluctuations are as well "inflated" to macroscopic size. The density variations arising in this way constitute the sprouts for any formations of large cosmological structures.

After the end of inflation the "normal" cosmic expansion begins, described by the general theory of relativity. For the first 10,000 years in the life of the universe, radiation energy density dominates over matter. This prevents any early increase in perturbations in the density of matter. The situation changes when matter gets the upper hand in the cosmic energy budget after some 10,000 years; the universe changes from being radiation dominated to being matter dominated. The reason is that radiation loses its energy more rapidly than matter due to the additional effect of redshift in an expanding space. From this moment of *matter–radiation–equality* on, matter density fluctuations are able to self-gravitationally amplify.

This effect of self-amplification concerns only so-called dark matter at first. This is some form of matter, the nature of which remains unknown at the time of this writing, that interacts only via the gravitational (and maybe the weak) force—this is also the reason for dark matter being hard to detect. Numerous observations show, however, that dark matter provides more than 80% of the substantial content of the universe. Only 15%–20% consists of "normal," so-called *baryonic* matter that makes up all interstellar gas and dust, the stars and planets and ourselves. Whereas dark matter can now obey the process of self-gravitation to develop local density peaks unhindered, baryonic matter is still prevented from doing so by the influence of the ubiquitous high-energy background radiation; the temperature in the universe is still high enough to keep all baryonic matter in the state of a *plasma,* a hot gaseous mixture of negatively charged electrons and positive atomic nuclei. The high-energy background photons thus permanently interplay with the charge carriers. Any attempt of the baryons to accumulate within some region would be scotched by the effect of radiation pressure.

Approximately 380,000 years after the BB, the global temperature falls enough to allow for stable combinations of electrons and atomic nuclei: Neutral atoms can form. Because electromagnetic radiation is not coupling to neutral particles, the large-scale streaming of baryonic matter is no longer influenced by the background radiation. The baryons are now able to stream freely into regions of high-density dark matter established soon after the BB. In the course of time these initially moderate high-density regions gain mass via matter accretion until they start to decouple from the general flow of cosmic expansion due to their self-gravity and finally constitute independent, isolated objects, so-called *dark matter halos*. Baryonic matter also becomes denser and denser within the dark halos until, again, its self-gravity is powerful enough to overwhelm its intrinsic thermal pressure and thus causes the gas cloud to collapse. This, just like the dark matter decoupling from the cosmic flow, as mentioned above, is called a *nonlinear* phase of structure growth. During the collapse, shock waves arise and heat the gas to millions of degrees Kelvin. Unlike dark matter, gas can cool via several atomic processes. Thus it can further contract around the dark halo center until it becomes a rotation-stabilized flat disk. Local condensations occur within this gas disk, forming molecular clouds in which stars can finally emerge.

It is known from observations as well as numerical simulations that there are fragmentation processes occurring inside molecular clouds, producing even higher-density peaks of small local extension. These *globules* are the cradles of the stars. Stars form in groups rather than singly. The progressively rising power of self-gravitation leads to a further compression of the globules, while the temperature increases due to the growing pressure. The collapse ends as soon as the thermal pressure becomes as strong as the gravitational force. When the inner temperature reaches some 15 million degrees Kelvin, the fusion of hydrogen can start to produce helium nuclei. This will provide for the energy production of the star over the largest part of its lifetime. Prestellar objects with less than 8% of the solar mass ($M_{®} = 1.99 \times 10^{30}$ kg) are not able to generate temperatures high enough to enable the hydrogen fusion process. These objects, much smaller than normal stars, are called *brown dwarfs*. On the other hand, stellar objects with more than 60 $M_{®}$ presumably cannot form because of strong winds being generated before the onset of the nuclear burning and blowing away a considerable fraction of the prestellar material.

During the star formation process, angular momentum conservation causes a gas disk, within which planets can form, to form around the prestellar object. Different from stars, planets form in a growth process, starting from microscopically small dust particles that stick together after encountering each other and thus form continuously growing clumps. The *planetesimals* that build up in this way collect material by gravitation along their orbit and thus accelerate their further growth. In this manner, planets half the size of the earth can form within only some 100,000 years. Such objects, thousands of kilometers in size, can successively build up huge planets with up to 10 Earth masses. Giants like these are additionally able to accrete gas from the surrounding disk, which can finally lead to gas giants like Jupiter and Saturn.

Cosmological Arguments

Cosmological arguments try to establish the existence of an uncreated creator of the cosmos. They argue for the conclusion expressed in the first verse of the Judeo-Christian Bible: "In the beginning God created the heaven and the earth." Although most cogently formulated by philosophers such as Saint Thomas Aquinas (1225–1274), al Ghazali (1058–1111), and Gottfried Leibniz (1646–1716), cosmological arguments have a powerful appeal also to those nonphilosophers who feel that the "ultimate" explanation for the existence of the *natural* universe is that it was created by some sort of *supernatural* entity: God.

Such arguments belong to religion, not science; to metaphysics, not physics. Along with various versions of the ontological argument and the teleological argument (argument from design), they constitute one of the standard "proofs" of the existence of God.

Yet a broad consensus of philosophers, including many who agree with the conclusion, hold that none of these arguments, however persuasive they may seem, really establishes the desired conclusion. This is why Immanuel Kant (1724–1804) concluded that the existence of God is not for reason to demonstrate but for faith to proclaim.

The *Kalam* Cosmological Argument

Of the countless versions of the cosmological argument devised by metaphysicians and theologians in the Greek, Roman, Judaic, Christian, and Islamic traditions, that devised by Arab scholars during the Islamic Golden Age (750–1258) is particularly noteworthy for its intuitive appeal, the sophisticated way in which it can engage the intellect of scientists and mathematicians as well as philosophers, and for its overall persuasive power. As reconstructed by the contemporary Christian philosopher–apologist William L. Craig, it is designated as "the *kalam* cosmological argument" (*kalam* means "talk" in Arabic, alluding to the seeking of religious principles through dialectic). Many of the lessons learned by examining its credentials can be applied to the evaluation of other versions.

Craig's Formulation of the Kalam Argument

Craig presents the first stage of his version as a simple syllogism:

Premise 1: Whatever begins to exist has a cause.

Premise 2: The universe began to exist.

Conclusion: Therefore the universe has a cause.

This first stage of the argument is valid. But are its premises true? And a second question: How does God get into the act, as it were? How does one get from the conclusion that there is a first cause to the further conclusion that this is God?

Aquinas thought it sufficed to say: "this all men call God." Craig, however, supplies a second stage of argument, claiming that the most plausible account of the first cause is that it is a personal God who, while creating space and time, is (or was) himself not in either.

Premise 1: *"Whatever begins to exist has a cause."* As with all other versions of the cosmological argument, the kalam has at least one empirical claim among its premises—a claim, that is, for whose truth we have to rely on our experience of the world around us. So the question arises whether, *in our experience,* everything that has a beginning does in fact have a cause.

To most people Premise 1 seems so obviously true as not to need defending. Objects don't just "pop into existence." Likewise with events (changes in things or states of affairs). They begin and end in a temporal series of causes and effects. Things, we say, don't "just happen." Rather, every event is caused by, and hence determined by, some event or events that precede it in time.

Yet this commonsense belief is not beyond dispute.

First, the standard interpretation of quantum physics maintains that the commonsense belief in universal causality must be abandoned. The occurrence of events at the microphysical level is unpredictable, uncaused, and indeterministic in character. Or so many claim. Yet if this interpretation of quantum phenomena is sound, then Premise 1 is just plain false, notwithstanding its endorsement by ordinary experience.

Second, the truth of Premise 1 is inconsistent with the account of free will that is embraced by many theists, Craig included. The problem is that, if it were true, and the chain of causes did indeed go back to God as the ultimate cause and creator of the universe, then God would thereby be made the ultimate cause of all the evils that universe contains. We would have to take him at his word when he claims, "I make peace, and create evil: I the LORD do all these things" (Is 45:7).

One way of avoiding this unpalatable conclusion is to say that genuine free will involves a break in the causal chain, that our free acts are uncaused by anything other than ourselves, and hence that it is we (and perhaps other free agents like Satan and his cohorts) who bring about all the evils in God's universe. But on this so-called contra-causal account of free will, Premise 1 is false. It makes our free choices *uncaused* causes of our free acts. Hence the theists' dilemma: Either accept Premise 1 and make God causally responsible for evil, or reject Premise 1 and abandon the cosmological argument for God's existence.

Premise 2: *"The universe began to exist."* Craig has two subsidiary arguments for the truth of the second premise. One involves an appeal to *empirical* evidence from current scientific cosmology. The other involves an a priori argument (an argument that requires no appeal whatever to experience) from the supposed impossibility of an actually infinite number of things or events.

Subsidiary Argument From Scientific Cosmology

Three main cosmologies have engaged the attention of physicists over the past half century or so: the steady state model; the oscillating model; and the big bang model. The first two hold that the universe never had a beginning but always existed, either in the same steady state or in successive states of recurrent expansion and contraction. Only the third postulates a temporal beginning of the universe.

Which of these models is correct? An overwhelming scientific consensus supports the big bang model according to which both the physical universe and time itself began about 12–14 billion years ago. Yet if empirical evidence tells us anything it is that, in the fullness of time, this model may give way to one of the others or to some other model yet to be conceived or empirically confirmed. Craig claims that models allowing for a beginningless universe are "physically impossible." But this is too strong. It presupposes that the big bang theory has been established beyond all possibility of revision and that any further tests of its truth would be fruitless. Yet such tests proceed.

But suppose that the big bang model is in fact true (not just currently accepted as true). Since it asserts that time and space began with the expansion of a so-called singularity, its truth would indeed lend support to Premise 2. But at the same time, its truth would undermine Premise 1. For if time itself began with the big bang, then no temporally preceding event can have caused it to begin. In short, current physical cosmology can be invoked to support Premise 2 only at the expense of having it controvert Premise 1.

Either the spatiotemporal universe had a beginning or it didn't. If it did begin—as the big bang model postulates—then, so far as science can tell us, Premise 2 is true but Premise 1 is false. On the other hand, if it didn't have a beginning—the scenario painted by both the steady state and oscillating models—then, so far as science can tell us, Premise 1 is true and Premise 2 false. On either scientific account, the kalam argument is unsound.

Subsidiary Argument From the Impossibility of an Actual Infinite

A common feature of all versions of the cosmological argument is the claim that the regress of causes postulated in Premise 1 "cannot go on forever." What distinguishes the kalam version from these others is that it offers an a priori argument for the impossibility of the regress of causes being infinite.

Craig presents this subsidiary argument thus:

> An actually infinite number of things cannot exist.
>
> A beginningless series of events in time entails an actually infinite number of things.
>
> Therefore, a beginningless series of events in time cannot exist.

Clearly this argument is valid. Equally clearly, the conclusion, if true, would rule out the kind of endless chain of events envisaged in both the steady state and oscillating models of the physical universe. It would provide a priori endorsement for the sort of beginning of spacetime that is postulated in the big bang theory.

But what, we need to know, is meant by an "actual infinite"? And what is impossible about the notion that an actually infinite number of things should exist?

A collection of things (objects, events, or moments of time) is said to comprise an actual infinite if it satisfies the conditions for being an infinite set as defined by the mathematician Georg Cantor (1845–1918), namely, that the members of that set can be put into a 1-to-1 correspondence with the members of one of its proper subsets. Consider the claim, "For every natural number there exists a successor that is itself a natural number." Clearly this claim entails the existence of an infinite set of natural numbers. This set satisfies Cantor's conditions for being an infinite set since the proper subset comprising just the odd numbers can be thought of as standing in 1-to-1 correspondence with all the natural numbers, even as well as odd.

The idea of a set all of whose members are equinumerous with one of its proper subsets is certainly counterintuitive. But this, it has been argued, arises from the fact that most of our thinking about sets focuses on the properties of *finite* sets, not infinite ones. So we have no good reason to suppose the latter to have the same properties as the former. In any case, despite its "paradoxical" consequences, Cantor's theory of transfinite numbers is logically self-consistent and cannot be shown to be logically impossible.

Now just as the statement, "For every natural number there is a successor that is a natural number" generates an infinite set of natural numbers, so the statement, "For every event that begins to exist there is a preceding event that is its cause" generates an infinite series of events. Likewise with the claim, "For every moment of time that begins to exist there is a moment of time that precedes it." Yet both these latter claims are entailed by Premise 1 of Craig's kalam argument. Hence if there is nothing logically impossible about the existence of an infinite set of natural numbers, there would seem to be nothing logically impossible about the existence of an infinite series of events or an infinite series of moments of time.

Craig is prepared to allow the logical possibility of infinite sets in mathematics, despite their paradoxical consequences. So on one interpretation of "things," namely, that in which the things concerned are abstract entities like numbers, he is prepared to allow (contrary to the first premise of his subsidiary argument) that an actual infinity of things can exist after all. What he cannot accept is that interpretation of "things" in which the things concerned are constituents of the spatiotemporal universe, such as physical objects, events, or moments of time. But infinite sets of the latter sorts of entity are no more paradoxical than are infinite sets of abstract entities.

The upshot of his second subsidiary argument then is this. If the paradoxical nature of infinite sets did indeed demonstrate that an actually infinite number of events in time cannot exist, then Premise 1 is false since it entails just such an actually infinite set. But if, on the other hand, the paradoxical nature of infinite sets does *not* demonstrate the impossibility of an actually infinite number of events in time, then it provides no grounds for holding Premise 2 to be true.

Interim Conclusion: "Therefore the universe has a cause."

Set aside the previously noted objections to Premise 1: that its truth is threatened by both quantum theory and the contra-causal account of free will, and that the infinite series of beginnings it entails is rendered impossible by the argument against actual infinites. There are still more problems.

Consider, once more, the experiential warrant that is claimed on behalf of Premise 1. It is that within our ordinary experience of things that happen *within the spatiotemporal universe,* the beginnings of all events are brought about, or caused, by preceding events that themselves had beginnings. That is the scope and limit of our empirical grounds for holding Premise 1 true. There is, therefore, no experiential warrant whatever for our extending its scope to the case of the beginning of the universe itself. It is not as if we have experienced cases of many universes beginning and have found from our experience of these universe-beginnings that all of them are caused.

If we were to be more guarded in generalizing about how things happen (at least at the macrophysical level) in the spatiotemporal universe we experience, we would formulate Premise 1 so as to read, "Whatever begins to exist *within the spatiotemporal universe* has a cause." It would then become clear that we have no warrant whatever for extending the limited universality of this more defensible premise to the beginning of the spatiotemporal universe itself. As Bertrand Russell (1872–1970) pointed out, to suppose that we do have such a warrant would be like supposing that from the statement that every human has a mother we can infer that humanity has a mother.

Final Conclusion: "The cause of the universe is God."

Set aside all previously noted objections and, for the sake of argument, suppose that the spatiotemporal universe did have a cause. What then entitles us to conclude that this cause is anything like the personal God of theism?

Many questions call for answers. Why should not the cause of our universe be, or have been, some entity in another physical universe, a being or group of beings, perhaps, endowed with God-like magical power to conjure other universes out of nothing? What sense does it make to invoke the existence of a supernatural being with the powers of a Grand Wizard who, by some incomprehensible means, conjures the natural world into existence? Why suppose there is just one such being? Why suppose that such a being, if there were one, is a person with personal attributes akin to our own? And wouldn't both the existence and the acts of any such being call for explanation in terms of what caused it to exist or to act?

Craig addresses only the last two questions. The creator, he argues, cannot be *in* time for then there would be an infinite series of events in his life; and that, according to his argument against actual infinities, is impossible. Hence, he concludes, God must be conceived as a changeless being in whom, prior to creation, no events whatever—not even sequences of thoughts—occurred. He is to be conceived as having been, so to speak, an ultra-catatonic being—a being who suddenly, but inexplicably, springs into action, creates a temporal universe, and only then begins his own temporal career.

But then still other questions arise. What *caused* this beginning of the series of events in God's temporal career since time began? Premise 1 demands that there be such a cause. Yet if there was one, it must in turn have had a cause, and that another, and so on ad infinitum. Any puzzles there might be about the beginning of the universe seem to be paralleled by puzzles about the beginning of God's involvement with that universe.

There seems no way of escaping the dilemma: Either something can exist without having been caused to exist by something else (in which case there is no reason why the natural world should not be that thing), or there must be a cause for God's existence, and for the being that caused him, and so on ad infinitum.

Is the timeless God postulated by Craig's kalam argument the kind of God in whom most theists believe—one who has existed "from everlasting to everlasting" (Ps 106.48)? That, as Kant would insist, is a question for the psychology of faith. But one thing is certain. As a logical proof of the existence of such a God, the kalam argument—arguably the best yet ventured—is a failure.

Cosmology, Cyclic

Cyclic cosmology refers to the concept that the cosmos undergoes continuous cycles of evolution. Time itself has generally been defined by the beliefs regarding the specific nature of the cycles.

Cycles of destruction and renewal have been a recurrent theme in mythologies and religions, inspired by such natural changes as day and night, the seasons, and birth and death. In the ancient world, the concepts of linear and cyclical time were already being debated, but nearly every culture recognized the existence of cycles and had its own beliefs about when they would occur. The concept of time was generally defined by the cycles of nature. For example, the duration of cycles in Hindu cosmology were related to periods of the life of Brahma, the god of creation.

The Greek philosopher Heraclitus was the first known person to address the inevitability of change and the need to understand its nature. Western thought generally favored cyclical cosmology up until the time that Christian interpretations of the Book of Genesis became influential, though examples of cyclical theories continued to appear. In the 18th century, James Hutton, considered the founder of modern geology, referred to the recurrent destruction and renewal of the "great geological cycle." In the late 19th century, German philosopher Friedrich Nietzsche developed the theory that, given the limitless nature of time, events must inevitably recur. Various cyclic models that failed to withstand the test of time were proposed in the 1920s and 1930s by cosmologist Richard C. Tolman and others.

Most recently, cosmologists Paul J. Steinhardt and Neil Turok have introduced the cyclic model of the universe as an alternative to the big bang theory, which they have described as having been generally dominant during the past 40 years.

The original big bang theory involves a singularity that occurred about 14 billion years ago, creating the universe from an infinitesimally tiny area of space with a density and temperature that were nearly infinite. Since then, the universe has continued expanding and cooling. A more recent version of the theory includes the concept of inflation, or the brief, accelerated expansion that occurred immediately after the big bang.

Steinhardt and Turok's cyclic model had its beginnings in the model of the ekpyrotic universe, which the two had developed earlier with other cosmologists. The word *ekpyrosis* is a Greek word for conflagration, referring to an ancient cosmological model wherein the universe was created in a burst of fire.

The cyclic model also includes a big bang, as well as a "big crunch" at the end of a cycle. But since the model indicates that the universe has no beginning or end, it should now be viewed as a bridge to a past of endlessly repeating cycles. When a big bang occurs, it creates heat and radiation at a finite temperature and then cools to form galaxies and stars. The bang represents a transition from a contracting phase to an expanding phase where matter spreads out to become a nearly perfect vacuum. The interval between big bangs is believed to be about a trillion years, far longer than the 14 billion years predicted by the inflationary model.

Steinhardt and Turok describe the concept of an endless universe as still in its infancy, but they believe the model might be able to explain some points not included in the big bang theory. Those points involve extra dimensions, branes, and dark energy.

The *string theory* in physics refers to particles as waves on strings and was conceived as a way to reconcile quantum mechanics with general relativity. *M-theory,* which unites all five existing string theories, allows for the existence of additional dimensions. The three dimensions that expanded and contracted in the older theory now should be seen as expanding and stretching from one big bang to the next. As the stretching rate slows, an additional dimension is squeezed to nearly zero size before it begins expanding again.

Branes (short for mathematical membrane) in string theory consist of surfaces of varying dimensions that can move through space. In the cyclic model, our universe is referred to as a *braneworld.* It is separated by only a small gap from, and collides at regular intervals with, a second braneworld that we cannot observe. Matter and radiation are confined to branes, which can always be stretched. The space between the two eventually shrinks to zero when the big crunch occurs, but energy doesn't become concentrated as described in the original big bang theory.

Though no specific role for dark energy had been established in the inflationary model, it plays three essential roles in the cyclic model. First, it speeds up the rate of expansion of the universe, allowing its components to spread out. Branes eventually stretch to a near-vacuum condition, resulting in an equal distribution of energy and smoothing out wrinkles so that each cycle begins with the same basic physical conditions. Second, dark energy serves as a stabilizing force by regulating the speed of branes and acting as a shock absorber to ensure that brane collisions don't become completely random. Finally, dark energy has the ability to shut itself off. As the energy draws branes together, it gradually changes from positive to negative. This allows the branes to speed up and for the additional dimension to contract so that the next cycle can take place.

Steinhardt and Turok point out that the before and after of the cycles can be described in a way that follows the laws of physics and is justified by current astronomical observations.

The cyclic model has been described as more optimistic than earlier models. The universe remains essentially the same. Every part evolves through a series of regular cycles, starting with a bang and ending with a crunch. The existence of dark energy is important in helping to keep the cycles on track.

Steinhardt and Turok emphasize that the cyclic model is still only a theory that should be discussed and tested by the scientific community along with alternatives. They express optimism that recent advances in astronomical observation, along with laboratory experiments, will lead to the identification of the best model to explain our universe within the next two decades.

Cosmology, Inflationary

The inflationary scenario constitutes an extension of the cosmological standard big bang model. According to the inflationary model the universe undergoes a phase of extremely rapid expansion starting around 10^{-35} second and ending 10^{-33} second after the big bang. Within this short time interval, the universe is believed to have expanded by a factor of about 10^{30}–10^{50}. Although not confirmable, the inflationary theory is considered as integral to the basic cosmological theories.

The epoch of inflation was presumably initiated by a phase transition (comparable with the transition from water to ice below the freezing point), causing the strong interaction to separate from the *grand unified force*. The basic ideas of an inflationary phase were proposed in 1979 by the Russian physicist Alexei Starobinsky and developed to a first consistent theory 2 years later by the American physicist and cosmologist Alan Guth. In 1982, inflation was brought to its modern shape independently by Andrei Linde, Andreas Albrecht, and Paul Steinhardt. The occasion to postulate an inflationary event in the very early universe was a number of unsolvable problems associated with the standard picture.

The Flatness Problem

Numerous observational hints independently suggest that the density parameter of the universe is $\Omega = 1$ with tight tolerance. That is to say, the mean density of the universe is close to a value known as *critical density,* which separates a universe of eternal expansion ($\Omega < 1$) from one that is to turn its expansion to a collapse in a remote future ($\Omega > 1$) due to the gravitational deceleration effect of its high mass content. In terms of Einstein's general theory of relativity, the cosmological classification according to the mean density is identical to 1, according to the intrinsic geometry of space: While a density parameter $\Omega > 1$ comes along with a "closed" geometry (the three-dimensional equivalent of a spherical surface), the under-critical "open" $\Omega < 1$ universe is affected by the intrinsic geometry of a saddle. The limiting special case $\Omega = 1$ finally accords to a flat ("Euclidean") geometry of a plane surface. The cosmological standard model predicts that any small deviation from $\Omega = 1$ in the early universe will be amplified massively in the course of time. Thus the universe should have a density parameter that is orders of magnitude larger or smaller than 1. Or, on the other hand, Ω has to be extremely close to 1 right after the big bang. This is a classical problem of fine-tuning.

Solution Within Cosmic Inflation

After rapid expansion comes to an end, the size of space by far exceeds the diameter of the region that makes up our observable universe today. However strong the cosmic curvature may be today, the curvature of "our" space region, the "universe" by definition is tiny, just as the earth's surface appears to be flat due to our limited perception.

The Horizon Problem

In theories of time and space one frequently uses the term *past light cone* of an event. An *event* is a point that determines a "here and now" in spacetime. The past light cone of an event E contains all events (points of spacetime) E_i in the past of E from which light or information could have reached the event E. An event E' is able to influence a (future) event E only if E' lies within the past light cone of E.

In 1965, physicists discovered a constant extragalactic microwave radiation that is now known to have been generated less than 400,000 years after the big bang. That so-called cosmological microwave background radiation is reaching us with identical physical properties from all directions of space. A close to perfect isotropy like this clearly seems to contradict the finite propagation velocity of light and information: The birth locations of the background radiation photons measured today have distances of 13 billion light-years from the earth. However, the cosmic background radiation, coming from opposed directions, is measured to have identical temperature and spectral distribution, while the past light cones of the according regions could not have overlapped 400,000 years after the big bang. There is no way to understand the isotropy of the cosmic microwave background in a universe without inflation.

Solution Within Cosmic Inflation

Prior to the onset of inflation the entire space of the universe may well have been in thermodynamic equilibrium. This means there was a common, well-defined temperature throughout the universe and all energy was smoothly distributed. In the course of inflation, all regions of space were torn apart at many times the speed of light and thus lost their causal contact—in other words, their past light cones would no longer overlap after the explosive separation.

Nevertheless, all physical properties have either remained constant or changed in identical ways (density, temperature) within any volume element while inflation happens.

The Monopole Problem

James Clerk Maxwell's (1831–1879) empirical formulation of the electromagnetic laws contains an asymmetry, running counter to the ambition of highest simplicity in modern physical theories: Classical electrodynamics does not allow for magnetic monopoles; that is, isolated magnetic south or north poles. In fact, a magnetic monopole has so far never been observed in nature. Electric monopoles (charges), on the other hand, are well known. In any case, grand unification theories predict that massive magnetic monopoles formed in the very early universe. Why are these undiscoverable today?

Solution Within Cosmic Inflation

According to grand unification theories, magnetic monopoles should have been created with extremely low numbers within much less than a second after the big bang. The monopole frequency should have diminished during the inflationary expansion in such a manner that there is a close to zero chance of discovering one today.

In terms of quantum theory, the universe was brought from a pure quantum mechanical being into a macroscopic classical one by inflation. Thus the inflationary scenario yields a possible explanation for the onset of structure formation in the universe: Due to Heisenberg's uncertainty principle, there must have existed tiny quantum fluctuations within matter and radiation (the "primordial soup") right after the big bang. While the rapid expansion of inflation was acting, these quantum fluctuations were being transformed to a macroscopic density contrast. Starting from this, large structures like galaxies and clusters of galaxies were able to form by gravitational instabilities in the course of time.

There is little agreement on the physical details of how inflation occurred. This is due partly to the uncertain state of knowledge of the corresponding high-energy physics. Second, cosmologists are far from being able to perform experimental tests of the inflationary model. In any event, inflation is in principle falsifiable in terms of Karl Popper's philosophy of science. This means one can think of feasible experiments that would allow (depending on their results) the inflationary scenario to be disproved. Such an experiment was performed by the NASA space probe *WMAP* launched in 2001. Its very detailed measurements of the cosmological microwave background radiation are compatible with the inflationary picture. Note, however, that this is by no means a proof of inflation.

Because the big bang itself cannot be considered as encompassed by the time evolution of the universe, inflation marks the first significant change in state of the universe and the beginning of its macroscopic being.

Creation, Myths of

"In the Beginning . . ." and "Long, long ago..." began the theogonies of creation myths that were composed by the primordial peoples who, in observing the celestial patterns in correspondence with the seasonal changes in their habitat, concluded from these extrinsic evidences theories of creation of the cosmos, flora and fauna, and especially of humankind. These myths became the foundations that shaped the distinct cultural worldviews, mannerisms, and rituals that their belief systems would dictate. There were gods that were personal and dwelt among humankind, gods that dwelt in the heavens, and a pantheistic god that is believed to reside *in* everything. Globally, the creation myths have a myriad of origins and important characters, yet similar motifs are evident. This entry examines analogous themes and will initiate each creation section with a passage from Genesis, as a bellwether creation motif, being one of the most recognized of creation legends.

Darkness, Divine Chaos, and the Primordial Gods

> In the beginning . . . the earth was without form, and void: and darkness was upon the face of the deep. And the Spirit of God moved upon the face of the waters. And God said, Let there be light . . . and God divided the light from the darkness. And God called the light Day, and the darkness he called Night. And the evening and the morning were the first day. (Bible, King James Version, or KJV)

The Romans tell of Chaos, the shapeless form of the four elements—water, fire, air, and earth—before the beginning of time; when these elements finally separated, the result was the formation of Janus, the "god of gods." From China, the gods Yin and Yang were the first to form from the *hun dun* or shapeless vapors; with the remainder of these vapors Yin and Yang created the universe and humans. The Hopi legends recount how the entirety of existence was endless space and the sun spirit; the sun spirit formed the earth from himself and endless space. The Mayans' "Book of Counsel" tells that there was silence in the beginning prior to creation. The Taoist Chuang-Tzu describes the subtle stages of "Being"; there was: "Not-Yet-Beginning-to-Be-Non-Being," and "Not-Yet-Beginning-to-Be-a-Not-Yet-Beginning-to-Be-Non-Being," and how "suddenly" the vitality of Being and Non-Being came to pass. A New Zealand Maori chant tells how everything emerged from a void origin. The Taoist Lao Tzu wrote of an unknown thing, "confusedly formed," with the potential of being the mother of worlds. In the Slavonic legends the dual forces of positive and negative created Byelobog the Black God, and Chernobog the White God. To the Haidas of the Pacific Northwest (of the U.S.), the Supreme Being is called "The-Light-of-the-Shining-Heavens," while the Incas call it the "Hidden-Face-of-God"; and the Iroquois call it the "Old-One-in-the-Sky." To the Hebrews, the name of God is so revered that it is unspeakable; in writing, the consonants JHVH were arranged to denote God. An Inuit legend describes Raven as being the creator, yet it is the Sparrow that not only accompanied Raven throughout the creation processes, but was there from the inception; while the Inupiaq of Alaska tell of the Primevous Shaman that created Raven the god-man, Raven who became a creator in his own right and transformed into a bird. In Siberia the Chukchi call the Reindeer Being their Creator. The Evenks have two names: Amaka the guardian for humans, and Ekseri who oversees the animals. The Korean Supreme Being is Hanullim, the "ruler of heaven." In Australia the Aboriginals recognize the "All Father," which goes by several names depending on location, and/or the "The Great Mother" or "All Mother."

The *Zohar,* a Judaic text, describes how the creator was without shape or form, and so created a divine man that he descended upon and utilized for further creations. The Memphis Egyptian legend recounts Ptah as the creator and "Father and Mother of all the gods." Within the Greek legends the "deep-breasted" Gaea, Mother Earth, was created from the chaos of the void. The Celts' "Good God," the Dagda, is known to them as the "Great Father." In Northern Europe, creation transpired within the merging point of the icy north and the inferno from the south; the melting ice from this fusion formed the giant Ymir. The dark nothingness and divine chaos that is prevalent in creation lore and that antedated creation and the primordial slime, is a similitude of the darkness, then the chaotic nebulae from the aftermath of the early stages of the evolution of the universe.

The Deep Waters and Children of the Gods

> And the Spirit of God moved upon the face of the waters . . . And God said, Let there be a firmament in the midst of the waters, and let it divide the waters from the waters . . . God called the firmament Heaven. And the evening and the morning were the second day. (KJV)

Some cultures believe that Father Sky and Mother Earth were in continuous lovemaking, in an inseparable embrace. These parents have numerous appellations: Apsu and Tiamat (Babylonian), Ouranos and Gaea (by Hesiod), Rangi and Papa (Polynesian), and An and Ki (aka Nammu) (Sumerian); in Egypt the parents are reversed and the mother is the sky and father the earth. Given that their children are imprisoned between them and more "offspring" are being created, the siblings launched a campaign against their parents to improve their living conditions.

In Japan the creative substance of primordial slime resembled oil or a gelatinous mass from which five gods took form and lived on the High Plains of Heaven; from these five gods, seven following generations of gods and goddesses were created. Then, Izanagi and Izanami, the youngest god and goddess, took a sacred spear, swirled it in the waters of the deep from the Floating Bridge of Heaven, and the drops that fell when retrieving the spear created the beginnings of land, their new home; their children would become the remainder of the creation process of Earth. These global motifs of gods forming from the mists, the waters separating, and the promontories arising from the endless body of water represent the nebula condensing into planets in the star systems.

Earth and the Cosmos

> And God said, Let the waters under the heaven be gathered together unto one place and let the dry land appear . . . Let the earth bring forth grass, the herb yielding seed, and the fruit tree yielding fruit . . . And God saw that it was good. And the evening and the morning were the third day. And God said, Let there be lights in the firmament of the heaven to divide the day from the night, and let them be for signs, and for seasons, for the days, and years . . . And God made two great lights: the greater light to rule the day, and the lesser light to rule the night: he made the stars also . . . And God saw that it was good. And the evening and the morning were the fourth day. (KJV)

In a Persian legend, a 9,000-year battle between light and darkness ensued prior to the world's formation. Globally, the theme of the separating of Father Sky and Mother Earth played an important role: for example, the children of Rangi and Papa are bent over and sideways; their miserable state prompts them to conjure conspiracies to destroy their parents, but the child "Father of the Forest" pushed the parents apart; in Egypt, it is Shu the child of the Air. In an early Chinese creation legend, the sky god Zhuan Xu orders the two grandsons Chong and Li to separate the sky and the earth; and in another version the sky had to be propped up from the earth, in another tied down to the earth. In Korean legends it was Miruk who separated heaven and earth and placed pillars to keep them in their place, then filled the sky with the stars, the moon, and the sun.

In the Eastern cultures, the cosmic egg arose from the primordial waters of the deep. From Hermopolis, Egypt, the creation legend tells of a mound that emerged from the waters of Nun, and upon the mound an egg from which the sun god appeared. In Orphic legend the egg is silver, and is cracked by Time and Need. Love, named Eros, "father of the night," emerges from the egg "wearing both sexes"; Eros fathered Zeus, who in turn swallows his father; Eros returns as the cosmos.

The Chandogya Upanishad of India recounts how the egg was half silver and half gold; the silver became the earth, the gold the heavens; the Brahman legends tell how a golden egg floated upon the waters a year prior to becoming the heavens and the earth. The Vedic hymns tell how each of Vishnu's seeds became golden eggs, and from each seed a universe was created; the god Brahma was born from Vishnu's navel; Brahma then created the stars and demigods to assist in the creation and control the earth and universe. With the Chinese, 18,000 years of incubation occurred prior to the egg separating into Yin and Yang: the Yang, being lighter, arose to create the heavens, while the Yin was heavier and lowered to mold into the world. In Africa, Mebege created the cosmic egg by combining a portion of his hair, brain, a pebble, and his breath; a spider brought the egg between the sea and the sky until the egg obtained the optimum temperature, at which Mebege fertilized the egg. Following the birth of his three children, Mebege created termites and worms to leave droppings, which thereby created land.

At times a god's or demigod's being was utilized as a cosmological body for the creation to be complete. In Babylonia it is the third-generation god Marduk, the sun god (Assyrians call him Assur), who slays the mother of the gods, Tiamat, and thereby creates the earth and heavens with her body. In Northern Europe the three brother gods Odin, Vili, and Ve slay the giant god Ymir and use his carcass to create the earth. From the southwest area of China, the being of the semi-divine human, giant Pan Gu, was formed while the Yang separated from the Yin; after an unspecified time the dying remains of Pan Gu were used in the finishing touches of the creation process of the earth: for example, his eyes were placed in the sky for the sun and moon, and his body lice become human beings. The Inupiaq tell of Raven killing a whale in order to create the world from its carcass.

Life on Earth was a paradise, explains the New Guinea legend, filled with flora, fauna, and demigods called *Demas;* but then, the world of paradise was burned to the ground by the demigods playing with fire. So Darvi, the great *Dema,* created rain, which not only brought a cessation to the flames, but formed rivers in the process. Enraged over the holocaust, the great *Dema* threw a charred piece of land into the ocean; this is the beginning of New Guinea, and brought a metamorphosis of the flora and fauna to be changed into humans. Also from New Guinea, a story of three brothers at the beginning of the world who became the ancestors of the people on Earth: people of the grassland and people of the bush, but the third brother left and was never seen again; the arrival of Europeans brought speculation that these were the descendents of the third brother. Another Oceanian legend recounts how the god Tiki made his wife from sand. Their children and children's children fill the island, giving Tiki the impetus to create more islands, the solution to the unprecedented population problem. Another island, Turtle Island, is the term from the Cheyenne of North America, whose legends inform that the Earth resides on the shell of Grandmother Turtle. In the Caribbean the sons of the supreme spirit Yaya were secretly consuming fish from a gourd that belonged to their father; upon hearing their father's arrival they accidentally overturned the gourd filled with fish and water, thereby creating the ocean. The Unambal tribe of Australia tells of two creators: the Ungud who is shaped like a python and finds its habitation within the earth, and the Wallanganda or one that "belongs to the sky" and dwells in the Milky Way; their creation process transpired during Dreamtime. In the North American Iroquois legend, "The-Old-One-in-the-Sky" impregnated Ongwe and then thrust her through a hole in the sky, resulting in the birth of the world.

A Mongolian story tells of seven unmoving and unbearably hot suns that grieved the residents of Earth. The hero, in human form, the intrepid marmot, shoots six arrows into the sky, to which six of the suns fell; this sent the seventh sun into a continuous cycle around the world. In the early Chinese calendar a week was 10 days, in which the sun goddess Xi He or Breath Blend conceived 10 children or suns that would alternate journeying across the sky, to each occasive conclusion; when all 10 decided to come out one day, which threatened Earth's habitat, the hunter god shot and pulled them down with cords attached to his arrows. Maui, a Hawaiian demigod, pulled the land out of the water, much like the sons of Bor raising the dead body of Ymir from the waters to create the earth. Maui also trapped and convinced the sun to slow its passage across the sky; prior to this the sun moved swiftly, making the days too short.

Within the diverse creation versions, the entry of humans occurs at various stages; some prior to the creation of the cosmos and others afterwards. In a Tlingit legend, all the world was dark and the people complained of the gloomy existence. It was the legerdemain of Raven that brought the sun, moon, and stars to the people; the trickster secreted into the drinking water of the daughter of the Great Chief, thereby impregnating her. Raven, now the grandson, cried until the Great Chief opened his bentwood boxes filled with his most valued clan items: the stars, the moon, and especially the sun. First, he let Raven play with the least of these, the stars, and Raven let loose the stars through the longhouse smoke-hole; next Raven released the treasured moon, when the slaves weren't looking; at the opportune moment he transformed into a raven and with the sun in his beak, he attempted his escape; the Great Chief commanded the smoke hole to be shut, it trapped Raven midway, the sun's fire and smoke blackened Raven's white feathers; he wriggled free and liberated the sun for the earth's inhabitants.

The ancient Chinese calendar recognized 12 moons; the moon goddess Chang Xi or Ever Breath's 12 children or moons rotated their pilgrimage across the sky. Another account has Chang E, or Ever Sublime, consuming a stolen potion of immortality, thereby creating her as the goddess of the moon as she rose up into the sky. Arctic dwellers describe the sun and moon originating from a man chasing his amour, his sister; they ran so quickly that their bodies lifted into the skies, his sister became the sun and he the moon, so that to this day the moon chases the sun; their brief embrace creates an eclipse. The Mayan legend reveals that the sun god's only journey through the sky was on the initial day; a disk with his reflection is now in the sky. The stars, according to Slavonic legends, are the children of the sun and the moon.

Thus, the earth and the universe were very personal to the early peoples of the world, to the point of being considered family or part of the clan. Many tribes, like the Pueblos, attempted to live in harmony with the movements of the planets, and so it is understandable why the earth and star systems were created in our image.

The galaxy, its movements, their movements, and accompanying legends powerfully influenced civilizations. Here is a representation of a Haida story concerning Raven and the Moon.

Humans, Animals, and Plants

> And God said, Let the waters bring forth abundantly the moving creature that hath life, and fowl that may fly above the earth . . . And God created great whales . . . And God saw that it was good. And the evening and the morning were the fifth day. So God created man in his own image, in the image of God created he him: male and female created he them . . . And God saw every thing that he had made, and behold, it was very good. And the evening and the morning were the sixth day. (KJV)

From Egypt, the Heliopolis explains how the god Atum, the "ancestor of humankind," created from himself the first human couple. In Northern Europe, the gods Odin and his brothers Vili and Ve, upon discovering two dead tree trunks, proceeded to create the human male—Ask, and female—Embla. In the Haida legends Raven finds humans emerging from a clamshell washed up on the shore. The African Togo legends inform that the creator brought the humans down from the sky via a chain, to live on Earth. Insects fell from heaven in the Korean legend, as Miruk prayed to be able to create humans while holding a golden tray and a silver tray; those that fell upon the golden tray transformed into men and those on the silver into women. From Uganda comes the legend of the creator Gulu and his daughter and son; the daughter married the primordial man and gave birth to children, and when they refused to allow her brother to marry their children, he created death. The *Brihadaranyaka Upanishad* of India tells of the creation of man; he was lonely, and so separated himself into male and female. A Greek legend told by Plato explains how the early peoples were male/female, female/female, and male/male. The gods split them in two; so that to this day, each person is still trying to find his or her "other half."

Some creations took several processes or numerous attempts to perfect. The primordial Hopis at one time lived in caves and resembled insects; Grandmother Spider escorted them through a long cavern, and the journey transmogrified them into animals. After another pilgrimage with Spider Grandmother they completed the evolutionary process into human beings. Then in order to separate from the evil people, a ladder of bamboo grown tall through the power of songs was employed to reach the sky world; then two young warrior gods transformed that world of mud into hills, valleys, and plant life. Afterward, Spider Grandmother instructed the people to make disks, and then to hurl them into the sky, and so created the sun and the moon. When the world was complete, the people emerged from the *sipapu* and were instructed to go separate ways and migrate. Among the Aztecs, legends recount how the world had undergone five creations and four destructions, each resulting from battles between positive and negative forces; and that humankind's final origins are a mythical island called Aztlan. With the Mayan creators Gugumatz and Huracan, four attempts were made before creating the kind of people they desired; during the process they even called upon *their own* ancestral diviners for assistance. The Inca god first created giants from rocks, then destroyed them; then fashioned people from clay and painted them distinctly to create various cultures.

In Greek mythology, humans were created twice; the first time Prometheus fashioned humans from earth and water; later when Zeus was upset with the humans' sacrificial offering, he withheld fire from them. Prometheus then stole it for the humans. At the behest of Zeus, Hephaestus formed the first female, Pandora, from clay and water, and she was sent with a gift, a vase filled with miseries that fell upon the earth. Zeus destroyed the first humans in a flood; after which it was Deucalion and his wife Pyrrha, with guidance from Titan Themis, who walked along tossing rocks over their shoulder to recreate humans; men sprouted from the rocks thrown by the husband, while women sprang from those of the wife.

Sumerian legends recount generations of gods, each with a specific duty on Earth. Some of the gods' tasks involved hard labor, which grieved them. Humans were created to spare the gods these menial tasks. In Babylonian legends, humans were created to "bear the yoke"; the blood of a slain god combined with clay created seven human beings. Clay was also employed in an Egyptian origin legend, when the god Khnum created people on a potter's wheel. In China the goddess Woman Gua sculpted humans from yellow clay, and then mass-produced more humans from mud falling in a furrow, thereby creating the upper and lower caste system.

Lesser gods were also nominated to "finish" the creation project, as with the brothers Enmesh (Summer) and Enten (Winter); or the two daughters of Spiderwoman, who were given baskets filled with objects to create flora and fauna. During the final stages of creation, humans and animals could converse with one another, as with the snake in the Garden of Eden; and in the Tlingit and Haida legends where humans and animals could transform into each other, marriages sometimes occurred among the species. Magic was evident as the mythical creations ensued; for example the legend of the man Naatslanei, who created killer whales by carving them from yellow cedar in order to institute revenge upon his brothers-in-law who deserted him for dead upon an island rock.

Amythia

The introduction of the theory of evolution, over 100 years ago, liberated the scientific mind while it shook the Christian world to its foundation. Christians were then subjected to the condition that Indigenous tribes worldwide faced during colonization: to be informed that their belief system was benighted, a myth, a fictional myopic story. Friedrich Nietzsche's *Thus Spake Zarathustra* not only makes the controversial declaration "God is dead," but adds that this resulted from our own "knives." In *The Birth of Tragedy,* Nietzsche further posits that "myth-less" humanity's displacement formulated the circuitous exploration for knowledge following the ruination of their mythical touchstone; later, philosopher William Barrett claimed that "neuroticism" was the consequence. The composer Richard Wagner's opera cycle *Der Ring des Nibelungen* theatrically encapsulated this moment in history, this witnessing of the theomachy and the death of the gods in power. It is Loyal Rue who coined the term *amythia* for the emptiness felt by these modern Christian peoples. Rue speculated that unless our cultures rebalance by discovering an approach to cosmology and morality that is framed in workable symbols once again, thereby creating a revised belief system, our survival may not be ensured through the end of the 21st century.

The Myth Returns

Richard Wagner's operatic poem *Der Ring des Nibelungen* contains a tetralogy of a unique perspective on the cycle of mythological archetypes. "Das Rheingold" reveals the deep primordial waters of the Rhine, from which the universe was created; we are introduced to the maidens of the Rhine who, much like Dagon of the Philistines, have a fishlike tail; the dwarfs come next, who in earlier versions were also partly creatures of the water, which would then represent the monsters that first formed from the primordial slime; then the gods and goddesses and giants appeared, which is similar to the Mayan stages. Then within "Die Walküre" the mortal children of the god Wotan incite his wrath, to the point of his ordering their annihilation, in similitude with Zeus' wrath toward the humans. The independent choices of the heroine Brünnhilde and her estrangement from her father parallel the autonomous actions of the children of Father Sky and Mother Earth, not to maintain the status quo, which forced a separation; as well as Prometheus' interception for the clans of humans. In "Siegfried," the hero wields the sword Notung, kills the dragon, receives the golden ring, and rescues Brünnhilde, reflecting the newly discovered power of the offspring of Father Sky and Mother Earth. The opera "Götterdämmerung" reflects the lingering magic, as when Brünnhilde reveals the protection she has bestowed on her husband. In the end the gods are destroyed, but the world continues. Interestingly, the Rhinemaidens are still as beautiful and youthful as ever, and Erda, Mother Earth it is assumed, still sleeps within the earth, perhaps using the Dreamtime to envision the next order of gods.

The culturally distinct transmundane myths of creation have been at the nucleus of humankind's belief system for thousands of years. It appears that mythological history has repeated itself in this modern age: since the end of the 19th century the world has witnessed the gods subjected to scrutiny by human children who were suffocating beneath the weight of religion. Meanwhile, the accumulated knowledge of the cosmos, of philosophy, of medicinal plants and agriculture (all ascertained during their ancestors' immersion in "myth") is being used to create a new world. Comparable to the chaos initiated by the beginning stages of the universe, the new scientific thought brought a chaos of its own and created a space and time for a world of new thought. Faith in the legends and myths of ancestors and the secular empirical science at first appeared at an impasse, and although traditionalists continue to hold fast to a 7–human-day creation (Genesis), growing numbers in today's diverse theology embrace both evolution and the divine. In turn, scientists are researching myths and legends for their symbolic patterns of the creation of the universe relating to scientific theories. In 1992 the COBE (Cosmic Background Explorer) satellite sent information about radiation from the big bang, proving a sudden creation; it was described as "the discovery of the century"—Stephen Hawking, and "like looking at God"—astrophysicist George Smoot. The scientific community rejoiced in the confirmation of a respected scientific theory, while the theological community celebrated the sudden birth of the universe, albeit some 13 billion years ago as opposed to the creation in 7 days, and viewed the discovery as verification of a Supreme Creator. The interpenetration of science and religion appears to be in progress, as scientific facts are integrated with the symbols of honored spiritual belief systems.

Creationism

In its broader sense, creationism is the belief that the universe was created by a personal God, at a specific time, and for a specific purpose. In its narrower sense, creationism is the belief that the account of creation as related in the Judeo-Christian Bible is completely reliable. This is held to be the case because of the unique authority of the Bible, and because contemporary science has confirmed its account as related in the Book of Genesis. More specifically still, creationism has come to amount to the following set of assertions: that the earth was a special creation by a creator; that the law of entropy reveals deterioration in the earth as opposed to the supposed evolutionary ideas of progress; that life is also a special creation by a creator; that, once created, each species remains fixed according to its initial model; that *Homo sapiens* has an ancestry distinct from the animals; that the flood as reported by Noah is a historical event, and that, as reported in the Book of Genesis, the earth is relatively young.

The core feature of these assertions, for creationists, is that they are true because they are found in the Bible. It is only an incidental corollary that science is believed to have confirmed them. The strong emphasis on the Bible explains the largely Protestant nature of contemporary creationism. In contrast, Catholic and Orthodox varieties of Christianity have had fewer qualms about accommodating evolutionary teaching within a Christian perspective. No less a Protestant than Martin Luther spoke in terms of a 6-day creation and a worldwide flood. In the United States the Adventist prophet Ellen White (1827–1915) was one of the first to insist specifically on the main features of what is now called creationism.

Historical Background

Origins

Without doubt, the core tenets of creationism owe a large debt to the five fundamentals laid down by the Presbyterian General Assembly of 1910 in the United States as being fundamental to Christianity. The first four fundamentals all relate to the dogma of Christ: his miracles, the Virgin Birth, his bodily resurrection, and his atoning sacrifice. But the fifth fundamental laid down is that the Bible is directly inspired by God and therefore literally true. It was from this document, and the ones that followed it until 1915, that the notion of being a "fundamentalist" derived. The word *fundamentalism* was not coined until 1920. The five fundamentals were important in the growth of creationism in America.

Creationism, like the Protestant fundamentalism of which it is an offshoot, is best understood as a by-product of secularization. Since the 17th century, the Christian scriptures have receded in importance as the sole source of authoritative accounts of how the universe works and of the place of humanity in that universe. This has provoked a range of responses among Christians, with most accepting the scientific account and understanding that an amendment to the role of the Bible is required. For a significant minority of Christians, however, this response seems inadequate. To people used to seeing the Bible as the sole repository of authoritative information about the world, the new authority of science could not go unchallenged.

What has come as a surprise to many people is the strength and resilience of this backlash. As the pace of scientific, technological, and social change has quickened, so has anxiety about them developed among fundamentalists, leading, in turn, to a determination to halt what they see as a collapse of the only world that makes sense to them.

Creationist thinking had been simmering away unnoticed in some lesser theological colleges in the United States early in the 20th century. Of particular importance was the Adventist George McCready Price (1870–1962), whose books, in particular *The New Geology* (1923), presented an essentially creationist account. Price had no formal training in any area of science, but had grown up familiar with the writings of fellow-Adventist Ellen White. Mainstream opinion seemed to be moving against them at the time, and the creationist account was seen as little more than a peripheral relic.

The Scopes Trial and Its Aftermath

All this changed in 1925 as a result of the trial of a young biology teacher, John T. Scopes (1900–1970), in Tennessee. The trial attracted widespread attention, not least because of the stature of the lawyers brought in to conduct each side's argument. The creationist case was conducted by William Jennings Bryan (1860–1925) and the evolutionist champion was Clarence Darrow (1857–1938), a very well-known progressive lawyer. The creationists can be said to have won the battle but lost the war. Scopes was found guilty, since Tennessee law specifically forbade the teaching of evolution. But the negative publicity, largely at the hands of the influential journalist H. L. Mencken (1880–1956), did much to discredit the creationists' cause.

The Scopes trial stimulated a flurry of protocreationist literature around the English-speaking world, as conservative Christians woke up to the threat they perceived evolution posed to their beliefs. A quick survey of titles published outside the United States will be instructive and help dispel a long-standing fallacy that creationism is a phenomenon peculiar to that country. An early example of British antievolutionary writing in the interest of evangelical Christianity was *The Bankruptcy of Evolution* (1924) by Harold C. Morton, who made specific use of the word *creationism*. Morton was familiar with some of the works of George McCready Price, but most of his sources were British or European. In the wake of the Scopes trial an evolution protest movement (EPM) conducted a series of debates and a pamphlet campaign critical of evolutionism and its necessary links with unbelief. Their chief spokesman was Douglas Dewar, a barrister and amateur ornithologist. The EPM was also active in Australia and New Zealand and achieved its greatest victory in New Zealand in 1947 when the government of the day responded to complaints from its leading spokesperson, Dr. D. S. Milne, about the content of a radio series called *How Things Began*. Milne complained that the series was "unbalanced" in its presentation of a naturalistic account of human origins. The minister of education agreed and pulled the series, to the dismay of the Royal Society of New Zealand and much of the public.

Another prominent British antievolutionist was R. E. D. Clark, whose *Darwin: Before and After* (1948) and *The Universe: Plan or Accident?* (1949) explored many themes used later by the American creationists, such as the appeal to entropy as a disproof of the supposedly "upward" trajectory of evolution. Clark's books were part of a series published by Paternoster, a religious publishing house, and designed as refutations of a popular series of publications by the Rationalist Press Association called the Thinker's Library. Paternoster's series was called The Second Thoughts Library.

Despite all their activity, it was clear that by the end of the 1950s the antievolution movement in Britain and the English-speaking commonwealth was petering out. Contemporary British fundamentalism has not developed exclusively along creationist lines. At about this time new impetus to the movement came once more from the United States. As a result of the Scopes trial, evolution was left out of American school science teaching. The

Tennessee decision remained in force until 1967. The need for change became apparent after 1957 when the United States was embarrassed to find its science program lagging behind that of the Soviet Union, which had recently put an unmanned spacecraft, *Sputnik*, into orbit in space. Realizing it needed to catch up, the U.S. government oversaw a comprehensive overhaul of science education, which included the teaching of evolution. But this decision, coming as it did shortly before the massive social and political upheavals of the 1960s, motivated religious fundamentalists once more to bestir themselves.

After Sputnik

The first evidence of this new assertion of creationism came in 1961 when Henry M. Morris (1918–2006), an engineer, and John C. Whitcombe (1924–), an Old Testament theologian, coauthored *The Genesis Flood,* which owed a significant debt to McCready Price's earlier work. Two years later Morris helped establish the Creation Research Society (CRS), which became a leading voice of creationism in the United States.

In 1972 Morris set up a new vehicle for his cause, the Institute for Creation Research (ICR). Coincident with the establishment of the ICR was Morris's next book, *The Remarkable Birth of Planet Earth* (1972), which reiterated the central role of the Bible as a record of the creation of the earth. Morris's handling of the issue of the age of the earth can stand as representative of his overall approach: "The only way we can determine the true age of the earth," Morris wrote, "is for God to tell us what it is. And since He *has* told us, very plainly, in the Holy Scriptures that it is several thousand years in age, and no more, that ought to settle all basic questions of terrestrial chronology." This, and many other similar works, including those by Duane T. Gish (1921-), became the staple of creationist literature, being short and designed for nonspecialist readers.

At first the creationists tried to have the teaching of evolution banned and replaced by creationism. But the tide of opinion was moving against them. In 1967, the Tennessee decision from the Scopes trial of 1925 was overturned by a second challenge by a high school teacher in that state, Gary Scott. The next year Arkansas followed suit. A case going to the Supreme Court ratified the states' decisions, confirming that the bans on the teaching of evolution were unconstitutional.

As a result of these defeats, the creationists turned to a new tactic. They rebranded creationism as "creation science." Overt Christian references were expunged and a more "scientific" flavor was added. As part of their campaign to gain acceptance as a credible scientific movement, the Creation Research Society (CRS) prepared a textbook for use in schools. *Biology: A Search for Order in Complexity* (1974), by J. N. Moore and H. S. Slusher, purported to be a credible scientific work. Alongside this came a shift in their campaign goals. No longer were the creationists campaigning for a simple replacement of evolution with creationism. Now the tactic was to argue for "equal time" for the two accounts.

This was a very shrewd move, as it tapped into a deeply held preference among Americans for open disputation and for all sides to get an equal hearing. The scientific community was at something of a disadvantage as they now had the difficult job of demonstrating why "creation science" did not merit equal time. The creationists' case was helped by the intervention of some prominent antiscience philosophers such as Paul Feyerabend. At the beginning of 1977 a large number of scientists and science educators signed an open letter condemning creationism. The sponsoring committee for the letter included Isaac Asimov, Linus Pauling, and George Gaylord Simpson. The preamble began by denying that creationism is a science at all, but rather a "purely religious view held by some religious sects and persons and strongly opposed by other religious sects and persons." As evolution had the confidence of the scientific community and most of the religious community as the best available explanation of the existence of diversity of living organisms, they saw no need for poorly supported and religiously inspired alternatives to be given equal time in schools.

Scopes II

The equal-time argument was a clever move and was beginning to win support for the creationist movement. A new tactic of turning their attention away from state legislatures to local school boards, which were easier to influence, was also beginning to pay dividends. For example, in Arkansas and Louisiana, pressure from these sources persuaded their state legislatures to pass legislation in 1981 requiring equal time for creationism with evolution.

The Arkansas decision, known as Act 590, could not go unchallenged and soon developed into a test case. And a lot was at stake; the case was widely seen as a rerun of the Scopes trial 56 years previously and became known as Scopes II. The American Civil Liberties Union (ACLU) filed a case against the Arkansas Board of Education. In the case that followed, a wide range of leading theologians, scientists, and philosophers testified. But it was not a simple science-versus-religion divide. Indeed, the case presented by the evolutionists included a large number of theologians and church historians whose testimony was probably the most decisive in the case.

On January 5, 1982, Judge William Ray Overton of the District Court overturned Act 590, ruling that creationism was not a genuine scientific theory and did not justify equal time in schools alongside evolution. Overton had clearly paid attention to scientists who had testified, because he outlined a simple 5-point criterion for something to be labeled scientific, including being guided by natural law; being explanatory by reference to natural law; being empirically testable; presenting tentative conclusions; and being falsifiable. Overton then described at length how creationism failed to meet any of these criteria. A court later that year in Louisiana made the same decision, adding that creationism's main goal was to discredit scientific evolution with a religious belief masquerading as a scientific theory.

Creationism never recovered any serious momentum as a major public force after these landmark defeats. The scientific credentials for creationism had failed to achieve traction, and now the "equal time" argument had been dismissed as spurious. This is not to say, however, that creationism withdrew from the scene altogether. It has continued its program within the American evangelical community and, increasingly, in other English-speaking Protestant countries as well. Its continuing success in holding this market is reiterated each time a new opinion poll emerges that shows a high percentage of Americans reject the evolutionary account of human origins. And in Kentucky a large and generously funded creationist theme park is being developed to cater to this market.

Recent Developments

More recently, the creationist community has regrouped and rebranded itself once again, this time calling itself "intelligent design." For a short while it looked as if it had finally acquired a degree of scientific legitimacy in the form of Michael Behe's work, *Darwin's Black Box* (1996), in which the design argument was applied at the biological and molecular levels of organization. But within 2 years the grave weaknesses of Behe's argument had been given a thorough airing. Behe, as with most other supporters of intelligent design, was anxious to distance himself from the discredited creationism, but few people saw a great deal of difference. Indeed, the essential similarities were part of an important decision in Dover, Pennsylvania, where, in December 2005, Judge John E. Jones III overthrew a move by creationist parents to impose antievolutionary teaching in the classrooms there.

From the beginning, the creationist movement was beset by contradictions, no more so than in its shifting positions on science and religion. On the one hand, it demanded it be seen as a valid arm of science, but on the other, it argued that science is no less a religion than Christianity. This then tied in with the other contradiction: Creationists insisted that "secular humanism," its bête noir, was a religion and should therefore be treated as other religions (which presumably included creationism) and be banned from the classroom.

One of the ironies of American creationism is that its closest allies are conservative Muslims, whose views are very similar regarding evolution, the fixity of species, and the paramountcy of scripture as a reliable creation record. There is little active creationism in the Muslim world to date, because there is very little in the way of a scientific critique of Quranic claims about creation. Active, organized creationism is strongest in Turkey, the most secular country of the Muslim world. There the Bilim Arastirma Vakfi, or Science Research Foundation, works in ways very similar to its American colleagues.

Creativity

Over time, the definition of the term *creativity* has evolved; there are more than 60 definitions in the literature of psychology alone. The Merriam Webster dictionary defines creativity as the ability or power to create something new, or improve upon an existing product or idea through imaginative skills. Creativity is considered boundless if nurtured but does not occur unless one devotes time to cultivating the imagination. To lose oneself in creative activity is to express what is at the root of the subconscious. Thus, creation occurs as a physical manifestation of mental images that emerge from the unconscious to consciousness.

Charalampos Mainemelis, a scholar noted for his work on the relation between time and creativity, explains that the creative process takes place within a state of timelessness or intense concentration. When one is in a state of timelessness, thoughts are directed away from the self and toward that which is outside the self. Timelessness has a major impact upon creativity because for some, a sense of timelessness is sometimes perceived as counterproductive. Even though creativity and time go hand in hand, more often than not some individuals express that it is a struggle to set aside a block of time to be creative. Nonetheless, the association between creativity and time cannot be ignored, because one's creation is a reflection of one's identity that only time on task can reveal. In addition, as some observers have pointed out, time to be creative should occupy a position of greater value in our culture because humanity benefits greatly from creative producers. Indeed, creativity is central to human activity and well-being.

The spirit of creativity is life sustaining. It provides energy and inspiration. Moreover, it provides joy and satisfaction. Creativity is the impetus for productivity; yet despite all of this, the challenge of connecting the importance of creativity with time still persists. Therefore time has a way of sabotaging creativity, especially when the creative process is misunderstood.

Daydreaming is an important aspect of creativity. However, in considering the cultural context of "work," that is, laborious efforts, it is understandable that daydreaming is not encouraged. Furthermore, daydreaming is considered by some to be an example of "killing" time. In this sense, time and creativity are at odds. If, for instance, educators continue to view daydreaming as a sheer waste of time, especially for primary and secondary school-aged children, inventiveness and imaginative creativity stand to be compromised.

In our struggle to be productive and meet the standards of what society perceives as useful, the very nature of a dream-like state is underrated. Then again, how often do we as individuals declare that before making a decision, we choose to "sleep on it"? True to creativity, dreams are known to tap into the creative spirit. Here, creativity and time reconcile because time to sleep is acceptable if it is not excessive. Yet it is during this natural periodic suspension of consciousness that a series of thoughts, images, or emotions occurs, as in dreaming. It is believed that the unconscious mind is far more open to insight than the conscious mind. While daydreaming cannot sustain itself without some unfocused time to allow for sparks of innovation to ignite, dreams work in concert with time. To dream is to permit the imagination to roam freely without judgment to suppress it due to time constraints. Time to dream and time to daydream are equally important for creativity. As Edgar Allen Poe said, "Those who dream by day are cognizant of many things that escape those who dream only by night."

This entry examines (1) creativity within the context of time, (2) what is deemed creative, (3) how creativity is utilized, and (4) some of those who have shaped our culture through their creativity.

Demystifying Creativity

The definition of creativity is often contingent upon the discipline, such as Art, Science, Business, but results in a product or an outcome that emerges from the creative process. For instance, through the process of generating questions and ideas that center on specific problems, many medical discoveries have emerged to prevent or cure diseases.

Besides referencing creativity as innovative ideas that emerge through the creative process across disciplines, creativity or creative expression encompasses a state of being or frame of mind. When the focus is upon a mission or an unsolved puzzle, a positive attitude and positive thinking motivate the individual to be productive, and within an organizational context it promotes a sense of belonging. That sense of belonging or ownership, as well an enthusiastic interest in common goals, boosts creativity. Simply put, creativity involves emotion.

With regard to creativity and emotion, Lee Humphries's work illustrates the relevance of passion and optimism. Originally trained as a musician, Humphries extended his expertise to systems theory, mathematics, linguistics, and cognitive science. Although he focused on problem solving in a traditional sense, more importantly, he expressed that the impetus for the flow of ideas is emotionally driven. According to Humphries, some of the most excellent creations emerge when the design, meant to improve the quality of life for one person, is more far-reaching and benefits the masses. However, if the initial goal of the creation is to benefit society, it is important to note here that this quest by no means negates the importance of a creation that is individualistically driven. Again, every aspect of creativity is important, whether the creation is intended to address a personal or a societal need. Emotional landmarks such as an illness, death of a loved one, divorce, or the birth of a child can serve as a catalyst for creativity. Indeed, personal pain is known to deliver some of our finest work. In the final analysis, emotions drive creativity and personal needs provide pathways to meeting needs for the greater good. In short, as Humphries asserts, the excellence of a creation is not measured by what the creation is, or for whom it is intended, but rather by the extent to which its benefits serve the "we" as opposed to the "I." Equally important, the creator receives a sense of accomplishment and camaraderie when, out of pain and suffering, the creation that was meant to entertain somehow serves humankind beyond expectation. In conclusion, emotions trigger creativity and the creator experiences a deeper sense of accomplishment when the creation does more than what was initially intended.

The Magnitude of Creativity: Artistic and Scientific Creativity

Generally speaking, one may not be able to anticipate the importance of a creation, especially when it transpires in the form of art. As an illustration, the depth of importance of a song may not be realized until it is tied to a message of hope, triumph, and survival after experiencing a personal loss. That is to say, music has the potential to have a positive impact upon an individual's emotional health similar to the ways in which a medical breakthrough offers hope of surviving a seemingly terminal illness. In general, creative activity has the power to nurture resiliency for both the creator and the recipient. Potentially, both artistic and scientific creativity play an important role in attitude adjustments. In this regard, music has the capacity to encourage optimism and one's ability to look beyond a difficult situation to see the beauty of the experience. For example, creative thinkers who use art and laughter as therapy focus less on pain and more on gain. As a designer, the creative thinker is challenged by obstacles and welcomes the subsequent lessons learned. Whether the emotional boost occurs from art or science, in this sense, one cannot determine the magnitude of either artistic creativity or scientific creativity when the question of importance becomes apparent.

The psychologist Dean Keith Simonton asserts that, rather than privileging one type of creativity over another, the process that involves scientific creativity is different from artistic creativity. The creative process for the scientist is more regimented. In this manner, creativity is detached from everyday experiences or from the emotions that fuel artistic creativity. On the other hand, the artist operates under fewer constraints and the creative process is fueled by lived realities, thus expressing the feelings of a broader audience. Simply stated, the artist experiences more freedom. It is essential for the artist to have freedom to tap into the natural flow of emotions and ideas in order to fuel the imagination.

If the creative process for the artist is all-encompassing, it has been argued that the creative process for the scientist is compartmentalized. In any event, the magnitude of creativity is immeasurable, as is the magnitude of the types of creativity (basket weaving, computer technology, theology, etc.) that may be generated. Perhaps what is important is that there are different creative outcomes and, conceivably, one must turn from the creator to the recipient to determine the value.

When a creation is shared, whether artistic or scientific in nature, it takes on energy of its own. Accordingly, the potential to meet the needs of others besides the creator is exponential. In the final analysis, it is important to value and trust the ideas that unfold from the human mind and to appreciate scientific discoveries, technological advances, and cultural contributions.

The most highly creative people, as noted by Pamela Braverman Schmidt, are said to have heightened reactions to their surroundings. In other words, they possess a keen sensibility that allows them freedom to draw from nature and to transform elements of light, darkness, and beauty into representational works of art. This keen sensibility to one's environment crystallizes one's sense of identity and promotes a sense of accomplishment. Hence, creativity feeds the human spirit. It provides an avenue to having an impact on social conditions when it is viewed as a vehicle to improve upon the quality of life. Creativity is at the heart of those novel experiences that are inherently unorthodox, and unique individuals are at the heart of capturing creative flashes from the imagination. At some point or another, all human beings are creators. Therefore, all human beings possess creativity, the magnitude of which is immeasurable.

Creative Genius: Theoretical Frameworks of Creativity and Intelligence

Consider the concept of "genius." Simonton views creative genius in terms of reputation; that is, how well known creators are for their work. If creativity is truly "something" that all human beings possess, it is important to examine it from a theoretical framework. Darwin's theory on evolution has proven useful in examining creativity or what comprises creative genius. His theory provides a framework of how cultures survive, namely, the coexistence of mental and material phenomena. How humans manage the social world is contingent upon human thought, as in creativity.

In reference to creativity, the primary focus of Darwinian theory is the degree of transferable variations. Therefore, when creativity is defined as the ability to generate variations of an idea or a creation, the pool of creative genius expands. Although some individuals are considered to be a "one-hit wonder," sometimes that one "hit" or creation earns fame for the creator due to the extent of creative versatility that the creation carries. Moreover, creativity is linked to every form of human endeavor. That is to say, creativity is the ability to transform nothing into something and something into something more. To this end, every human being is engaged in the creative process at some point or another.

Psychologist Howard Gardner views creativity as phenomenological. He explains creativity as divergent thinking (e.g., brainstorming and elaboration) and intelligence as convergent thinking (i.e., more analytic and evaluative). When creativity is viewed from multiple levels such as spiritually, socially, economically, or intellectually, Gardner's working theory on multiple intelligences (MI) provides yet another theoretical framework with which to view creativity. Although the word *intelligence* is used to explain a process of how individuals learn or process information, Gardner's eighth MI, naturalistic intelligence, provides understanding of an individual who is aware of how nature impacts human existence as we know it. In other words, the naturalist understands how to interpret the patterns in nature (e.g., planting, harvesting, and conserving), as well as being able to extract cures for human ailments from nature.

Gardner's most recent intelligence concerns existentialism. Existentialism entertains fundamental questions that center on human existence, the meaning of life, spirituality, universal truths, and cosmology. Although questions concerning life, death, and the existence of other life forms elsewhere in outer space are now common, existentialism as intelligence could be controversial because it hinges on nontraditional ways to view the world. At this time, existentialism is yet to be included in Gardner's list of multiple intelligences. Nevertheless, the existentialist offers unconventional ways of examining creativity. In other words, creativity unlocks the door to questions that focus on how human nature interacts with Mother Nature, Father Time, and the unknown.

In addition, creativity does not always refer to original creations or authenticity. Creativity is the ability to come up with multiple associations or uses for an existing creation and make use of it beyond what was originally intended (e.g., a paperclip becomes a key). Whereas art and creativity have been closely linked, intelligence and creativity have been thought to be one and the same. Similar to defining creativity, how to define intelligence is just as expansive in its interpretations. Philosophically speaking, one might agree that intelligence and creativity are interdependent processes because it is essential that the individual possess a level of intelligence in order to be creative. Yet ways in which one may view creativity could possibly place a different spin on intelligence. The most creative people may not be thought of as the most intelligent people. For instance, a political figure may be perceived as being "highly" intelligent as opposed to being regarded as creative or vice versa. Due to the spirit of the concept of creativity, the word *genius* partners most often with intelligence. If one examines the genius of Charles Darwin or Albert Einstein, one might develop a deeper respect for creativity and how intelligence impacts humanity.

Although societal views reflect that "highly" intelligent people are creative, Roger L. Firestien argues that all human beings possess creativity and that creativity exists in every aspect of human thought. Case in point: Intelligence is not an indication of creativity as in "highly" intelligent. For example, Charles Darwin's self-assessment informs us that he considered himself a slow learner as compared to his younger sister. Further, his teachers viewed him as ordinary. Yet according to Dean Keith Simonton, Darwin's genius has become an eponym or household word that represents discovery.

Darwin's eponymic status emanates from his theory of evolution, thus Darwinism and Darwinian theory are still referred to and discussed as a basis for understanding not only biological evolution, but cultural evolution. Although creativity and intelligence are linked, one cannot measure one's intelligence based upon one's level of creativity. Gardner, for example, looks at how individuals are intelligent or "smart." To further this point, creativity or how individuals demonstrate or exhibit their creative nature may serve to determine how they are intelligent or gifted. However, creativity and intelligence are not the same. According to psychologist Joy P. Guilford's research, an individual may be far more creative than intelligent or vice versa. In brief, individuals express creativity in various ways. For example, the Dalai Lama demonstrates creativity in how he expresses his views on peace and peaceful coexistence between humankind and nature, whereas Luther Vandross demonstrates his creativity in more traditional ways through music and lyric. Nonetheless, both ways are essential in that creativity enhances the thinking process and promotes balance in one's thinking and behaviors. Creativity spawns neutral spaces where differing perspectives can meet. All things considered, in order to differentiate between creativity and intelligence and for the purpose of this work, I view intelligence as the process of acquiring knowledge, and creativity as the process of transforming that knowledge into something that is functional.

Creativity and Social Acceptance

As previously established, the relationship between creativity and time is not always reciprocal. Beyond that, other friendly and unfriendly relationships occur; for instance, creativity and social acceptance. Without a doubt, creativity has been suppressed or supported based on social acceptance or public opinion. In some cases, new ideas are sometimes regarded with suspicion, particularly when these creative expressions challenge the status quo or the ideas appear to be too futuristic. Accordingly, creative thinkers have themselves suffered ostracism and even banishment. Thus, creativity can be very political. Furthermore, the freedom to engage in creative expression can be regarded as a privilege, especially when the creator is subject to social constructions of, but not limited to, race, class, and gender. Hence, the fate of the creator depends heavily upon public acceptance.

To illustrate how politics impact creativity, the musical career of Igor Stravinsky is a prime example. Historically, musicians and composers have struggled to gain respect for their craft. In the early 20th century, when scientific pursuits and technological innovations were accorded greater prestige than the arts, Stravinsky invigorated music by reinventing the image of the musician as a skilled professional requiring the dexterity of a carpenter and the expertise of a jeweler. Such expertise resulted in a proficient manipulation of pitch and rhythms to produce variations of sound referred to as music. Stravinsky himself became recognized as a master of his craft.

With respect to creativity and social acceptance, gender imposes tension upon women creators. Hildegard Von Bingen (1098–1179), also known as the "Sybil of the Rhine," is an extraordinary study. She exemplifies creativity and spiritualism. Hildegard achieved remarkable status as an intellectual, an artist, a healer, and a theologian during a time when women were seldom valued for their opinions, let alone for their creativity. To be more precise, Hildegard achieved respect for her musical compositions, poetry, and spiritual interpretations. She made extraordinary achievements in a time when creative expression was afforded mostly to men. Some of her artistic expressions are: *Scivias* (Know the Ways of the Lord), *Liber vitae meritorum* (Book of Life's Merits) and *Liber divinorum operum* (Book of Divine Works), and *Physica* and *Causae et Curae*. Although she was not a physician, she had natural abilities to obtain healing properties from nature. Perhaps her religious path and her spiritual credentials allowed her to leave a legacy of important work that, in addition, greatly influences naturopathic professions.

As was the case with Veronica Franco (1546–1591), whose gender and class were primary in her struggle to become a respected literary figure. Although she was educated, advancing as a creative thinker was not easy in a time when women's voices were silenced by a patriarchal system. As well, her profession as a courtesan interfered with her progress in gaining social acceptance. However, Franco's creativity redefined women, not only those in the writing profession, but to a certain extent, women in general. Rather than drawing from antithetical representations of women, Franco advanced an ideology that positioned women as moral agents. As a courtesan, she took advantage of the relative freedom afforded her by virtue of her profession to participate in intellectual milieus and civic projects. To her literary credit, Veronica Franco published poetry and selected letters (*Terze rime* and *Lettere familiari a diversi*).

Concerning gender and class, Veronica Franco's life illustrates unfriendly relationships between creativity and social acceptance. Frances Ellen Watkins Harper's life, however, makes clear how creativity and social acceptance were shaped by race, class, and gender. Watkins Harper, though not a slave or born of slave parentage, was subjected to laws that governed slaves. Here, the effects of a divisive institution that advanced the enslavement of the personhood of men and women of African descent helps us to see how creativity and social acceptance were at odds. As previously stated, creativity is an important aspect of human activities. Watkins Harper used creativity to address social problems. She lectured and focused her literary work on antislavery and temperance issues (Christian principles for black women). Much like spiritual credentials for Hildegard, temperance work within the context of Christian liberation provided a space where creativity and social acceptance could become friendly acquaintances for Watkins Harper. During her era, social acceptance and creativity in the face of race, class, and gender oppression were not easy accomplishments. To her credit, Frances Ellen Watkins Harper published her poetry in 1854. *Forest Leaves, Eliza Harris Crossing the River on the Ice, To the Union Savers of Cleveland* (a piece about a young slave girl), and a host of papers and letters are examples of her work.

Zora Neale Hurston did not gain recognition for her creativity. However, her creativity was encouraged by her mother, Lucy Hurston. Although

Zora did not live during the period of American slavery, acceptance for her artistic abilities was disadvantaged by race, gender, and class bias. As well, her career was suppressed by literary themes that depicted people of African descent as victims. Public opinion also had a negative impact upon the finances of many artists. Although financial dependency weighed heavily upon Zora, her creative spirit rose to document black life with characters that fed imaginations across cultural boundaries. Zora Neale Hurston did not receive full recognition for her creativity during her lifetime. She left a humanizing genre of folklore, poetry, novels, plays, and her autobiography in spite of her intellectual lynching. Some of her most popular pieces are: *Dust Tracks; Their Eyes Were watching God; Mules and Me; Tell My Horse; How It Feels to Be Colored Me; Moses, Man of the Mountain;* and *Jonah's Gourd Vine*. Through the work of Zora Neale Hurston and a host of other artists, creative expressions grace our lives in spite of barriers such as social acceptance and time constraints.

The Potential Within Time: The Creators

Over time, humankind has made great strides in the awareness of the potential to be creators. Although creativity and time are inextricably linked, these terms do not overlap in meaning. Also, it is the prevailing ideas at the time along with culture that determines what is deemed creative. Again, Simonton speaks of scientific creativity as being different in structure compared to artistic creativity. In addition, the nature of creativity varies based on the motivation for the creative process, as in creative problem solving or the ways in which an individual disseminates knowledge. Creative thinkers are multifaceted, and creativity therefore manifests itself in many ways.

With each creative thinker comes an evolution of how humans view themselves and experience the world around them. Creativity has launched the unthinkable, as well as unleashed ideas from imaginative spaces that have improved the quality of life over time. A glimpse into the minds of creative thinkers provides a common thread: how humankind has come to be. Charles Darwin provided questions and answers concerning the meaning of life such that other philosophers, scientists, and social scientists continue to use his work to distinguish between science and spirituality.

Pierre Teilhard de Chardin, philosopher and scientist, presented what some might feel were conflicting ideas with respect to God and the universe (i.e., Catholic doctrine and evolutionary theory). Hence, some believe that God is misplaced or displaced when science is used to explain the "always was and always will be." In terms of creativity, Teilhard de Chardin's perspectives placed him in opposition to the church, and he was excommunicated. However, Teilhard de Chardin's work exemplifies the synthesis of theological, philosophical, and scientific thought that provides yet another way of understanding human creativity.

The philosopher Henri Bergson was also fascinated with the intellectual form of human thought. He explained human reality through biology, astronomy, and environmental adaptation. He viewed the life process as a plan of renewed creativity. As Arthur Mitchell put it, species survival is based upon changing the imposed conditions of existence. Alfred North Whitehead, a 20th-century British philosopher, viewed science as a way to explain modes of human perception of what is (e.g., sounds and shapes) and how lived realities are shaped. He spoke of two modes of perception: presentational immediacy and causal efficacy. Presentational immediacy is represented by symbols that are cultural in that they provide a deeper understanding of shared realities. On the other hand, causal efficacy refers to human emotions. Here, humans become aware of what has an effect on the human psyche. In this way we come to understand that creativity is dependent on the time that one is willing to invest to become creative. The physicist Albert Einstein devoted his entire life to creative thought; his revolutionary ideas on gravity, space, and time continue to influence our views of intelligence and creativity, and his theories still stand as a challenge to future thinkers and creators.

Cretaceous

In geological time, the Cretaceous (from Latin *creta* meaning "chalk") is the third and last period of the Mesozoic era; it follows the Jurassic period and precedes the Paleogene. The Cretaceous extended from 145 to 65 million years ago, and it presents 12 globally recognized subdivisions (ages): Berriasian, Valanginian, Hauterivian, Barremian, Aptian, and Albian (Lower Cretaceous); and Cenomanian, Turonian, Coniacian, Santonian, Campanian, and Maastrichtian (Upper Cretaceous). The beginning of the Cretaceous is not marked by a significant mass extinction event and, by international consensus, is located coinciding with the lowest occurrence of the ammonite *Berriasella jacobi* in the fossil record. The end of the Cretaceous (also called the K-T boundary) is marked by the mineralogical and geochemical anomalies related to the impact of the Chicxulub bolide, and with the Cretaceous–Paleogene catastrophic mass extinction event.

The Cretaceous period differed from our present world in several major respects: It was a much warmer world with high oceanic volcanic activity and sea levels higher than those of today. Moreover, there were complex biological continental and marine communities dominated by large reptiles such as the dinosaurs.

Continental Breakup

By the beginning of the Cretaceous, the old supercontinent Pangea divided into two large continents: the northern Laurasia (including present-day North America, Europe, and Asia), and the southern Gondwana (including present-day South America, Africa, Antarctica, Australia, and India-Madagascar). They were separated by an east–west equatorial seaway known as the Tethys Ocean. During the Cretaceous, there was a second phase of continental breakup. In Laurasia, the drifting of the continents caused the separation between North America and Europe and the birth of the North Atlantic Ocean. Moreover, Gondwana began to break into four large pieces: South America, Antarctica-Australia, Africa, and India-Madagascar. The progressive drifting of these continents opened the South Atlantic and Indian oceans. These plate tectonic movements during the Cretaceous were concurrent with a period of unusual seafloor spreading. For example, the volume of mid-oceanic crust produced in the Aptian-Campanian interval was almost three times greater than in the Jurassic or Paleocene periods. The high oceanic volcanic activity caused flooding of the continents, especially around the Cenomanian–Turonian when the sea level was about 200 meters higher than at present, and one third of present-day Earth's land area was submerged. During that time, Europe was an archipelago.

Climate Change

The abundant emission of volcanic greenhouse gases (mainly carbon dioxide) into the atmosphere-ocean system caused a global warming during the middle part of the Cretaceous, about 120 to 80 million years ago. This interval is considered an example of ice-free greenhouse climate conditions. Fossil records suggest a gentler latitudinal temperature gradient becoming the high-latitude climate that was one of the warmest in the earth's history. For example, Upper Cretaceous dinosaurs and palm trees were present in the Arctic Polar Circle, in Antarctica, and in southern Australia; Cenomanian breadfruits flourished in Greenland; and crocodiles and turtles inhabited the Turonian–Coniacian Canadian Arctic. Although there is evidence of some cooler episodes in the Lower Cretaceous, geological and geochemical data support that the global annual mean temperature during the Cretaceous was 6°C to 14°C higher than at present.

The absence of high-latitude ice caps during most of the Cretaceous contributed to the maintenance of considerably higher sea levels, forming numerous Tethyan shallow seaways in southern Laurasia platforms. Warm waters coming from the Tethys were transported northward, warming the polar regions. In contrast to what occurs at present, oceanic circulation during the Cretaceous was driven mostly by warm, saline deep water derived from low-latitude areas with high evaporation. The locus of deepwater formation was not the cold polar waters, which occupy the deep ocean at present, but the warm Tethyan waters. These conditions were favorable for the development of the well-known oceanic anoxic events (OAEs) that occur only during short intervals of very warm climate that is characterized by high levels of carbon dioxide. OAEs stratigraphic records consist of widespread, episodic deposits of organic-rich shales in the ocean basins. The characteristic anomalous accumulation of organic matter in these rocks corresponds to conditions of low levels of dissolved oxygen (anoxia), high biological productivity (atmospheric carbon dioxide led to increased weathering of the continents and greater delivery and availability of nutrients in the marine realm), and poorly oxygenated deep water. It is thought that mid-Cretaceous OAEs were the result of an excess of carbon dioxide in the atmosphere-hydrosphere system from volcanic eruptions, and of the alteration of deepwater circulation patterns.

Effects on the Biosphere

Tectonic forcing of climate and ocean fertility had a profound impact on terrestrial and marine ecosystems and on the evolution of life during the Cretaceous. The breakup of the Laurasia and Gondwana supercontinents led to increased regional differences in flora and fauna between the resultant continents. The mild climatic conditions favored the development of ectothermic animals like reptiles, amphibians, or fish, whose internal body temperature is the same as the temperature of their surroundings. Dinosaurs are generally reckoned to have been the dominant terrestrial vertebrates from the Upper Triassic through the K-T boundary. Some Cretaceous dinosaurs are popularly known, including *Tyrannosaurus, Triceratops,* and *Velociraptor.* The large sauropods (quadrupedal herbivorous dinosaurs) that had dominated in the Jurassic period declined during the Cretaceous, being replaced in importance by the iguanodontids, such as *Iguanodon.* Pterosaurs were common for most of the Cretaceous, though not in the last millions of years due to ecological competition with new types of birds. During the Cretaceous, giant crocodile and new insect and mammal groups appear, as well as the first flowering plants (angiosperms).

Mild climatic conditions and the existence of extended shallow tropical seas strongly affected the evolution of marine communities. Plesiosaurs, mosasaurs, and other marine reptiles coexisted with rays, sharks, groups of modern fishes, and with ammonites and belemnite cephalopods. Rudist and inoceramid bivalves, echinoderms, and benthic foraminifera were abundant in the bottoms of the Cretaceous seas. Floating at the sea surface, microorganisms with calcareous test, such as coccolithophores or planktic foraminifera, were ubiquitous. The gradual accumulation of the minute calcite plates and test on the sea bottom formed a large quantity of chalk, a soft, white, porous sedimentary rock that is very abundant in the Cretaceous.

Growing interest in the Cretaceous climate is largely a product of the current concern over modern human-induced global warming. Studying the complex Cretaceous world offers a good opportunity to understand and appreciate how the biosphere responds to climate change in terms of migration, extinction, adaptation, diversification, and organic evolution.

Critical Period Hypothesis

The critical period hypothesis states that there is a specific and limited time for language acquisition. More specifically, this hypothesis states that the first few years of a child's life is the critical time in which an individual can acquire language if presented with adequate stimuli. Proponents of the hypothesis argue that if a child does not receive the appropriate stimuli during this "critical period," then the individual will never achieve full command of language. In other words, once a child passes a certain age without language acquisition, it is not possible to learn language at a later age.

The scientific focus on a critical time for language acquisition began in the late 1950s when neurologist Wilder Penfield discussed language acquisition from a physiological perspective. Penfield pointed to the superiority for learning language demonstrated by young children. He argued that children learn language easily before the age of 9; however, after the age of 9, learning language becomes difficult. Penfield claimed that the reason for this change in the ability to learn language was due to the plasticity of the human brain. The brain of the child is plastic, whereas the adult brain is rigid.

In 1967, linguist Eric Lenneberg further advanced the idea of a critical period for learning language in his classic work, *Biological Foundations of Language.* Like Penfield, Lenneberg asserted that the acquisition of language, like other biological functions, was successful only when it was stimulated at the right time and in a linguistically stimulating environment. Drawing on evidence from studies of brain growth and from clinical studies of deafness, mental retardation, and brain damage, Lenneberg claimed that there are age constraints on language acquisition caused by brain maturation. He maintained that the critical period for language learning occurs between the ages of 2 and puberty, with the crucial period occurring between 4 and 5 years of age. Lenneberg argued that before the age of 2 the brain has not developed the capacities it needs for learning language. He maintained that after puberty the brain's lateralization shuts down the brain's ability to acquire language. Therefore, if an individual did not learn language within the critical period, the individual would never be able to acquire language in any normal sense.

More recently, in 1994, psychologist and cognitive scientist Steven Pinker similarly claimed a critical time period for language acquisition by stating that language is instinctual. Language, Pinker asserted, is a biological adaptation rather than a cultural creation. He asserted that the brain contains innate means of creating an endless number of grammatical sentences from a limited vocabulary. Pinker held that the acquisition of normal language would occur for children up to 6 years of age when properly stimulated. He asserted that, after 6 years of age, the possibility of normal language acquisition declines and is rarely successful after puberty.

What evidence exists to support the critical period hypothesis? A basic limitation of the critical period hypothesis is that testing this theory, using traditional scientific methodology, is unethical. Scientists cannot intentionally isolate a child from the rest of the world for several years and then assess the effects of such isolation on language acquisition. Therefore, scientists have documented evidence of the critical period hypothesis mainly from abused and feral children who grow up deprived of exposure to language in childhood and who, consequently, do not acquire language normally. The most famous example used to demonstrate evidence of this hypothesis is the case of Genie, a pseudonym for a girl discovered in 1974, at the age of 13, strapped to a potty chair and wearing diapers. Genie had little linguistic ability and, over several years of rehabilitation, was unable to acquire language completely, although researchers involved in Genie's rehabilitation disagreed on the degree to which she acquired the normal use of language.

Critics of the critical period hypothesis point to the use of examples of abused children and feral children as the central limitation of empirical evidence for this hypothesis. They argue that the lack of language in later life may be due to deprived and extreme social and physical environments that cause neurological changes in the brain, rather than specifically to the lack of exposure to language. In addition, behavioral approaches challenge the biological view of language acquisition and maintain that individuals learn language like any other behavior, through positive reinforcement. Therefore, they argue, it is possible to gain new skills, including learning language, at any age.

Researchers have extended the study of the critical period hypothesis to deaf children learning American Sign Language (ASL) and older learners of a second language. For deaf children learning ASL, there is evidence that language learning ability declines with age, but there is no sudden drop off at puberty. Children exposed to ASL at birth become the best at learning the language. Research examining older learners of a second language consistently indicates that most individuals are able to learn a second language when they are well into adulthood. However, there is a continuous decline in the ease of learning a second language with age. Researchers have found that learning a second language from mere exposure to the language declines after puberty. Therefore, in the adult years, the individual wanting to learn a second language has to spend much time and focused effort studying the language. Moreover, research indicates that adult second language learners nearly always retain an identifiable foreign accent that children as second-language learners do not display.

Critical Reflection and Time

Anthropology, biology, geology, and physics evolved a compilation of theories and related methodologies born from the critical reflection and creative deliberation of some of history's most brilliant minds. Yet, theories from evolution to relativity did not emerge spontaneously. Their named progenitors needed a key ingredient to assist in their ideas' long germination. That key ingredient is time.

Giordano Bruno (1548–1600)

Infinite space and eternal time were Bruno's great visions; as departures from the orthodoxy of his time, these visions ultimately cost him his life. Trained in theology as a monk, Bruno held vast knowledge, which he vigorously added to, likely until the day of his execution for heresy. Between years of nomadic existence and offering public and academic lectures, Bruno reflected on and perceived fallacies in the universal understandings of his day. Staying a step ahead of the authorities who sought his arrest for heretical beliefs, Bruno found reflection inspiring and vehemently defended his philosophical discoveries, even under severe duress. While his collected knowledge, through self-education, armed the philosopher with insight, it was undoubtedly his time in solitary reflection that brought about his comprehension of and belief in a universe of eternal time without end.

Baruch de Spinoza (1632–1677)

Spinoza reasoned that every occurrence, physical or mental, was integral to a larger, sustaining entity that he equated interchangeably with God and Nature. Such a profound perspective, however, was not attained overnight. Spinoza spent much of his adolescence and adulthood investigating new technological advances while simultaneously weighing and considering the philosophical theses of his contemporaries and of earlier philosophers. Ultimately, Spinoza arrived at the aforementioned ideas, as well as a critical geometrical methodology, well in advance of the prevailing thought of his time. Yet, it was not the role of a teacher or wealth through inheritance that provided Spinoza the opportunity to reflect on others' discoveries and discourses. For most of his adult life in the city of Amsterdam, Spinoza pursued the trade of crafting and cleaning glass lenses, a career that provided the philosopher not only with the means to survive, but also the time to reflect on all that he had encountered.

Charles Darwin (1809–1882) and Alfred Russel Wallace (1823–1913)

Evolutionary theory, as proposed by Darwin and Wallace, revolutionized science in general and the understanding of biological development throughout time in particular. Darwin certainly received more recognition than Wallace did for the theory of natural selection and held different perspectives on issues, including the placement of Indigenous peoples within the framework of evolution. Yet, both naturalists spent considerable time reflecting on their observations of biological specimens before proposing their ideas about organic evolution. Darwin's legendary voyage on HMS *Beagle,* particularly its visit to the Galapagos Islands (1835), and Wallace's excursions into South America and Indonesia, provided each with a wide array of species to observe and study over extended periods of time. With both of them guided by the research of contemporary geologists and paleontologists, they separately developed ideas about evolution, taking years to reflect on their experiences before publishing their findings and conclusions. For Darwin and Wallace, time for critically reflecting on the diverse environments and multiple species they encountered provided the impetus for the eventual generation of the idea of natural selection. One has to wonder where our understanding of evolution would be had each quickly published his notes, as opposed to taking time to reflect on them.

Alfred North Whitehead (1861–1947)

Whitehead's life represents the epitome of critical and creative reflection. With a broad array of interests, especially process philosophy and relativity physics, he embraced life through the study of thought, time, and change. Ultimately, his experiences led him to perceive life as reflecting what individuals encounter and how they react to events. As with the great thinkers previously mentioned, Whitehead did not reach his cosmological conclusions as a youth. Rather, it was over a span of nearly 70 years and through multiple careers that he acquired his impressive understanding of time, change, and creativity.

Albert Einstein (1879–1955)

Einstein is arguably the most famous physicist of the 20th century. Through his own observations and collaborations with others, he ultimately influenced the world as few other scientists have. As a young man who often struggled to find employment or worked in less than optimal jobs, such as his work at the Bern patent office, Einstein used his time away from work to delve into physics and philosophy, consequently venturing off on his own intellectual path. Einstein's own view on the failure of his early conclusions substantiated his continued search for a universal physics as a result of rigorous reflection on scientific experiments and philosophical speculations. Today, Einstein's highly original theories of relativity are justifiably considered a major triumph of scientific thought and the very model of a solid contribution to theoretical physics. It is the time that Einstein reserved for critical reflection that ultimately enabled him to generate his greatest ideas.

Pierre Teilhard de Chardin (1881–1955)

Teilhard, a Jesuit priest who was also an avid scholar, is widely acknowledged for his contributions to geology and his advocacy for the theory of evolution. Unfortunately, Teilhard did not live to see the publication of his great works concerning evolution and his own thoughts on God. Yet, from even a cursory evaluation of Teilhard's efforts and writings, it is clear that his interests in the evolutionary sciences, his excursions to study the geologic formations of China (including the Zhoukoudian site), and his exposure to the tragic events of World War I, as well as his personal struggles to support the teaching of evolution, helped to shape his own thoughts over his lifetime. Teilhard's ultimate views on God and the place of humanity in a spiritual universe, evidenced in works including *The Phenomenon of Man* (1940) and *Man's Place in Nature: The Human Zoological Group* (1950), highlight his belief in an evolving universe. According to Teilhard, evolution will lead all humankind to an incomprehensible, mystical future existence, which he referred to as the Omega Point. Through careful observation of geological and biological processes, the comparison of remains of past and present human species, and after decades of reflection on what he had witnessed as a scientist and priest, Teilhard arrived at an unorthodox vision of the meaning and purpose of humankind within the process of evolution.

Cronus (Kronos)

In ancient Greek myth, Cronus (Κρόνος = Kronos) is the youngest brother of the titans and son of Uranus, the god of the sky, and Gaia, the goddess of the earth. In connection with Chronos, the personification of time, he plays an important role in time perception in ancient Greek myth. Later he was associated by the Romans with Saturn, god of the planets and of agriculture.

Cronus' father Uranus so hated his children that he banished them to Tartarus, below the earth. Consequently his wife Gaia gave birth to her children secretly. Eventually she put her son up to fight against his father. Cronus took a sickle, castrated Uranus, and threw the genitals into the sea. Aphrodite, the goddess of love, grew out of the sea's arising foam and was therefore called Aphrodite (the foam-born). Furies, giants, and nymphs emerged from Uranus's blood that dripped on the ground. Cronus liberated his brothers and sisters, and they proclaimed him their ruler. A prophecy told him that a fate similar to his father's would strike him. To prevent this prediction from coming true, he swallowed all children to which his wife Rhea gave birth, but she planned to deceive him to protect her son Zeus. She delivered Zeus in the secret place Lyktos and instead of the child, Rhea gave her husband a stone to eat, which was wrapped up in clothes. Zeus, successfully hidden by his mother, grew up, and when he was a young man, cunningly castrated his father, bound him, and forced him to spit out the swallowed children.

The further destiny of Cronus is unclear. According to Homer's opinion, Cronus once again sits in Tartarus; Hesiod, on the other hand, describes him as a friendly king of the dead heroes on the isle of the blessed at the edge of the universe. Under the supremacy of Cronus, the people were believed to have lived in happiness, without worries and fears. They did not have to work, ate wild fruits and honey, and did not age. As a result, this period is described as the Golden Age.

Cronus is usually represented as an old, weakly, grumpy, melancholic man with a sickle, which became a scythe in the Middle Ages, the attribute of death. However, this imagination of the god gained meaning only with the modern age. In connection with time, the sickle often gained other meanings, too. It could be an allusion to the castration of Uranus. It is also a symbol of time because the sickle is able to cut out and into something. But it could also refer to Cronus as the god of harvest. Although he was not worshipped like the other gods, once a year a kind of harvest celebration took place in his honor; it was called *Kronien.* Plutarch describes the celebration as cheerful and merry, and one in which social differences were abolished and servants also could feast.

Nevertheless, in ancient Greek representations, Cronus had no special characteristics. In the second part of the 5th century BCE he was described as a man of mature age with hair, a beard, and a coat that covered the back of the head. The Orphics saw Cronus as a dragon with the heads of bulls and lions on its hips.

Since antiquity, the titan and ruler Cronus was identified with the personification of time, chronos. According to some theories the similar spelling and pronunciation in Greek is the reason for the misidentification, because only the initial letters of the two words differ. For example in Cicero's writings you can find the equation of Cronus (Κρόνος) and Chronos (χρόνος). Associating Cronus and the word *time* continues to have consequences. Plutarch refers to this extension of meaning with reference to Cronus as the father of truth.

Chronos (χρόνος = Kronos) is the personification of time. In the Orphic theogony, Chronos/Cronus plays an important role. In some interpretations it is seen as a continuation of Hesiod's theogony, sometimes it is regarded as a parallel idea that reminds of the sovereignty of gods and grants him some special honors. In the old Orphic tradition, Chronos is missing, but he appears in Hellenistic time. There he emerges as the third original paradigm from water and mud and appears as a never-aging snake or dragon with heads of different animals. Only the rhapsodic theogony regards Chronos as a personification of time, which was not divine, as the beginning of the world. In this view he is a snake that has heads and wings on its shoulders. Chronos produced both the calm Aither and Chaos, which was seen as a high, dark room without any solid ground. He created a silver egg, from which hatched Phanes, who had four eyes, four horns, golden wings, bellowed like a bull and a lion, and was a hermaphrodite. As original god of the universe, Chronos was a symbol of development and change. In addition, Chronos was called father of truth, an allusion that might play with the idea that time brings everything to light.

In Roman religion, Cronus is equated with the god of planets, Saturn, who is also the god of agriculture.

Chronos as well as Cronus did not have a fixed place in the Greek mystery cults, so there are hardly any known rites, ritual acts, or mythological stories, and the meager information we do have is often contradictory or incoherent.

Nevertheless, this figure associated with time was absorbed by various forms of art. Paintings with illustrations of Chronos, Cronus, and Saturn were created by, for example, Vasari, Veronese, Blanchard, Rubens, Van Dyck, and Goya. They mostly focus on themes such as the castration and the swallowing of the children. In literature, the Cronus motif was used by Johann Wolfgang Friedrich Goethe in the poems *An Schwager Kronos* or *Kronos als Kunstrichter;* by Friedrich Hölderlin in the poem *Saturn und Jupiter;* and by Günter Grass in the poem *Saturn.* In fairytales like *Little Red Riding Hood* and *The Wolf and the Seven Little Goats,* the motif of swallowing and bringing somebody back is reflected, too. In music, works like Gioachino Rossini's *I Titani* and a libretto by Pietro Metastasios can be mentioned.

Cryonics

Cryonics comes from the Greek word *kryos,* meaning icy cold. Today, cryonics is the practice of lowering the body temperature of a person who is recently deceased or terminally ill to prevent the death and deterioration of living tissue. Even when a person is considered "clinically dead," a majority of the cells in the body are still alive. The hope is that by freezing either the head or the whole body, the cells that are still alive can be preserved for an extended period of time. Advocates believe that in the future, when the technology becomes available to cure diseases, the body can be restored to health. For some, cryonic suspension is considered a realistic and feasible way of overcoming death.

It was the book *The Prospect of Immortality* by Robert C. W. Ettinger that spread the idea of cryonic suspension of a human being in the United States. Published originally in 1964 and revised in 1966, the book described Ettinger's theories about life and death. In it, he states that "most of us now breathing have a good chance of physical life after death—a sober, scientific probability of revival and rejuvenation of our frozen bodies." He believed that even if the techniques of today for freezing are rudimentary and flawed, given enough time, "sooner or later our friends of the future should be equal to the task of reviving and curing us." In 1976, Ettinger helped establish and was subsequently elected president of Cryonics Institute in Clinton Township, Michigan. Known as the "father of cryonics," he remained president until 2003.

The process for preserving a body is begun as shortly after death as possible. This is to reduce further tissue deterioration. The water within the body is replaced by a cryoprotectant that, when cooled to very low temperatures, hardens like glass. This is necessary because if a cryoprotectant were not used, the cells would burst: When water freezes, it expands and forms ice crystals that would damage or kill all of the cells. This process of converting cells to a crystalline-free solid is called vitrification and is the backbone of the cryonic suspension procedure. Vitrification can also be seen in nature. Some animals, like the wood frog, can survive days or weeks with up to half of their body water frozen. The liver in these frogs produces glycerol, which lowers the freezing point and reduces ice crystal formation, causing the water to harden like glass. Patients are generally frozen using liquid nitrogen at a temperature of –196° C. Liquid nitrogen is used because it lowers the temperature in a very short time. One important effect is that when water is frozen very quickly, it does not have time to form ice crystals. This, in addition to the use of cryoprotectants, preserves as many cells as possible.

The reason why freezing a body, or any living tissue for that matter, preserves it is that lowering the temperature decreases metabolism. Metabolism is the conversion of nutrients into energy. Within normal physiological temperatures, the body breaks down nutrients to acquire energy and sustain life. As temperatures lower, metabolism slows because the chemical and enzymatic reactions that use up energy occur less rapidly. Many animals, such as the frogs mentioned earlier, can survive long periods without food as a result of decreased energy consumption. The practice of lowering metabolism is not limited to lower forms of life. The ability of the bear to survive throughout an entire winter without food is due to its low metabolism while hibernating.

The first person to be cryonically frozen with the intent of future resuscitation was Dr. James Bedford, on January 12, 1967. The 73-year-old psychology professor was frozen by scientists from the Cryonics Society of California. Using dimethyl sulfoxide (DMSO), a primitive cryoprotectant, his body was frozen first with dry ice and then transferred to liquid nitrogen. Of the 17 people preserved between 1967 and 1973, Dr. Bedford is the only one still being cryopreserved. In 1982, he was moved to the Alcor Life Extension Foundation in Scottsdale, Arizona, where he remains today. Alcor currently has 77 cryonically preserved patients. The Cryonics Institute in Michigan cares for 84 patients and an additional 50 pets.

The cryonics movement progressed slowly and was generally rejected and dismissed by the general public. Since cryonic suspension had little scientific credibility, most in the scientific community did not support it either. For some, however, the idea that a body could be preserved for thousands of years was very alluring. Through the 1980s and 1990s, scientific developments in the fields of molecular nanotechnology, computer science, and mathematics made great strides toward overcoming the biological obstacles of cryonic suspension. For example, advancements in cryoprotectants made them more effective and less toxic. A more precise understanding of organ preservation also changed the way in which the body is cooled after death. In addition to lowering the body temperature before transport to a cryonics facility, where it will then be frozen, the body's blood is first replaced with an organ-preserving solution. This solution is not a cryoprotectant. Its only purpose is to protect the organs from further cell death during transport. Prior to vitrification, it is replaced by a cryoprotectant at the cryonic facility. But for all the publicity and money spent on research, the successful freezing and thawing of a human being is not yet possible; it is the complicated thawing process that will take more time to perfect. Because the body is deceased when frozen, even if every living cell were to be resuscitated successfully, the body would still be "clinically dead."

Although the successful cryonic suspension and resuscitation of a human being is still very far off, it is not irrational to maintain that someday the technology will exist to repair any cellular damage in the body. If all obstacles are overcome with time, then the possibilities for human beings could be endless. Not only could humans live an indeterminate life span on Earth, but a cryonically suspended body could travel to places in the universe millions of light years away, and the trip would be seemingly instantaneous to the traveler.

Cryptozoology

Cryptozoology is the study of animals that are hypothesized to exist, but concrete physical evidence to prove their existence has not yet been found. These "unknown animals" could be either undiscovered species or living specimens of species thought to be extinct. The term is derived from the Greek, and means literally "the study of hidden animals." Individuals who study and search for these animals are referred to as cryptozoologists, and the elusive animals investigated are called cryptids.

The origin of the term cryptozoology is widely credited to Bernard Heuvelmans, a Belgian zoologist. However, in Heuvelmans's own book, *On the Track of Unknown Animals,* written in 1955, he credits Ivan Sanderson, a Scottish explorer, with coining the term in 1947 or 1948.

Cryptozoology is a combination of biology and anthropology. It relies heavily on eyewitness accounts and circumstantial evidence. Stories, legends, and local folklore attract cryptozoologists, who then expend most of their energy trying to establish the existence of a creature. Then a live specimen has to be found. Throughout history Western explorers have dismissed these tales as fantasy, only to be proven wrong years later. When first reported by natives, the giant squid, mountain gorilla, platypus, and panda, to name a few, were considered hoaxes by European explorers.

Most people have heard of the more extreme examples of cryptids. Bigfoot, the Loch Ness Monster, and the Yeti are familiar, but there are literally hundreds of species rumored to exist. Cryptozoology generally does not refer to newly discovered small organisms. New species of insects and frogs, for example, are not uncommon. They are not especially difficult to find, there is simply the time factor involved in cataloging them. Cryptozoology also does not refer to ghosts, UFOs, psychics, or anything paranormal. It is also not intended to describe out-of-place animals, such as exotic pets released into the wild by disenchanted owners.

Cryptozoology has acquired a bad reputation as a pseudoscience. Critical thinking and solid research are necessary when investigating claims of a new species. An individual who hunts for a sasquatch one month and a sea serpent the next may have little background in either. A primatologist or physical anthropologist studying evidence of a sasquatch would be more likely to synthesize and apply known data properly to new evidence. Likewise, scientists with a degree in marine biology would be better able to evaluate claims of sea serpents or lake monsters. Until detailed, methodical research becomes standard practice among cryptozoologists, the field will remain disrespected by more traditional biologists and zoologists.

CYBERTAXONOMY

Cyber-enabled taxonomy, or cybertaxonomy, represents a fusion of cyberinfrastructure and the goals of descriptive biological taxonomy. Taxonomy is the science of biological classification; its goal is to compare organisms in order to place them into groups based on defining characteristics. Cyberinfrastructure is a technological solution to obstacles that have slowed progress in descriptive taxonomy and is comprised of a foundation that provides speed and capacity for data analysis, storage, and communication, plus domain-specific hardware and software that meet the specific needs of taxonomy. Examples of domain-specific cyberinfrastructure include robotics, imaging technologies, instrumentation, and data acquisition, searching, and interpretation systems. Cybertaxonomy represents the future practice of taxonomy and promises to accelerate the processes of descriptive taxonomy without sacrifice of theoretical and procedural excellence. Virtually every aspect of descriptive taxonomy from collection, preparation, and curation of specimens to electronic publication of revisions and monographs can be improved or transformed through cybertaxonomy.

Most of the impediments to rapid advances in taxonomy have to do with issues of access: access to specimens, historic literature, existing data, and colleagues around the world. Cybertaxonomy has the potential to open access to research resources required by practicing taxonomists as well as opening their research findings to a wide range of user communities. The traditionally high standards of taxonomic research are evident in taxonomic revisions or monographs, comprehensive comparative studies of all previously described species with the addition of all newly discovered species. Due to such comprehensive studies of thousands of specimens, at most only a few monographs are completed per century for any given taxon. Consequently, a perception exists that descriptive taxonomy is inherently slow and inefficient. This is not so. Such comparative studies are in fact highly efficient means for testing large numbers of hypotheses about species simultaneously. The vision of cybertaxonomy is to compress this time of hypothesis testing by making monographs living, dynamic electronic entities that are continually updated as new specimens and characters are found. Another aspect of cybertaxonomy involves teamwork, using cyberinfrastructure to enable colleagues in several countries to collaborate by examining specimens together and consulting in real time, thereby accelerating the discovery and testing of species. Thus cyber-enabled knowledge communities would arise that are focused on particular taxa and that collaboratively manage and update all information associated with species of a given taxon.

Rudimentary examples of cybertaxonomy exist, including virtual libraries and herbaria, online monographs, remotely controlled microscopes, and access to specimen and collection databases. Cybertaxonomy, in time, will reduce the need to loan or handle specimens as well as the time and effort required to access historic literature and data from other institutions. Online monographs reduce the cost of collaborative projects and increase the visibility of taxonomic revisions or discoveries. The demands of cybertaxonomy are underpinned by innovations in digital imaging, visualization software, databases, the development of data models since the mid 1990s, and, more recently, robotics. Cybertaxonomy is dependent on emerging technologies and online communication tools rather more than on physical access to museum collections, libraries, and collecting sites. The future merger of cyberinfrastructure with goals of traditional taxonomy will increase the visibility of museum collections and vastly accelerate the work of descriptive taxonomists, making taxonomic information both openly accessible and understandable to the many users who need it.

Why Cybertaxonomy?

The current biodiversity crisis has resulted in a demand for stable classifications and reliable specimen identification. Traditional taxonomy, underfunded during the 1990s and 2000s in part due to an overemphasis on technological "solutions" to the practical problems of identifying species and assessing their cladistic (phylogenetic) relationships, has not produced the number of descriptions and revised classifications needed in order to satisfy the demand of end users, such as ecologists, policymakers, conservationists, agriculturists, foresters, and fisheries managers. The demands of end users as well as taxonomists themselves have led to the creation of hundreds of databases that reflect information content associated with specimens, many accessible through the Global Biodiversity Information Facility (GBIF) portal, growing support for a registry of animal names, scanning legacy literature, and creating a Web page for every known species. A typical specimen database minimally includes the species name, reference to higher taxa, collection locality and geographic coordinates, date of collection, name of collector, method of collection, and the name of the institution and a unique identification number. The pace at which taxonomic classifications are revised and published has slowed due to the amount of effort invested in databases and technology outweighing the number of adequate taxonomists. This imbalance has led to new initiatives in data storage, such as combined databases, library catalogs, digitized bibliographies, and image databases. Even so, a large majority of these projects do not provide taxonomists with ways to access specimens or efficiently "truth" and improve the data. Alternative technologies aimed at end users of taxonomic information are intended to provide ways with which to identify and classify species quickly without the need for traditional taxonomic methods. These technologies have put a greater burden on taxonomy, contributing to poor funding and employment opportunities. Ironically, such databases are accelerating access to information that is less frequently updated and verified than in the past.

Previous efforts to revitalize taxonomy have focused on user communities in the hope that they would step up to the challenge and do their particular part to revive species discovery, description, and testing. The high cost of emerging technologies and the lack of access to collections have prevented many user groups from revitalizing taxonomy in a way that preserves the integrity of its best theories and practices. Cheaper technologies such as online descriptive keys and DNA bar coding are being adopted by user communities as ways to mimic reliable identifications and classifications. Data associated with specimens are accessed efficiently at the same time that the testing and enhancement of the information content of those collections are ignored. User-driven initiatives tend to focus on species identification and access to existing publications and data rather than acknowledging the significant work required to create, update, and verify the status of species and the reliability of associated data. As technologies rather than theory-dependent methodologies, such approaches ultimately fail to describe, classify, and identify taxa reliably. Their use in taxonomy is highly questionable and detracts from the important scientific questions associated with taxonomy as an independent science. DNA bar coding, for example, appears to be limited as an identification tool and is potentially misleading as a species discovery tool. Its appropriate application requires the prior discovery and delimitation of species and the creation of a complete reference "library" in order to approach the reliability of traditional species identification methods. The debate surrounding end user needs versus the needs of taxonomists has generated controversy in the scientific media. Many have called for an end to the "taxonomic impediment" through quick identifications, while others have highlighted the demise of taxonomic training and funding. The taxonomic impediment entails a lack of awareness of the importance of reliable descriptions, robust classifications, and effective identifications and the continuing need to train taxonomists as well as provide opportunities for funding and employment of taxonomists, and the improvement of taxonomy's research infrastructure.

Ironically, calls to resolve the taxonomic impediment include adopting inferior alternatives rather than increased taxonomic funding, further fueling the debate between technology-driven expediencies and rigorous taxonomy. The development of cybertaxonomy is not intended only to meet end user demand, but primarily to serve taxonomy and increase the opportunities for taxonomists. Through enabling taxonomic research at the highest levels of quality and efficiency, end users will gain access to the most reliable information possible, which is presumably what all end users would choose. And taxonomists will be positioned to pursue the "big questions" of their field that remain unanswered and that are fundamental to understanding Earth's biological diversity.

Taxonomy in Practice

Taxonomy, as noted earlier, is the science of biological classification; the goal of taxonomy is to compare organisms in order to place them into groups based on defining characteristics. These groups may be artificial, for example based on one arbitrary character system; or natural, based on shared or common relationships. Artificial groups are often based on few characteristics, such as the sexual organs of plants as devised by the 18th-century naturalist Carl Linnaeus (1707–1778), although they may be based on large numbers of characteristics as in phenetics, popular in the 1970s. Although artificial systems can help in identifying organisms through the generation of identification keys, they do not necessarily reflect the relationships that unite natural or real groups. A major breakthrough in taxonomy occurred in the early 19th century when taxonomists Augustine Pyramus de Candolle (1778–1841), Antoine Laurent Jussieu (1748–1836), and Jean-Baptiste Lamarck (1744–1829) attempted to order groups based on relationships, or homologies, that are shared among members of a natural group. Many taxonomic groups described in the 19th century remain in use today. Nevertheless, classifications must be repeatedly revised and taxa added or deleted if they are to remain reflections of our full knowledge and evidence of such natural groupings.

Willi Hennig (1913–1976) refined the concept of natural classifications even further. His vision was for classifications to be the general reference system for biology, reasoning that the only common thread running through all life was phylogeny, their shared history. Hennig understood that classifications provided a conceptual framework within which to consider any biological fact or phenomenon in the context of evolutionary history; that such natural classifications were the best all-around way to store and retrieve information; and that natural classifications allowed for predictions about the distribution of attributes not yet known. The ultimate goal of taxonomy is such a natural classification. Contributing to this goal are cladistic or phylogenetic analyses that reveal natural relationships that subsequently can be reflected in formal classifications and names.

Nomenclature

The formal naming of species and groups of species plays a role in biology whose importance cannot be overstated. Names refer to species or groups and allow for the storage, retrieval, and communication of information about them. They are also notations for taxonomists' hypotheses about taxa and their characteristics, providing an efficient way to refer to the accumulated knowledge associated with such names. International codes of nomenclature exist that guide the proper naming of species of plants, animals, and microbes.

These include provisions for dealing with situations where a type specimen is lost or destroyed. In such cases, replacements or neotypes may be designated, usually based on specimens from the original type locality, and not infrequently elevated from material available to the original describer, paratypes.

Names for species and certain other categories in the Linnaean system are typified. Types are specimens that are the name bearers for species. Types serve like international standards against which changing ideas about the identity of species or higher taxa may be referenced. There is no expectation that a type specimen is in any sense typical of its species or that it reveals all or even any particular characteristics of the species or groups to which it belongs. Species, higher taxa, and their characteristics are all hypotheses and like other hypotheses are subject to improvement through time as more specimens or evidence becomes available. If a species is later found to be comprised of several previously unrecognized species, the name applies to that division in which the type specimen is deemed to belong. Types are most often specimens that have been named, described, diagnosed, and photographed or illustrated, published, recorded, and cataloged within a museum collection. Taxonomists frequently must reexamine type specimens in order to resolve species boundary disputes and ensure stability in the application of names. Because type specimens are unique and usually fragile, many museums and herbaria are appropriately reluctant to lend them for study and taxonomists are forced to travel to many institutions in order to resolve such problems. Cybertaxonomy offers two avenues of assistance in this regard. First, as archives of images of type specimens accumulate, many questions about the specimens can be resolved by simply examining these images online, some of which may be three-dimensional (3-D) or detailed images of diagnostic characters. Second, as remotely operable microscopes become more commonplace a taxonomist can potentially examine, manipulate, and photograph a specimen from any computer in the world linked via the Internet.

A recent trend to analyze phylogenetic relationships and publish "trees" rather than revised formal classifications has resulted in a widening gap between what we think we know about natural groups and the names that refer to them. Such studies underestimate the inherent strength of precision of scientific names. Trees alone may suffice to meet the needs of a few scientists attempting to interpret their observations in the light of phylogeny, but they are not a substitute for formal classifications and names or Hennig's general reference system. Significant confusion may ensue in verbal and written communication, published findings, and use of public databases when such a gap remains unclosed.

Collections

Any specimen material that is collected in the field is deposited in a collection of some kind. Ideally, museum collections are publicly accessible repositories where types and other specimens are stored, registered, and maintained. New specimens are always being added, and some museums act as official state or national repositories for all types. Museum collections ensure that specimens are available in order to be compared to new species. Without collections it would be difficult to create new species or to validate species names. Many museums and universities allow interinstitutional loans of specimens, although this is not practical for large, fragile, or rare specimens. A large proportion of such loans rely on individual honesty and a reliable postal system, and many specimens have been lost or damaged while on loan.

Collections will remain the primary infrastructure for cybertaxonomy, just as they have been for taxonomy for centuries. Many collections have been developed largely for taxonomic research and as such may appear curious to other biologists. Collections typically do not reflect relative abundance of species in a habitat or frequency of particular "morphs" within populations. There are often as many or more specimens of species that are rare in the field as there are of species common in the field. Taxonomists place a premium on access to the full range of variation within and among species and access to as many species as possible for comparative studies. The ultimate goal of such collections is to provide a comprehensive representation of species for study and comparison. The scientific value of collections resides in their information content. Unless we know where and when specimens were collected or their identities and relationships, their value to science is enormously diminished. Thus, curators of collections and the institutions that possess collections have two fundamental obligations. First is to provide for the physical care of the specimens to maximize the period of time they remain available to science. This involves temperature and humidity control and protection from pest species. Second is to provide for the care of the information content of the collections. This primarily involves support for taxonomic research that ensures that species are accurately identified and reflect the state of our knowledge. Unless existing specimens are reassessed and newly accessioned specimens included in taxonomic works, collections retain or add very little scientific value.

Collections are at the heart of cybertaxonomy, and many of the priorities of cybertaxonomy involve access to or enhancement of the information content of collections. Ways to maximize the growth and development of collections and the expansion and improvement of taxonomic knowledge will remain the core of cybertaxonomy. Above all else, the deposition of specimens in collections makes taxonomic assertions and descriptions testable by virtue of reexamining the actual material upon which such works were based. If dire predictions of species extinctions in the 21st century are realized, collections will take on even more importance. The estimated 3 billion specimens in museums and herbaria around the world already reflect most of what we know of biodiversity. As biodiversity is diminished, collections will become literally irreplaceable evidence of biodiversity.

Literature

Taxonomic revisions, new species, or nomenclatural notes are published in scientific journals, monographs, books, and online. The majority of taxonomic literature is published in scientific journals and kept in museum or university libraries. Any revision or addition of a new species needs to be compared not only to a vouchered type specimen, but also to its diagnosis and description. The practice of recording new species or revised species, genera, and families was introduced by Linneaus in the 18th century. Publication of new species names, synonymies, or revisions is essential in keeping track of the number of described species and valid names. Access to relevant publications is limited due what each individual library holds and what material is kept elsewhere. Taxonomists who need a particular publication rely on electronic library catalogs in order to track publications in other libraries. Many museum or university libraries receive interlibrary loan requests from taxonomists. Taxonomists may also rely on societies or other scholarly networks in order to access literature that is not found in online library catalogues. Taxonomists often need to travel to libraries that do not loan rare or fragile texts.

Monographs and Revisions

The process of revision is based on periodic comprehensive reviews of all species previously described in a taxon plus the incorporation of specimens accumulated since the most recent revision, adding any newly discovered characteristics, and critically reassessing previously documented characteristics. Conclusions are expressed in revised and corrected diagnoses, and descriptions and verification of appropriate and stable name usage also typically require reexamination of type specimens. Species described in the context of revisions and monographs are almost always preferable to isolated species descriptions. In the past, the amount of unsorted material that had accumulated since the most recent revision and the number of isolated species contributed to the literature were usual indicators of the time when a new revision was called for. In the context of cybertaxonomy and taxon knowledge communities, it is possible to envision a process whereby the "knowledge base" for a taxon (the sum total data from which a current monograph could be assembled) is continuously updated as new specimens and characteristics arise. This would make monographs dynamic and always up-to-date "documents" rather than infrequently completed studies that are out of date for most of their existence. Monographs are so important in taxonomy because their focus is on a single group; they provide a comprehensive treatment of all known species in that group and all available relevant information about them. Taxonomists typically focus on monophyletic groups, meaning that they transcend geographic and ecological boundaries that often shape other biological studies. In the case of revisions, they may or may not include all species, some revisions being restricted to one or more but not all biogeographic regions. In botany there is a strong history of such geographically focused species treatments—floras—although these not infrequently follow monographs.

Any artificial constraint, such as setting arbitrary geographic bounds, obviously detracts from the comprehensive comparativeness that gives monographs their greatest strength, yet such regional works have very great value to users of taxonomic literature who need to identify species in the field. Cybertaxonomy promises to meet both needs by creating a community "knowledge base" from which monographs, floras (or faunas), or region specific species treatments could be extracted at the touch of a button. Academic societies, museums, and publishers tend to print monographs in small print runs. While demand at any one moment may not be great, the longevity of monographs is impressive. A well-done monograph may remain a standard reference for a century or more, and may change with electronic or e-monographs that are potentially renewed with every addition or correction and that can be produced on demand.

An e-monograph is an online electronic document, such as a word processing file, that contains an embedded database. The document can be reviewed by several authors, who could edit the text simultaneously. The e-monograph can be published when the initial edition is completed, either as an electronic file or as hard copy with an assigned DoI (digital object identifier). Any changes made to the e-monograph will be recorded for the next edition and updated on linked online databases such as EoL (Encyclopedia of Life) and GBIF.

End Users of Taxonomy

Taxonomists make species identifiable, provide names that enable us to communicate about species as well as retrieve data about them, and classify species in a cladistic context that enables us to interpret their attributes in an evolutionary (historical) context as well as make predictions about the distribution of properties among poorly studied species. Ecologists, conservation biologists, agriculturists, aquaculturists, government agents, policymakers, breeders, farmers, fishmongers, greengrocers, gardeners, and eco-tourists are just some of the many end users of taxonomy. The importance of a correctly identified species that is linked to a scientific name (and in some cases to standardized common names) is vital in all areas of industry, government, conservation, and biological research. Correct species descriptions ensure accurate identification of pests. Correctly assigned names help policymakers target the right groups for conservation. A misapplied name or poor species identification, for instance, could lead to mass poisoning, species extinction, or crop failure and famine. Providing high-quality taxonomy is essential in maintaining scientific integrity and rigor within society. A complete inventory of species allows biologists and land managers to detect increases or decreases in biodiversity, ecologists to detect introductions of nonnative species, and border agents to recognize trade in endangered species and to intercept introductions of pest species or potential agents of bioterrorism.

End User Impediments

The number of taxonomists and taxonomic monographs has dwindled since the 1980s. The biodiversity crisis has led to much funding being diverted away from taxonomy and toward environmental assessments, conservation projects, or molecular genetics. A lack in funding has also reduced career prospects in taxonomy and dampened the productivity of existing taxonomists. Many large, diverse, and economically, ecologically, or evolutionarily important taxa have few living experts. Because no young taxonomists are apprenticing, much existing knowledge stands to be lost and will be recreated only through inordinate expense and effort. Recent advances in molecular systematics have also had an impact on attracting younger people to phylogenetics, population dynamics, and evolutionary biology. Taxonomy as a science of classification has received criticism for being nonmolecular or "stamp collecting." Given that environmental assessments, conservation biology, and molecular systematics are dependent on taxonomy, the lack in funding since the 1980s has led to an *impediment* for end users; that is, a lack of reliable taxonomic information for those who need it. Molecular systematics and ecology are using taxonomic groups that have not been described, which leads to poorer phylogenies and environmental assessments. Because such undescribed, unnamed species are rarely vouchered with museum or herbarium specimens, many such studies cannot be repeated and are thereby marginally scientific. The call for more reliable taxonomic information sparked a debate in the late 1990s as to how to store and update taxonomic information in a reliable and user-friendly way. Cybertaxonomists will increasingly use these and other systems to more efficiently make what is known of species readily accessible to users.

Biodiversity Informatics

Electronic databases for generating keys, providing geospatial species information, and editing names and synonymies has existed since the mid-1990s as *biodiversity informatics*. The rationale behind biodiversity informatics has been to provide end users of taxonomy with data via an easily accessible technology such as electronic databases, keys, and georeferencing tools. End users can modify those data, which are then updated instantly, avoiding the need for printed publications. The innovations provided by biodiversity informatics has lead to a number of electronic resources and tools that can help taxonomists, such as online databases or names and descriptions that are edited by taxonomists, and virtual libraries.

Electronic Databases

An electronic file that contains structured data (i.e., records) is an *electronic database*. Computer software may utilize the database either by extracting the data in order to make a key or by editing the data in order to keep records up to date. The database is simply an efficient way to store data based on some types of categories. In taxonomy, a database can contain names, synonymies, descriptions, distributions, numbers of specimens, where they are kept, and the name of the person who collected them. New data can be added at any time based on data extracted elsewhere, such as another database. The Encyclopedia of Life (EoL) uses a database to organize its information on any given species. Information that is missing can be extracted elsewhere, added, and edited. Databases may be accessible to all, as in the case of Wikipedia, or only to registered users (e.g., FishBase). In some cases any edited or newly added data need to be reviewed for rigor before they are accepted and published online. Databases are used for all information systems in biodiversity informatics.

Digital Libraries

The benefit of a digital library is that it eliminates the need to borrow taxonomic texts or travel to libraries to consult rare or fragile books in order to do taxonomy. Rules of nomenclature dictate that all available names, names proposed in accordance with the codes, be taken into consideration. As an example, in zoology taxonomists must generally be aware of every species described since January 1, 1758. Thus taxonomists have a special and unusually demanding dependency on access to such rare publications. A digital library contains a database and images of texts. The database contains *metadata,* that is, a structured template that provides information such as author's name, year of publication, title, publisher, number of pages, and plates and figures. Catalog software extracts the relevant information from the database, informing the taxonomists where a particular author, title, and/or subject can be found. A digital library differs from most online catalogs in that it can also find particular words within a text, such as species names or descriptions. This information is extracted from scanned or photographed images of whole texts using optical character recognition (OCR) software. A fully accessible text in any given virtual library can provide all the information given by the metadata. The innovation of digital libraries is that texts, normally unavailable, can now be searched page by page.

Cybertaxonomy in Practice

Cybertaxonomy is emerging in a series of initiatives that each seek to resolve some aspect of the *taxonomic impediment*. Any hindrance to taxonomy, the employment or training of taxonomists, and taxonomic funding is a taxonomic impediment. The National Science Foundation (NSF) has several relevant initiatives, including Partnerships to Enhance Expertise in Taxonomy (PEET), Revisionary Syntheses in Systematics (RevSys), and Planetary Biodiversity Inventories (PBI). Other grants exist to build, maintain, and house museum collections as well as provide funding for taxonomists; for example, the Australian Biological Resources Study (ABRS). The future of cybertaxonomy lies in furthering these initiatives by incorporating technology from biodiversity informatics, medical sciences, and space exploration in order to expedite species descriptions and identifications; provide remote access to collections and virtual libraries; assist in collecting specimens in the field; and attract a new generation of taxonomists, training possibilities, and funding.

Collecting

Sampling and collecting populations in the field is time consuming and costly. The procedure for any fieldtrip involves obtaining permissions to enter reserves as well as to collect, which is followed by organizing a team of taxonomists and resources. No online technology is tailored to organize fieldtrips, obtain permissions electronically, and contact the taxonomic community. Currently, several software programs exist that are used by the travel and hospitality industries to achieve similar aims (i.e., visas, package tours, accommodation, travel, etc.). In the future, cybertaxonomy will be able to reduce the time involved organizing fieldtrips through incorporating the existing cyberinfrastructure from industry. Similarly, hardware used in remote sensing, such as satellites and geospatial technology, can be used to assess whether areas are physically accessible. Robotics used in space exploration (e.g., Mars rovers) can also be used to collect in areas not easily accessible (e.g., hydrothermal hot springs, deep sea vents, caves, boreholes). Similar advances are on the horizon for the preparation of specimens and making those specimens more accessible to experts around the globe.

Specimen Curation

The practical difficulties of specimen curation can be resolved through creating online databases that can track specimen loans, register specimens, and produce specimen labels and tags. Several software programs exist that use such databases and provide the necessary services. In the future, specimens might also be housed in collections operated by automated archival systems powered by robotics. Similar systems are in use for a large array of services from car parking to document archives. Prepared and labeled specimens could be archived in an automated system with minimal risk of damage or loss.

Remote Access to Specimens

Currently, taxonomists are impeded by collections or specimens that are housed at distant institutions. In order to complete a revision, a taxonomists would need to visit institutions that either contain rare or fragile specimens (such as types) or house specimens too numerous to send via an interinstitutional loan. Viewing specimens in this way is costly and time consuming. Taxonomists have overcome such hurdles through examining photographs of specimens, but these provide only a single view of the specimen. Technology such as remote microscope access overcomes these impediments. In the future, microscopes linked to museum or university collections could provide taxonomists with the opportunity to view the specimens in real time. Remote robotics used in medical sciences to perform live operations could be linked to such systems to give taxonomists the opportunity to examine, dissect, and rotate specimens without the need for interinstitutional loans or travel. Remote microscopy and robotics are a reality in the biological and medical sciences, and over time will be standard within all natural history museums. Advantages to institutions include having leading authorities study and photograph the specimens, contributing to online libraries of images that can obviate the need to examine the specimen again for many purposes.

The combining of both technologies in taxonomy will advance species exploration and attract students who will be able to be taught online. The full implications for educating taxonomists is yet to be realized, but the potential for students, teachers, and specimens to each be located in different cities or countries completely changes the educational possibilities.

Comparative Morphology Research and Visualization

Morphological descriptions require communication of complex visual information. A photograph with one focal point is rarely sufficient. Well-executed drawings will retain great value in comparative morphology as an artist is able to convey the meaningful parts of a structure and avoid "noise" from associated uninformative structures. A new species description contains a photograph of the type(s) and a detailed drawing or reconstruction of the specimen. The digital world of cybertaxonomy opens many additional options for creating, analyzing, sharing, and imaging morphological information. Digital images, whether from electron microscopes, digital imaging systems, or digitized artwork, are easily transmitted, and electronic monographs need not be constrained by printing costs associated with large numbers of images. Multiple focal depths can be sutured together into a single image for convex specimens. Computer-assisted tomography and other emerging systems permit fully digitized 3-D images that can be rotated or "printed" as 3-D models. Rapid progress is being made in new ways to visualize complex structures both in theaters and in single-user devices. All this promises to revolutionize the study and enjoyment of morphology for future generations.

e-Monographs and e-Revisions

An e-monograph is an online electronic document, such as a word processing file, that contains an embedded database. The document can be viewed by several authors who could edit the text simultaneously. The e-monograph can be published when the initial edition is completed, either as an electronic file or as hard copy with an assigned DoI. Any changes made to the e-monograph will be recorded for the next edition and updated on linked online databases such as EoL and GBIF.

Cybertaxonomy is the future of taxonomy. In 2006, Google recorded up to 10 hits. Within 2 years this had expanded rapidly to 1,600. Over a short period, taxonomists and the end users of taxonomy have adopted a new science, one that will define the future of biology and ways in which biologists will communicate and interact over time.

Dalí, Salvador (1904–1989)

Salvador Dalí was an artist, self-publicist, showman, screenplay writer, poet, and clothing designer. His many occupations and interests took on his own unique style, which he considered to be true surrealism. As a surrealist, he expressed the unconscious mind such as what might be seen or thought of in dreams. Because time does not take on a solid form in the unconscious mind, Dalí found the idea of time fascinating and often used the idea in many of his paintings. Dalí was awarded the Grand Cross of Isabella the Catholic, the highest Spanish decoration. In December 1936, Dalí appeared on the cover of *Time* magazine.

Dalí was born to a middle-class family in the Catalan town of Figueres on May 11, 1904. Later in life, he and his wife, Gala, built their home in the nearby Port Lligat, where they would retreat for solitude and a chance to rejuvenate. The nearby scenery of rocks and cliffs often provided the landscape for the background in Dalí's paintings.

Although his father and mother did not encourage the youthful Dalí to pursue an artistic career, others—such as the nearby Pichot family and his drawing teacher Juan Núñez—encouraged him in his dream career. In the early 1920s Dalí went to Madrid to study painting and was drawn to the surrealist movement then attracting the attention of avant-garde artists. Many of his most famous paintings come from the late 1920s and the 1930s. In his paintings Dalí would invest an irrational object with symbolic significance, but no matter how bizarre the images in his paintings seemed, the technique and details of the objects were on an academic level of accuracy. For this, Dalí was considered a craftsman and a technical virtuoso.

Dalí used symbolism in his works referring to time. Many of the forms in his paintings are characterized by a certain fluidity, as if to demonstrate that nothing contained in the human mind is fully formed and rational. Grasshoppers or locusts, of which he had a particular phobia, appear in his works as symbols of fear and waste. Open drawers imply the presence of the unconscious mind, open for thoughts to come and go as they please. In many paintings he depicted eggs, which convey a sense of prenatal hope and love. Also, crutches, which symbolize the fragility of reality when in the mind, are a Dalí trademark. The crutches hold up and support reality so it can keep its form.

In the 1930s, Dalí spent time in Italy studying the art of the Renaissance. Many of his paintings show the influence of great painters such as Leonardo da Vinci, Caravaggio, and Velazquez. Later in his career, Dalí took a step toward mysticism. This step was influenced by the 1945 dropping of the atomic bomb in World War II, which engendered ideas concerning nuclear physics and the universe being made from particles. Many objects in his paintings would take fragmented forms as Dalí tried to show fragmented parts of an object coming together to create the one object as a whole.

Dalí not only wanted to show the unity of substance, but he also spent time during this era focusing on a spiritual theme. The iconography of

Christianity provided him a range of highly charged imagery. Many paintings focused on intermediaries between heaven and earth as representations of the spirituality of substances. To him, God was a concept that could not be grasped, and so he painted angels, heaven, and objects reaching up to the skies, such as elephants on long spindly legs.

Major Works

One of Dalí's most famous works is the *Persistence of Memory,* painted in oil on canvas in 1931. As is often found in surrealist works, there is a common image that is in some way irrational, such as the watches that appear soft and fluid in this painting. This idea of soft watches subverts the notion of a rule-bound order in nature and also focuses on the human preoccupation with time. Dalí claimed that the idea for this painting came while meditating upon the nature of Camembert cheese one night after dinner while Gala had gone out with some friends for the evening.

The background is composed of the Port Lligat scenery that he often depicted, and the painting took him only a few hours to complete. Dalí's dormant head, an image reoccurring from earlier paintings, such as the 1929 *Lugubrious Game,* is present in the painting underneath the center watch. In the bottom left corner are ants, a common symbol for Dalí of death and decay. In this case a watch covered with ants indicates that time is being devoured and is melting away, a sign that time is relative and not fixed.

Persistence of Memory *(1931) by Salvador Dali, is shown in New York's Museum of Modern Art, where it has been displayed since 1934. Perhaps Dalí's most famous painting,* Persistence of Memory *is widely viewed as a commentary that time is less rigid than most people assume.*

Source: Topham/The Image Works.

Dalí's *Crucifixion,* a 1954 oil on canvas, holds a hypercubic cross in which the body of Christ acts as the ninth cube in a grouping of cubes. This phase in his paintings indicates his turn toward mathematical conceptions. This idea of cubes may reflect the influence of Cubism, which was in vogue during the period when he was a student in Madrid. In that analytical phase, he arranged fragmented shapes in parallel formations in his paintings.

The Discovery of America by Christopher Columbus, painted in 1959, is another significant work of Dalí's. This painting came from a series in which Dalí decided to paint historical images metaphorically, in celebration of his fatherland. In this painting, earlier techniques are combined with a representation of his particle period, which stemmed from his thoughts on quantum physics and of small particles forming the matter in life.

The painting includes Saint James, the patron saint of Spain, and it is photographically precise. Columbus is depicted as a young adolescent to represent America as a young continent. The banner he carries has a painting of the Blessed Virgin on it in the form of Gala, Dalí's wife. Dalí often painted Gala and used her to represent the Virgin Mary in his paintings. In his famous painting *The Last Supper,* Dalí used Gala's face for the face of Jesus. At the front bottom center of this painting is a small sea urchin with an odd halo around it. This symbolizes the other planets that America would some day explore. With the passing of time since Dalí lived and painted, admiration and interest in Dalí's artistic creations has not diminished.

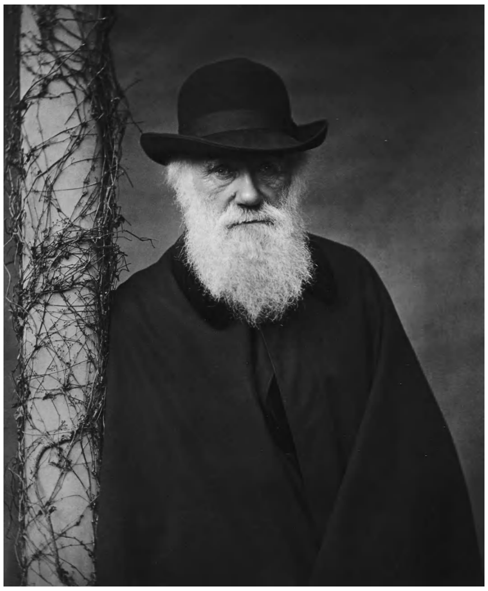
Darwin, Charles (1809–1882)

Charles Robert Darwin is one of the greatest naturalists who ever lived. He was not only the father of evolution but also a remarkable scientist whose ideas and discoveries about the earth's history resulted in new areas for ongoing research in geology, paleontology, biology, and anthropology. His contributions to science, particularly concerning organic evolution, were possible because he would eventually embrace the vast temporal framework that was being argued for in the emerging disciplines of historical geology and comparative paleontology. Taking both time and change seriously was crucial for the young Darwin, as it resulted in his rejecting the fixity of species and, instead, accepting the mutability of life forms throughout the biological history of this planet.

Darwin's intellectual life evolved from his being a part-time naturalist, interested especially in geology, to his becoming a full-time scientist devoted primarily to biology. He developed a comprehensive orientation in geobiology, and his life was a long series of fortuitous coincidences that collectively propelled him to make major discoveries in the natural sciences. Whether speculating on the formation of coral reefs or reflecting on the similarities between the human species and the apes, Darwin came to see both geological structures and biological forms slowly changing due to the influences of natural forces on them over immense periods of time. His conceptual revolution of organic evolution also challenged the entrenched ideas of Aristotelian philosophy and the dogmatic beliefs of Thomistic theology. Consequently, as a result of Darwin's dynamic worldview, the modern thinker would never again see the earth, life forms, or humankind itself in terms of eternal fixity.



Charles Darwin at his home at Down House, Downe, Kent, United Kingdom, circa 1880.

Before Darwin

Aristotle, the father of biology who contributed to embryology and taxonomy, had taught that plant and animal species are eternally fixed within nature. In accordance with his claim that experience reveals reality, it appeared to him that forms of life are static. Likewise, for Aristotle, the same species have always been and always will be on this planet, with none of them ever changing into a different form of life or becoming extinct. He held that, because nature is forever the same, no new species will appear on the earth. However, Aristotle maintained that the human intellect is capable of organizing biological types into a natural hierarchy of ever-increasing complexity and sensitivity; he referred to this order of species as the Great Chain of Being. Although he classified hundreds of organisms and was interested in the embryonic and postnatal development of animals, it never occurred to Aristotle that, through time and change, one species could evolve into a new species. The idea that life forms are eternally fixed dominated Western thought until the scientific writings of Charles Darwin.

Organic evolution was glimpsed in the thoughts of the Roman philosopher Lucretius, geological history was pondered by the Renaissance artist Leonardo da Vinci, and the fact that a species may produce varieties of itself was admitted by the biologist Carolus Linnaeus. Because these three thinkers held ideas that were outside the Aristotelian worldview, however, their concepts on time and change were not taken seriously.

The first major evolutionist was Jean-Baptiste de Lamarck (1744–1829). After long consideration of the geological column with its fossil record, he eventually concluded that the empirical evidence (admittedly incomplete) demonstrated that species had evolved throughout the earth's history. He presented his heretical interpretation of life in the book *Philosophy of Zoology* (1809), which first appeared in the year of Charles Darwin's birth. However, Lamarck was unable to give a satisfactory explanation for the mutability of species. His speculations on organic evolution were grounded in both the inheritance of acquired characteristics (through use and disuse), as well as a form of vitalism. However, there were no facts to support either explanation. As a result, Lamarck was unable to convince any other naturalist that species have evolved over time throughout the history of this planet.

Early Influences on Darwin

As a curious youngster, Charles Darwin had been interested in rocks and insects. He enjoyed taking nature walks into the English countryside, studying rocks, and collecting beetles. His inquisitive mind was inspired by these experiences, and it remained open to new ideas and challenging perspectives throughout his life. As a result of his activities in nature, Darwin continued to develop his acute powers of observation, description, and speculation. Years later, these mental powers would allow him to meticulously analyze organisms (e.g., barnacles, orchids, and worms) and synthesize vast amounts of empirical evidence. He was then able to derive both brute facts and those meaningful generalizations that are needed to explain complex phenomena in nature. Furthermore, over time, Darwin developed a disciplined imagination that would eventually allow him to envision the earth's history in terms of millions of years and, as a result, to accept the counterintuitive scientific truth of organic evolution.

Despite his studies in medicine at Edinburgh University and then in theology at Christ's College of the University of Cambridge, Darwin had no desire to become either a countryside minister or a medical doctor. He remained interested in geology and entomology. Like most naturalists at the time, Darwin thought that species were fixed and immutable throughout the earth's history. Although somewhat religious, he had not taken his theological studies seriously. Even so, Darwin found William Paley's *Natural Theology* (1802) to be intriguing in its argumentation. However, a few years later, he would reject its theistic premise in light of his own evolutionary explanation for life that replaced the assumed permanent design in nature. For Darwin, the alleged design in the world would be seen to be merely a temporary order rather than the manifestation of a preestablished divine plan. Of special consequence, Darwin was fascinated by the writings of the naturalist Alexander von Humboldt (1729–1781), who had made extensive travels in South America. Within only 7 years, as a result of his own trip to the southern hemisphere, Darwin's early conceptions of time and life would be turned upside down: Pervasive change would replace eternal fixity.

A Voyage of Discovery

After having accepted an invitation to join the H.M.S. *Beagle* on its 5-year voyage around the world to survey and chart the coastlines of South America, Charles Darwin anticipated studying rock strata, collecting fossil specimens, and describing wild organisms in their natural habitats. He could not have foreseen how his own view of time would radically change during this exceptional scientific journey of extraordinary discoveries. The major influence on his conception of earth history came to Darwin as a result of his reading Charles Lyell's three-volume work *Principles of Geology* (1831–1833). Lyell claimed that this planet is millions of years old, and over vast periods of time, natural forces have slowly altered its geological structures. The empirical evidence was so compelling and the rational arguments so convincing that Darwin came to accept Lyell's new interpretation of geological history. Furthermore, as climates and environments are always changing, Lyell's dynamic view of the earth's history in terms of geology now suggested to Darwin a dynamic view of the earth in terms of biology.

If, for Darwin, his voyage on the *Beagle* was the single most important event in his scientific life, then his acceptance of Lyell's geological perspective was the pivotal moment during this trip. Over the coming years, Darwin's piercing insights and a convergence of evidence would result in a paradigm shift in natural science from fixity to evolution.

Giving priority to science and reason, Darwin eventually rejected the age for this planet that had been determined through a strict, literal interpretation of the biblical story of Genesis. He now held the age of the earth to be in the millions of years (rather than being only a few thousand years old). Within this extraordinary time framework, Darwin was able to imagine the sweeping process of organic evolution.

As the *Beagle* sailed along the coastlines of South America, it frequently made stops at major ports. Some landings offered Darwin the opportunity to explore inland. In Brazil, he was delighted by the lush tropical jungles with their incredible diversity of insects. Next, in Argentina, working with crew members, Darwin helped to unearth the fossil remains of now-extinct giant mammals. Yet, these fossil specimens resembled a few of those mammals that were still living on the continent. This uncanny resemblance between past and present forms of life suggested to Darwin that there had been a historical continuity in life from prehistoric organisms to extant species (with extinctions occurring throughout the history of life on Earth). He subsequently wrote about the complex web of evolving life.

Captain Robert FitzRoy of the *Beagle*, a biblical fundamentalist, dogmatically believed the age of the earth to be no more than 10,000 years old; despite growing evidence to the contrary, he never doubted his religious opinion. In sharp contrast, for Darwin, several crucial experiences gave scientific evidence to support Lyell's dynamic interpretation of historical geology. In Chile, Darwin saw those geological changes that had recently been caused by earthquakes, tidal waves, and volcanic eruptions. These alterations to rock structures gave credence to Lyell's immense temporal framework, as it would take enormous periods of time for natural forces to significantly change the geological surface of the earth. Furthermore, Darwin had found seashells and fossil fish in the top rock strata of the Andes. He correctly reasoned that these geological layers must have once been below the surface of the Pacific Ocean and that slowly, over millions of years, natural forces had elevated these rock strata to form the mountain range of today.

For Darwin, however, the most important event of the *HMS Beagle* voyage was a 5-week stay on the Galapagos Islands in 1835. This unique archipelago consists of 15 major volcanic islands located near the equator, about 600 miles west of Ecuador. In his journal, Darwin wrote: "Hence, both in space and time, we seem to be brought somewhat near to that great fact—that mystery of mysteries—the first appearance of new beings on this earth." He was able to explore several islands, carefully describing and interpreting their geology and biology. He was surprised to discover that different species of finches, mockingbirds, iguanas, and tortoises lived on this group of islands. Moreover, these species resembled species on the mainland of South America. Nevertheless, he did not appreciate the far-reaching implications of these facts for evolution until after he had critically reflected on all the evidence from these islands when he was back in England after the trip had been completed. He concluded that the ancestors of the Galapagos species had managed to reach this archipelago from elsewhere ages ago, where they then speciated over time into different forms for different habitats. It had become obvious to Darwin that there is a direct relationship between the biological characteristics and behavior patterns of an organism and its environment in terms of adaptation, survival, reproduction, and evolution (or extinction). Even the Galapagos Islands and their unusual life forms have been changing throughout time.

The Theory of Evolution

It is very unlikely that Darwin would have developed his scientific theory of organic evolution without having read Lyell and taken the voyage on the *HMS Beagle*. When Darwin returned to England, he was convinced that species are mutable. The overwhelming scientific evidence, especially from paleontology and biogeography, clearly attested to the adaptive evolution of life forms throughout organic history on the earth; Darwin's biological framework supplemented Lyell's geological perspective. Darwin acknowledged both the creative and destructive aspects of organic evolution. Unfortunately, he still lacked an explanatory mechanism to account for the dynamic divergence and often extinction of species over unimaginable periods of planetary time.

In 1838, by chance, Darwin read Thomas Robert Malthus's monograph *An Essay on the Principle of Population* (1798, 1803). Suddenly, Malthus's description of life as a "struggle for existence" gave to Darwin his primary principle of natural selection, which would help to explain biological evolution. Despite being elated, the ailing and introverted naturalist had no plans to rush a volume on his controversial theory of evolution into print. Instead, he focused on those notes he had written during his groundbreaking trip and published them in *The Voyage of the Beagle* (1839). Furthermore, he wrote a 35-page abstract on evolution in 1842 and expanded it into a 230-page manuscript in 1844. Neither the abstract nor the manuscript was published.

The scientific philosopher Herbert Spencer (1820–1903) referred to natural selection as "the survival of the fittest," a phrase that Darwin himself would use and come to prefer in his later writings. Unlike Darwin, however, Spencer extended the evolutionary framework to include everything from the history of the entire universe to the development of human societies and ethics.

As a scientific theory, organic evolution by natural selection had enormous explanatory power. It accounted for the diversity of species on the Galapagos Islands. Organisms in different habitats required different physical characteristics and behavior patterns in order to adapt, survive, and reproduce. Over time, from a common ancestry, species would radiate into different varieties (or new species) to fill different environments. If conditions suddenly changed, then organisms were threatened with extinction; the fossil record shows the complete demise of trilobites and dinosaurs after their millions of years of successful adaptive evolution. All plants and animals, including the human species, are products of biological history in terms of organic evolution. Darwin's own interpretation of this ongoing process was mechanistic and materialistic; it rejected vitalism, essentialism, teleology, spiritualism, and a divine plan, as well as the fixity of species. For Darwin, the process of biological evolution had no meaning, purpose, direction, or final goal. He was correct in fearing that a bitter controversy would ensue over his theory of "descent with modification" (as he called it). For 20 years, his attention focused on numerous research projects ranging from domesticated pigeons to insectivorous plants, while his theory of evolution remained in the background.

The Evolution Controversy

In 1858, Darwin received a letter and manuscript from Alfred Russel Wallace (1823–1913), a naturalist who was living in Indonesia. Like Darwin, Wallace had read Lyell and Malthus and had spent time studying the biology of oceanic islands. Reading the manuscript, Darwin was shocked to learn that Wallace had independently discovered the theory of evolution by natural selection. Even so, on July 1, the members of the Linnean Society in London gave priority to Darwin for having fathered the scientific theory of organic evolution 20 years earlier.

Darwin finished his book on evolution *On the Origin of Species*, which was published on November 24, 1859. In this volume, he deliberately refrained from discussing human evolution and its disturbing ramifications. Darwin had only written: "Light will be thrown on the origin of man and his history." Nevertheless, anyone reading the *Origin of Species* could easily see that the theory of evolution should also be extended to account for the origin and history of the human species. As such, one may argue that the controversy over evolution was actually due to a topic that Darwin himself had consciously avoided including in his major work. As Darwin had feared, serious issues over evolution emerged in both academic and public circles. Of special significance was the 1860 confrontation held at the University Museum Library in Oxford (neither Darwin nor Wallace was present). Bishop Samuel Wilberforce ("Soapy Sam") pontificated on the biblical account of the 6 days of Creation, while the anatomist Thomas Henry Huxley ("Darwin's bulldog") defended organic evolution and its geological framework. Especially because of Huxley's informative and persuasive arguments, it was held that Darwin had won the day for evolution, science, and reason.

Along with Huxley in England, the biologist and philosopher Ernst Haeckel in Germany and the botanist Asa Gray at Harvard University in the United States championed the evolutionary perspective. However, interpretations of organic evolution ranged from materialism to spiritualism. Despite the ongoing controversy between science and religion, it was becoming increasingly difficult for other naturalists, as well as philosophers and theologians, to ignore the accumulating evidence for both the immense age of this planet and the great antiquity of the human species.

No radiometric dating techniques were available in the 19th century. Therefore, most naturalists did not share Darwin's sweeping geological perspective, which held that the earth must be at least 600 million years old. Darwin reasoned that his theory of evolution needed an awesome amount of time to account for the staggering diversity of life forms that had emerged throughout organic history. The slow evolution of vision, from a mere sensitive spot in a primordial organism to the complex eye in the human species, would take millions upon millions of years to accomplish through the gradual accumulation of slight but favorable individual variations and the mechanism of natural selection.

Human Evolution

Twelve years after his *Origin* volume appeared, Darwin published *The Descent of Man* (1871). Finally, the now world-renowned naturalist focused on the evolution of the human species; Huxley and Haeckel had already written on this contentious subject several years earlier. Darwin wrote that the human animal is closest to the two African great apes (chimpanzee and gorilla), with which it shares a common primate ancestor in the remote past. Furthermore, he reasoned that this common ancestor would be found in the fossil record of African rock strata. His rigorous consideration of comparative biology led him to claim that humans differ from apes merely in degree rather than in kind. For many thinkers, the philosophical implications and theological consequences of human evolution were disquieting. In fact, Darwin himself found his own pervasive materialism to be upsetting in its stark implications for human existence.

Darwinian evolution had dealt a serious blow to the alleged uniqueness of the human being; humans were now thought to be evolved apes rather than fallen angels. Consequently, as a result of scientific discoveries in the 20th century, the biological history of the human species was extended back millions of years to the apelike forms in the remote fossil record. Moreover, anthropologists also compared the genes, behavior patterns, and mental activities of humans with those of the living great apes. The results clearly demonstrated that humans are closer to the apes than Huxley or Haeckel or even Darwin himself could have imagined at the end of the 19th century.

For Darwin, even human feelings and emotions had their origin in the feelings and emotions of fossil apes. As such, he also grounded human morality in the distant past. Thus, from biology to psychology, humans are linked to the living apes through organic evolution. A remaining question about human evolution concerns when, in the early history of apelike forms, the successful split had occurred that resulted in a crucial distinction between the ongoing evolution of apes and the emergence of those proto-hominids that were ancestral to the appearance of true hominids, who were capable of both sustained bipedal locomotion and the making of stone implements.

After Darwin

After his return from the southern hemisphere, Darwin never made another trip outside of England. He spent his time thinking, writing, and doing research at Down House in Kent, near Bromley. Twice each day, Darwin would stroll the Sandwalk, a path through the woods and fields behind his residence. No doubt, during these walks, he reflected on his fortuitous voyage around the world on the *HMS Beagle* and his own theory of organic evolution. Lyell's persuasive thoughts had introduced the young Darwin to geological history with its awesome temporal framework. Subsequently, Darwin's own scientific theory had given the enlightened world an evolutionary perspective with its overwhelming views of time and change in terms of biological history. The complexity and unity of life on Earth are the result of organic evolution, and this ongoing process has encompassed millions of years. Even profound ideas, cherished beliefs, and social values have an evolutionary history. Nothing escapes the Darwinian revolution.

In his *Autobiography,* written in 1876 and published posthumously in 1887, Darwin admitted that his theory of evolution challenged the theology of Christianity. He did not speculate on the origin or the end of this universe. Furthermore, an explanation for the beginning of life eluded him, as did envisioning the distant future of the human species and the end of all life. Darwin's own mechanistic and materialistic interpretation of organic evolution was atheistic, while his cosmology remained agnostic. He simply left the philosophical questions and theological issues surrounding the fact of evolution for other thinkers to grapple with. One may argue that Darwin's crisis of faith, due to his own pervasive materialism, resulted in a failure of nerve, since he did not share his final thoughts on religion and theology during his lifetime. Unfortunately, not until 1958 was an unexpurgated edition of his *Autobiography* made available to the public; his devoutly religious wife had intentionally deleted all of Darwin's opinions on God and Christianity from the original manuscript before its first publication. For sure, there was a glaring contrast between Darwin's scientific understanding of evolutionary time and his wife's religious commitment to the biblical account of divine creation.

When Darwin died in 1882, he was buried in Westminster Abby near the tomb of Isaac Newton. Over the following years, his theory of evolution has been strengthened by ongoing advances in science and technology. New dating techniques have determined the age of the planet Earth to be 4.6 billion years old, and human-like fossils are now dated back over 4 million years. The discovery of endless specimens in the fossil record of the geological column has revealed both evolutionary patterns and periods of extinction throughout the vastness of biological history. Moreover, ongoing comparative studies in biology, from biochemistry and genetics to embryology and morphology, have shed new light on taxonomic relationships and common ancestries. Continuing studies in the biogeography of both plants and animals reveal the complex adaptive relationships between organisms and their environments. And, modern computers generate dynamic models of the phylogenetic histories of species, filling in the gaps of an admittedly incomplete fossil record. With all this growing empirical evidence, it is becoming more and more difficult for enlightened thinkers to ignore the fact of evolution and its obvious inferences for time and change.

Supplementing historical geology, organic evolution has greatly expanded the concept of time in terms of the origin and history of life forms on Earth (including all aspects of our own species, from religions to technologies). In the mid-20th century, with the discovery of the DNA molecule, scientists developed the so-called synthetic theory of organic evolution, which added genetic variations or mutations, found in dynamic populations, to Darwin's fundamental concept of natural selection. Furthermore, the evolutionary framework was extended to include the history of this universe. And, there is the probability that life forms, including intelligent beings, are evolving on planets elsewhere in other solar systems among the countless stars. In fact, the concept of time itself has come under rigorous scrutiny by scientists, philosophers, and theologians. No doubt, Charles Darwin would be surprised at, and delighted with, the modern awareness of time concerning both cosmic and biological levels of existence.

Darwin and Aristotle

Charles Darwin (1809–1882) and Aristotle (384–322 BCE) represent the greatest dichotomy of thought regarding the concept of time and its influence upon natural history (science) and philosophy. Separated by the vastness of time and intellectual advancements of their respective eras, the temporal concepts of finitude (infinity and the finite) are juxtaposed within both a cosmological and a human ontological and teleological framework. In the works of both thinkers, issues concerning the temporal nature of the universe, Earth, and humankind were explored for the ultimate understanding of both humanity and humankind's place in nature. With the combination of both acute observations of the natural world and rational speculation, Darwin's and Aristotle's individual contributions marked a theoretical shift that brought about a conceptual revolution that still reverberates in the modern world. A diachronic perspective, as in this entry, affords a comparative view of the conflicting metaphysical basis of time and the human experience as understood by these two key figures.

Aristotle, father of biology, taxonomy, and logic, provided a comprehensive view of nature that was separate from prevalent or traditional mythology or superstition. Although some works survive only in fragmentary form, his noted works titled *Physics* and *Metaphysics* provided essential clues as to the conceptualization of time, being, and ontological fulfillment within a logical and categorical framework. In this framework, matter and form became united within a developing and finite ontology and finitely directed teleology of the underlying substance (essence). The implications for species' ontogeny, especially with the human primate, become explicitly clear when examining the nature of change and humans' relationship within the natural world.

The relationship between a geocentric universe and nature was depicted as a series of processed actualization, such as an ebbing flow of potentiality to actuality, within the backdrop of the eternal and finite universe. Individual development, initiated and sustained by the "four causes" of change, results in the actualization of being. Categorically, each being expresses the qualitative "soul" that is essential in the Form for that particular living thing, example, vegetative, sensitive, and rational. Expressions of the soul, driven by the final cause, manifest themselves in terms of motion (e.g., spatiotemporal measurement of physical growth and development). Although physical changes are expressed (e.g., ontogenetic development), the substance and incorporated soul of living things remains fixed. For Aristotle, species are fixed within nature. However, it is important to note that the cosmological aspect of all motion is eternal and originated from the Unmoved Mover. It is the form and substance of the universe expressing a final cause from an eternal *logos,* or *nous.* The eternal and infinite intelligibility of the world reflects both the infinite and the finite nature of humankind.

Aristotle's depiction of humankind's place in nature is anthropocentric, whereby humankind is placed at the earthly apex within the Great Chain of Being. This placement is directly related to the human species' possession of a rational soul and the ever-present potentiality of reason with the possibility of actualization. In terms of the temporal nature of being human, Aristotle acknowledges the finite aspect of existence. The soul, by which existence is irrevocably linked to form, became viewed as temporally finite. Upon death, when animus ceases, the existence of matter and form are terminated in nonexistence. The psychological conception of time, on an individual level, is closely linked with the awareness of this mortality. In its totality, each species lives out its categorical existence within clearly defined teleological ends. For the human species, this Aristotelian perspective provides both psychological security and stability, that is, ontological and teleological justification for ethical and political structures. Furthermore, these ideas were later adopted and adapted for theological purposes by Saint Thomas Aquinas (1225–1274), whereby the conceptualization presented by Aristotle, along with scriptural interpretation and dogmatic thought, set the prevalent tone in the Western mind, in which the sciences operated. Nevertheless, changes in philosophical thought and the empirical sciences were established. The greatest divergence can be seen in the discoveries and theoretical perspectives of Darwin.

Charles Darwin, the renowned English naturalist, provided empirical evidence with rational speculation in support of a theory that was contrary to the established influences of Aristotelian thought within science and philosophy. Darwin's perspective directly challenged the traditional concept of the temporality of the universe, Earth, and the nature of species. Along with explicit differences, such as in taxonomical relationships, there are implicit metaphysical implications that challenge the conceptual security of humankind and humanity. It was Darwin's inquisitive mind and creativity that directed his early experiences as a naturalist on board the H.M.S. *Beagle* to postulate one of the most influential theories, the theory of organic evolution.

In the publications *On the Origin of Species* (1859) and *The Descent of Man* (1871), Darwin presented the accumulation of empirical observations from the Galapagos archipelago and South America, with the contextual influences of Charles Lyell, Thomas Malthus, and Jean-Baptiste de Lamarck. This resulted in the dynamic assessment in the age of the earth in terms of millions of years, dynamics of populations, relations among species within an environment, and the mechanism for the appearance of new traits in a species. Together, the origin of species is not only rooted within the ancient natural history of the earth, geologically speaking, but also affected by the arbitrary pressures of natural selection. The process of natural selection, resulting in species' proliferation or extinction, is temporally finite on an individual level and gradually finite on a species level, resulting in a gradual and nondirectional speciation. This illustrates the precarious nature of existence. The existence of each species enters into a spatiotemporal relationship that stresses not only the unity of life but also the common struggle for the continuity of existence as a species.

Contrary to Aristotle's position, Darwin held that humankind was a gradual product of evolution. Darwin speculated that humans share an affinity with primates (differing in degree and not in kind), and thus humans could no longer be considered the apex of life; rather, the human species, according to Darwin, is one part of a nondirectional continuum that is subjected to adaptation and the possibility of extinction. The process of change through time, not fixed within time, is key to the human species' origin, development, and future. Although Darwin did not explicitly comment on the human species' mortality, the metaphysical implications become evident. Humans were neither created nor designed, there is no teleological end, and a shared common ancestry (temporal continuity) with primates topples the Great Chain of Being. Furthermore, the metaphysical implications for theology are certain. Not only is the concept of the eternal soul rejected but also the theological underpinning of redemption and salvation of humankind's eternal existence in a destined afterlife (which also includes reincarnation). Aspects of ethics (morality) and beliefs (e.g., eternal soul) are psychological adaptations within the primate social structure.

Contrasting the views of Aristotle and Darwin shows that the influences of each thinker are extremely profound. The dichotomy of their thought, in each instance based on acute observation, illustrates not only the temporal nature of the human species but also the temporal nature of science. On an individual level, time is relative to human existence. Science, on the other hand, is relative to the precocious timing of scientific advancements set within a social framework. For the first time in human history, metaphysics and science intersect with the ability to direct the future and timing of human evolution. However, each instance of progress, with its metaphysical implication, is ultimately subjected to the pressures of natural selection within an evolutionary framework.

Darwin and Nietzsche

The concept of time plays a fundamental role in Charles Darwin's theory of evolution as presented in his book *On the Origin of Species* because it answers one fundamental question raised by his theory. One critique Darwin anticipated when elaborating his theory of evolution was the the missing biological link; that is, the "absence or rarity of transitional varieties" If two species descended from common ancestors, then one should expect to find transitional varieties at the present time and in each region: "But in the intermediate region, having intermediate conditions of life, why do we not now find closely-linking intermediate varieties? This difficulty for a long time quite confounded me". According to Darwin, this phenomenon can be explained only by taking into consideration both the imperfection of the fossil records and the enormous time period that has passed since the first occurrence of life on Earth. This second point leads Darwin to widen the focus on human time. By comparing natural selection with human-made selection (domestication), Darwin exclaims: "How fleeting are the wishes and efforts of man! how short his time! and consequently how poor will his products be, compared with those accumulated by nature during whole geological periods". For Darwin, this insight implicates the necessity to widen the focus on the human time concept. When comparing "domestic" and natural instincts, Darwin remarks that the former are "far less fixed or invariable than natural instincts" because they have been transmitted in a much shorter period of time. Referring to Charles Lyell's geological research, Darwin claims that the denudation of certain areas of the earth's crust has required such a long and almost inconceivable period of time that the sheer attempt to envision this geological period of limited time is comparable to the vain attempt to envision eternity.

The other revolution of the time inspired by Darwin's reading of Lyell and other geologists is the rejection of rhythmic concepts of time. Darwin stated that the old notion of a recurring catastrophe sweeping away all inhabitants of the earth is generally given up by geologists. Instead, Darwin has shown that every new variety can become extinct because it is less favored than a competing one.

The question of how deeply the philosopher Friedrich Nietzsche (1844–1900) was influenced by Darwin, mainly by his conception of time, is hard to determine. On the one hand, Nietzsche polemized against Darwin's alleged "materialistic" and externalistic conception of evolution; on the other hand, he acknowledged Darwin for being one of the main exponents of a philosophy of becoming (*Philosophie des Werdens*). It is exactly in this regard that Darwin is seen as one of Nietzsche's antecedents. But at the same time, Nietzsche tries to downplay the actual meaning of Darwin by contrasting him with Jean-Baptiste de Lamarck and Georg Wilhelm Friedrich Hegel. In a posthumously published fragment written in 1885, Nietzsche remarked: "We are historical through and through. That is the great turnaround. Lamarck and Hegel—Darwin is only an aftereffect".

This short remark is characteristic of Nietzsche's ambivalent mind-set toward Darwin. Nietzsche honors the fact that Darwin's theory of evolution, especially his acceptance of the transformation of species, has proven that there is no eternal validity, neither of the concept of species nor of the logical categories. Nietzsche goes so far as to parallelize Darwin's transformationism with his own disbelief in eternal logical structures: Just as time transforms the species, it changes the logical categories, too. Hence, the main purpose of Nietzsche's reference to Darwin is to show that everything, even and especially the logical categories, is affected by transience.

However, much unlike the medieval *vanitas* thinking, this is not meant as a statement of the vanity of the fugacious earthly beings. On the contrary, Nietzsche points out that his insight—that everything, even the logical structures, is transitory—results in a deep affirmation of transience.

This motive pervades his entire thinking. It is already in his early work *Untimely Considerations* (*Unzeitgemaesse Betrachtungen*) that Nietzsche criticizes "antiquarian history" and pleads the art of oblivion. Thus, the early Nietzsche favors the unhistorical over the historical because the former refers to the "art and power to forget and to surround oneself in a limited horizon". In this early writing, Nietzsche still talks about the "hyperhistoric" manifested in art and religion that "bestows the character of the eternal and the continuous".

The connection between Nietzsche's theory of oblivion and remembrance on the one hand and his theory of becoming on the other hand is the chief motive for his concept of time. In his *Gay Science* (*Die fröhliche Wissenschaft*), Nietzsche points out this extraordinary importance of the concept of becoming: "We Germans are Hegelians [. . .] in so far as we instinctively attach a deeper value to becoming, to evolution than to that, what 'is'—we hardly believe in the authority of the concept of 'being'". At the same time, oblivion and remembrance are seen as organic functions. As Nietzsche points out in one posthumously published fragment from 1884, the process of life is made possible only by the embodiment of experiences: "the actual problem of the organic is: how is experience possible?"

At this point, Nietzsche refers not to Darwin but to Lamarck and this alleged theory of the "hereditary transmission of acquired characters" in order to support his own position. The notion that every action, every experience is transmitted to the following generations causes, in Nietzsche's view, the extraordinary relevance of physiology understood as an ethical doctrine.

The radical affirmation of transience is finally expressed in Zarathustra's "Yes-and-Amen-song" where each aphorism ends with the sentence "Because I love you, eternity!" However, this eternity is not made up of the everlasting and the immortal but by the affirmation of human transience and mortality. It is not by the belief in immortality or resurrection but by the affirmation of sexuality and siring first brought to mind by ancient mysteries that eternity is achieved.

This notion seems to be the inner meaning of Nietzsche's cryptic doctrine of the eternal recurrence of the same (*Ewige Wiederkehr des Gleichen*). The core of this doctrine (which was repeatedly modified by Nietzsche) is that every little thing, every moment repeatedly recurs in a long period of time—not similarly but *in the very same way* it was experienced the first time. The underlying time concept is clearly a rhythmic one. Nietzsche (who tried to prove this doctrine by referring to physical theories) often stated that the affirmation of the thought of eternal recurrence is the greatest challenge for every thinking being because the unreserved affirmation of a recurring eternity means to completely accept one's own transitory human existence. Thus, the affirmation of eternal recurrence is possible only for those who have first accepted the transience of human existence. Consequently, the doctrine of eternal recurrence can be considered as a touchstone for true salvation.

Dating Techniques

For as long as time travel remains the stuff of dreams and science fiction, archaeology will continue to provide the most direct means to gain access to the remote past. Historical sources (such as written texts) and ethnoarchaeology provide abundant and invaluable insights concerning ancient times, but even these approaches have significant limitations. For example, the earliest written sources date from only about 5,000 years ago, and such evidence is restricted to certain regions and found in a limited number of literate cultures. Thus, all of prehistory stands beyond the reach of historical research, strictly defined, and the radiometric (science-based) dating techniques, including the so-called radiocarbon revolution, are all the more valuable. The availability of written evidence (e.g., inscriptions in stone, clay tablets, coins, papyri) can provide firm dates for archaeological strata and artifacts by historical association with, for example, references to astronomical events or names of rulers. In principle, however, archaeological excavation, armed with a wide array of dating techniques, allows access to *any* period of prehistory and history in all parts of the world, even when and where no documentary evidence exists.

Of course, archaeology (the systematic recovery and analysis of the material remains from past cultures) faces its own limitations: theoretical, logistical, financial, and methodological. Archaeologists desire to bring order to, and understand, the various types of data that survive in the ground. Therefore, the search for better techniques by which to link sites and artifacts to particular periods and the need to understand them within a relatively narrow chronological framework remain important. Archaeology contributes to, and benefits from, chronometry (the scientific measurement of time). Many well-known scholars have contributed to a host of procedures used in archaeological dating (e.g., Jacques Boucher de Perthes, Christian Jürgensen Thomsen, Charles Lyell, William M. F. Petrie, Pitt Rivers, Andrew Ellicott Douglass, Willard F. Libby); the steady advance of chronometric techniques, especially those developed by physicists and chemists, promises even more precision for scholars who will examine the past in generations to come.

The field of archaeology emerged from a background that included several academic disciplines (e.g., geology, anthropology); its early practitioners included antiquarians from the Age of Enlightenment, whose views about the past ranged from naive to sophisticated. Once these early scholars accepted the idea of a past that differed from their own day, they began to develop means by which to date their discoveries and impose order on the past. As in all the sciences, progress depended on the development of reasonable methods of research and the invention of instruments to measure and analyze data. Because archaeology focuses on cultural changes through time, archaeologists have always sought methods that offer reliability and precision in dating materials from the past. Nowadays, archaeologists have access to many different dating techniques; these are the conceptual tools and instruments used to reach back in time to create a chronological framework for the prehistoric and historic eras.

In the broadest terms, these dating techniques fall into two categories: (1) *relative* dating, which identifies the sequence of archaeological materials (e.g., stratigraphy, ceramic typology), and (2) *absolute* dating, which assigns actual dates (however approximate) to sites, artifacts, and events (e.g., dendrochronology, radiometric dating [i.e., various techniques that determine age by measuring radioactive decay]). These approaches include some older, well-established methods that have demonstrated their value and a number of more recent scientific techniques. All of these dating methods have significant limitations (e.g., cost, kinds of materials that can be tested, span of time for which reliable results can be expected), and scholars who use these techniques must acknowledge problems where they exist (e.g., identification of variables, danger of contamination). Because dating is a pivotal aspect of archaeological analysis, archaeologists and scientists who work with multidisciplinary research teams must constantly work to refine dating techniques, improving the old standbys and perfecting the newer scientific methods, most of which were developed during the latter half of the 20th century.

As noted earlier, many different dating techniques are available, and scientists continue to invent new methods and improve the old ones. These different approaches focus on a variety of recognizable and measurable data, all of which allow archaeologists to date materials in relative or absolute terms. Sheridan Bowman has conveniently categorized the more science-based dating techniques and identified significant examples of each. The first category includes methods that are based on radioactive decay (e.g., fission track dating, potassium-argon dating, radiocarbon [carbon-14] dating, and uranium-series dating). Bowman's second category, dating techniques based on climatic change, includes calcite banding, dendrochronology, ice cores, oxygen isotope dating, and varves. The third type of dating method is based on special properties of materials (e.g., amino acid racemization, archaeomagnetic dating, electron spin resonance, fluorine uptake, thermoluminescence). Techniques based on diffusion processes, Bowman's fourth category, include obsidian hydration dating and nitrogen and sodium profiling.

Foundational Approaches

The most fundamental principle of archaeological excavation, borrowed from geology's focus on stratigraphy, is the law of superposition. On a complex archaeological site, this law provides the basis for the main concept of relative dating by noting that one normally finds older remains in the lower strata of a site, as they are covered by more recently deposited materials. The careful delineation of stratigraphic relationships provides invaluable information concerning site history (sequence of site occupation and use) and the relationships among all deposits, features, and artifacts in the site. As excavators soon discover, a variety of factors can complicate the picture and turn the site into something other than a picture-perfect sequence of easily defined strata. Nevertheless, the primary objective of excavation is the removal of layers (and their contents) in the reverse order in which they were deposited. More sophisticated approaches, like the Harris Matrix, lend precision to this process by forcing excavators to identify sequential, chronological links. Along the way, more precision becomes possible as researchers isolate and assign dates to features, materials, and objects through one, or more, of the scientifically based techniques, comparison with datable items from other sites (cross-dating/synchronisms), or through historical associations. Occasionally, evidence of well-known seismic or volcanic activity helps pinpoint a site's history, as in the case of Vesuvius's eruption in 79 CE.

Another foundational approach in archaeological dating is known as *typology.* Typology takes advantage of archaeologists' attention to detail and to their interest in imposing order on materials recovered from a site. The typological approach, applied to the full range of artifacts or even architectural features (e.g., stone or metal tools, gate plans, pottery), arranges archaeological materials into an order that reflects change and moves toward a hypothetical (relative) chronological order. Once a specific object, like a type of pottery lamp (distinctive in form, decoration, and manner of production), becomes linked with a fixed date at one site, the pottery assemblage of which that lamp is a part assumes a place in the optional dating tools available to the archaeologist (at least for a particular region). Though a ceramic typology can often provide fairly close dates, pottery and other materials arranged into typologies provide only relative dates (such as Thomsen's "three-age system" [stone, bronze, and iron], with elaborate applications to deal with cultures around the world). In fact, archaeologists make frequent use of the terms *terminus ante quem* and *terminus post quem* to distinguish between types of chronological evidence and to highlight the central role that relative dating continues to plays in interpretation.

Another type of relative dating is called *seriation,* a method that helps archaeologists arrange artifacts into chronological sequences by noting the "life cycles" of changes (in which typological features appear, experience extensive use, and fall into disuse). William M. F. Petrie first developed this approach in Egypt to provide a sequence for some 900 predynastic graves. He gave special attention to changes in ceramic forms, including wavy ledge handles that featured prominently on jars in the early ceramic repertoire. Petrie's use of the "concentration principle" makes this one of the earliest applications of statistics to archaeological research. In a period of research in southern Palestine, especially through observations he made during his brief excavations at Tell el-Hesi, in 1890, Petrie also recognized the nature of a stratified mound and laid foundations for the development of stratigraphy and typology.

Decades later, William F. Albright developed a significant ceramic typology ("ceramic index") on the basis of his work at Tell Beit Mirsim. Many scholars subsequently improved upon the perceptive observations made by Petrie, Albright, and others, but their contributions represent similar breakthroughs made around the world by many other pioneers in archaeological dating. Though it is not unique in this regard, ceramics has played a special role in providing a chronological framework for thousands of historic and late prehistoric sites in the Middle East.

Dendrochronology

Dendrochronology, which offers a genuinely absolute date, measures and links the annual tree rings of wood samples that comprise master chronologies for particular regions of the world. This technique developed out of climatic research, but anthropologists quickly recognized its potential in determining the age of ruins in the southwestern United States. Now species of trees known for their longevity, like the bristlecone pine and the European oak, provide a nearly continuous timescale that reaches beyond 10,000 years ago and serves as the primary component of the all-important "calibration curve" in radiocarbon dating. As with the radiocarbon analysis of wood samples, archaeologists must always consider the possible gap between the date assigned to, say, a roof beam and the actual use of that timber in an archaeological context (i.e., distinguish between the age of the wood and the date of the archaeological "event" itself).

Radiometric Techniques

The second half of the 20th century witnessed the invention and development of a host of scientifically based dating techniques, almost all of which derived from distinctive physical or chemical properties. Many of these newer methods are radiometric in nature; that is, they provide more-or-less absolute dates that are tied to known rates of radioactive decay and a precise measurement of isotopes. As indicated earlier, use of the term *absolute* requires some qualification, as laboratory results on any tested sample will include a margin of error, even when scientists are working with known rates of decay and the nuclides function somewhat like a clock. Scientists measure the deterioration of these radioactive substances in half-lives (e.g., the half-life of carbon-14 is 5,730 years). Precision is enhanced through multiple samples and cross-checking with other dating techniques, when that is possible.

Without a doubt, carbon-14 analysis of organic materials is still the best known radiometric dating technique; a by-product of research related to the Manhattan Project, this process was initially developed in 1949 by W. F. Libby and colleagues. After nearly 6 decades, research on the application of carbon-14 to archaeological dating and the resultant "radiocarbon revolution" continue at full speed, with no indication that the latter will slow down. The major journal *Radiocarbon* (published at the University of Arizona) and a regular series of related conferences provide invaluable international venues for discussion about carbon-14 and other isotope dating. As a result of this constant research and refinement, scientists have a much better understanding of the factors that have caused, and still cause, fluctuations in the carbon-exchange reservoir in the atmosphere, oceansphere, and biosphere. The radiocarbon "calibration curve," based on corrections provided by dendrochronology and uranium-series dating, promises much greater reliability and precision. Today's accelerator mass spectrometry (AMS) dating, which allows a direct counting of the carbon isotope ratios, has significant advantages over the conventional carbon-14 method, especially with respect to the small sample size that AMS requires. Even with carbon-14's relatively short half-life and the possible sources of error, the radiocarbon timescale gives good results for samples that date to 50,000 or even 70,000 years before the present. The recent application of Bayesian statistical analysis also enhances the usefulness of radiocarbon, and the future undoubtedly holds other improvements for the carbon-14 method of dating.

Other radiometric dating techniques, which have timescales that reach further into the past than the radiocarbon method, include alpha recoil dating, fission track dating, potassium-argon dating, radiocalcium dating, rubidium-strontium dating, and the uranium-series dating. The potassium-argon method achieved notoriety because of its early use in the study of hominid fossils at Olduvai Gorge (in research carried out by Louis Leakey, Mary Leakey, and colleagues) and other East African sites. By means of sensitive instrumentation, this geochronological process measures the parent-to-daughter decay of potassium-40 to argon-40, isotopes that appear in volcanic lava. The half-life of this potassium isotope is 1.25 billion years, and therefore this technique finds its primary application in geological dating.

Conclusion

Archaeology will continue to refine its array of dating techniques so that field research and laboratory analysis can provide more precise benchmarks in time and space, as well as offer a better understanding of past cultures. Better dating techniques also provide safeguards against fraudulent claims, as in disputes over pieces of art or even the infamous Piltdown hoax.

Decay, Organic

When a living organism dies—be it a fungus, a plant, an animal, or a human being—decay is the final event to occur. The individual parts of the body decompose at different rates. In various ways and in numerous stages, they are reduced to small pieces, decomposed, and finally broken down to low-molecular-weight, inorganic basic substances (carbon dioxide, water, etc.). This process can happen through enzymes of the body itself; through animals, fungi, and bacteria as biotic factors; and finally through abiotic (chemical–physical) factors. The time required for the decomposition crucially depends on the temperature, humidity, oxygen content, pH value, and biological milieu.

Within an ecosystem, decomposition plays an important role. Not only do many organisms feed on the dead organic material, but through decomposition, nutrients that were once absorbed by living organisms can be released and used again by primary producers (most of all by plants). However, the decay process can also come to a standstill or it can slow down significantly—bodies can mummify, ice or amber can conserve them, bodies can form grave wax, or they can remain as skeletons or bog bodies for posterity.

Knowledge of the processes of decomposition and decay is important for forensics, archaeology, physical anthropology, ecology, and in the funeral and cemetery management industry.

Preliminary Remarks on Time

How long a body takes to decompose and what accelerates or decelerates this process depends on the nature and condition of the remains. At the death of a mammal, numerous circumstances have an impact upon the process of decomposition. Important factors can be whether the animal was slim or fat before death and also if it had a fever or any open wounds. In case of infection (sepsis), germs may have entered the body, thus accelerating the process of decomposition. Antibiotics in the body might have delayed the growth of bacteria and therefore may have slowed down the postmortal microbiotic decomposition. The time needed for the decomposition also depends on the ecological circumstances. It is therefore of utmost importance to factor in what animals, fungi, and bacteria had access to the cadaver as well as to consider the weather and soil conditions (moist/dry, warm/cold, acidic/basic). Another issue to be taken into account is whether the cadaver lay close to the surface of the earth, deep within the ground, or in water. Acidic, warm, and humid milieus (with a permeable soil) accelerate decomposition, whereas basic, dry, and cold milieus are usually more preservative. Due to the wide variety of these factors, the time given as an estimate of the relationship between time and the degree of decomposition in Casper's rule can therefore be used only as an approximation in a multifactorial process. Casper's rule provides an estimation as follows: The degree of degradation of a corpse that has been lying on the soil surface for 1 week corresponds to that of a corpse that has been lying in water for 2 weeks or buried in soil for 8 weeks.

Death and Dying

The death of multicellular organisms is a gradual process. For example, if the cardiovascular system of a human being collapses, the individual organs, tissues, and cells can still be vital for several hours or days. The proliferation activity of the epidermis is an example of such "intermediate life," which finishes at 20°C ambient temperature after 35 to 40 hours. It is possible that some cells and tissues are still viable, while other parts of the body have already started to display evidence of decomposition. Not until life on the cellular level has also been completely stopped can one speak of absolute death.

Processes of Decomposition

Autolysis

Autolysis is the self-digestion of cells and tissues caused by the body's own enzymes. In cells of a dying body, the defect cell compartments set free enzymes such as proteases or lipases. They attack the proteins of the cell itself and dismember and denature them. The degrading enzymes can also enter the intercellular spaces and destroy the connection between the different cells (tissue necrosis).

The tissues, which are sensitive to failure of the oxygen supply, and cells, which have many hydrolytic enzymes, are strongly affected from the beginning. Many autolytic enzymes have their temperature optimum at 34°C to 40°C; therefore, a warm milieu enhances autolysis (warm surroundings or fever before death).

Animals

A vast number of animals of different species and classes feed on dead plant and/or animal material (necrophages) or on excrements of other animals (coprophages), and so they are all part of the chain of organic decomposition. On the one hand there are animals that only occasionally feed on dead material, such as omnivore animals eating a carcass (e.g., rats, gulls, ants). On the other hand there are animal species that feed only on dead organic material or that depend on it during a certain stage of development. In particular, several articulates belong to these species. The larvae of snow scorpion flies, for example, feed on dead plant material and also on carcasses. Other animals may also particularly favor a certain species (e.g., the pine sawyer beetle on the pine tree). Certain remains, like the keratin of feathers, horn, or hair, can be utilized by only a few animals such as the fur beetle.

Not all species that take part in the decomposition process appear simultaneously on the dead substrate. In each case the point of time of their appearance depends on their requirement profile (e.g., fresh cadavers, intermediate products of the decomposition, or feces as feed). Therefore one speaks of a succession.

Bacteria and Fungi

Among the organisms of decomposition processes are bacteria and fungi, whose demands on the substrate are very different. Often they excrete exoenzymes, which disintegrate high-molecular-weight substrates (e.g. lignin, cellulose, protein) outside the organism to form more basic products that can be reabsorbed. The substrate is reduced by several species through many stages and is finally assimilated and/or transferred into an inorganic compound (so-called remineralization). In nature, whole groups of different organisms often work together by ingesting and feeding on decomposition or waste products so that their feces can then be used by another species as a feeding substrate.

Chemical–Physical Influences

The chemical milieu, the temperature, and moisture all have an effect on the time needed for autolytic, microbiotic, and animal decomposition. Besides the aforementioned indirect effects, abiotic factors also have a direct effect on the animal or plant material. Mechanical damage can be caused by wind and water. Frost can disperse tissue, variations in temperature and moisture can cause cracks to form (e.g., in bones), and pressure can also have an impact on buried substrate. Substances can dissolve in a moist milieu and can be carried away, especially in permeable sediments. The pH value of the soil can be preservative (depending on the composition of the body parts) or destructive; calcareous compartments (shells) can be affected by an acidic milieu, whereas in an alkaline milieu they are preserved for centuries.

Examples

There are many examples of the decomposition of organic materials (organic decay in the sea, in lakes, of insects, of a dung heap, etc.). Two types are discussed here.

Litter and Wood

The litter (leaves, needles) on the forest soil is disintegrated by articulates, by bacteria, and most of all by fungi. The decomposition takes place in many stages: In the first step the fallen but almost undamaged leaf and needle material has to be made accessible for the destructive microorganisms (destruents) because it is almost impossible for the microorganisms to get through the cutinized layer. An entry is primarily made possible for them through the damage caused by the macro fauna (arthropods and snails that tear the epidermis). Leaves that have fallen to the ground are mostly disintegrated by earthworms, which also eat intact foliage that they have pulled into their tubes during the night. The reduced pieces of the litter and the droppings of the primary decomposers can further be reduced by secondary decomposers such as springtails, mites, roundworms, and potworms. In the third decomposition phase, soil microorganisms (such as fungi; bacteria, especially actinomycetes) can totally decompose the rehashed litter of animal feces up to its inorganic elements.

Decomposition proceeds best under well-aerated, warm-humid conditions (e.g., in the tropical rainforest) because of quick and direct microbial oxidation to carbon dioxide, water, nitrates, and the like. Under cold, acidic, and partially anaerobic conditions, the decomposition is slowed down and peat accumulation can occur. In temperate soil the decomposition depends on the interplay of soil animals and microorganism. The better the soil fauna is developed (e.g., in deciduous mixed forests), the higher the level of decomposition that will occur.

In nature the wood of dead trees is mainly decomposed by fungi. Animal and bacterial decomposition does not play such an important role, but the decomposition through fungi can then lead to insects being able to digest the wood. As far as fungi are concerned, basidiomycetes with a hymeneal fruiting body are far more often involved in decomposition of wood than are ascomycetes and fungi imperfecti. Their hyphae grow into the wood, and during their growth they disintegrate the polymeric carbohydrates and the lignin (creating wood decay). Normally not all substances of the wood are attacked equally, and in fact the secreted enzymes affect the substances of the cell wall differently. This allows a classification of the wood decay by fungi. It occurs as brown rot, white rot, or soft rot.

In the case of brown rot, the fungi (exclusively the fungi of the basidiomycetes) feed on cellulose or hemicellulose so that the lignin part of the wood remains. For example, in 6 months the weight of sapwood can be reduced about 43% by the house fungus. The wood becomes brown, is transverse cracked, and molders cubically. Brown rotten wood parts can last for centuries within the soil because of the high lignin proportion.

In the case of white rot, which is often a very fast decomposition process, lignin, cellulose, and hemicellulose are being decomposed by releasing oxidizing enzymes. The rotten wood becomes white and long-stranded because of the bleaching process. It is possible to distinguish between simultaneous rot and selective delignification. In the case of the former, the carbohydrates and the lignin are being degenerated almost instantaneously; in the case of the latter the lignin is the first to be degenerated, whereas the cellulose is left for later decomposition.

The third type is soft rot. First of all the cellulose is decomposed to hemicellulose, whereas the lignin is more repressive. The wood becomes very soft in texture and gray to dark brown in color. In contrast to the brown rot, the soft rot is not caused by basidiomycetes but by ascomycetes and fungi imperfecti.

Human Corpse

Approximately 4 minutes after death, the decay of the cadaver begins with the process of autolysis. This can initially be noticed in the organs, which have a huge energy requirement, or many lysosomes, such as the intestine, stomach, and accessory organs of digestion. Without clear boundaries between the stages, this autolysis moves to decomposition by putrefactive bacteria and finally ends with skeletization.

The anaerobic conditions that develop within the body, and the nutrient-rich fluids released due to the autolysis, stimulate bacterial growth (especially endosymbiotic gut bacteria). Their emigration out of the gut is supported by the pressure caused by gases produced during decomposition. Bacteria can also enter the body via the skin (especially through open wounds), the mouth, the nasal cavity, and so forth. The bacteria disintegrate released carbohydrates, proteins, and lipids to different acids, gases, and other substances. They cause a change of colors and odors. The organs soften and finally become fluid. The detachment of the epidermis and its attachments and also the bloating of tissue are evident.

After the fluid produced during the decomposition has run off, normally the oxidative processes intensify. In this case the decay occurs in a rather dry milieu; organs and tissues decompose into peat, which is often supported by fungi, especially by molds.

In addition to chemical and microbacterial factors, animals can also be involved in the decomposition of a corpse. An example of a typical series of insects that would interact with a human corpse on the soil surface is as follows:

Shortly after death, attracted by hydrogen sulfide and ammoniac substances, blowflies begin to fly around the orifices and wounds. After oviposition, maggots hatch out of the eggs, they shed their skin twice, and after the termination of their feed intake, they usually leave the corpse to pupate. The speed of the development cycle depends mainly on the fly species and the ambient temperature. If these parameters are known, the time of the first colonization can be calculated (that is the job of the forensic entomologist). The dominant blowflies are accompanied by the fleshflies and the houseflies. As the decomposition progresses, cheese-skippers and latrine flies can be found, and later, fruit flies and humpbacked flies also appear. As the dehydration of the cadaver takes place, larder beetles and caterpillars of the clothes moths appear; these are responsible for the decomposition of the skin. The last remains are removed by the spider beetles and meal worm beetles.

Under "normal" conditions, that means in water-permeable and aerated soil and in 1- to 3-meter depth, the skeletization takes 5 to 7 years. The decomposition proceeds in order of anatomic strength and condition. Joint connections, which are held by a strong ligament and tendon apparatus, are preserved the longest, in particular, the pelvis girdle and the spine.

Concerning the decomposition of bones, once again biological, chemical, and physical factors contribute. The fragmentation of the bone can be caused by pressure of the soil or frost wedging. In acidic soil the hydrolysis of the mineral components (above all, hydroxyapatite) is accelerated. The big inner surface of the bone provides a large area for microorganisms, which are able to produce acidic metabolites and therefore to hydrolyze the apatite and finally to decompose the then unmasked proteins of the bone (above all, collagen). In this way the skeleton can finally decompose completely. Sandy soil indirectly promotes the decomposition of the bone because soluble components can dissolve, while loess soil, on the other hand, promotes the preservation of the bone.

Interrupted Decay

Normally a certain type of physical or chemical milieu is the reason that small animals and microbes are unable to decompose organic substances: high aridity, temperatures under the freezing point, exclusion of light and oxygen, high salt concentrations, or a low pH value. Some instances where organic decomposition under normal conditions is interrupted are described next.

Plants and animals that die in a cold season and cannot be reached by warm-blooded animals or articulata that produce warmth are either preserved or decompose more slowly than usual. Under the right conditions, dead creatures can be preserved for centuries within the ice as the low temperatures avert the microbial decomposition, just like a freezer. Prominent examples are the carcasses of mammoths that were enclosed in the Siberian permafrost (c. 10,000 years old) and the glacier mummy (called Ötzi by researchers) who died in the 4th century BCE in the Alps.

In an acidic, raised bog the soft tissue of animals can be preserved, too, because of the oxygen deficit and the high concentration of antibacterial humic acid. The humic acid also causes the decalcification of the bones and gives a tan color to skin and hair. Sometimes even inner organs are preserved. The most prominent examples for such preservation are the bog bodies of Northern Europe, which go back to the last ice age.

Preservation can also take place in resin that encloses plant parts or small animals. The hardened resin, which can turn to amber when pressurized, conserves the organic substances. Famous examples are the fossils found in amber from the Baltic Sea (c. 50 million years old) or in Dominican amber (c. 30 million years old).

Under anaerobic conditions in a moist milieu, grave wax (adipocere) can be formed. Bacterial activity transforms the unsaturated fatty acids of the corpse into saturated fatty acids (above all, palmitic and staritic acids)—a process that can take months or even years. Adipocere can be preserved for centuries. To a large extent the corpus of the dead body is preserved in its exterior layers (the fat tissue). The inner organs can also be well preserved if they are soaked with fatty acids. The parts of the body that contain less fat (often head and limbs) are usually skeletized. Grave wax corpses can form, especially if a fat corpse remains underwater or if water cannot drain from an earthen grave.

Mummification most commonly occurs where there is extreme dryness, heat, and especially draught. The tissues rapidly dry out and are therefore protected from microbial decomposition. It can happen at different stages during decomposition and can involve the whole corpse or only some limbs.

Finally, the hard parts of an animal body (shell, bones) can be preserved in basic and neutral milieus for centuries, even thousands of years. If secondary mineralization takes place, skeletons can finally form fossils.

DECAY, RADIOACTIVE

In the early days of chemical manipulation, medieval and Renaissance alchemists sought means by which they could transform, or transmute, base metals into gold and silver. In the 20th century, scientists discovered that the transmutation of elements was not an impossible dream. In nature, radioactivity results from the spontaneous decay or disintegration of certain kinds of atoms (with unstable nuclei); these unstable nuclei emit energy (i.e., radiation) as decay particles or electromagnetic waves. Such subatomic changes have occurred naturally throughout Earth's history. Nowadays nuclear physicists artificially alter the composition and behavior of chemical elements for industrial, medical, and military purposes. Because each radioactive isotope decays at a definable rate (known as a half-life), the decay processes of radioactive substances can serve as "clocks" and offer unique opportunities for the measurement of time.

The closing years of the 19th century and the opening decades of the 20th century witnessed remarkable advances in our understanding of matter. Indeed, many famous names from the history of science are associated with early research into atomic structure and the nature of radioactivity (e.g., Becquerel, the Curies, Thomson, Rutherford, Soddy, Chadwick, Bohr). Although some of the terminology has changed over the years, many fundamental concepts related to radioactive decay appear in a brief overview of the early investigations into this phenomenon. Soon after Wilhelm Röntgen's discovery of X-rays, A. H. Becquerel accidentally discovered the phenomenon of natural radioactivity, in 1896, as he conducted experiments on the phosphorescence of uranium salts. As a result, Marie Curie and Pierre Curie dedicated years to the study of radioactivity and discovered the elements polonium and radium through their painstaking analysis of pitchblende (uranium ore); the Curies introduced the term *radioactive* to describe the emanations of uranium and these other heavy elements, which were much more "active" than uranium. Meanwhile, J. J. Thomson's 1897 discovery of the electron, coupled with these other breakthroughs, negated John Dalton's earlier views on the indivisibility and stability of the atom. (Modern particle physics examines the components, forces, and behavior of a subatomic world that is more intricate than Dalton's early 19th-century model, when chemists knew only 33 elements.)

One of Thomson's most productive students, Ernest Rutherford (through his research and experiments in New Zealand, Cambridge, Montreal, and Manchester), collaborated with other pioneering physicists and examined a number of significant aspects of radioactive decay. As a pivotal participant in the golden age of physics, Rutherford, with his curiosity and tenacity, was nothing short of inspirational. In 1898, he discovered that radioactive atoms emitted at least two distinct types of rays (later designated as particles), which he called alpha and beta. Rutherford and his colleagues used these decay particles (later identified as equivalent to the nucleus of a helium atom [a cluster of two protons and two neutrons] and high-speed electrons, respectively) in much subsequent research on the nature of radioactive materials. He also suggested that a third type of radiation might exist; Paul Villard identified the existence of the gamma-ray (electromagnetic radiation) in 1900. These major types of radiation have different properties (e.g., velocity, reaction to magnetic fields, penetrating power).

After discovering radon, a radioactive gas, Rutherford worked with Frederick Soddy and demonstrated that certain heavy radioactive atoms seek stability through disintegration (subatomic change). Rutherford, Soddy, and Otto Hahn conducted research on thorium and other elements that demonstrated their change from one form to another. This research into so-called decay chains resulted in a general, initially shocking, understanding of radioactive disintegration, namely, that elements are not immutable and that parent atoms of certain elements decay to daughter (and granddaughter) products through the loss of particles. For example, the radioactive decay series that begins with unstable uranium-238 ends with lead-206, a stable nuclide. In his study of the transformations that took place in these disintegration series, Soddy referred to atoms that had the same atomic number but different atomic masses as isotopes (also called nuclides nowadays).

Along with Hans Geiger and Ernest Marsden, Rutherford helped create a more accurate model of the atom, as their experiments directed alpha- and beta particles toward sheets of metal foil and observed patterns of divergence and deflection (as these particles reacted to an atom's positively charged nucleus). With Geiger, Rutherford developed an instrument to detect radioactive particles, a noteworthy advance in a field that depends on sensitive instrumentation. He also had a hand in the development of C. T. R. Wilson's cloud chamber, a relatively simple but effective detector that played a major role in the analysis of charged particles, including cosmic rays. (Physicists continue to develop hardware by which they can probe the subatomic cosmos, and much of this research focuses on high-energy particles and radioactive isotopes, e.g., reactors, accelerators, and cyclotrons.) Rutherford also used the versatile alpha particles to bombard light elements and brought about the first artificial transmutation of one element to another (the alchemist's dream) by disintegrating nitrogen nuclei and changing them into oxygen ("playing with marbles," as he described it). As representatives from a slightly later period of research on radioactive decay, Frédéric Joliot-Curie and Irène Joliot-Curie (the daughter of Madame Curie) worked on natural and artificial radioactivity and the transmutation of metals. Later, the Manhattan Project and the subsequent worldwide development of nuclear weapons generated a vast amount of research on fission and radioactivity, research that continues today for nonnuclear scientific and applied purposes.

Every radioactive element has a known rate of decay, or half-life, which is defined as the amount of time required for half of a sample's radioactive atoms to undergo decay. The half-life of some elements is extremely short while the half-life of other elements is extremely long, from a fraction of a second to several billion years. Isotopes whose half-lives are brief are quite radioactive, but elements with longer half-lives cause contamination for a longer period of time. Whereas the decay is random and spontaneous, the rate of decay (or activity) for a sample that contains a large number of the same atoms is predictable. As a result of their investigation of the radioactive decay of thorium, Rutherford and Soddy developed the exponential equation and the so-called decay constant used to calculate this decay rate. The international standard for measuring this disintegration or decay is the becquerel (= 1 disintegration per second).

Various nuclides are useful in radiometric dating, and, as discussed elsewhere in this encyclopedia, different techniques are applied to date archaeological remains and geological samples, from Earth and extraterrestrial sources. There are two kinds of radiometric dating techniques: (1) those based on the known parent-to-daughter decay rate of radioactive isotopes (e.g., radiocarbon [limited to organic materials], uranium–thorium, potassium–argon, uranium–lead), and (2) those based on the measurement of damage caused by the decay of certain radioactive elements (e.g., thermoluminescence, electron spin resonance, fission track). Of course, these methods provide approximate dates that include a range of error. Results from several methods of radiometric dating, applied to numerous samples (meteorites and lunar rocks), suggest that Earth and our solar system are some 4 1/2 billion years old.

Déjà Vu

The French phrase *déjà vu* is literally translated "already seen" or, less precisely, "already experienced." It refers to the uncanny sensation caused by an experience in the present that appears strikingly familiar to an experience from a vaguely defined past. The present feels as though it is being remembered. Often, déjà vu is used synonymously with paramnesia; however, there are terms for varieties of paramnesia having to do with other senses and similar sensations.

Explanations of experience similar to déjà vu arose in occultist and parapsychological circles prior to properly scientific investigation, and authors as far back as Pythagoras and Aristotle in ancient Greece examined the phenomenon. Such theories as hereditary transmission of experience, telepathy, precognition, or reincarnation were popular accounts of the sense of time transcendence experienced during déjà vu.

References to and descriptions of the déjà vu phenomenon have appeared frequently in fiction since the early 19th century, and it was first discussed in scientific literature of the late 19th century. Credit for coining the term is often attributed to Émile Boirac in a letter to the editor of *Revue Philosophique* (1876); however, some note that the topic was discussed by name as early as Arthur Ladbroke Wigan's *The Duality of the Mind* (1844).

With the rise of the Freudian psychodynamic perspective in psychology, many began hypothesizing that déjà vu is the result of remembering an unconscious wish, blurring of the boundary between one's self and external environment, or the rousing of a repressed memory. Gestalt psychologists believed déjà vu to be caused by structural familiarity of a past experience—lived, dreamed, read, or imagined—to the experience in which the déjà vu occurred.

As scientists found methods for examining the brain, their explanations moved farther away from phenomenological descriptions. The main causes purported in this community became epilepsy, temporal lobe abnormalities, and time lag between brain hemispheres or cognitive processes.

The development of even more advanced research methods in cognitive and biological psychology has sparked a resurgence of interest among those favoring these explanations. Often, contemporary theorists suggest that an adequate account of déjà vu must rely on an eclectic combination of these causes. Different causes might explain different experiences, for example, auditory or visual, and possibly even different occurrences of the same experience.

Social, cultural, and media studies theorists have also taken up interest in this topic today. Under the influence of psychodynamic theory's resurgence in continental philosophy and postmodernism, this literature may be seen as part of a broader interest in the study of culture and memory.

Deleuze, Gilles (1925–1995)

In contrast to thinkers such as René Descartes and Immanuel Kant and the static world that they envisioned, Gilles Deleuze, a French philosopher who taught at the University of Paris, emphasizes becoming, contingency, irony, play, difference, repetition, and chance. Deleuze advocates becoming a nomadic thinker with neither past nor future. A wandering, nomadic, erring type of journey leads to the embrace of difference and repetition. Therefore, Deleuze constructs an anti-Kantian model of thought that is aconceptual, nonrepresentational, disjunctive, and inchoate. With this type of impetus, Deleuze's philosophy can be grasped within the context of the turn to difference that occurs in the 20th century with thinkers such as Martin Heidegger and Jacques Derrida.

If Deleuze is anti-Kantian, he is also anti-Hegelian in the sense that he is opposed to all closed or total philosophical systems. In a later work coauthored with Félix Guattari, titled *What Is Philosophy?* the job of philosophers is envisioned to be the creation of new concepts. Borrowing from Friedrich Nietzsche, Deleuze agrees that thought is a matter of creation, and truth is a creation of thought. This does not mean that philosophical concepts represent the truth independent of the plane of immanence upon which they are constructed. According to Deleuze, concepts are complex singularities and intensive multiplicities that do not represent anything. The creation of concepts occurs when a thinker determines a problem on a plane or set of pre-philosophical presuppositions, which he calls the plane of immanence. He also refers to it as the image of thought, by which he means an image that thought gives itself of what it means to think. The sources of truths are problems, which represent the differential elements of thought. More than merely questions to which thought provides answers, problems form the underlying and unanswerable questions that govern the creation of knowledge in a particular sphere.

Deleuze views his philosophy as a form of empiricism, which creates concepts in response to problems. Deleuze's empiricism is also experimental, by which he means introducing thoughts and acts that change an individual perspective. At the same time, Deleuze wants to find hidden differences and the destruction of illusions of permanence. The solving of a problem merely transforms it and offers new challenges rather than breaking the cycle of ever newer problems. Therefore, we must find a way to live with a problem rather than thinking that we can solve it for the foreseeable future. The problem of time is an example of a difficulty that begs for a new conceptualization.

Time in Deleuze's Thought

In his early major work *Difference and Repetition,* Deleuze considers three syntheses of time, which he considers in conjunction with the notion of repetition in each of them. By synthesis, Deleuze means a passive synthesis, or one that does not demand a representation of the sequence of moments to be synthesized within an active consciousness. Deleuze wants to overcome the representational mode of thinking because it is counter to the affirmation of real difference and is opposed to the eternal return. Therefore, Deleuze perceives a problem in the traditional way that philosophers have grasped repetition because it eventually culminates with identity, which renders it an equal, flat, and featureless timeline akin to a succession of moments.

The first synthesis of time is represented by circular time, which Deleuze identifies as the founding of time. Circular time is evident in mythical and seasonal time, which manifests a repetition of the same in the sense that it is a succession of instants governed by an external law. With circular time, a person experiences the present passing as moments cyclically because of the coexistence of past, present, and future. The repetition associated with circular time is concerned with habit, which is the passive synthesis of moments creating a subject.

Within this initial synthesis of time, repetition is not an objective property; rather, it is located in the experience, which is contradictory in the sense that prior moments are located in later instances. This scenario creates an expectancy because the repetition becomes synthesized in the present.

The second synthesis is identified with the foundation of time that Deleuze links with Kant, in which time is conceived as a straight line. With this second synthesis, the past coexists with the present, but it acts as a past that has been present. This scheme places events into time by not viewing a chain of events as constituting time because of the passing of present moments. If the present moment can pass away, it is because the present is already past, or it embodies a past element within it. From Deleuze's perspective, the present moment already possesses a past element in order for it to pass away. By passing away, a present moment becomes a past event for any future present. Repetition assumes an active sense because it repeats something in memory that was previously nonexistent.

Within this second synthesis of time, habit does not play a role because nothing returns. Deleuze refers to this second synthesis as memory, which is not connected to the present as is habit. Memory is associated with the past, or that which has never been present. By synthesizing from passing moments, repetition plays a role by repeating something in memory that did not previously exist, although this feature does not save it from identity. An important philosophical consequence is the radical bifurcation of the subject into the self of memory and a self of experience.

The final synthesis of time is identified as the unfounding of time, in which a pure and empty form of time unfolds. This pure form of time for Deleuze is repetition, which does not represent identity or the same. Repetition is related to difference in the sense that when beings are repeated as something other, their difference is revealed. This scenario suggests that Deleuze adopts Nietzsche's notion of eternal return, which is unrelated to habit. The advantage that Deleuze perceives in the eternal return is related to the fact that it does not suppress difference; rather, it represents a return of becoming and difference. In fact, it affirms difference even under the guise of multiplicity, becoming, and chance. This means that the eternal return is the repetition of that which differs from itself. This implies that whatever exists as a unity will never return; it is only that which is different from itself that can return.

Repetition possesses the power to accelerate or decelerate time, although this is something that cannot be intellectually grasped by an identity discovered in a concept or something similar in a process of representation. Being identified by Deleuze with the power of difference, the event of repetition disappears even as it happens because repetition lacks an in-itself, even though it possesses the ability to alter the mind that encounters it. Because repetition disappears as it appears, it is essentially unthinkable, incomplete, and cannot contain total reality.

If habit is the time of the present, or the always already becoming, and if memory, an old present, is the being of the past, repetition is the eternal return that is the time of the future. Pure repetition disturbs the repetitions of habit and memory and the paradox of the coexistence of past and present. This disturbance is related to the replacement of the linear succession of present moments and the cyclical recognition of revolving past moments by the eternal return of difference. Repetition is analogous to a dice throw, a risky act with an unknown result.

Moreover, Deleuze's notion of time possesses important implications for traditional philosophical modes of thinking. If the present and its previous presents are not similar to two consecutive instants on a linear line of time, Deleuze's conception of the nature of the present makes it difficult for representational thinking to work successfully because the present represents the former present instant and itself as a particular, and the past is presupposed by every attempt at representation. For the past and the future, representing dual asymmetrical elements of the present, this means that the past is caught between present moments, and it is futile to attempt to recreate the past from the present moments. Deleuze stresses the past as the foundation of time, and he acknowledges a basic paradox: the contemporaneity of the past with the present. A second paradox revolves around the coexistence of the moments of time, which results with the past being a synthesis of itself, the present, and future. This indicates that the present and future are mere dimensions of the past.

Another implication of Deleuze's position is related to time and being. Because repetition is unconnected to continuation, perpetuation, or prolongation of something with an enduring identity, Deleuze equates being with difference and repetition. Deleuze associates this equation with the ambiguity and deceptive nature of the notion of origin. For Deleuze, there is no union between being and time because everything is radically relative, without ground, depth, identity, or universality. According to Deleuze, the genuine character of being is the simulacrum in which everything is reduced to differences, which fragments them. If everything becomes simulacrum for Deleuze, there can be no resemblance of time to ontology or space.

Demiurge

Plato was concerned with the relationship between the eternal Demiurge as creator of the world and the birth of time. Time as becoming is understood by humans through astronomy and mathematics.

Plato's *Timaeus* picks up after the discussion in the *Republic* regarding the best form of society. It begins by recounting some of the major points of this discussion, beginning (significantly) with the point that each craftsman should be an experienced specialist and not interfere with the work of other craftsmen. In Book VII of the *Republic,* the education of those who are to guide the society (the guardians) is described; they move from arithmetic through geometry (plane and solid) to astronomy, which will make the soul "look upward"; the beauty of the patterns in the sky will provide a model for earthly patterns. The maker of the sky (the Demiurge) has provided a beautiful example of order for the earthbound craftsman to emulate. Socrates, content that they developed a good design for the ideal state the previous day, would now like to hear about it in action; this gives rise to a tale of the great island city of Atlantis, which sank beneath the sea. Critias finds remarkable the number of common characteristics between the "city in speech" and Atlantis. They then try to shift the comparison to the living city of Athens.

The first to speak in this endeavor is the astronomer Timaeus who, Critias tells us, will begin with the birth of the world and end with the creation of man. The world *does* exist, so there must be a reason, a cause for its existence. The world is a world of becoming, of coming-into-being and passing-away, so it cannot be perfect; but it *is* good. So it must have been fashioned after an eternal model; an account of the model can be (if it can be achieved) the truth, but an account of the sensible world, which is always changing, can be at best a "likely story"—"as being is to becoming, so is truth to belief (*Timaeus* 29b). The world has a maker (the Demiurge) who, like any good artisan, looks to an ideal model and creates the best copy possible. Some copies are better than others, and copies of copies are inferior (as in Book X of the *Republic*, Plato tells us how a painting of a bed is inferior to a bed made by a craftsman in imitation of the ideal Form of Bed). And a copy that has life and moves is superior to one that is static (just as Socrates and his companions desire to see the "city in speech" created in the *Republic* now in motion).

The Demiurge creates an order and harmony, according to mathematical principles and out of geometrical building blocks (the simplest of which are triangles). The created world is a living creature, with a body and a soul, made in the likeness of the ideal Form of Living Creature (the genus containing all the species). And it has a figure—it is spherical, the figure that contains all figures. The world needs a medium in which it comes into being; this medium Plato calls the Receptacle, the Nurse of Becoming. It is something like a room, or a womb; it is the mother to the creative father-force (energy) of the Demiurge copying the model. It is something like a mirror that takes on qualities. This space is eternal and "provides a home for all created things" (*Timaeus* 52b). It cannot be known through the senses (because it has no sensible qualities of its own) but must be apprehended by a kind of "bastard reason"; it seems we infer that it must exist. Qualities appear in the Receptacle, constantly changing, "without reason and measure"; the Demiurge brings order to this chaotic mix, fashioning "by form and number" (53b).

Just as the craftsman (consider a woodcarver) must wrestle with the resistance of the material he works in, the Demiurge is faced with the recalcitrance of his material (which Plato refers to as Necessity). Reason or Mind (represented in the Demiurge) must persuade Necessity to guide things for the best. The Demiurge is assisted in maintaining order by various lesser "gods" (the stars and planets, which are fiery). The need for the gods to bring about order by persuasion is represented in Greek mythology—at the end of the *Odyssey,* by the need for Zeus and Athena to intervene and wipe clean the memories of the families of the dead suitors, so peace can come to Ithaca; and at the end of Aeschylus's *Oresteia,* where Athena must persuade the Furies, who are frustrated because Orestes has been let go free, not to pour venom on the land but to accept a holy sanctuary and friendship mixed with worship. In both cases, the endless cycle of blood-vengeance must be stopped by reason; the analogy to the Demiurge bringing order out of chaos by reason is clear.

For Plato in the *Timaeus,* Space (the Receptacle) is a precondition of creation; but what of Time? Time is a different case; it comes into existence along with the world (he even refers to the "birth" of Time [39e]). The Demiurge desired to make his creation as much like its ideal model as possible. The model is eternal, and it is impossible for a generated cosmos, which is a realm of becoming, to be eternal as true being is. But he could have "a moving image of eternity" (37d); he made the image (Time) "eternal but moving according to number," whereas eternity itself "rests in unity." Thus we have the proportion (analogy)

$$\frac{\text{Time}}{\text{Eternity}} :: \frac{\text{Number}}{\text{Unity}}$$

Unity (the One) is the *arché* (generating principle) of number(s); eternity provides the model of which time is the image. The moving image of the model (eternity) generates time(s). Plato (or Timaeus) suggests that the heavenly bodies that reckon time teach humans to count and develop mathematics, "and from this source we have derived philosophy, than which no greater good ever was or will be given by the gods to mortal man" (47b).

Democracy

Democracy is based on the idea of political self-determination. The emergence of democratic communities dates back to the ancient Greeks. Between 800 and 600 BCE, the political system of *isonomia* developed, a system of equality upheld by the willingness of its citizens to act in the interest of the common good. This lifestyle evolved as part of a cultural development, fostered by the interaction of a variety of factors, including geography and religion. Of particular significance was that in a Greek polis, the potential socioeconomic powers were relatively widespread. A tyrant was usually unable to stay in power for long; moreover, monarchy was not a generally popular idea in ancient Greece. So politics was a matter concerning a wide range of social classes in a polis (*demos*); it was not something "invented" by centers of power. However, this idea of integrating the masses has often been rejected by political philosophy. It is true that Aristotle (384–322 BCE) centered his concept of polis around the idea of free and equal citizens, and he emphasized that the ability to rule, as well as to be ruled, was a political virtue. Yet he rejected democracy as a political community under the rule of the rabble, as, for instance, Socrates (469–399 BCE) and Plato (427–347 BCE) had done before.

This perspective has proven most effective in the history of ideas: Until the modern era there was hardly a notable political philosopher who spoke out in favor of democracy, with the exception of Baruch de Spinoza (1632–1677). One of the reasons is that in earlier times democracy was often equated with direct democracy, such as in the writings of Immanuel Kant (1724–1804). So when democracy is discussed, it is always necessary to explain precisely what form of democracy is meant: Are there limits to democracy, for example, in a body of regulations? Is democracy seen as an end in itself, or does it serve other (higher) purposes? Are democratic decisions the immediate expression of the people's voice, or is the people's voice mediated by representative institutions?

Under the conditions of modern societies, democracy is typically temporary rule. The principle of political self-determination can be appropriately applied only by allocating power temporarily—first and foremost, by electing parliamentary representatives but also by selecting and democratically controlling government officials. The question of power separation and control was pointed out in the Federalist Papers, a series of articles in favor of ratifying the U.S. Constitution in 1787–1788. In Article No. 53, it is precisely described as follows: the greater the power, the shorter its reign; and vice versa. The lesser the power, the less dangerous it is to lengthen its reign.

In many ways, democratic elections are full of prerequisites. One prerequisite is that the political participants consent to prevailing conditions; another prerequisite is that the "loser" accepts the election results, and the "winner" is committed to carrying out his or her political responsibility for the common good during his or her term in office. However, using elections to achieve division of power represents nothing more than a temporary consensus that can be justified only in the light of a people's political self-determination, provided the democratic "rules" of the political system permit a real chance for a change of government. In this sense, the conditions governing the right to vote are of particular significance, as well as the structures of the party system, both of which determine whether all the relevant groups of a population are allowed to participate politically and essentially form a new majority.

The change of majorities is connected to the idea of creating an innovative contest among the pluralist concert of opinions to find a better argument, one that distinguishes the democratic system from other systems. This type of pluralism, which is upheld primarily by parties and political associations, binds time and therefore gives the impression of being "lethargic" with regard to democratic institutions' abilities to learn and respond. In fact, the cost of making decisions increases with the amount of time required, and that usually depends on the number of participants. As a result, democratic processes must be examined on a regular basis to evaluate the balance among the elements of participation, innovation, and efficiency. Yet, only such systems in which today's minority can become tomorrow's majority are capable of integrating political dissatisfaction and achieving reform. The key figures in this type of system-derived process are the floating voters. Nevertheless, a decisive prerequisite for this type of voting behavior is that decisions and responsibility are conveyed rationally (and, in that sense, topically), so that the voter can develop his or her own opinion on the matter in question.

Finding the right moment to make a political decision (*kairos*) is a question not only of luck but also of judgment that belongs, in an Aristotelian understanding of ethics, to prudence—a capacity that especially distinguishes the extraordinary politicians from the run-of-the-mill types. Following sociologist Max Weber (1864–1920), particularly democratic systems should have a strong interest in prudent political leadership, because the temptation is omnipresent that lures politicians to act in accordance with opinion polls to increase their own popularity (if only temporarily). Nonetheless, politics often require unpopular decision making, thus opening the way for a range of actions that are contrary to contemporary thinking or outside the spectrum of long-established routines. In view of accelerated developments in science and technology, not only has an alienation toward the past been growing but also the political responsibility not to submit to the linearity of events. It is important to retain the opportunity to reverse decisions. Otherwise, the limits of the majority principle are quickly reached: It loses its peacemaking character when decisions with irreversible results are made by the present generation for following generations—specifically in the field of risk technologies.

Just as democratic politics should not waste their energy dealing with the inherited problems of a former government's sins of omission, the horizon of political design should not be limited to one legislative period. According to the 20th-century German sociologist Niklas Luhmann, temporalized systems should always be capable of differentiating between reversibility and irreversibility. This challenges political systems to gain temporal autonomy with regard to the surrounding systems; the functionality of democracies depends primarily on the time available for negotiating decisions. Essentially this type of "limited government" is the result of a historical development, which also takes time. A democratic culture grows over centuries, a constitution begins to take shape only over decades, and several years are necessary to achieve governmental efficiency. If there is only "one" specific time period for the development of a democracy, it is, according to political scientist and sociologist Claus Offe, hardly possible to prevent the dilemma of simultaneousness. The transformational societies in Central and Eastern Europe during the 1990s fittingly illustrate this point; the failing attempts to democratize countries in the Middle East would be another case in point.

Failed attempts to implement democracy should not divert attention from democracy's almost inexorable triumphant progress. There is hardly a political system left that can refuse to justify its decisions democratically—or to at least create the impression of democratic legitimacy. This tendency is further promoted by the processes of globalization and particularly economic liberalization. In a modern state the relationship between a liberal economy and democracy may not be compulsory, but it has proven to be effective. With the increasing internationalization of political (as well as economic and ecological) challenges, the following question becomes more and more significant: How can democratic responsibility be organized on a global scale? History shows how democracy has been culturally bound to polis and the nation state. But what a democratic cosmopolis looks like remains to be seen.

DERRIDA, JACQUES (1930–2004)

The Algerian-born French philosopher Jacques Derrida was a prolific writer whose influence extended to such varied fields as literary theory and semiotics as well as philosophy. Among the many issues addressed in his work is the concept of time. Noteworthy for his pervasive use of irony, Derrida is a master of playfulness. There is, for instance, an element of risk in his philosophy because he contends that his thought might not mean anything. Overall, Derrida offers no thesis and no philosophical position, because any distinctions that he makes he also undermines at the same time. Even though he leaves a reader with no identifiable philosophical position, he does adopt a method that he calls *deconstruction.*

Derrida's method promises to undo what he calls onto-theology, which can be identified with metaphysics, or what he calls *logocentrism,* which Derrida defines as the subordination of writing to the spoken word (*logos*). He equates logocentrism with the metaphysics of presence, which is the archenemy of deconstruction. As an expression of the metaphysics of presence, the fundamental error of logocentrism represents an illusion that reality and its categories are directly present to the mind.

Deconstruction is a method that does not produce anything, but it does reveal what is already present in a text. It is possible to grasp deconstruction as a simultaneous dismantling and building up because whatever position is taken is immediately negated. Deconstruction is exorbitant in the sense of exceeding the track of its orb. By passing through the line that it traces, deconstruction is a double crossing: a breaking through and a violation. Its exorbitant nature also means going beyond what is reasonable, just, or proper. In this regard, deconstruction undermines the propriety of reason.

Deconstruction is also a kind of double reading because it retraces a text to its limits, and it also marks the limits of a text. It is the trace that exposes the blank spaces of the text, that indicates what the text fails to constrain. At the same time, the process of deconstruction leaves tracks in the text in the form of remarks, that are like memory. This suggests that a track is already in a text, and it is only revealed by deconstruction, a process that also leaves a track in the original text. This implies that deconstruction leaves a text not dissimilar from its condition prior to deconstruction, but yet it is not the same. The remarks cut the text, and they perform an act of castration, so to speak, by clipping the logos of the text. The basic aim of deconstruction is to return to the metaphoric, poetic language where the power of signification has not been exhausted, in a process that leads to greater self-awareness. Being the deconstructionist, Derrida performs like a mime who occupies a position outside, or on the edges of the logocentric Western tradition. The mime's actions allude to nothing, reflect no reality, and produce merely effects of reality.

Because the concept of time is connected intimately with metaphysics and its concomitant presence, there is no alternative notion of time possible from the viewpoint of Derrida. As this is the case for Derrida, an alternative approach to the problem of time and its metaphysics of presence is his neologism *différance,* which is a finite movement preceding and structuring all opposition, that possesses a spatiotemporal significance for Derrida. *Différance* originates before all differences, and its "ance" ending indicates that it is neither simply a word nor a concept; it is neither active nor passive; and it is neither existence nor essence. It makes no appearance because it is not a phenomenal entity, whereas its movement represents a play of traces. This play of traces possesses no sense, because by presenting itself, a trace simultaneously effaces itself.

Différance is etymologically associated with the English term *differing,* which suggests a kind of spacing, and its association with *deferring* implies a temporalizing in the sense of a delay or postponement. Being simultaneously spacing and temporalizing, *différance* precedes time conceived as presence because the nothing of *différance* takes priority over being or time. This implies that absence precedes the presence of the present moment or being present, which suggests that presence is always deferred.

By thinking from the standpoint of *différance,* Derrida opposes any unity between being and time or place and time because their unity represents sameness, which suggests something static and unchanging. As Derrida thinks that there is no realm of *différance* because it subverts every realm, including its own, this implies that space and time are not intrinsically interconnected because spacing designates no presence, which is an irreducible exterior and a displacement indicating an irreducible otherness.

Because *différance* is in a constant state of flux, neither presence nor the present moment has a privileged place in Derrida's philosophy. This constant movement represents the play of traces, which is devoid of sense because the traces constantly efface themselves. The trace compromises the present moment and any residue of a past experience. In other words, the trace makes it impossible for a person to ever be located in a self-contained present moment.

Derrida's notion of time is also characterized by deferral, which suggests that what is happening is always to come. This implies that time is always slipping away. Nothing is ever stable or static; everything is subject to a process of change. Consequently, all past change can be recognized only from the perspective of the future, which is also subject to a process of transformation. For Derrida, the future is not something that will become present, but the future is rather that which makes all presence possible and at the same time impossible. A major consequence is that a self cannot become present to itself. Even though our existence is temporal, the experience of self-presence always eludes us. Instead of self-presence we must wait, or our experience is deferred, which Derrida refers to as messianic.

Derrida's notion of messianic must not be confused with the historical faiths of Judaism, Christianity, and Islam, because these monotheistic religions expect a Messiah with certain characteristics, such as maleness. Derrida calls and waits for the wholly other, or Messiah, to arrive. Derrida's Messiah, however, can never actually arrive, which is true even if the Messiah does come.

Because the futuristic Messiah is a completely ungraspable and unknowable other, we cannot truly know him even when he is present. Derrida thinks that our existence involves waiting expectantly for a messianic future event. We can wait actively or passively, but we must have openness toward a future that is noncircumscribable by any prior horizons of meaning that we impose upon the possible future. This is not a future that can ever become a present moment; it is forever deferred. We must thus remain open to an unknown and ungraspable futurity. For Derrida, time thus represents a disunity and uncertainty.

Descartes, René (1596–1650)

René Descartes is one of the most important figures in the history of philosophy. Many of his ideas—for instance, his demand for a foundation of the sciences on an apodictic principle; his use of mathematics as a paradigm for natural science; his concept of science as a systematic totality; and his first principle of all philosophy, the famous *cogito, ergo sum* ("I think, therefore I am")—deeply influenced Western European philosophical and scientific thought. At the same time, Descartes articulated some general problems still contentious in today's philosophical discussions, such as the problem of body and soul, the irreducibility of the first-person perspective, and the problem of the existence of an external world. Descartes also earned much criticism for his dualist conception of human beings as consisting of two real, distinct substances (body and mind/soul) and his mechanistic model of the (animated) body.

René Descartes was born in 1596 in La Haye (today called Descartes), a village near Tours, France. Between 1606 and 1614 he was educated in the Jesuit College of La Flèche. Although this college was grounded on scholastic tradition, especially the philosophy of Aristotle, Saint Thomas Aquinas, and Francisco Suárez, it did not ignore the study of (natural) science. Descartes also came into contact with the works of ancient mathematicians, such as Pappus and Euclid. Deeply inspired by the validity and evidence of mathematical proof, Descartes became dissatisfied with natural philosophy based on Aristotelian principles, such as the doctrine of substantial forms and self-motion of animated bodies as being caused by their souls. He also disagreed with a foundation of philosophy on theological principles and stressed the necessity of a separation of reason and faith.

French mathematician and philosopher René Descartes (1596–1650). His views about knowledge and certainty, as well as his views about the relationship between mind and body, have been very influential over the past several centuries.

After his time in La Flèche, Descartes studied law in Poitiers. In 1618 he enlisted in the Dutch, and later in the Bavarian, army. One year later, Descartes became acquainted with Isaak Beeckman, a Dutch scientist and mathematician, under whose influence he began working on mathematical studies of natural phenomena. Between 1619 and 1629, Descartes traveled widely and also frequented a circle of mathematicians and physicists gathered around Father Merin Mersenne in Paris. From 1629 on, Descartes lived in different domiciles in Holland for about 20 years. During this time, Descartes was working on optical, meteorological, and geometrical issues. At the same time, his concern was to find the final principles of the sciences and philosophy. In 1637 Descartes published his *Discours de la mèthode (Discourse on Method);* 4 years later his famous *Meditationes de prima philosophia (Meditations on First Philosophy)* appeared. The *Principia philosophiae (Principles of Philosophy),* Descartes' second main work, followed in 1644; his final work, the *Les passions de l'âme (Passions of the Soul),* was published in 1649. In the same year Descartes moved to Stockholm at the invitation of Queen Christina of Sweden, who employed him as philosophical and mathematical tutor. He died in 1650.

The Concept of Time in Descartes' Works

At first sight, the concept of time does not seem to play an important role in Descartes' thought. In both his major works, the *Meditations on First Philosophy* (Med.) and the *Principles of Philosophy* (PP), time seems to be of little interest. In Med. III Descartes discusses the *natura temporis* (nature of time) in a very short passage as a supporting argument for his first proof of God's existence; in the PP time merely serves as an illustration for general epistemological and ontological problems. At second sight, however, the issue is far more complicated. Although the singular passage in Med. III discussing the concept of time seems to be marginal because of its shortness, it nevertheless marks the zenith of the whole proof of God's existence; in the PP, the concepts of time and duration show an irritating ambiguity. The following sections discuss Descartes' reflection about time in the *Meditations* and provide an outline of Descartes' definitions of *time* and *duration* in the *Principles of Philosophy.*

Time in the Meditations

Descartes' aim in the *Meditations* is to establish certain and indubitable knowledge. For this purpose he starts scrutinizing the validity of the opinions he formerly had believed to be true. Descartes does not try to prove his opinions to be false; it is enough for him to show their doubtfulness, since "my reason convinces me that I ought not the less carefully to withhold belief from what is not entirely certain and indubitable, than from what is manifestly false, it will be sufficient to justify the rejection of the whole if I shall find in each some ground for doubt" (Med. I 1). Sensual perception soon appears to be no candidate for indubitable truth; first, the senses "occasionally mislead us respecting minute objects" (Med. I 4); second, Descartes perceives "clearly that there exist no certain marks by which the state of waking can ever be distinguished from sleep" (Med. I 5). In a third step, Descartes doubts the validity of rational and mathematical insight by constructing the concept of a "malignant demon [*genius malignus*] who is at once exceedingly potent and deceitful" and "has employed all his artifice to deceive me" (Med. I 12). However, although the result of the First Meditation seems to be "that there is nothing certain" (Med. II 1), in the Second Meditation Descartes soon finds "one thing that is certain and indubitable" (Med. II 1), namely, the fact of his own existence:

> Doubtless, . . . I exist, since I am deceived; and, let him [sc. the malignant demon] deceive me as he may, he can never bring it about that I am nothing, so long as I shall be conscious that I am something [*quamdiu me aliquid esse cogitabo*]. So that it must, in fine, be maintained, all things being maturely and carefully considered, that this proposition *I am, I exist,* is necessarily true each time it is expressed by me, or conceived in my mind. (Med. II 3)

An investigation of the question "what I am" and the consideration that the existence of bodies is dubitable—since bodies are the objects of sensual perception that has been doubted in Med. I—brings out the conclusion that all Descartes can be absolutely certain of is to be "a thinking thing [*res cogitans*]. . . . But what is a thinking thing? It is a thing that doubts, understands, [conceives], affirms, denies, wills, refuses; that imagines also, and perceives" (Med. II 9). In other words, Descartes cannot be certain whether the objects of his acts of consciousness, including his own body, exist independently of these acts, but he nevertheless can be certain that these mental acts themselves and he as the "thing" (*res cogitans,* mind [*mens*]) in which they are produced exist. The aim of the following Third Meditation is to transcend this solipsist perspective by working out the basics for the proof of an external world. This, however, cannot be done unless God's existence and truthfulness are demonstrated: "I must inquire whether there is a God, as soon as an opportunity of doing so shall present itself; and if I find that there is a God, I must examine likewise whether he can be a deceiver; for, without the knowledge of these two truths, I do not see that I can ever be certain of anything" (Med. III 4). For this purpose, Descartes analyzes the idea of God by focusing on two aspects: first, whether Descartes himself as a finite thinking substance could be the cause for this idea's existence within his mind; second, whether there is a need to ask for a cause for this idea's existence at all. The concept of time plays a crucial role in Descartes' discussion of the second question.

Descartes starts with a definition of God: "By the name God, I understand a substance infinite, [eternal, immutable], independent, all-knowing, all-powerful, and by which I myself, and every other thing that exists, if any such there be, were created" (Med. III 22). As a finite substance, Descartes argues, he cannot be the cause of the infinity involved in the idea of God. "For though the idea of substance be in my mind owing to this, that I myself am a substance, I should not, however, have the idea of an infinite substance, seeing I am a finite being, unless it were given me by some substance in reality infinite" (Med. III 23). Descartes also denies that God's infinity and perfection could be set within himself potentially, "for . . . although it were true that my knowledge daily acquired new degrees of perfection, and although there were potentially in my nature much that was not as yet actually in it, still all these excellences make not the slightest approach to the idea I have of the Deity, in whom there is no perfection merely potentially [but all actually] existent" (Med. III 27). In addition, Descartes argues that it is impossible to interpret the infinity and perfection involved in the idea of God as mere abstract negations of his (i.e., Descartes') finitude and imperfection. Nevertheless it is still possible that the divine features of God's idea do not require a cause for existing in Descartes' mind. Thus, Descartes asks himself "whether I, who possess this idea of God, could exist supposing there were no God" (Med. III 28). In this case, either Descartes was the cause of his own existence or there was no cause for his existence at all. Descartes tries to demonstrate the impossibility of both suggestions by discussing the nature of time:

> And though I were to suppose that I always was as I now am, I should not, on this ground, escape the force of these reasonings, since it would not follow, even on this supposition, that no author of my existence needed to be sought after. For the whole time of my life may be divided into an infinity of parts, each of which is in no way dependent on any other; and, accordingly, because I was in existence a short time ago, it does not follow that I must now exist, unless in this moment some cause create me anew as it were, that is, conserve me. In truth, it is perfectly clear and evident to all who will attentively consider the nature of time [*natura temporis*], that the conservation of a substance, in each moment of its duration, requires the same power and act that would be necessary to create it, supposing it were not yet in existence; so that it is manifestly a dictate of the natural light that conservation and creation differ merely in respect of our mode of thinking [and not in reality]. (Med. III 31)

The temporality of the "I" thus involves the metaphysical dependence of the finite self from an infinite cause, that is, God. Because time has no intrinsic continuity but appears as a series of relatively independent moments, any continuity of duration calls for a cause; and since continuity is equivalent with permanent creation, which needs a power that Descartes cannot find within his own existence, only God can be the cause for the permanent being of the "I." Thus, according to Descartes the mere fact of one's own temporal existence immediately indicates the existence of God in a way that knowledge of myself involves knowledge of God:

> When I make myself the object of reflection, I not only find that I am an incomplete, [imperfect] and dependent being, and one who unceasingly aspires after something better and greater than he is; but, at the same time, I am assured likewise that he upon whom I am dependent possesses in himself all the goods after which I aspire [and the ideas of which I find in my mind], and that not merely indefinitely and potentially, but infinitely and actually, and that he is thus God. (Med. III 38)

"Time" in the Principles of Philosophy

In the *Principles of Philosophy* Descartes takes a more objective perspective on time and duration. However, he seems to be irresolute where time and duration have to be located in ontological terms. He states: "Whatever objects fall under our knowledge we consider either as things or the affections of things, or as eternal truths possessing no existence beyond our thought. Of the first class the most general are substance, duration, order, number, and perhaps also some others, which notions apply to all the kinds of things" (PP I 48). "Duration" here seems to be a "thing" (*res*) just as a body or a mind. A few pages farther, however, the concept of duration is denied to designate a thing; it is merely the name for a mode (accident):

> We will also have most distinct conceptions of duration, order, and number, if, in place of mixing up with our notions of them that which properly belongs to the concept of substance, we merely think that the duration of a thing is a mode under which we conceive this thing, in so far as it continues to exist; and, in like manner, that order and number are not in reality different from things disposed in order and numbered, but only modes under which we diversely consider these things. (PP I 55)

Again the situation changes when Descartes discusses the relation of time and duration. Now duration seems to be something in the thing (substance) itself, while time now appears to be a mere mode of our thinking:

> Of these attributes or modes there are some which exist in the things themselves, and others that have only an existence in our thought; thus, for example, time, which we distinguish from duration taken in its generality, and call the measure of motion, is only a certain mode under which we think duration itself . . . [;] that we may comprehend the duration of all things under a common measure, we compare their duration with that of the greatest and most regular motions that give rise to years and days, and which we call time; hence what is so designated is nothing superadded to duration, taken in its generality, but a mode of thinking. (PP I 57)

While time is nothing but a measure of comparing the durations of things and thus a mode of our thought, not of the things themselves, duration itself cannot be separated from the enduring thing unless by abstraction—that is, as a mode of our thought: "For example, because any substance which ceases to endure ceases also to exist, duration is not distinct from substance except in thought (*ratione*)" (PP I 62). Descartes' indecision about the ontological and metaphysical location of time and duration results from a fundamental ambivalence of the Cartesian concept of substance, as the term *substance* can indicate one individual being among others of the same genus (e.g., one singular body) as well as the genus itself (e.g., "the extended substance" in the sense of "extension as such").

Descartes' concept of time and duration as a discontinuous series of moments and the temporal vagueness of the *sum* ("I am") has been extensively discussed and critiqued by other philosophers, in the 20th century perhaps most notably by Martin Heidegger.

Design, Intelligent

Most broadly construed, intelligent design (ID) is the name chosen for a controversial strategy, combining both theory and practice, which is aimed at giving the ancient, philosophical design argument new life in the sciences, especially in U.S. public high school life science classrooms. More narrowly, the term is qualified so as to collect acts, persons, or propositions as elements related to the strategy—as in ID theorist, ID conference, ID tenet, or ID curriculum. The most contentious of these is surely ID science, or any connotation of the same. Indeed, ID flatly rejects contemporary science, including its thinking about time.

As theory, ID is the thesis that the sciences require an appeal to intelligent design to succeed at appointed explanatory tasks. As practice, ID embraces numerous forms of publicity for its theory, especially those that create the impression that the theory is, or ought to be accepted as, good science. These practices include television and radio appearances, private funding, journal articles, conferences, Web sites, rhetoric, sophistry, lawsuits, textbooks, mass-market books, curriculum packages, teacher-training programs, membership drives, campus events, and a host of religious, social, and political associations. ID theory and practice are carried out almost exclusively under the auspices of the Discovery Institute, a conservative think tank located in Seattle, Washington.

The full strategy of ID was described by Phillip Johnson in his book of 1997 and again in an online document, known as the *Wedge Document,* prepared for the Discovery Institute. Both treatments envision three phases scheduled over 20 years. The latter commits ID to the task of defeating "scientific materialism and its destructive moral, cultural and political legacies" and to replacing "materialistic explanations with the theistic understanding that nature and human beings were created by God." In the first phase, envisioned as a 5-year operation starting in 1999, ID proponents in the United States will publish 30 books and numerous articles. In the second phase, they will seek publicity for their work by contacting and cajoling U.S. broadcast media, lawmakers, congressional staff, and op-ed pages in newspapers. This phase is meant to prepare the public for reception of ID thinking. The third phase aims at "cultural confrontation and renewal." At this point the movement plans to use the courts to force their ideas into science classrooms.

ID and "Creation Science": Court Cases

A court case arose sooner than expected. In the 2005 case of *Kitzmiller v. Dover Area School District,* public school inclusion of the theory employed by the ID strategy was found to violate the establishment clause of the U.S. Constitution, and ID was legally ruled religion, not science.

The same fate befell ID's forebear, creation science, which was found to violate the establishment clause in the 1982 case of *McLean v. Arkansas Board of Education.* Like ID, creation science combined both theory and practice. As theory, it was strictly anti-evolutionist, embracing what is known as Young Earth creationism, which holds that the earth is between 6,000 and 10,000 years old. Its claim to scientific status was based on a dismissal of traditional earth and life sciences, including radioisotope dating and the accepted understanding of the geological and fossil records. In place of these it offered what is known as flood geology, which asserts that geological strata and the entire fossil record were laid down in the Great Flood described in the biblical story of Noah's ark. As practice, creation science pursued publicity, political connections, and a place in the science curriculum of public schools.

In their respective court cases, both ID and creation science were found to rely on a failed, two-model approach in which criticisms of one model are fallaciously taken as evidence in favor of the other model. Creation science pointed to weaknesses and omissions in evolutionary theory as evidence in favor of flood geology. In *Kitzmiller v. Dover Area School District,* the court found that ID did much the same. Omissions in evolutionary theory were adduced as evidence in favor of the ID theory that complete scientific understanding requires an appeal to intelligent design. Also in both cases, the supernatural was appealed to as an explanatory principle, in violation of the basic, naturalistic assumptions of science.

ID differs from creation science in that it does not assert a young earth; however, it does not officially deny one. ID is a broad movement, able to attract and accommodate both young earth and old earth creationists. In addition, ID does not rely on biblical literalism, though it carefully courts churches and flocks who do. ID is also importantly different from the thesis known as theistic evolution, which asserts that evolution is merely God's way of creating life forms. This view is officially held by most mainline Christian denominations; they necessarily accept an old age for the earth because they also accept the science of evolution. In addition, theistic evolution must accept evolution at all levels, whereas ID need not. ID accepts only what many creationists call microevolution, meaning that genetic anomalies can lead to prevalent changes within kinds. Many proponents of ID, such as William Demski, explicitly deny what is called macroevolution, that is, the mutation of kinds, or the fluidity of species—the whole notion of a common ancestry among fish, birds, amphibians, humans, and amoebas. Instead of macroevolution, these theorists assume what is often called special creation, the view that each species or kind was created in an individual act of creation, roughly as they are now barring microevolutionary changes. Thus, although it appears to accept an older earth than does creation science, ID is in fact compatible with a young earth and incompatible with theistic evolution.

Theory, Tenets, and Pseudoscience

In accord with the plans laid out by Johnson and the Discovery Institute, ID proponents frequently appeal to one another's publications and credentials to bolster their own individual cases. This echo chamber creates the impression of a wealth of expert agreement on the scientific value of ID theory. As a matter of fact, however, favorable expert evaluations of ID tenets are common only among cohorts of the Discovery Institute. Experts unaffiliated with that entity are unanimous in their agreement that ID's positive contributions to science are none, whereas its positive contributions to anti-intellectualism, misology, and sciolism remain inestimable.

ID practice centers on promoting the use of its textbooks and curriculum packages, most notably *Of Pandas and People,* which was originally a creation science textbook but was reinvented as an ID text more than a decade ago. Although ID publications and orators recommend this work, they make more frequent reference to Michael Behe's *Darwin's Black Box* and Demski's *The Design Inference* and *No Free Lunch*.

Behe, a microbiologist, claims to accept macroevolution, known in biology as common descent. But his pronouncement is at odds with his famous theory of the bacterial flagellum. According to this view, the flagellum would be useless if one of its parts was missing, and a structure that exhibits this property, dubbed "irreducible complexity," could not have evolved gradually, that is, from first having several of its parts to later having all of them. Instead, it must have been designed roughly as is, and Behe is stuck with flagellated bacterial species as deriving from special design, that is, from an individual act of creation. In that case, the common descent of these bacteria and any other life form is impossible, and Behe's position directly rejects the thesis of common descent. In response to it, the literature has developed numerous proposals about the evolution of the flagellum. The literature also reveals no serious modification of Behe's position since its publication and no interesting experiments or insights stemming from it.

Demski's contributions to ID theory revolve around the notion that eliminating chance and necessity as probable causes argues for intelligence as a probable cause. He calls "specified complexity" a property of objects that match an independently given pattern. For example, if you write down the opening of Hamlet's soliloquy, "To be or not to be," you reproduce a pattern that was specified by Shakespeare. Any random string of letters is complex, but some strings match independently specified patterns. When we see many of these successful matches, we conclude that intelligence is behind them, rather than chance (because the matches are not random) or necessity (because the matches obey no natural law). To the extent that organisms exhibit specified complexity, Demski holds, they too, like a sentence, must be understood as intelligently designed. He is impressed with the complexity of the flagellum described by Behe, seeing it as realizing an independently given pattern, a pattern that includes the kind of engineering we see in human contrivances, such as O-rings and a motor. The eye, he contends, exhibits the kinds of contrivances found in human camera design. Specified complexity, evidence of intelligent design, is all around us, waiting to be described. In *No Free Lunch,* Demski argues that mathematics suggests that the theory of natural selection lacks the power to do the things that biologists think it can do. Hence, the specified complexity he seeks to explain lies beyond the ken of conventional evolutionary biology—meaning that chance and necessity can be ignored as explanatory avenues, and intelligent design is all we really need. Although he is careful to avoid referring to his intelligent designer as a deity, and offers to not choose between its being either a deity or a race of sophisticated aliens, his works make clear that Demski is committed to an essentially religious conception of the sciences, in which, as he puts it, no theory has value "apart from Christ."

Some critics, such as Eugenie Scott, accuse ID proponents of relying on a fallacious appeal to ignorance, because one of the theory's premises asserts a lack of knowledge. "We lack a natural explanation in domain E; therefore, the phenomena in domain E were intelligently designed." Others, such as Mark Isaak, argue that ID proponents rely on a premise asserting incredulity, or disbelief, which inscribes a fallacy of the form: "It is inconceivable that X developed naturally; therefore, it must have been designed." ID can also be seen as an all-or-nothing mistake: Either historical biology can do all, or it cannot do enough in some domain, without recourse to the design thesis. This assumption yields fallacies of the form, "Evolution cannot fully explain Y; therefore, intelligent design helps to explain it." This is thoroughly mistaken because to assert that anything in the universe is the way it is because God or a race of sophisticated aliens made it that way is to offer an unscientific account, because it is an account that cannot be confirmed or disconfirmed empirically. In addition, the belief that a structure was intelligently designed does not help us to understand how it works. Hence, it explains nothing. These simple fallacies have been pointed out repeatedly, but the movement has not taken them to heart. Instead of modifying their thinking, and eliminating mistakes, they insist instead, and all the more loudly, that their ideas are being suppressed.

As described by R. T. Pennock, creationism has evolved from a crude attack on biology to a more sophisticated attack on the nature of science. Its new, ID thinking properly belongs more to the philosophy of science than to science proper. In contrast, Massimo Pigliucci treats ID as science in a weak sense that includes astrology, alchemy, and numerology, though it is unscientific in any stronger sense. ID is specifically not empirical because no observation or set of observations will ever prove whether an individual, an ecosystem, or the whole of nature is intelligently designed or not. In fact, the design thesis is widely understood to be consistent with any observation statement, making it metaphysical rather than scientific.

As described in the *Wedge Document,* a major strategy of the ID movement involves creating the public impression that scientific accounts of the origins of life are in serious crisis, and that those scientists who reject the notion that life evolved deserve a place in the sun. This impression was already worked on in the 1980s by Michael Denton. Of course, there are few scientific challenges to the thesis that life evolved, and cohorts of the Discovery Institute are not being suppressed. Nonetheless, the movement insists that there is a deep controversy over the evolutionary foundations of biology, and that the best way to treat dissenting scientists fairly is through the pedagogy of "teach the controversy," which would require that ID doctrines be taught in science classrooms. Because ID is not really science but rather a religious way of thinking, teaching the controversy over ID amounts to treating a theological or metaphysical debate as a proper content of high school science classes. Tellingly, religious neutrality is often invoked as grounds for demanding the inclusion of ID in the classroom. But of course, religious neutrality means treating all religious thought equally, which is most easily achieved by leaving all religious doctrines equally out of the science curriculum.

A simple and elegant solution like that will not satisfy proponents of ID, because their fundamental complaint is that science does not include God. Their project, on the basis of which they appeal for funding and political associations, is to put God at the beginning of science, as the beginning. Johnson has argued that knowledge is incomplete as long as the thesis that God created the universe is not accepted as the starting point of science. He misunderstands science, which can begin only when God and other supernatural agencies are left out of the picture. Johnson's position, along with the fact that there has been no modification of ID theory in the past decade, suggests that the pseudo-science published by ID theorists such as Behe and Demski exists merely to gain access for demolitionists of science, who plan to wreck and rebuild on religious foundations.

DESTINY

Destiny is one of those subjects of interest in quests for the meanings of reality, human life, and the world at large. The term *destiny* can mean a predetermined occurrence of happenings, a future that is inevitable and unavoidable or not maneuverable, or an event fixed to take place at a particular point in time. It is also associated with a fate with which one is set up as one's lot. Destiny is a pattern of an occurrence of events that are out of the reach or control and in the hand of an external power. This notion of destiny thus entails a belief that there is an order that exerts agency over the happenings of events in the lives of human beings and the universe as a whole.

Among the various cultures, religions, and societies around the world can be found different notions and interpretations of destiny. The philosopher Messay Kebede, for example, in his book *Survival and Modernization,* formulates the central place of the notion of destiny in Ethiopian culture. According to him, destiny is referred to as *idil*—an Amharic term close to the meaning of chance, fate, or fortune. According to Kebede, the notion of destiny is embedded within the conception of time in Ethiopian philosophy.

For Ethiopians, according to Kebede, time is the doing and undoing of things, the ups and downs of life. Time is the good and the bad that may happen to someone or a particular group. Time is associated with fortunes and downfalls or failures. Thus people are said to have a favorable period of time when they attain power and access to authority and wealth and enjoy a good state of affairs of life in its various aspects. In all aspects of life, destiny is associated with the notion of time that success is viewed as a measure of the position of time being on one's side, whereas failure or loss is an indication of time being unfavorable, thus against. This can be in trade, war, a day in court, an accident, joy, sorrow, crop yield on a farm, or assuming or losing political position. Inherent in the notion of time, in Ethiopian culture, is the idea of promotion and downfall—time as the advent of destiny. Those who are bestowed with time in their favor are strong and unconquerable, whereas those who are disfavored by time are destitute and helpless.

Social orders and political systems and practices are all manifestations and reflections of time. It is time that gives power to those who are in a leadership position, and it is also time that causes others to be ruled and assume a lower position in the social hierarchy. From this perspective, Kebede argues, the Ethiopian conception of time is different from the Western notion. For Ethiopians, events are time or outcomes of time phenomena. Thus events and time are linked, and time is destiny. Time is the happening of events in a cyclical fashion—the ups and downs, not a linear progression from the past through the present into the future.

Claude Sumner, who studied Ethiopian cultures extensively and over many decades, outlines the notion of time in the Ethiopian culture. In his analysis of the *Book of the Philosophers,* a document considered to be an embodiment of Ethiopian philosophy, Sumner elucidates the various meanings of time. As a linear continuum, time is exemplified by what has happened that never comes back, like a spear that moves forward to its target. Accordingly, time is not cyclical; it is irreversible. This, Sumner presents, is a historical notion of the linearity of time, which has a past, a present, and an unknown future. Whatever happens never comes back, and life as events of time follows the same pattern. There is time for everything, and a wise person is one who knows the right time for the right actions. On the other hand, Sumner outlines the concept of time in association with the eternal, transcendental, and infinite notion of God in terms of creation—Creator versus creation. In this line of thought, human beings' choice in life leads to eternity, whereas the choice of falsehood results in death. Viewed this way, time is life and death, forms of the expression of destiny.

In conclusion, among other interpretations, destiny is understood as the series of events and happenings of life in the unfolding of time phenomena. In cultures such as that of Ethiopia, destiny is tied to time as the good and the bad of life. Be it cyclical or linear, time can favor or disfavor with consequences—fortunes and downfall.

Determinism

The abstract noun *determinism* functions like a family name for a group of philosophical doctrines each of which asserts that, in one sense or another, events occur *of necessity* when and as they do. Different members of the family stake out different doctrinal territories, some construing the necessity involved in purely logical terms, some in causal terms, and still others in terms of predictability. Each has to do with necessary connections between past, present, and future.

Much confusion can arise from failing to distinguish one member from another. Much more can arise when they are taken to be identical with, or somehow allied with, other, less defensible doctrines: fatalism and predestination, for example. And still further confusion can arise when one or the other is taken to imperil such cherished beliefs as that in our own free will. It is important, therefore, to sort out the differences between them. We need to comply with the philosophical maxim, "Be careful with concepts and the words in which we express them." Sadly, there are some who bandy about the terms *determinism* and *deterministic*—often using them as terms of abuse—without saying exactly what they mean by them.

Three main members of the determinist family call for careful attention. The most basic is logical determinism, which asserts that future events (i.e., changes in states of affairs), like past events, are determinate and that statements about them are determinately true or false. It claims that if a statement about the future is true, then *of necessity* the events it is about will occur. It claims that the future will be what it will be, just as the past was what it was. These claims are evident tautologies. Yet, despite its evident logical credentials, this version of determinism has been called into question, often on the grounds that it seems to imply fatalism.

The term *determinism* is usually taken to refer to the doctrine of causal determinism. This holds that future events are caused by, determined by, or necessitated by, present ones and that these, in turn, are caused by past ones. It holds that nothing happens by "pure" chance. Causal determinism is an *ontological* doctrine: It makes claims about the contents and character of reality, holding that events that occur within it are connected in a temporal chain of cause and effect.

Unfortunately, causal determinism is often confused with predictive determinism, the view that if one *knew* in precise detail what events and states of affairs had occurred in the past, one could thereby predict present and future events and states of affairs. The 18th-century French mathematician and astronomer Marquis Pierre-Simon de Laplace (1749–1827) couched his concept of determinism in these terms, envisaging a hypothetical intelligence so vast that its knowledge of the laws of nature and the precise state of the universe at any given time would enable it to predict any future state of the universe with complete precision. Yet it is clear that this version of determinism adds an *epistemic* claim (a claim about our knowability of the world) to the ontological claim made by causal determinism. They are by no means identical.

Predictive determinism presupposes the truth of causal determinism, and that, in turn, presupposes the truth of logical determinism.

Logical Determinism

Logical determinists are committed to a realist account of truth. A statement is true if and only if reality is as the statement says it is. A statement's truth or falsity, therefore, does not depend on our perceptions or conceptions of reality, let alone on our knowledge (or lack of knowledge) of reality. By definition, there is only one reality (only one world), though there are many different conceptions of it. It is by virtue of this "correspondence" between true statements and the way the world is that logic gets its grip on reality. Hence the philosopher Ludwig Wittgenstein (1889–1951) claimed that logic is not just a body of human-made doctrine but is a "mirror image" of the world.

Logical determinists insist that the laws of logic apply to *all* statements, including statements about the future, for example, "A huge asteroid will destroy the earth in the year 2020." Logical determinists hold that the law of dentity (if P then P) shows that necessarily if this event is going to occur in 2020 then it will occur at that time; that the law of excluded middle (either P or not-P) shows that necessarily it will either occur or not occur in 2020; and that the law of noncontradiction (not both P and not-P) shows that it is impossible for it both to occur and not to occur in 2020.

Objections to Logical Determinism

Some people would object to the claim, on which the realist theory of truth is based, that there is only *one* reality. Such an objection is fostered by postmodernist and relativist claims about each of us having his or her "own" reality and, hence, that there are *many* different realities. It is doubtful, however, whether this sort of talk can be translated without loss of meaning into talk of many different conceptions or beliefs about the single reality that comprises all that was, is, or will be, the case.

Others would object to the realist account of truth, professing themselves to be deeply puzzled by the notion that true statements "correspond with" reality. But truth need not be explained in terms of correspondence. It suffices to say that a statement has the property of being true just when things are as it says they are. That formulation seems much less mysterious, as it focuses on the *conditions* in which a statement is true as opposed to wrestling with the abstract question, "What is truth?" It lets us understand what truth is by concentrating on our use of the predicate *is true* rather than on the abstract noun *truth*. The conditions under which a statement has the property of being true are different from the conditions under which we can *know* a statement to be true. Truth is not the same as verification (knowledge of truth). If it were, it would be absurd to suppose that there are undiscovered truths about the universe, awaiting discovery in such realms as the natural sciences, mathematics, or logic. It would be to suppose that we already know all the truths there are to know.

The notion that logic is a reflection of the basic structure of reality has also come under attack by those who suppose logic to be nothing more than a human-made doctrine about relationships between statements in human language. There isn't just one logic, they say, but many. We can invent new logical notations, including ones that abandon such traditional laws as the law of excluded middle. That "law" allows only two truth-values (being determinately true and being determinately false) with no allowance for intermediate truth-values. Hence, to escape from the threat of fatalism that logical determinism poses in the minds of many, some logicians have devised three-valued logics, allowing a statement to be neither determinately true nor determinately false but, in some sense or other, "indeterminate."

Formal systems for these and other multivalued logics can indeed be devised. But the question then arises as to the precise *meaning* to be attached to "indeterminate." In what sense of the word should we describe the statement that an asteroid will destroy the earth in 2020 as indeterminate? Can "indeterminate" coherently be understood as meaning anything other than "not known to be true or known to be false"? If not, then a defender of the law of excluded middle can reply that the proponent of these alternative logics is confusing truth and falsity with our knowledge of truth and falsity.

Similar questions can be asked about the proposal that we should adopt some nonclassical logic to handle problems in quantum theory. Is quantum "indeterminacy" to be construed in terms of anything more than a failure of our attempts to ascertain what the *determinate* state of a quantum system happens to be at a single point of time?

Causal Determinism

Logical determinists stake their claim on the truths of logic: truths that are said to be truths of reason, truths that we can come to know a priori, that is, without needing to appeal to experience. By way of contrast, causal determinism—roughly, the claim that the causal principle, "Every event has a cause"—makes a claim that we can certify, if at all, only *empirically,* that is, only by appeal to experience.

But is causal determinism in fact true? Certainly our everyday experience suggests so. "Things don't just happen," we say, meaning that things don't happen by so-called pure chance. Science, as commonly conceived, is the investigation of the unknown causes of various kinds of phenomena: the causes of asteroid collisions, the causes of global warming, the causes of physical and mental illnesses, and so on. That is to say, scientists try to discover hitherto unknown general truths (laws of nature) about how the universe works.

In principle the laws of nature seem to apply universally: not just to inanimate objects but to animate ones as well, including human beings. The more we discover about the mechanisms that make our bodies and minds work as they do, the more our behavior yields to explanation in terms of the interplay of a complex network of causes. Can *all* our behavior, mental as well as physical, be so explained? Are we just a product of nature and nurture? What are we to make of free will?

Belief in the universal reign of causality came under threat during the early 1900s with the development of quantum mechanics, the study of the behavior of the elementary constituents of the physical universe. The Danish physicist Niels Bohr had initially conceived of atoms as being like miniature solar systems, each with electrons spinning around a central nucleus in much the same way as the planets and asteroids revolve around the sun. But whereas in the case of the planets and asteroids about which, ever since Johannes Kepler and Isaac Newton, we have been able to formulate causal laws governing their behavior, in the case of electrons supposedly "spinning" around the atomic nucleus, we have not. Quantum theory, it turns out, does not yield strict causal laws about the behavior of the "ultimate" constituents of the universe. At best it yields only probabilistic estimates of how they will behave. Does this show that causal determinism is false? Or doesn't it?

Objections to Causal Determinism

Many thinkers think that the doctrine of causal determinism imperils the idea that we have free will. Indeed, it is often simply taken for granted, by those who haven't thought carefully about what "free will" means, that the two are logically incompatible. How can one be free, it is asked, if everything one does is determined by causes lying in the past? We cannot make the past other than it is. So if our present and future actions are necessitated by past causes, we cannot be free to do anything other than what those causes dictate that we will do. But we *are* free. Therefore, our free actions cannot be caused. So goes the argument of those subscribing to the libertarian's so-called contra-causal account of free will.

Some determinists agree with the libertarians that the ideas of free will and causal determinism are incompatible. But far from concluding that the doctrine of causal determinism must give way, they conclude that it is our beliefs in free will and responsibility that have to be abandoned. No one is ever *really* free or *really* responsible, they say. From their perspective, criminals deserve therapy and treatment, not blame and punishment. Such determinists are known as hard determinists.

Many philosophers, however, say that both the libertarians and the hard determinists have given a mistaken account of the conditions in which we are held to be free and responsible. On an alternative account, a person is free to act (roughly speaking) if he or she acts as he or she chooses, and does so without constraint or impediment. Only in those conditions can we properly hold people responsible. Such philosophers are known as compatibilists. Many well-known philosophers—John Locke, David Hume, J. S. Mill, F. H. Bradley, Bertrand Russell, Moritz Schlick, and A. J. Ayer, for example—have taken this position. A compatibilist can regard the question whether causal determinism is true or false as an open one, one that may yet be settled by further empirical inquiry. Some compatibilists, however, stick to their belief in universal causality. They are known as soft determinists.

Given this range of well-argued positions taken by philosophers on the issue of free will, it is naive to simply assume—as so many people do—that there are only two alternatives in the dispute: belief in causal determinism, on the one hand, and belief in free will, on the other.

Sadly, even sophisticated thinkers from disciplines outside philosophy may share this simplistic assumption. One of the founders of quantum physics, Werner Heisenberg, claimed that his newly discovered principle of indeterminacy opened the door for a belief in free will. How a lack of causality at the quantum level could be identified with responsibility-conferring freedom, he did not explain. Nor did he explain how we can be responsible for choices that occur, not from causal necessity, but just by *sheer chance*. The notions of freedom and responsibility seem as out of place in a wholly indeterministic universe as they seem to be in a deterministic one. Little wonder that compatibilists insist that these notions, when carefully analyzed, turn out to be compatible with both.

Predictive Determinism

Whether or not causal determinism is true, and whether its truth or falsity can in principle be established by quantum physics, one thing is clear: Current quantum theory does not enable us to make precise predictions about what is going on at the quantum, or subatomic, level of reality.

What, if anything, does this imply about the belief in universal causality? Remember that predictive determinism adds an epistemic thesis to the ontological thesis of causal determinism. This means that predictive determinism could prove to be false without causal determinism also being false. Albert Einstein's lifelong critique of quantum theory capitalized on this purely logical point. From our inability to measure the precise states of elementary particles, he argued, it does not follow either that they don't *have* determinate states or that those states are not *determined by* previous states.

Will physicists who are as philosophically well read and conceptually astute as Einstein eventually conclude that quantum physics provides a conclusive refutation of the ordinary belief in causality? Or will some future theory find a way of reinstating it? Perhaps time will tell.

Devils (Demons)

Devils and demons have been ingrained in cultural and religious beliefs for thousands of years. Throughout time, the struggle between good and evil has been expressed through a belief in spirits, a belief that influences the manner in which we live our lives. Certain faiths expressed this theoretical concept as a tangible entity. Subsequently, demons were part of the physical and ethereal worlds and became both an explanation and advertence for certain human behaviors.

Demons initially referred to any spirits, whether or not they acted maliciously. The Greek word *daemon* (δαίμων) was often synonymous with *Theos* (gods). In pre-Islamic Arabic cultures no discrimination between gods and demons existed; instead the term *jinn* was used to describe inferior divinities. In the Islamic tradition, jinn are believed to be made of smokeless fire, whereas humans are made of clay. Evil jinns are *shayāṭīn,* or devils, and are led by Iblis (Satan), a former servant of God who became envious, arrogant, and defiant after the creation of humankind. Although God condemned Iblis to hell, He was additionally granted the ability to live to the end of eternity, misleading humankind and jinns. In addition to the jinns, the *guls* consume the bodies of the dead, the *sealah* inhabit the forests, and *skikks* are half-human creatures.

Within the Hindu faith there existed three classes of beings: *devas* (demigods), *manushyas* (humans), and *asuras* (demons). Asuras lived in Patala, the dimension between Naraka (hell) and

Bhu loka (earth), and were constantly in conflict with devas over supremacy. Asuras were once looked upon as divine creatures; when translated into early Iranian languages *asuras* becomes *Mahura,* the god in the Zoroastrian religion. However, the term *asuras* eventually became a reference to demons solely. In keeping with their belief in reincarnation, Hindus hold that if humans commit sinful and harmful acts in their lives, their souls (Atman) will be turned into evil spirits, such as *vetalas* (animate corpses), *pishacha* (vampires), or *bhutas* (ghosts). These Asian demons are depicted as being hideous creatures, with an extreme hatred of loud noises. A common practice to ward off oriental demons is to adorn hideous masks and light fireworks. This ritual is demonstrated during the Chinese New Year celebrations.

The modern Judeo-Christian system of demonology originates from the teachings of the prophet Zoroaster. One of Zoroastrianism's main influences upon demonology is with the concept of Ahura Mazda (the sole God figure) defeating his antithesis, Angra Mainyu or Ahriman (the Devil figure), in an epic battle of good versus evil. Alongside Ahriman is the queen of the demons, Lilith, "Mother of Ahriman." Lilith was later portrayed in the Jewish faith as having brought the demons, *lilin,* and evil spirits into the world with Adam while he was separated from Eve for 130 years out of penance for his sin. Later Lilith would be portrayed in certain texts as Adam's original wife.

Judaism incorporated the Zoroastrian class systems of demonology and angelology into the Hebrew Bible with the notions of the *se'irim* and the *shedim.* The se'irim (hairy ones) are satyr creatures, comparable to the Eastern religions' jinn. Shedim are spirits acting either in a benevolent or malevolent fashion. Three forms of shedim exist: Rabbi Loew's Golem is an example of the benevolent variety, *mazikin* (harmers) are the malevolent form often responsible for bodily possessions, and *ruhot* are evil spirits. The term *shedim* refers back to the *shedu,* the seven evil deities of the Chaldean mythology. These shedu are often depicted as protective winged bull figures outside royal places. Under some rabbinic sources, a king of the demons existed. This individual was either Samual "the angel of death," as described in older versions of the haggadah, or Asmodai. Satan is mentioned as well, though not as the king of the demons.

As Judaism and Christianity spread, the past religions and concepts were built upon and constructed into their own faiths. Their template for the devil comes from the Persian devil, whereas Lilith and winged angels are both copied from Babylonians. Due to the incorporation of Zoroastrian dualism, Satan changes from being the servant of god, distributing evil on behalf of God, to becoming God's adversary. As Christians overtook new lands, they also overtook the old temples. They integrated their own icons into the temples, changing the statues of Venus and Cupid into the Blessed Mother and Baby Jesus, and demonized the gods of their enemies. This demonization is apparent in the iconography of certain demons. Regularly a demon is portrayed with horns, hooves, and a pointed tail; this is evocative of the satyr god-creature Pan. Past gods are not the only demonized figures; the opponents of early Christianity were also labeled as being allied with the devil. Even Zoroaster himself was demonized as being Ham, the wicked son of Noah.

With the Judeo-Christian faith, new stories relating to the genesis of demons were introduced. The most widely known of these tales is that of the fallen angels. It is said that all those that sided with Lucifer were banished from heaven and became demons. The Book of Enoch provides another story: When the fallen angels slept with the daughters of man, giants and demons were produced. As the dynamic of the devil as the adversary grew, new religious beliefs resulted. On August 12, 1950, Pope Pius XII declared, in the *Humani Generis,* that Roman Catholics must regard the devil as a true person walking upon the earth. To resist Satan and his demonic forces, a strict adherence to cultural orthodoxy and religious dogma followed.

Dialectics

Dialectics is the formal study of change, of how everything changes over time. Dialecticians attempt to understand change by using universal and theoretical principles to analyze transformations over extended periods of time. With a comprehensive set of guidelines, the dialectical method can be used in the study of philosophy and in physical, biological, or social sciences.

Hegel and the Dialectical Method

The dialectical method, as used by Georg Wilhelm Friedrich Hegel (1770–1831), is employed to understand the history of rational thought or philosophy. Rational ideas are the creators of history. Using this method, we begin with an original idea. This is the *thesis*. The thesis has a limited life span because of its innate contradictions. Born out of this conflict is a new contrasting proposition, or the *antithesis*. The antithesis also contains contradictions. The solution between these rival influences fashions a resolution with a new thesis of the two opposing philosophies. This new philosophy contains its own intrinsic contradictions, and thus the process renews itself. By examining the basic contradictions of the new philosophy, we discover the inherited contradictions that begin the process of birth and death all over again. This is the way Hegel understood history. History has a pattern and not a hodgepodge of unconnected particulars.

Working with the concept of "essence of being," something is negated in the process of creating something new, which leads to what Hegel calls the "sum of essence." The new essence is only a manifestation of being, thus temporary and fleeting. This development is completely conditional; that only perceptible estimate of "being." The resulting contradiction is the negation-of-the-negation of the essence of being, leading to the "actuality" of a more advanced harmony. This brings together essence or "real meaning" with "existence." At each stage in this process, Philosophy is moving closer to the "absolute."

Dialectical Materialism

Dialectical materialism states that everything in the universe can be understood in terms of material substance, which occupies space and is in motion. The universe, nature, and human communities are natural and thus a part of a tangible process continually unfolding in a never-ending course of transformation.

Beginning with Karl Marx (1818–1883), the dialectic changes its orientation. The dialectic now becomes a materialist perspective that assumes matter in motion and change over time as the basis for all other understanding. The entire universe is interconnected and made up of interrelated parts. Matter neither vanishes nor is it formed anew. The physical field of material formations consists of interacting and interconnected particles transmitting movement from one body to another. This is the substantive reality of existence. Motion, space, and time are the basic expressions of matter.

According to Marx's collaborator Friedrich Engels (1820–1895), all of nature is continuously coming into existence and ceasing to exist at each moment in time. These changes are continuous. Trivial and hardly noticeable quantitative changes lead to a final break, followed by rapid and basic qualitative changes. Everything we can study is made up of opposing internal contradictions that break down the old while the new is being formed.

To summarize, there are three general laws of nature that constitute dialectics. First, the process begins with the law of unity and the conflict of opposites. Second, the slow accumulation of quantitative changes appears over time, until there is a final breakdown; this breakdown is followed by rapid qualitative change and the birth of something new. Finally, the law of the negation-of-the-negation occurs, which is based upon the Hegelian triad of thesis-antithesis-new thesis.

In the view of dialectical materialism, history begins with the material expression of actual people living their everyday lives. History moves forward with people living in association with nature. Through these relationships with nature, humans produce their own means of subsistence. Nature includes not only material nature but also the social nature of human communities. Each generation takes over from the past and provides for a new beginning with regard to their means of subsistence and then transforms it to fit their modified needs. "Human nature" of the individual is shaped by the specific historical and cultural setting of a particular group. Production determines how people are organized and how they interact.

Nature and Labor

Nature and labor are two critical aspects of the human condition. We are human because we labor. We take what we need from nature, and through our actions we change nature to fit our needs. This in turn changes us. Humans and human society are always a part of, and never separate from, nature. Our social world is merely an expression of the natural world. Human beings are seen in context as being fully integrated into nature, a part of nature. Humans are active, proactive, and interactive within our environment in a way that guarantees transmutation of humanity. This evolution of the human condition is continuous as we humans change and adapt to our environment.

The human condition, then, is set in the animal and social circumstances of people. This existential fact of our dual nature is found at the very beginning of hominid evolution and is a central concern of all human beings ever since. The human condition, which is universal and historically specific, includes biological necessity, social necessity, and the broad abstractions of psychological necessity.

We become human in a social setting. This setting is founded upon coming together to interact with nature. We call this interaction labor. Labor is our connection with nature, and through labor we create ourselves physically, socially, and emotionally. Through labor we become social beings, that is, beings that are culturally defined with individual personalities. It is through social activity that human life is possible. Labor is both social and material. Labor also symbolically and culturally manifests notions of self-expression. The human animal rationally develops into a culturally defined social being.

Labor, as seen in the perspective of dialectical materialism, is both symbolic and natural. Labor is born by combining symbols of creation with real human needs or wants. By working together in an existing environment, to take from nature and alter it in ways to meet our needs, we bring forth new needs by this action. This in turn changes our interaction with nature and each other. It is through this process of being human that society and cultures are created, and only in society are we fully human. In affinity with others, we can decidedly attain our power of creativity and of expression and fully maximize our humanity.

Modes of Production, Social Classes, and Culture

Human unity with nature exists through industry. Social science must reflect this if it is to elucidate the deeper underlying connections between specific social actions and global trends. In industry, commerce, production, and exchange establish systems of distribution, which in turn give birth to ideological possibilities. Along these lines, socioeconomic classes are determined by the mode of production. The needs of every class-society create its own ideological support. For example, with the evolution of bourgeois society, science developed to meet the needs of its mode of production. This was possible because the ruling ideas of any class-society are that of the ruling class. Those who control the material forces of society also rule the ideas of that society. Workers are subject to those ideas. The dominant ideology reflects the dominant material relations.

Manifestations of the human condition can be defined in specific social and cultural terms. These manifestations are continuously and historically in a state of metamorphosis, based upon the historical alternatives within the dynamic of an environment that is itself historically created. The appearance of the human condition is defined in specific social and cultural terms. Agency is the motor of this change. Agency is the instrument of the transmogrification of the social and cultural environment. Agency is defined as choice, which presupposes a limited free will, in a predetermined environment, with the options also predetermined.

Force of production is the natural environment combined with technology and the demands of population pressure. The relations of production are the sum of our social organizations, including work organizations, authority organization of work, property relations, and methods of product distribution. Political culture is reflective of this interaction, as is the ideological superstructure.

The forces of production set the limits of what is possible for the relations of production and in turn the relations of production offer continual feedback to the forces of production, thereby changing the nature of the forces of production. The relations of production generate the necessity of the specifics of a historically defined political culture. The political culture offers direction for the relations of production. The political culture creates, guides, and controls the ideological superstructure. The ideological superstructure provides the necessary knowledge for the operation of everything else, including the forces of production.

Culture is defined by the methods with which humans adapt to their environment and change that environment, thereby demanding and allowing humans to readapt to the changes in the environment. This dynamic operates within human communities as an interactive part of a larger world nature.

Thus we can say that because of the existence of humans as a part of the world and nature, humans and all other species in the greater ecosystem coevolved. Within this dynamic, the human condition specifically and historically defined the social, cultural, and biological, in order for the individual to survive and the community to meet its members' needs. These needs are met with specifics of the sociocultural setting that interact with nature and with other societies. This is carried out within the social setting of continual historical change and creates the individual, born within an historical setting that limits the options possible. Within this dynamic, the critical element is circumscribed free will, an assertion of choice.

Unfettered, unimpeded, lustfully creative, and aesthetically imaginative labor is fundamental to our human identity and a universal basic need of all people. Through labor, we become social beings, and through social activity, life is possible. Labor is thus both social and material. Labor also symbolically and culturally manifests notions of self-expression. The human animal rationally develops into a culturally defined social being. Truly free labor is a function of artistic creativity and aesthetic enjoyment.

The foregoing analysis blends the determinism of historical sociology with an element of inescapable freedom, made popular by the existentialists. When labor is introduced into this synthesis, labor becomes the unity of freedom and determinism.

This is the beginning of historical anthropology. Humans in fact create themselves and their society through their productive action, which we call labor, in the material world of nature. Productive powers are resources, including the ability to labor, which people use in that process. It is through the action of people using symbols, ideas, and objects to change nature that the historical core of the very production of society and its culture is created. We produce, alter, create, and ultimately bring forth ourselves through labor. Thought and action through labor produce new thought and action continuously. Culture, through communication and collective expressive validity, creates meaning. That meaning becomes basic to cultural explanations. Socially knowledgeable people in turn produce themselves by creating culture.

Productive powers are anything that can be used in production. Through production, people interact with nature. These forces and powers are used by people in such a way that material production occurs, because material production is organized to meet people's needs. This contribution to production is, in fact, planned. There must be an objective knowledge of how to use the tools of production, the process of production, and the needs that this activity satisfies. This interpretive composition of comprehension is within a culturally defined set of meanings, surrounded by a context that is relative to the conscious needs of a people. The processes of production are related to an interactive complex of meaning for the actors involved. This is central to the interpretation of symbols needed to carry out production. Productive powers include raw materials and technology, along with the skills and knowledge about the use of technology within that environment. All human social relations and their functions have an incontestable influence upon material production, and material production directly influences these relations.

Societies, to a certain degree, are internally consistent. There is a fundamental interactive relationship between economy, politics, and religion in a mutually reciprocal way that enables these institutions to be intellectually defined within a larger social whole. These "social totalities" have somewhat consistent arrangements of institutions that define the type of character a society has, in spite of the variation within the whole of that society. In any social and historical setting, there are limited options placed upon choices people make and the degree of social change possible by the formation of these structures. The types of societies form epochs. The epochs are shorthand for the basic themes of production of human social life in an entire historical era.

Humans need to realize themselves through labor. Through labor, people develop power and skills in an ongoing dialectic with nature. Productive knowledge is central to this actualization. Differing productive powers (forces of production) express themselves in different societies. Different relations of production give internal groups different interests in technological changes in these different societies. Most social revolutions would appear to preserve the level of productive powers achieved. Yet this tendency of expanding powers can best be seen at the world level, because local relations of production can prevent technical development beyond a certain point. The population size and average productivity of labor lies resolutely in the conditions of mass productive powers.

It is power that decides differing social groups' access to control over the means of production and the division of the fruits of labor of that society. Relations of production lead to productive inequalities. These relations of production are expressed through the affinity between groups within a society where some groups dominate and others remain subordinate in production and distribution.

Social beings determine social consciousness. This way of describing the material social life of people's productive activity, including the means of subsistence, lays the foundation for the intellectual, cultural, and spiritual life of a society. People, and only living people, make culture. Humans, as biological animals, create their own social life. Forces of production (including environment, technology, and population pressure) and exchange of material goods with other societies create the possibilities of what the relations of production or social organization will look like. This in turn limits the possibilities for the cultural world of a people.

Economics is the science of how people provide for their material and social needs and desires. This is historically determined within a specific environment, modified through trade with other societies. Each society is constantly changing as the environment changes. Each society has its own culture. The culture is formed through adaptation to an environment. By the use of culture, people adapt to an environment; through adaptation, they change that environment. The society and its culture become maladaptive to that environment and must alter culture to readapt to a new environment. In addition, all natural environments are changing naturally. Thus, the model used is both materialist and dialectical.

People are the authors of their social life within their societies. From the perspective of dialectical materialists, people create humanity and not God. Within communities, people make conscious choices. These in turn have real but unintended consequences. This establishes social phenomena beyond people's command. Social laws, like natural laws, exist outside people's control. Laws are intellectual constructs to explain these natural patterns. People collectively work as a unit to survive, and this creates the starting point for a social reality. Through collective labor, people interact with the natural environment and make human life possible. Thus, humans are not only social animals now but were always an interactive part of nature. People's changing relationship with nature is the foundation of a changing social reality they live with as a group. As there are changes in the natural environment and changes in the technology used to work with that environment, there are also changes in the social organization of that society. These changes then define the relations of production, which are the most basic part of a society. This is never a simple cause and effect relationship but a continual feedback system in which the cause is also the effect and vice versa.

Law, being heuristic, provides guiding principles that serve to indicate ways of allowing humans to make informed decisions. The laws of social reality, like the laws of nature, are knowable through careful observation and study. Through these studies, people learn about the multifaceted basics of social episodes. People can learn what is possible and what is not and thus make better choices instead of reacting blindly to those forces beyond people's control. Historical necessity provides the raw materials people work with in creating the choices they make. This, in turn, creates another historical necessity with new possibilities. With better information individuals can make better decisions, and the unforeseen consequences become less absolute. It is through the knowledge of objective necessity that people gain factual data. This deterministic model can elucidate the possible alternatives. True freedom within society, like within nature, is possible only if a deterministic model is used to explain the objective reality of society and the real options existing at any one time for people. Subjective free will is an illusion masking blind reactions to unknown outside forces that limit any real hope of freedom.

Until now, these changes operated as if they were blind forces of nature. Cultural and political structure reinforce the existing relations of production and become overpowering forces that individuals can never hope to change without precise information about what, in fact, exists. This is affected by understanding how society changes and by understanding the relationship between actions taken by a society and the social reality affecting those decisions.

Diaries

The word *diary* is defined as a book or text in which one records one's own events and experiences, over time, most often on a daily or regular basis. The word *diary* comes from the Latin *diarium,* which is translated to mean "daily allowance."

There are no rules to diaries, as they include a personal collection of whatever suits their author: thoughts, feelings, complaints, poetry, art, and so on. Because of the private nature of diaries, individuals may be more candid about their feelings, relationships, and innermost thoughts.

To some extent, the words *diary* and *journal* have come to be used interchangeably, although many agree there are inherent differences. The largest difference between the two is probably that diaries, at least during their time of use, are intended more to be private, whereas journals, while personal, are often meant to be read by others.

Diaries have long been a part of human history, but in their beginning they were written only by those in the higher classes. Before the turn of the 20th century, only the highest-class citizens were literate and therefore were the only ones writing diaries. With greater industrialization and education, higher literacy rates meant more diaries were being written.

Over time, more and more diaries have been published. Published diaries offer a somewhat exclusive glance into the past. In addition to allowing a particular event or era to become timeless, published diaries can be one of the most intimate ways for history lovers and researchers to better understand the differences between contemporary living and times past. Diaries also offer a firsthand look into attitudes, feelings, and untold stories in times of economic depression, war, and other significant events. This may allow another side of the story to be told, offering a more complete glimpse into times of historical importance. One of the most famous diaries in this category is undoubtedly Anne Frank's *Diary of a Young Girl,* first published in 1947, as it offers a personal story and helps its readers gain a more complete understanding of the effects of the Holocaust.

More recently, the practice of writing "diaries" for immediate publication has become popular among political figures and celebrities. Many such works would be better categorized as memoirs or autobiographies, as they rarely are republished versions of actual diaries kept.

Reflective journals have become a popular teaching method throughout all levels of schooling, helping students to organize their thoughts and hone their writing skills.

Diaries have expanded well beyond the binding that once held them and have been transformed into more public than private texts. With the rapid growth of the Internet, online diaries quickly followed. Web logs, or blogs, are a popular place to capture one's own thoughts, opinions, experiences, and events. Although these certainly are not as private as diaries once might have been, they are growing in popularity, with as many as 8% of Internet users having created their own blog, and another 39% regularly reading blogs.

Blogs have allowed writers to reach a much wider audience, yet may still have the benefit of anonymity. Through the use of usernames or screen names, people can easily hide their identity but share their thoughts, feelings, and experiences.

As with most other media, the existence of diaries will likely continue, but with a change in times, education, and technology, they too will continue to evolve over time.

Diderot, Denis (1731–1784)

Denis Diderot was foremost a philosopher and writer in France during the time of the Enlightenment. He is best known, however, for being editor in chief of the *Encyclopédie,* first published in 1751. It is believed that the *Encyclopédie* helped not only to promulgate the latest advances and discoveries in science and technology but also to spread the democratic ideas that sparked the French Revolution. Although it is debatable whether or not the creators of this work intended to incite social change, the consequences were far reaching.

Diderot was born October 5, 1731, in Langres, Champagne, France. His family was part of the bourgeois class that had been growing in France since the 15th century. Diderot's parents realized his academic talents at a young age and sent him to study with the Jesuits. His teachers saw a bright future for him in the clergy. At age 13 he became impatient with his schooling and decided to become an abbé at the local cathedral where his uncle was canon. After 2 years his uncle died and intended to leave his religious office to young Diderot. Unfortunately the church leaders gave the job to someone else. After this disappointment, Diderot moved to Paris and later attended the Jansenist Collège d'Harcourt.

While studying in Paris, Diderot worked as a tutor for wealthy families, wrote sermons, and did English translations, among other odd jobs. In 1732 he earned a master of arts degree in philosophy. He gave up his dream of going into the clergy and pursued a career in law. This was short-lived, and in 1734 he decided instead to become a writer.

In 1743, he married Antoinette Champion and had one child, Angelique. He struggled as a writer for many years, but through a bit of good luck, he obtained the post of librarian for Catherine II of Russia and earned a yearly salary to support his family.

As part of the growing Bohemian culture of Paris, he socialized with many of the period's greatest thinkers, such as Voltaire. Diderot's first philosophical work was titled "*Lettre sur les aveugles,*" published in 1749. It primarily describes the reliance of people's ideas on their senses. The works that followed dealt with the concepts of free will and relativism and gained him a good reputation among the thinkers of the day.

Diderot was asked to translate a dictionary of arts and sciences into French. Instead of accepting this task, he decided to create a new project that would do more than just define terms. He proposed the idea for the world's first modern encyclopedia. The publishers were excited by the prospect of such a project and named him editor in chief. In the *Encyclopédie* all of the ideas of this exciting intellectual period were compiled into one publication. The areas of history, philosophy, and poetry were included. For the first time it was possible for scholars, as well as the average citizen, to keep up with cutting-edge concepts. Some entries were seen as antiestablishment, and the encyclopedia was eventually suppressed and censored by the government in 1759, but volumes continued to be published until 1765. Diderot dedicated 2 decades of his life to this enormous project. He spent his final years writing plays and art criticisms and died of emphysema on July 31, 1784.

Dilthey, Wilhelm (1833–1911)

Wilhelm Dilthey was a German philosopher, pedagogue, and psychologist who is known mainly for his work on the foundation of the humanities and his philosophical theory of understanding (hermeneutics). Dilthey contrasts the notion of time of physical objects to the inner experience of time in human beings. He furthermore rejects Immanuel Kant's idea of time as a condition of perception and opts for a realistic interpretation of time.

Dilthey was born in Biebrich, Germany. After studying theology, philosophy, classical philology, and history both in Heidelberg and in Berlin, he became a professor of philosophy in Basel (1867). He then taught in Kiel (1868–1871), in Breslau (Wrocław; 1871–1882) and in Berlin (1883–1911). The main aim of Dilthey's philosophical works is to develop a systematic and historical foundation for the emerging *Geisteswissenschaften* (humanities). Following Kant, who presented in his *Critique of Pure Reason* a philosophical foundation for the empirical sciences, Dilthey aims at a project that he calls a *Critique of Historical Reason.* Whereas Kant takes the abstract rational subject as his starting point, Dilthey starts with the real, living, historically determined individual. Thus the categories of *Erlebnis, Ausdruck, Verstehen* (experience, expression, understanding) are the key categories of his work in the field of psychology and hermeneutics.

Dilthey analyzes and rejects Kant's highly influential philosophical understanding of time. Kant has argued that time is not an empirical object; that is, time is not a real thing within the world. It is rather (together with space) the form by which we structure our experience of the world. Time and space make experience possible; the world as such beyond our experience is completely unknown to us. Dilthey, however, argues in favor of a realistic interpretation of time. For him space and time possess a reality outside the subject and as real features of empirical objects. Time is therefore a real absolute condition of the existence of all objects that we find within the world.

Dilthey analyzes the notion of time not only in the context of physical objects but also as the inner experience of living persons. In opposition to the natural sciences, Dilthey emphasizes the subjective experience of time that cannot be measured with the help of the methods of the natural sciences. He distinguishes between objective time and time as related to the life of the individual. Dilthey considers the concept of a regular, mathematical objective time in natural science merely as a formal abstraction. He situates his understanding of time in the context of an analysis of the categories of human life: Our own inward experience is deeply linked to our temporal being that is structured in past, present, and future. Dilthey especially emphasizes the role of the past, which we experience in our memories and which we try to interpret as a part of our biography. The human concept of time therefore relates time to the idea of a unity of a life (*Lebensverlauf*), in which the different moments of our experience relate to each other and can be judged as "meaningful." By extension, Dilthey argues that the same objective time is not the same for different persons: "A year is not the same for a youth as for an old man."

Dinosaurs

Dinosaurs are a highly distinctive group of vertebrates that played a dynamic role in terrestrial ecosystems for 165 million years of Earth's history. Fossils of their teeth and bones are found in abundance all over the world, sometimes along with evidence of soft tissues, nests, eggs, feces, and footprints. Collectively these remains comprise an excellent record extending from their emergence in the Triassic period up to the Cretaceous extinction, testifying to the great diversity of dinosaur species. First described in the early 19th century, dinosaurs were once thought to be sluggish, lizard-like reptiles. Our conception of these animals has changed with each new discovery; modern science shows that many dinosaurs were energetic, dynamic creatures more akin to birds and mammals in their activities. Their majesty and variety inspire perennial fascination, and scientific research on the group has vastly improved our knowledge of evolution and survival strategies in ecosystems under pressure.

Dinosaurs arose from archosaurian reptiles during the mid-Triassic period, approximately 230 million years ago. They became a hugely successful group, surviving several mass extinction events and evolving into a vast array of forms throughout their 165-million-year reign. During this time the dinosaurs achieved remarkable feats of specialization. The smallest were about the size and weight of a modern-day crow, while the largest attained lengths over 40 meters and weights up to 60 tons or more, the most gigantic land animals ever known. Some were quadrupeds, others bipeds, and some could move in either mode. Some were frightful, sharp-toothed carnivores; others were herbivores of such voracity that they altered the landscape with their feeding. Their range of forms and adaptability ensured that while not being the most abundant of terrestrial species, they ruled the top of the food chain in whatever niche they occupied and dominated their habitats over an exceptionally long period of life's history on Earth.

The term *dinosaur* is derived from the taxonomic group *Dinosauria,* a term coined by Sir Richard Owen in 1842. The fossils of many large and fantastic animals were being discovered in England at the time, including the carnivorous *Megalosaurus,* the herbivorous *Iguanodon,* and the armored *Hylaeosaurus.* Owen noted that the anatomy of these creatures differed significantly from that of modern and fossil reptiles but felt obligated to respect earlier research classifying the huge beasts as reptiles. He thus invented the name *Dinosauria,* meaning "fearfully great lizards."

One modern way of defining groups of organisms is through phylogenetic taxonomy, whereby organisms are related strictly by common ancestry. In this manner, Dinosauria can be defined as all members of the group descended from the most recent common ancestor of *Megalosaurus, Iguanodon,* and *Hylaeosaurus,* as these are all quite early forms of the two great dinosaur lineages Ornithischia and Saurischia. Dinosaurs can also be broadly defined as large terrestrial vertebrates that lived only during the Mesozoic era. Contrary to images in movies and popular culture, the prehistoric aquatic reptiles are not dinosaurs, nor are the flying pterosaur reptiles. Dinosaurs were predominantly terrestrial in nature, although fossil traces testify that some dinosaurs swam on occasion. Likewise, although the skeletons and feathers of certain species suggest some sort of flying ability, and theropod dinosaurs did indeed give rise to birds, this entry follows common usage in restricting the term *dinosaur* to nonavian dinosaurs unless specifically noted.

The earliest known dinosaurs were lightly built, agile bipeds with grasping hands. Although this body plan would later evolve immensely, certain important features defined at the start of the lineage were retained by all dinosaurs. All dinosaurs possessed a perforate acetabulum, that is, a hole in the wall of the hip socket that accepts the ball-like end of the upper thigh bone, the femur. This arrangement allowed dinosaurs to position their hind limbs closer to and underneath the body, allowing a full-time, "erect" stance compared to the more splayed-leg reptilian posture. The benefit of the more upright stance is that the limbs move within a vertical plane, with flexion and extension aligned to more efficiently convert muscular effort into forward movement. In either bipedal or quadrupedal mode, this improved mobility; dinosaurs could move around faster and stay active longer than most of their immediate ancestors. The upright stance is also capable of sustaining a greater body weight compared to a sprawled posture, allowing massive future growth potential. Other common characteristics of dinosaurs include an elongated ridge along the top of the upper arm bone and a hinge-like joint in the ankle. This last feature allowed dinosaurs to better adopt a digitigrade stance, where the longer foot bones and ankle are raised from the ground and weight is distributed over the toes and front "balls of the feet." Early dinosaurs also had "hands" with a semi-opposable thumb, grasping ability, and reduced outermost digits. This adaptation was coeval with their primary shift to bipedalism. Later on, when dinosaurs diversified further, some of these defining features were lost in some lineages. Most of these initial traits, however, were retained across all groups.

Dinosaurs are divided into two primary orders, originally based on the shape and form of their hip bones. The Saurischia ("lizard-hipped") dinosaurs have hip bones with the pubis pointing down and forward, similar to reptiles. The Ornithischia ("bird-hipped") dinosaurs have hip bones with the pubis pointing down but backward, almost parallel to the ischium. As this trait turned out to be a rather weak discriminator for subsequently discovered taxa, Ornithischia and Saurischia are now also defined by a range of skull and skeletal features. The essential division remains valid, however. It should be noted that the most bird-like theropod dinosaurs, while nominally lizard-hipped, in fact have a typical bird-shaped hip.

Within these general classifications dinosaurs evolved incredible adaptations, diversified into a wondrous range of sizes and shapes, and grew their formidable teeth and claws—in short, they acquired all those qualities of such fascination to humans. The diversity of their anatomy reflects a similar diversity of habitat; dinosaurs lived in cold polar regions and hot arid plains, by seaside cliffs and highland lakes, and their fossils are found on all continents. Dinosaurs truly dominated their time; new discoveries reveal there was likely a dinosaur in many of the ecological niches that are occupied today by small animals and mammals, including those that could burrow and climb, were active in darkness, and could not only glide but achieve true flight.

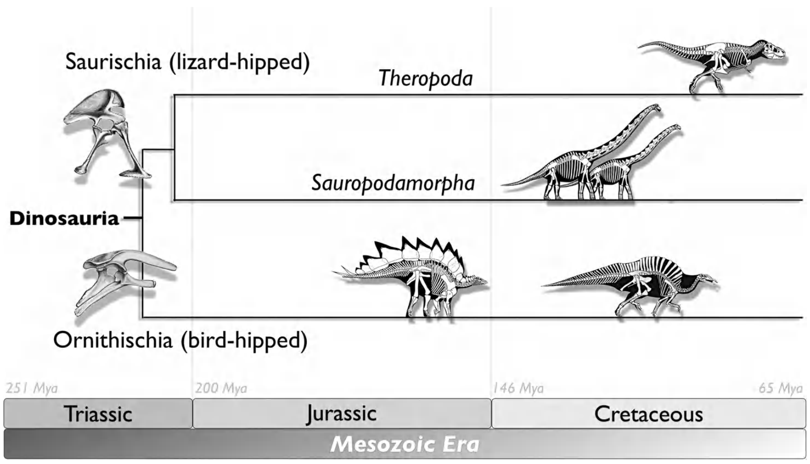

Figure 1 Basic dinosaur classification

Notes: Basic classification of Dinosauria with timescale and geological periods. Dinosaurs are divided into two primary orders, originally based on the shape and form of their hip bones.

Evidence

Because there are no dinosaurs alive today, our knowledge of them comes exclusively from fossilized remains and traces. Fortunately, the fossil record is abundant and extensive. Several thousand largely complete dinosaur skeletons have been located and collected, not to mention hundreds of thousands of isolated bones and teeth. From these remains, many hundreds of genera and thousands of species of dinosaurs have been classified to date, with additional taxa based on fossilized footprints and trackways.

Nevertheless, it is clear that the fossil record is far from complete. Nearly half of the dinosaur genera are based on a single specimen, and complete skulls and skeletons have been found for only about 20% of the identified species. This is due to the process of fossilization being extremely haphazard, particularly for terrestrial vertebrates; only a minuscule fraction of any population will ever leave fossil remains.

This large fossilized femur of a sauropod dinosaur was discovered and excavated by Paleo-explorer Tim Quarles. The white portion along the top of the bone was exposed at the surface, leading to the discovery.

Source: Photo by Tim Quarles. Used with permission.

A rare collection of factors is necessary to preserve the body of an animal in fossil form. In even the best environments for fossil formation, such as a river floodplain, most animal remains are destroyed quickly by natural decay—scattered, trampled, and gnawed while being eroded by wind, water, and sun. The coalition of physical and chemical erosion is unrelenting—before long, no trace of the animal is left to join the geological record. The process of destruction may be temporarily halted, however, if a substantial flood breaks the river banks and sweeps over the plain, depositing a layer of sediment over any bones and remains, thereby protecting them from the surface elements. The completeness of the fossil record in this environment is thus largely determined by the frequency of flooding, which can occur at intervals ranging from tens to thousands of years. The resulting fossils form a series of snapshots in time rather than an ideal continuum. In less ideal environments where there is little chance of sedimentary deposition, the record becomes even more scant.

If the remains are deeply buried for a long enough period, the sediment may undergo diagenesis and transform into rock. It is during this process that bones fossilize; the forms of softer tissue are sometimes preserved as well. Later on, massive geological processes such as mountain formation are required to raise fossil-bearing rocks back to the surface. Just enough erosion is then required to expose the fossils, where with luck they may be discovered just prior to their terminal destruction, as weathering again conspires to convert the fossil to dust.

Given all these criteria, it is not surprising that the fossil record of dinosaurs is incomplete. Rather, it is astonishing that the record is so extensive and detailed. By recognizing the rarity of fossil formation, it then becomes possible to appreciate the sheer abundance of dinosaurs over time.

The best-known dinosaur remains are body fossils, which come from the physical remains of the animal itself. These are most commonly isolated bones and teeth, but sometimes articulated parts or even whole skeletons are found. Bumps, grooves, and scars on the fossil bones show sites of muscle attachment and let us make educated guesses regarding their body shape and abilities. The form of the jaws and teeth indicates preferred food types. In very rare cases the contents of a dinosaur's stomach are still intact, preserving not only its last meal but also a sample of the environment in which it lived.

Holes in the skull reveal the size and shape of their brain, ears, eyes, and nostrils. Indeed, the very shape of the braincase allows us to infer some of its functional capability by examining the size and location of specific lobes. For example, scientists might be able to recognize that a part of the brain used for olfactory processing was relatively large. From this evidence we can infer that the dinosaur had a well-developed sense of smell, and we may draw some conclusions concerning its potential behavior.

Occasionally traces of soft tissue are preserved along with the skeletal remains, usually as mineral replacements shaped like the original organic material (pseudomorphs). Spectacular examples of dinosaur fossils may display evidence of muscles and internal organs, skin, and feathers. Thanks to recent technological advances, researchers have even found preserved biomolecules in partially fossilized material. In these exceptionally well-preserved specimens, the molecules include bone-related proteins (collagen and osteocalcin) and blood proteins such as hemoglobin. Although much work remains before we fully understand the mechanisms of preservation, it appears that an exciting new area of dinosaur exploration may be opening up on the molecular level. Further progress may eventually lead to the recovery of DNA fragments, which can be used to directly demonstrate evolutionary relationships among taxa.

In addition to body fossils, there are trace fossils that also can provide useful information on dinosaurs and their environs. Footprints and trackways can tell us the animals' weight, stride length and speed, and the position of legs relative to the body. In some cases they also provide insights into behavior such as herding or predation. Fossilized dinosaur nests and eggs, some containing embryos, have been found on several continents. These provide important evidence on dinosaur reproduction and parental behavior. Coprolites (fossilized dung) are a good source of information on dinosaur diets and, in some cases, their habitat and distribution. Collectively the fossil record of dinosaurs is vast and detailed, allowing us to gain a deeper understanding of how they may have behaved and interacted as well as how they appeared physically.

Emergence and Ascent

Dinosaurs are members of Archosauria ("ruling reptiles"), a significant clade of terrestrial reptilian vertebrates of the Mesozoic that, during the mid-Triassic period, included two significant groups; the Crurotarsi and Ornithodira. Some members of Crurotarsi became quite large, cow or ox sized, and evolved into a range of diverse, mostly carnivorous forms that included phytosaurs, aetosaurs, rauisuchians, and crocodylomorphs (ancestors of modern crocodiles). The Ornithodira, by contrast, were smaller and acquired a more specialized upright stance, longer rear leg and foot bones, and an extended neck with an S-shaped curve. It is believed that the flying reptile Pterosaurs evolved from this branch of Ornithodira, while another branch further developed the fully erect posture and a new, hinge-like ankle joint, the Dinosauromorphs. From among these, the first dinosaur evolved.

The earliest known dinosaurs are *Pisanosaurus, Eoraptor,* and *Herrerasaurus,* whose body fossils are all found in 228 million-year-old (Late Triassic) sedimentary rocks of the Ischigualasto Formation in Argentina. These were lightweight obligate bipeds of small or moderate size. *Pisanosaurus* and *Eoraptor* were both about 1 meter in length, while *Herrerasaurus* was about 5 meters. Other early dinosaurs found slightly later in other parts of the world include *Staurikosaurus* and *Guaibasaurus* from Brazil and the ornithischian *Lesothosaurus* from South Africa.

As the oldest taxa are of similar geological age and lie close to the emergence of dinosaurs within Dinosauromorphs, identifying the first known dinosaur is a bit problematic. *Pisanosaurus* is regarded as the most basal ornithischian and already showed grinding teeth adapted for herbivory, with inclined tooth-to-tooth wear facets that assisted in slicing and processing plant matter. *Herrerasaurus* and *Eoraptor* were contemporaneous predators with adaptations for carnivory such as curved, serrated teeth and elongate hands specialized for grasping prey. They are generally regarded as the most basal saurischians, the great primary dinosaur lineage that later split into the herbivorous sauropodomorphs and the mostly carnivorous theropoda. Although the grasping, raking hands and curved teeth of *Eoraptor* suggest classification as a saurischian theropod, its lower jaw is not jointed like that of the slightly more derived *Herrerasaurus*. Because members of both saurischian and ornithischian lineages existed at this earliest time, the two divisions must have evolved from a common ancestor even earlier in

Eoraptor. The 228 million-year-old skull of the most ancient dinosaur yet found.

Source: Courtesy of Mark James Thompson.

the period, likely in the mid-Triassic. But this specific ancestor has not yet been found, if in fact it was ever preserved in geology. As *Eoraptor* exhibits fewer specializations that define saurischians and ornithischians, it is widely regarded as the first known dinosaur and is thought to be very similar to the original ancestor.

The world over which the first dinosaurs strode was a place of intense competition and major upheavals in the land fauna population. The dinosaurs' archosaurian relatives had diversified into a wide range of niche-dominating forms: terrestrial quadrupedal carnivores, semi-aquatic predators, and armored herbivores. Many of these animals were bigger than the earliest dinosaurs and existed in greater numbers. A huge variety of nonarchosaurs were also present, including early mammals and mammal-like reptiles. By the start of the Late Triassic, dinosaurs were only a small part of the total land fauna.

Yet from this humble start, dinosaurs had become the dominant land animal by the beginning of the Jurassic period 30 million years later. The reasons for their rise to eminence—and why their contemporaries faded away—have been the subject of much debate. Did the dinosaurs evolve some significant advantage that allowed them to overcome their competition, or did they just get lucky during oppressive environmental crises and extinction events?

It has long been thought that, once they had emerged, the dinosaurs swiftly replaced their closest relatives, the dinosauromorphs, and most other archosaurs. However, recent discoveries suggest that the rise of dinosaurs during the Late Triassic was a more gradual process. It now appears that dinosaurs coexisted with dinosauromorphs for a prolonged period, 15 to 20 million years, without establishing clear dominance. Although genetic and environmental factors must have prompted their evolution and emergence, dinosaurs clearly possessed no significant advantage over their contemporary land animals, as under normal environmental conditions they did not overpower their competition.

As the Triassic drew to a close, however, several global scale events occurred that caused mass extinctions of life. As with the more famous Cretaceous–Tertiary mass extinction, which occurred some 140 million years later, it has been suggested that one or more catastrophic events were involved. Global climate change due to sea-level fluctuations, severe volcanic activity, and bolide impacts have all been postulated with evidence for each hypothesis. The event probably best associated with the extinctions is the volcanic activity in the central Atlantic magmatic province. This was a rapid and massive outpouring of basalts and gases related to the rifting and breakup of Pangea during the Late Triassic that may have affected global atmospheric conditions and disrupted food chains.

The nature and timing of these extinction events is still poorly understood. There appear to be two phases of extinction defined by vertebrate loss. The first, around 220 million years ago, defined the end of the Carnian subperiod and wiped out the dicynodonts and basal archosaurs. The dinosaurs then continued to live alongside top predator competitors, such as the ornithosuchids and rauisuchians, for the remainder of the Triassic. By the end of the period, approximately 200 million years ago, 20% of existing families and about half of all species disappeared, both on land (the basal archosaurs and many mammal-like reptiles) and in the sea (all conodonts, most ammonites, and many bivalves). Indeed, almost all of the archosaurs perished at this time: Only dinosaurs, pterosaurs, and crocodylomorphs remained. Some aspect of anatomy, physiology, or distribution had contrived to allow Dinosaurian survival (see "Dinosaur Success," later in this entry), and the environmental bottleneck that depleted many of their competitors had provided a vast open ecospace in which to roam. Taking advantage of their "lucky break," dinosaurs expanded their territory, occupied new niches, and grew into worldwide terrestrial dominance.

The Triassic

The world that gave rise to and shaped the dinosaurs was quite unlike that of today. The Triassic period, so named because it naturally divides into three periods (from the Latin *trias*), spanned the period from 251 to 200 million years before the present. The early Triassic world possessed only one landmass, the supercontinent Pangea. While the dinosaurs were emerging, Pangea was splitting into Laurasia (North America, Europe, and Asia) and Gondwanaland (South America, Africa, India, Antarctica, and Australia), but this was not yet complete. The climate was warmer than it is today, with no really cold regions on land. The coasts and certain low mountain ranges hosted marshes and swamps, in which grew an abundance of moisture-loving ferns and horsetails. Pangea was so large, however, that rain struggled to reach its far inland regions. These were occupied by vast, arid deserts and dryland forests, where gymnosperms ("naked seeds") such as conifers, yews, and ginkgoes grew. Other tree-like plants such as cycads and bennettitaleans were also present at this time. Some evidence indicates that atmospheric oxygen levels were perhaps only 50% of modern levels.

The two main lineages of dinosaur evolution were already established by the Middle to Late Triassic, with representatives of both Saurischia and Ornithischia found in the earliest populations of dinosaurs. The saurischia evolved further into two major clades, the herbivorous sauropodomorpha ("lizard feet") and the mostly carnivorous theropoda ("beast feet"). The theropods were the major group of carnivorous dinosaurs for the entire Mesozoicera, although some later subbranches would adapt to be omnivorous or herbivorous. They possessed blade-like, serrated teeth and retained the bipedal stance of their ancestors. At this stage of the Triassic, some theropods appear to have dominated the sharp end of the food chain by force of numbers. Their abundance is evidenced by a mass mortality site at Ghost Ranch, New Mexico, containing many hundreds of individual *Coelophysis*.

Meanwhile the sauropodomorphs, long-necked plant eaters, steadily increased body size while retaining relatively small heads. Their leaf- or peg-shaped teeth and skulls indicate an unsophisticated feeding style, coarsely stripping and swallowing vegetation for major processing in the gut. Alongside them the smaller-bodied ornithischian herbivores were evolving a more specialized feeding anatomy, as seen in the primitive ornithischian *Eocursor.* They would crop vegetation and preprocess it with rows of shearing and grinding teeth, while muscular cheeks kept the food from spilling out. As the Triassic progressed, taxa of both herbivore lineages increased in average size and decreased using their hands for feeding, becoming more and more quadrupedal to better support their weight. Eventually the herbivorous dinosaurs would evolve the ground-shaking sizes that characterized the succeeding Jurassic period.

The Jurassic

The end of the Triassic was marked by several large extinction events, which severely weakened the archosaurs and decimated the dinosauromorphs. These catastrophes appear to have had little impact on the dinosaurs, however. This relatively new group survived and then thrived, radiating outward and diversifying, with a trend toward increasing size evident in most lineages. The Jurassic period ranges from 200 to 146 million years before the present and is named after rocks deposited at this time in the French and Swiss Jura Mountains. Pangea was rifting and breaking up, well on its way toward forming the continents we know today. Dinosaurs could still travel between the continents until quite late in the period, however. Geological activity was characterized by the steady deposition of sedimentary rock providing fertile beds for fossilization. The climate was still generally warm, with intermittent periods of extreme dryness. Shallow seas invaded much of North America and Europe, and rains reached lands that had been deserts in the Triassic. Plants grew thickly along the rivers snaking through seasonal floodplains. This period has been called the age of the cycads, but these palm-like plants were actually less successful at the time than their relatives the bennettitaleans. (The latter, however, are now extinct, so clearly the cycads were more successful in the long run.) Both groups flourished along with conifers, ferns, and tree ferns in the moister tropics.

During the Jurassic, dinosaurs underwent a massive rate of diversification within the main lineages laid out in the Triassic. This period is marked by the evolution of gigantism in some dinosaurs, and many early bipedal herbivores became obligate quadrupeds with their increasing size; the sauropods, in particular, became the largest land animals ever to have lived. Indeed, they pushed the boundaries of what is physically possible for terrestrial animals. Several clades of sauropods routinely exceeded 20 meters in length and weights over 15 tons, while some clades, such as the argyrosaurids, antarctosaurids, and brachiosaurids, became supergiants of greater than 30 meters in length and weights exceeding 50 tons.

Like elephants, the Jurassic sauropods possessed columnar limbs and a graviportal gait. They all had relatively long necks to a degree, but although some sauropods such as *Brachiosaurus* evolved necks set in the iconic upright pose similar to modern-day giraffes, this adaptation was relatively exceptional. Most sauropods had shoulders set lower than their hips and probably carried their necks in a horizontal posture, balanced beam–like by their rearward center of gravity and extensive tails. They would then sweep their heads from side to side, feeding over a radius of predominantly lower vegetation or were able to lean out over boggy ground for riverbank herbage.

Many dinosaur communities appear to have had several sauropod species at the same time, indicating a sort of niche partitioning where herbivores adapted to ground-feeding, mid-level feeding, or high feeding. At the ground to mid-level, sauropods likely competed with a radiating lineage of ornithischia that became very successful in the latter half of the Jurassic. The ornithopoda ("bird-feet") were herbivores with specialized skulls and jaws for more efficient grinding of foliage compared to other ornithischians at the time. They achieved this by utilizing a pleurokinetic hinge, a joint in the upper jaw and skull that allowed parts of the face to rotate and align both upper and lower tooth rows at the same time. There were no Early Jurassic ornithopods, but in the latter part of the period there were several clades expressed by such genera as the small delicate *Hypsilophodon* found in Europe, medium-sized *Dryosaurus,* and the larger-sized *Camptosaurus.* The ornithopods would go on to become a most successful group of dinosaurs, both abundant and globally distributed, later giving rise to the famous duckbill forms during the Cretaceous.

Another lineage of ornithischians sprouted armored nodes around the outside of the body to provide increased protection from the larger carnivores of the Jurassic. These Thyreophora included the earliest armored dinosaurs, *Scutellosaurus* and *Scelidosaurus,* and toward the end of the Jurassic this branch produced the famous plate-backed dinosaurs such as *Stegosaurus* and the thickly armored, tank-like *Ankylosaurus.*

It is not surprising that the plant-eaters evolved new ways to deal with carnivores, as the Jurassic marks a great diversification of theropods into a vast range of lineages around the world. Teeth and claws became highly specialized depending on habitat, and while there was an overall trend toward gigantism there was also the evolution of some smaller lineages. So while tiny theropods like *Compsognathus* or medium-sized *Dilophosaurus* chased insects and lizards, *Ceratosaurus* grew up to 8 meters long and *Megalosaurus* and *Allosaurus* were large enough to stalk large ornithopods or small sauropods.

The coelurosauria also appeared at this time, evolving larger brain-to-body ratios and longer feet, and some members appeared with protofeathers. This lineage produced a vast range of significantly smaller, hollow-boned theropods, with some groups having well-developed feathers and other characteristics that could be adapted for use in flight. Indeed, they later evolved the ability to glide or fly and eventually would give rise to the clade Aves, modern birds. One famous example of early coelurosauria is the flight-feathered *Archaeopteryx,* whose fossils are found in the famous Solnhofen limestones of the Late Jurassic. The stage was set for an explosion of small, feathered carnivorous dinosaurs, and the turnover of large dominant herbivores.

The Cretaceous

Starting 146 million years ago and ending 65.5 million years ago, the Cretaceous was the final and longest period in the Age of Dinosaurs. The landmasses of Pangea had splintered further to form numerous smaller continents. This process created new seas and expanded the old ones, further increasing the distances between continents. Weather patterns became more dynamic as the smaller landmasses had less stabilizing atmospheric influence. During this period the various dinosaur families became more geographically isolated and suffered from localized habitat fragmentation. This led to more intense competition for resources in some places, perhaps accelerating the process of specialization and encouraging greater diversity in both plants and animals.

By the start of the Cretaceous many of the sauropods had become extinct in North America and Europe, replaced as dominant herbivores by successive waves of beaked dinosaurs specialized for low feeding. Although sauropods continued to flourish in the southern hemisphere, where giants such as *Saltasarus* and one of the largest dinosaurs ever, *Argentinosaurus,* still roamed.

As plants and herbivores are always locked in an evolutionary struggle, it has been suggested that the increased pressure on plants by the voracious dinosaurian herbivores encouraged a takeover by plants that could grow and reproduce more rapidly. Such plants could colonize a grazed area quickly, producing a new generation before the herbivores returned to crop the area once more. One of the plant types best suited for such an environment was the angiosperms, or flowering plants. Today almost all the species we recognize as plants fall into this category, but in the Late Jurassic they were a struggling minority dominated by the slower gymnosperms. At about the same time that low-feeding dinosaurs were taking over as the major herbivores, angiosperms were flourishing. Worldwide, the great forests changed: The decline of gymnosperms accelerated and flowering plants multiplied. Broad forests of oak, hickory, and magnolia dotted the landscape, while swamp cypresses, giant sequoias, and China firs took over in swampy areas. Are the dinosaurs thus responsible for the flowers we know today, if only indirectly?

All families of ornithischia peaked in numbers and diversity during the Cretaceous, with specialized teeth for chewing the new plants with tougher leaves. One branch of ornithopods gave rise to the hadrosauriformes, such as the Early Cretaceous *Iguanodon* and mid-Cretaceous *Ouranosaurus.* By the Late Cretaceous this group evolved the clade hadrosauridae—the "duckbilled" dinosaurs, which were to spread widely and diversify extensively across the northern continents. Some species evolved large, elaborate cranial architecture, an extreme example being the trumpet-headed *Parasaurolophus.* The hadrosaurs attained large sizes (commonly up to 12 meters long and even longer for some Asian forms like *Shantungosaurus*) and became one of the dominant herbivore groups as the sauropods declined.

Theropod evolution also peaked in the Cretaceous, which saw a vast array of the largest carnivores ever to walk the earth. Each part of the world evolved its own version of gigantic carnivore: *Tyrannosaurus* and *Giganotosaurus* appeared in North and South America respectively, while *Spinosaurus* and *Carcharodontosaurus* stalked the wetlands of Africa. Meanwhile, at the other end of the scale, the small theropods exploded in diversity and abundance, from small feathered types to medium-sized "raptor" forms. Deinonychosaurs, dromaeosaurs, and troodontids were representatives of the many derived lineages of coelurosauria

Australia and the Dinosaurs

The land now called Australia was long thought to be too cold for dinosaurs in the Early Cretaceous. At that time Australia was only just beginning to break away from Antarctica, and parts of its landmass were within the Antarctic Circle. Nevertheless, early in the 1980s abundant hypsilophodontid remains and traces of an allosaur-like carnivore were unearthed on its south coast. Also found were isolated bones that may indicate various ceratopsian, oviraptorosaur, caenagnathid, and ornithomimid dinosaurs. Oxygen isotope studies indicate that the mean annual temperature at the time of deposition was about 5°C, perhaps ranging from −30°C in the winter up to +20°C in the summer. This discovery lent support to the hypothesis that at least some dinosaurs were endothermic, as ectothermic creatures would struggle to be active through such conditions. Being so far south also meant it was also quite dark for some 3 months of the year. Some dinosaurs, such as the little ornithopod *Leaellynasaura,* adapted larger optical pathways for enhanced low-light vision.

that were part of the clade Eumaniraptora. These were small to medium sized bipedal carnivores, with specialized arms and some with feathers, including the infamous sickle-clawed *Velociraptor.* Some taxa such as *Microraptor* had well-feathered arms and also rear legs, displaying skeletal features indicating at least a gliding ability. Other branches of the eumaniraptorans underwent extensive miniaturization, tail reduction, and evolved shoulder girdles with potential for powered flight; the Avialae, the group that would evolve various groups of true winged dinosaurs and, ultimately, Aves—birds in the truest sense. In the latter part of the Cretaceous the flying reptiles were forced to share the sky with a vast array of essentially flying dinosaurs: primitive birds and their descendants. As the Cretaceous progressed, the marginocephalians also evolved extensively from their Late Jurassic ornithischian relatives. Marginocephalia—dinosaurs with extensions and protrusions of bone around the skull—further split into two main lineages: the pachycephalosauria ("thick-headed lizards") and the ceratopsia ("horned faces"). The ceratopsia lineage started in the mid-Jurassic, marked by basal members such as *Yinlong* from China, but during the latter part of the Cretaceous they evolved an enormous variety of frill-necked species, including *Triceratops* and its close relative *Torosaurus*. The latter has the largest skull of any land animal that ever existed. It seems that in some terrains the marginocephalians came to dominate the hadrosaurs, and at least in one location, the Saskatchewan province of southern Canada, the author has observed the last dinosaur remains occurring before the end of the Cretaceous are the marginocephalian *Triceratops*.

At the end of the Cretaceous period, approximately 65.5 million years ago, events occurred to cause apocalyptic environmental pressures to bear down on the planet. Despite the vast scope of the dinosaur spectrum, no member of Dinosauria outside the clade Aves proved capable of surviving the subsequent mass extinction.

Birds From Dinosaurs?

The phlyogenetic relationship between dinosaurs and birds has been intensely debated for at least a century, amid growing recognition of the many skeletal features found in both groups. Some theropod dinosaurs have a hand and wrist structure virtually identical to that of birds except in size, following a pattern found only within Dinosauria. They also have almost identical shoulders, hips, thighs, and ankles. Theropod dinosaurs have light, hollow bones as birds do, often with a dense system of blood vessels—a feature never found in reptiles. Birds and dinosaurs have a secondary palate—reptiles do not. Some dinosaurs are known to have uncinate processes, small extensions of bone on the ribs that assist high-flow breathing in nearly all modern birds. This feature suggests at least some dinosaurs had an avian type respiratory system. Likewise, the vertebrae of theropods and sauropods have pleurocoels: scoops and hollows in the bone that accommodate expanding air sacs in modern birds.

Dinosaurs also laid eggs, and although their eggs differ somewhat from those of birds, at least some dinosaurs are known to have nested in colonies and cared for their young in the nest. Incubation behavior has been supported by certain fossil discoveries, such as a large oviraptorid skeleton found in the classical brooding position on top of a nest containing eggs. The number of eggs found and the absence of eggs in the adult's body support the idea that the oviraptor was truly incubating the eggs, not simply laying them. There are many other interesting specimens, such as the small *Mei long* found with its tail encircling the body and head tucked around onto the back or wing, perfectly matching a typical sleeping or resting posture of living birds.

Even one of the most evident differences between birds and dinosaurs, the question of feathers versus scales, is no longer much of a difference at all. Many dinosaurs are now known to have evolved feathers, including asymmetric "flight" feathers, "downy" feathers, and other types that develop in different stages of modern bird life.

Several theories have been put forth to explain the similarities between birds and dinosaurs. One is that the birds are simply descendants of dinosaurs, as first suggested by Thomas Henry Huxley in the late 1860s. Another is the theory of parallel evolution—perhaps their similarities arose in response to similar environmental pressures as birds and dinosaurs evolved from an earlier separate ancestor. A third theory, originally proposed by Abel in 1911, is that dinosaurs are actually descended from birds rather than the other way around. The parallel evolution and birds-came-first theories had the majority of scientists convinced until 1973, when John Ostrom from Yale University successfully demonstrated that the skeleton of *Archaeopteryx,* considered by most researchers to be the earliest bird, was actually that of a coelurosaurian dinosaur with feathers. Ostrom later showed that other dinosaurs such as *Velociraptor* possessed the most distinctive of all bird-like bones: the furcula (wishbone).

Many of the difficulties in solving the bird versus dinosaur problem stemmed in part from the lack of skeletons of early birds. However, an explosion in the discovery of such skeletons in the 1990s has produced both early birds and "transitional" forms in large numbers. This evidence has greatly strengthened the argument that birds are descended from dinosaurs. The transitional *Unenlagia* ("half-bird") from Argentina is especially noteworthy, having arms that fold exactly as bird wings do. The Mongolian nesting oviraptorid dinosaurs demonstrate bird-like brooding behavior, or at least a protectiveness of their eggs not characteristic of reptiles. The dromaeosaurid-like bird *Rahonavis* from Madagascar also has a peculiar mixture of bird and dinosaur characteristics, with well-developed wings but also the sickle claw typical of the maniraptoran carnivorous dinosaurs.

However, undoubtedly the greatest discovery has been a number of feathered dinosaurs unearthed recently in China. Feathers were long considered a bastion of "birdness," and although the driving force behind feather evolution is not well understood (they likely did not evolve originally for flight; perhaps for insulation, display, or even as a metabolic clearance system for excess minerals), it had generally been considered that only the discovery of a genuine feathered dinosaur would provide definitive proof that birds had a dinosaurian origin. The announcement by Chinese paleontologists that they had discovered *Sinosauropteryx,* a basal coelurosaur dinosaur with evidence of an integumentary structure similar to feathers, thus sparked much debate. This revelation was followed by more Chinese finds from the same area, dinosaurs that were definitely feathered. *Protarchaeopteryx* and *Caudipteryx* were first announced as basal birds on this shifting disbelief. However, several investigators have since demonstrated that both are theropod dinosaurs—*Caudipteryx* is an oviraptorosaur, and *Protarchaeopteryx* is a maniraptoran dinosaur. Also discovered were a feathered therizinosaurid, *Beipiaosaurus;* the dromaeosaurid *Sinornithosaurus;* and a plethora of superbly preserved similar specimens. *Microraptor,* another dromaeosaurid, even displayed "flight"-style feathers on its legs. The resulting arrangement of wing surfaces almost resembles a biplane. Most paleontologists now accept that birds—Aves—arose somewhere within the theropod dinosaur lineage; the only remaining question is how far back they were present and so exactly where the split occurs. An emerging consensus seems to indicate that the common ancestor of theropods and birds may date back at least to the Early Jurassic.

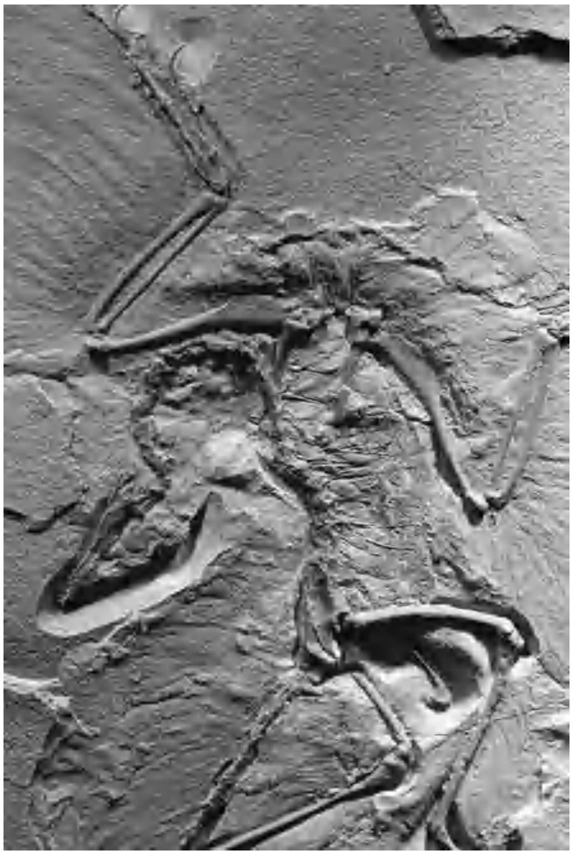
As more and more specimens are found, the evidence in favor of birds as dinosaur descendants continues to grow. At the same time, the dividing line between theropod dinosaurs and birds becomes less and less clear-cut. The gap between birds and dinosaurs has essentially been bridged—birds *are* highly evolved dinosaurs.

Dinosaur Success

It is now known that in the Triassic period, dinosaurs spent many millions of years competing with their archosaur and mammal contemporaries, without achieving dominance. Dinosaurs expanded and evolved at an easy tempo, and although they diversified early on, their adaptations were hardly unique among their contemporaries. Their erect gait, for example, was essentially shared by some other archosaurs (e.g., aetosaurs, ornithosuchids, and some crocodylomorphs) and the dinosauromorphs who also (presumably) shared similar physiology. But after the end of the Triassic extinction events, dinosaurs had assumed not only the roles of top predator and large herbivore but also most other roles all the way down. Only niches for very small animals remained to be filled by mammals and other reptiles. Why did dinosaurs survive when their closest relatives, which had a similar posture and many of the same anatomical adaptations, did not? And given that mammals have such an enormous advantage today, what are we to make of the whole Mesozoic era when, for 165 million years, the dinosaurs reigned supreme and few mammals could grow larger than a modern domestic cat?

One of the few measurable differences in the comparison of dinosaurs to their archosaur and dinosauromorph cousins was their limb proportions and foot posture. Dinosaurs have a longer fibula and tibia in relation to the femur and had better evolved the digitigrade stance. Could such subtle differences have provided a crucial advantage in the competition for food during periods of rapid environmental change? Possibly. The increased leverage of the legs may have allowed dinosaurs to get food resources faster or to retain energy during low food availability. But such anatomical differences do not explain how dinosaurs also managed to keep mammals subservient for so long, when we know that warm-bloodedness is a potent evolutionary advantage. We must therefore also consider the physiological characteristics of dinosaurs: that they may also have been warm-blooded, to some degree, and capable of significantly different respiration than that of their mammal and reptile competitors.

Among today's fauna, we find no large land predators that are cold-blooded. Crocodiles, the sole exception, occupy only one very specific ecological niche and are basically water dwellers.



Cast of the Berlin Archaeopteryx *specimen.*

Central to any discussion of birds and dinosaurs is *Archaeopteryx.* First discovered in Bavaria, Germany, in 1861, it has been and continues to be the source of numerous controversies. Although there is now consensus that it lies somewhere close to the divergence of birds from dinosaurs, until recently there was still considerable disagreement as to which side of the divergence it comes from. Paleontologists tended to look at its skeleton first, which is almost indistinguishable from that of a small theropod. As the shoulder girdle was not derived enough to anchor flight muscles, they deemed it a ground-dwelling dinosaur. Ornithologists fought back by pointing out the feathers (which are identical to the flight feathers of today's birds), wings, claws, broad tail, and hollow bones. It seems likely that *Archaeopteryx* was capable of gliding, although to what degree and under what conditions are still open questions. At the moment it is generally acknowledged that *Archaeopteryx* is the oldest bird-like feathered dinosaur. Although it is certainly not a direct ancestor of modern birds, it testifies to the evolutionary pressures causing "birdness" to arise in the theropod dinosaurs.

During the entire Cenozoic era as well, virtually all large predators were warm-blooded. This is because the position of top predator is very competitive, and the ability to control and maintain body temperature (i.e., being warm-blooded) means that the animal is not as dependent on the environment for its activity rate. It can hunt at any time of the day (or night), in any season; warm-blooded animals can thus operate at maximum efficiency and tend to have a strong advantage on land.

Of course, the terms *warm-blooded* and *cold-blooded* are something of an oversimplification. Virtually all animals, if examined under the proper conditions, will appear to be "warm-blooded"; that is, their internal body temperature will be roughly constant over time. The more important aspect of this trait is the *mechanism* by which body temperature is maintained. The terms *endothermic* and *ectothermic* are more appropriate: An ectothermic animal relies on heat from the outside (i.e., the environment) to maintain body temperature, whereas an endothermic animal relies on the heat generated within its own body by metabolic processes. Endothermic animals will therefore have a higher metabolic rate, because they need to generate more internal heat. There are even animals whose metabolic processes fall in between endothermy and ectothermy. This is far from an either/or proposition, as a large number of physiological mechanisms are potentially involved. The enormous range of dinosaur sizes implies that they did not share a common physiology, nor did they use the same strategies and mechanisms to maintain their metabolic state. Given that all we have left are lifeless bones and footprints, is it even possible to produce evidence supporting the warm-blooded dinosaur hypothesis? Surprisingly the answer is yes, although such evidence must be largely inferential. For example, we can consider lines of evidence in bone structure, histology, and bone isotope composition, growth rates, posture, speed and agility, rate of evolution, similarities with birds, insulation, and the existence of Arctic and Antarctic faunas.

By comparing these aspects of dinosaurs, mammals, and cold-blooded reptiles, we find considerable support for the idea that dinosaurs were warm-blooded. At the very least, they clearly had a much higher activity level and metabolic rate than do modern cold-blooded creatures.

Not surprisingly, some counterarguments and alternatives have been presented as well. The question has yet to be decided, but on balance the likely outcome seems to be heavily weighted in favor of at least partially warm-blooded dinosaurs. The same tests for endothermy have been applied to the fossil remains of mammal ancestors (cynodonts, dicynodonts) and archosaurs. In both cases the results suggest that they were more warm-blooded than cold-blooded. Thus, it seems that endothermy may have evolved in both lines at an early period. In this scenario, dinosaurs were simply one group in a long line of warm-blooded animals.

An additional point of difference that may help explain dinosaur success is their increased activity potential as a result of evolving a unidirectional airflow lung and air sack respiratory system, as seen today in their avian descendents. Compared to mammals, which have a "piston" lung system whereupon the diaphragm does most of the work in sucking air into the lungs, at least some lineages of dinosaurs evolved a more avian-type respiration system that was "high flow" and more efficient at extracting oxygen out of the air. The evidence is in the pneumaticity of bones in sauropod and theropod lineages, uncinate processes on the ribs of some maniraptoran dinosaurs, and the astounding growth rates of some clades. During the Late Triassic extinctions, such potential may have been critical when atmospheric oxygen content was less than half that of present day.

Although much work needs to be done to confirm these lines of investigation, the combination of new fossil discoveries and modern-day technology are without doubt overturning the old paradigm of dinosaurs as sluggish, maladapted creatures. We now see that they represent an epitome of productive evolution; as a group they were innovative, adaptive, and successful long term. The ability to metabolize oxygen efficiently and maintain constant, high body temperature meant dinosaurs could remain active and successful during times of environmental stress. It required one of the greatest environmental catastrophes the world has ever known to bring them down and clear the way for our own ancestors.

The Great Extinction

Earth's geological record contains evidence of many different extinction events, some large enough to disrupt ecosystems on a global scale. Three such events occurred during the dinosaurs' reign. The first occurred in the Late Triassic and has been postulated as one of the main reasons for their rise to dominance. Another, at the end of the Jurassic, is associated with the disappearance of many large sauropods and ornithopods. This extinction may also have been related to the proliferation of flowering plants. Then we have what is probably the most notorious extinction of all time: the Cretaceous-Tertiary (K-T) event that destroyed all nonavialan dinosaurs 65 million years ago. Earth also lost a massive range of other taxa—terrestrial and marine, vertebrates and invertebrates. Floral communities also went through a dramatic turnover in abundance and diversity. The great reign of the dinosaurs was over, and no convincing evidence has ever been found that dinosaurs survived for even a short time after the K-T event.

The carnage has been attributed to several large-scale geological events occurring at or near the K-T boundary. This includes a period of massive volcanism, which poured out cubic kilometers of basalts to form the Deccan traps in India and Pakistan; global sea-level regression, which is notable in the sedimentary record of North America's western interior; and finally an asteroid impact large enough to form a 170 kilometer-diameter crater on the Yucatan Peninsula of Mexico. Individually or collectively, these events are thought to have invoked habitat loss and fragmentation, global climate change, and food chain disruption. The rapid environmental devastation overcame the abilities of many organisms to adapt and survive, causing one of the five biggest mass extinctions of life on Earth.

Whereas any of these cataclysmic events may account for the loss of life observed in the fossil record, all raise problems that have not yet been resolved. In particular, the apparent selectivity of the extinctions has yet to be explained. Large, nonavialan vertebrates such as dinosaurs were entirely wiped out, but so too were large marine reptiles. Amphibians survived very well, but many lizards and small reptiles did not. The avialae (birds and their closest relatives among the dinosaurs) survived, but flying reptiles such as pterosaurs did not. It can be recognized that life on Earth suffered a relatively rapid disruption that impacted ecosystems all over the world, if to varying degrees. As the selectivity applies to both land and sea, freshwater and saltwater, a successful theory of mass extinction must be able to explain why some survived and others did not.

Unfortunately, few areas of the world record this period of geological time in detail. Probably the best known and most studied are the upper Hell Creek and lower Tullock formations of eastern Montana in the United States. One research site produced more than a hundred samples of vertebrates from 12 major taxa: sharks, bony fish, frogs and salamanders, multituberculate mammals, placental mammals, marsupial mammals, turtles, lizards, champsosaur, crocodilians, ornithischian dinosaurs, and saurischian dinosaurs (not including birds). At this site it was observed that nearly half of the total species survived across the K-T boundary, but 75% of the extinctions occurred in just four of the groups: sharks, lizards, marsupials, and dinosaurs.

The same pattern of selective termination is seen worldwide in both animal and plant communities: Some life forms were entirely wiped out, whereas others, in seemingly similar conditions, remained untouched. Whereas the patterns of the K-T mass extinctions make the cause very difficult to interpret, the asteroid impact hypothesis has stood the test of time. For one thing, it has made predictions that have been supported by exploration and evidence, such as that an iridium-enriched layer of soil should occur globally and that extinctions should be not only global but relatively abrupt and synchronous. This turns out to be the case. It also has the advantage of being the most parsimonious explanation. While it fails to explain certain details of the selectivity, our understanding of the complex interactions caused by such impacts is still incomplete. Furthermore, the dinosaurs are known to have previously survived sea-level transgression/regression and volcanism on large scales. While acknowledging that these changes may have played a role, the asteroid impact better explains the scale and tempo of this environmental catastrophe. Although it may be attractive to invoke all the geological events in unison (the "everything that could go wrong did go wrong" theory), this solution is not necessary in light of the simple and effective asteroid impact.

Fortunately for Homo sapiens, the demise of dinosaurs freed up numerous ecological niches into which placental mammals could expand and diversify. The dinosaurs' death left behind a fertile world in which mammals could finally come out of the shadows and go on to become dominant terrestrial vertebrates.

Today, it is interesting to compare the K-T event to the mass extinction of life currently under way. Human activities are causing an impact of similar strength and rapidity on the habitats of many species, including birds. It would be ironic as well as tragic should our species go on to achieve what the K-T mass extinction could not: the extinction of birds, the last true descendants of dinosaurs.

Changing Interpretations

Sporadic work on fossils started as long ago as the 15th century, but it took hundreds of years for scholars to agree that fossils were even of biological origin. For one thing, recognizing this fact implies that extinction is real: that most of the organisms that have ever existed are now gone, leaving only their descendants. Researchers then (and now) had to deal warily with the extrapolations of their discoveries. Supporting the idea of extinction could be life-threatening in cultures where the dominant religion held that all animals were created at the same time to populate a world that looked much like it does today. It took a great deal of physical evidence collected from sites all over the world to raise the threshold of enlightenment.

During the 18th century, fossil marine reptiles and other "different" creatures such as pterosaurs were being found in quantity all over Europe. This led to swelling public interest, a passion that really ignited when a huge and viciously toothed *Mosasaur* jaw, the "Monster of Maastricht," was found in Belgium in 1770. The preponderance of evidence shone light on the debate over extinction and the origin of fossils, and the latter carried the day. Researchers soon moved on to classifying and interpreting the remains, a task made easier by the newly developed technique of comparative anatomy.

By the 1820s fossilized dinosaur bones had been found in English gravel quarries. Their strange appearance caused a plethora of interpretations. Various publications likened them to lizards, birds, mammals, and crocodiles. Scientists, artists, and the public proved insatiable, demanding more knowledge on what these long-lost animals looked like and how they might have behaved. But a combination of factors would collude to imprint one particular interpretation of dinosaurs on the public and scientific psyche.

The first dinosaur described by scientists was dubbed *Megalosaurus,* which literally means "big lizard." The next was named *Iguanodon,* simply because its leaf-shaped teeth are similar to those of the South American iguana. Having been tentatively identified as prehistoric ancestors to modern reptiles because of the shape of their teeth, dinosaurs quickly became associated with reptiles in every way. In 1842 Sir Richard Owen coined the term *Dinosauria* ("fearfully great lizards") for this growing group of strange creatures, and his work was published (almost as a footnote) in *Report on British Fossil Reptiles.* A side effect of this usage was that most subsequent dinosaur names were suffixed with *saura,* meaning "lizard" or "reptile."

Laypersons and scientists alike began to assume they were cold-blooded and sluggish, as some reptiles are today. Such an interpretation complemented other attitudes of the time, namely, that human beings were the pinnacle of nature. Any extinct life was necessarily more primitive, slow, and dim-witted than humans. Thus, the first complete dinosaur skeletons went on display as very large lizards with odd spikes and claws. This representation of dinosaurs as splay-legged, heavy-set quadrupeds would hold sway for almost the next 150 years.

Even at this early stage, however, several investigators realized that these animals strongly resembled birds. Thomas Henry Huxley in 1868 went so far as to suggest that birds might be descended from dinosaurs. He and other workers found considerable evidence in contradiction of the sluggish reptile theory, evidence supporting a more active and dynamic model of dinosaur behavior. But the dinosaurs-are-lizards paradigm was already entrenched; it would take time and several bursts of scientific endeavor to break it down.

In 1877 the hub of dinosaur discovery moved from Europe to North America. A vast number of complete pristine skeletons were discovered at Como Bluff in Wyoming and later on in Utah.

Some of the discoveries included dinosaur lineages recognized as bipedal, a distinctly unreptile-like trait, but this had little effect on the prevailing view. In 1925, however, Earl Douglas used the accumulated evidence in his collection of 350 tons of sauropod bones to mount and display the massive specimens in a parasagittal stance, with their legs oriented beneath the body like columns. This started a debate that was to last for decades. The argument was finally settled by the fabulous Paluxy dinosaur trackways, discovered in the bed of a Texas river. The careful measuring of the undoubted sauropod footprint tracks confirmed that sauropods indeed had a fully erect stance and not the previously accepted sprawling reptilian posture.

Another part of dinosaurs' reptilian image had been washed away, at least anatomically, but the entrenched idea of sluggish, cold-blooded behavior persisted. Andrews and Osborn found fossilized dinosaur eggs and nests while exploring the Gobi Desert in Mongolia during the 1920s, indicating dinosaurs' similar habits to modern birds. Theropod dinosaurs, such as *Velociraptor* later discovered in the same area, also beautifully displayed hollow bones similar to birds. Despite growing evidence that dinosaurs were more bird-like in their morphology, habits, and physiology, the concept was still not getting widespread traction.

In 1969 John Ostrom published detailed work involving the Early Cretaceous theropod *Deinonychus,* demonstrating that it was a lightly built and likely agile predator. This convinced many that at least some dinosaurs were very active and were more bird-like than reptilian in their behavior. Ostrom also investigated horned and duckbilled dinosaurs, reinterpreting them as sophisticated feeders rather than plodding primitives. This began a period often called the "dinosaur renaissance": Research accelerated amid a growing sense that dinosaurs were substantially dynamic animals. Earlier recognized but ignored aspects of the bird–dinosaur relationship were revisited and examined afresh, fueled by new discoveries. The Trexler family's 1978 discovery in Montana of hadrosaur hatchlings still within their nests led to the description of *Maiasaura* ("good mother lizard") by Jack Horner. This convincing evidence of postbirth parental care increased the growing perception of dinosaurs as dynamic animals with complex behavior. Then in the 1990s, a flood of small feathered dinosaurs with clearly bird-like attributes was discovered in China. These specimens helped confirm the new paradigm, and dinosaurs are now widely regarded as lively rather than sluggish creatures.

In some ways another wave of "dinomania" started around this time, to be inflamed later by blockbuster films such as *Jurassic Park* and the BBC television series *Walking With Dinosaurs*. Previously esoteric questions, such as whether dinosaurs were really warm-blooded and how they came to be extinct, became topics of interest to the public at large. People wanted to learn about how they mated, how they cared for their young, and what their migration patterns were. This trend of popularity seems set to continue with every generation.

New discoveries and further research continue to evolve our interpretations of dinosaurs, but old

Fossil Skull of Nigersaurus. This skull shows an amazing linear muzzle of teeth and other adaptations suggestive of low browsing or grazing, contrary to historical concepts of sauropod feeding strategy.

Source: Sereno, P. C., Wilson, J. A., Witmer, L. M., Whitlock, J. A., Maga, A,. et al. (2007). Structural Extremes in a Cretaceous Dinosaur. *PLoS ONE* 2(11): e1230. DOI:10.1371/journal.pone.0001230 habits die hard and many aspects of these fascinating creatures are counterintuitive. An example is the customary view that sauropods were high feeders, using their extensive necks to reach up and browse on trees similar to the modern-day giraffe. New discoveries and ongoing research show that although there were certainly some very tall sauropods that specialized in mid and high browsing, most seemed better adapted for low fodder.

The discovery and study of *Nigersaurus,* a medium-sized Cretaceous sauropod from West Africa displays extreme adaptations for a low-browsing feeding strategy first established among diplodocid sauropods during the Jurassic. The alignment of the cervical column, combined with an endocast of the braincase revealing the ear canals, indicates *Nigersaurus*'s head was held habitually pointing at the ground. In this ground-level posture it could nip off soft vegetation with its linear dental battery running along the front of its muzzle containing many hundreds of small teeth that continually replaced themselves at a monthly rate. Reinterpretation of the Jurassic sauropods *Apatosaurus* and *Diplodocus* has revealed they too were likely specialized for low browsing, including lacustrine feeding, based on their head-down attitude, neck pose and flexibility, specialized dentition, and a center of mass located back near the hind limbs.

Nigersaurus is an example of new dinosaurs that help broaden our outlook on all dinosaurian biology (beyond the fact that sauropods may not have resembled any living forms in how they carried out their lives). If we let the fossil bones tell their own story, these remarkable creatures help us critically reexamine preset rules of interpretation and thus dinosaurs have finally recovered from several centuries of the misplaced lizard stereotype to play an ongoing role as ambassadors of adaptability, complexity, and long-term survival.

The study of dinosaurs is now progressing at an unprecedented rate. Advances in the sciences of taxonomy, phylogeny, biogeography, paleobiology, and stratigraphic distribution have been providing frequent leaps of insight. Vigorous research programs are under way in many countries around the globe, many involving entirely new methods such as genetic sequencing and the search for biomolecules. Meanwhile, new detection and surveying technology has greatly accelerated the discovery and excavation of new dinosaur remains. There is also a trend toward more attentive excavation, which helps preserve fossil evidence of soft tissue. Finally, many researchers are choosing to focus on specific information that may assist us in dealing with our own biodiversity loss and climate change.

The total number of dinosaur types that have ever lived is estimated at 900 to 1,200 genera. If this is accurate, then the known fossil record of dinosaurs is presently only about 25% complete. This sets a tantalizing and challenging target for dinosaur paleontology. As research continues, there can only be one certainty—this perennially fascinating animal group has many more surprises in store for us.

Diseases, Degenerative

The progressive deterioration or atrophy of tissue over time is the characteristic of a degenerative disease. Such conditions may be due to poor lifestyle choices, immune responses, genetic diseases, or just the wear and tear of time. Degenerative diseases also include those in which tissues change from a higher to a lower form, generally meaning a form that is less functionally active. Degenerative diseases are often contrasted with infectious diseases, diseases caused by pathogenic agents, including bacteria, viruses, and parasites. However, this comparison is not always straightforward, for infectious diseases often have degenerative symptoms, as in the case of tuberculosis.

General Degenerations

Many types of degenerative diseases are not tissue specific, affecting many different tissue types in the body. One such disease is dystrophic degeneration, in which the body as a whole degenerates as a result of poor nutrition. This is usually associated with various psychological eating disorders such as anorexia nervosa and bulimia. The malnutrition associated with these diseases may also lead to other degenerations, such as atrophic pulp degeneration, in which the pulpal cells in dental pulp degenerate. A classical systemic degeneration is senile degeneration, in which the age of the patient has caused bodily and mental degenerations, and the toll of time causes widespread changes. This includes the atrophy of muscles, declining sight (macular degeneration), dulling senses, a decrease in mental retention and abilities, and fibrous and atheromatous changes. Everyone experiences senile degeneration to some degree as they age and their muscles weaken through time; however, the rate of degeneration depends on many factors, including diet, exercise, familial history, and lifestyle.

The immune system also plays a large role in the degeneration of cells. Cloudy swelling degeneration occurs during the local inflammatory response of the immune system. Here, the cells take on water as the macrophages and fluids move to the offended site. This may also be called vacuolar degeneration, as the vacuoles tend to grow as well. If the injury has somehow affected the metabolism of the cell, this cloudy swelling degeneration may persist, but it generally goes away with time. A severe form of cloudy swelling degeneration is hydropic degeneration, in which water droplets can be visualized within the cell. This is also known as ballooning degeneration. Following the immune response, the body immediately begins the rebuilding process. The plasma protein fibrin migrates to the offended site and begins to aggregate to form a clot. This process is known as fibrous degeneration, or fibrosis. This is considered a degenerative process, as a lower form of tissue is replacing a higher one. This fibrous tissue is what forms scars and is a normal part of the healing process. However, when fibrosis becomes excessive, it can lead to many problems within the body. For example, if fibrin is activated within the bloodstream, it may form a blood clot within the vessel, which may travel as an embolus to the heart, causing a myocardial infarction (heart attack), or to the brain, causing a cerebrovascular accident (stroke).

If tissue is not repaired, it can lead to death of the tissue, or necrosis. Necrosis is characterized by several different degenerations, including the aforementioned fibrous degeneration. Another type of necrotic degeneration is caseous degeneration, or caseation. The soft, cheesy appearance of the necrotic tissue characterized by this degeneration earned it the name of "cheesy degeneration" as well. This is a common degeneration found in the lungs of tuberculosis patients. Necrosis of striated muscle is known as Zenker's degeneration, or waxy degeneration, in which the muscle cells die and take on a glassy appearance. This often is the result of a severe infection, such as typhoid fever.

Integumentary and Epithelial Degenerations

The skin, sweat glands, hair, nails, and the external covering of the body compose the integumentary system. The integumentary system is of course prone to senile degeneration like everything else, as the skin tends to become thinner and weaker, especially at the top layer, the epidermis. Epidermal atrophy has also been associated with lupus, hypothyroidism, and hyperadrenocorticism. Alopecia is the scientific name given to baldness. In certain types of alopecia, follicular degeneration occurs, in which hair follicles are destroyed and replaced with scar tissue. New hair cannot grow from these hair follicles, and hair growth is no longer observed. Colloid degeneration is when tissue is replaced by a gelatinous form. A common form of colloid degeneration is colloid milium, in which papules, or small hard elevations, are formed on the skin and give the appearance of amber acne. This disease has been linked to prolonged sun exposure. Colloid degeneration is not limited to the integumentary system, and benign colloid tumors or growths can occur throughout the body, including the brain.

The epithelial system includes the inner lining of all internal organs, most notably the gastrointestinal and pulmonary systems. One degeneration common to all epithelial systems is mucinoid degeneration; this includes mucous, mucinous, colloid, and myelinic degeneration. In mucous and mucinous degeneration, mucous is abnormally deposited in epithelial tissues. Increased mucous deposits may form in response to irritants and infections. An increase of mucous deposits is also a characteristic of cystic fibrosis, a recessive genetic disorder that affects all endocrine and exocrine glands but affects the epithelial cells most profoundly. This mucous degeneration is also a characteristic of mucinous carcinoma, an aggressive tumor. Research has indicated that tumors comprised of 60% mucus or more tend to be more aggressive than other forms of cancer. Mucous tumors are also called colloid tumors. Myelinic degeneration is characterized by a deposition of myelin and lecithin, important substances in the lining of the gastrointestinal tract. If this layer erodes, harmful stomach acids and enzymes may attack the intestinal wall, leading to infections and ulcers.

Muscular and Skeletal Degenerations

As a result of our evolutionary shift to bipedality, our skeletal system, especially our spine, is highly prone to degeneration. Degenerative disc disease of the spinal column is a perfect example of this, in which the spongy disc of connective tissue between the vertebrae is injured. This degeneration is often caused by trauma to the disc, which can occur from something as seemingly harmless as lifting a box. It can also be the sum of many small traumas over time. This disease is also known as spondylosis. Because the discs have very limited blood flow, they generally have a difficult time repairing themselves. Therefore, after the trauma, the discs dry out and lose their shock-absorbing capability. This can compress the nerve fibers radiating from the spinal column, causing a radial pain or numbness. These nerves may swell as part of an immune response, making the compression and pain even more severe. Surgery, most often a spinal fusion, is a frequent choice of treatment; this may be combined with physical therapy and anti-inflammatory medications. Experimental treatments are also available that attempt to rehydrate the discs; however, many of these are still in the early stages of development.

Another very common degeneration of the skeletal system is osteoporosis, in which the bone mineral density of the patient is significantly decreased. This disease is most common in postmenopausal women, but it also may be present in patients with chronic illnesses, especially hormonal disorders. This disease itself has no symptoms but is characterized by an increased risk in fragility fractures, fractures that would not occur in healthy patients. Fractures that reduce mobility, especially hip fractures, can lead to more threatening conditions, including deep vein thrombosis, pneumonia, and pulmonary embolism. This disorder can be treated with a combination of medications as well as an increase in vitamin D and calcium in the diet. Lifestyle changes that help to treat and prevent this disease include exercise and a reduction in tobacco smoking and alcohol consumption.

Degeneration in the muscles, or muscular atrophy, is a very common occurrence with age. However, muscular dystrophy is a group of diseases characterized by severe muscular degeneration, regardless of age. There are nine forms of muscular dystrophy and more than 100 diseases with similar symptoms. Duchenne muscular dystrophy is the most common of these dystrophies and is inherited by means of the sex-linked X chromosome. Duchenne muscular dystrophy and Becker's muscular dystrophy, the two most common forms, occur due to a mutation in the gene that codes for dystrophin, which, as of 2007, has the longest coding segment of any known allele. Dystrophin is a cytoplasmic protein that forms a complex pivotal to muscle form and function. Without this protein in its fully functional form, muscle function declines severely. Muscular dystrophy has no known cure, but physical therapy and orthopedic instruments may be helpful in treating the disease short term.

Gastrointestinal Degenerations

Many of the degenerative diseases of the gastrointestinal system were included in the epithelial degenerations, including mucous and myelinic degeneration. However, some of the most debilitating degenerative diseases of the gastrointestinal system are from abnormalities in the liver. The liver is responsible for the breakdown of fats into triglycerides, less complex substances that can be stored in the body. When this process is disrupted, it can lead to fatty degeneration of the liver, also known as steatosis. This condition is characterized by fat droplets (mainly triglycerides accumulating within the cells) as they cannot be broken down and stored by the normal processes. This is also known as adipose degeneration. This disease is most commonly caused by chronic alcoholism, but it also may be caused by pregnancy, malnutrition, or poisoning. Fatty degeneration usually has no outward symptoms; internally the patient's liver may grow to be up to three times the normal size, which may cause pain from crowding in the abdominal cavity. In more severe forms, the patient may appear jaundiced. This condition is generally reversible as long as the underlying problem, such as alcoholism, is corrected.

Hepatolenticular degeneration, or Wilson's disease, is characterized by a systemic accumulation of copper within the tissues. Patients with this autosomal recessive disease often initially present with liver problems at a young age (10–14 years) but may also have neurological symptoms as well. The mutant allele in Wilson's disease prevents the normal excretion of copper in the bile, resulting in excessive buildup in the liver cells. This leads to chronic hepatitis and eventual cirrhosis and may even lead to complete liver failure. Once the liver cells are significantly damaged they release the copper into the bloodstream, which then affects the entire body, especially the heart and nervous system. Treatment of this disorder includes medications such as trientine hydrochloride that remove copper from the tissues in combination with a diet low in copper and high in zinc and vitamin B6.

Genitourinary Degeneration

The deposits of uric acid throughout the body characterize uractic degeneration. This disorder is caused by the inability of the kidneys to regulate the amount of uric acid expelled in the urine. The uric acid is instead transported in the bloodstream and eventually forms crystals that deposit throughout the body, most commonly in the large toe. The condition is known as gout and is characterized by intense joint pain and inflammation. High levels of uric acid can also result in one form of kidney stone as well. Treatments generally focus on treating the inflammatory response in the joints as well as pain management, but an increase of vitamin C in the patient's diet as well as a reduced intake of purines help to lower the uric acid level in the bloodstream.

Degenerations in the uterus are very common in premenopausal women. One such degeneration is leiomyoma, which may be found in nearly 20% of all women. This degeneration is characterized by the formation of benign uterine growths or cysts in the smooth muscle of the uterus. Because estrogen and progesterone usually stimulate growth, leiomyomas tend to grow in size during pregnancy. Symptoms of this disorder include uterine bleeding, and if left untreated anemia and even infertility may result. Oftentimes leiomyomas undergo further degenerations themselves. The most common form of degeneration of leiomyomas is hyaline degeneration, in which the cyst takes on a glassy appearance. Other degenerations include mucous, fatty, cystic, and carneous or red degeneration, in which the tissue loses blood flow and becomes necrotic. Laser removal of these cysts is becoming a safe and common treatment of this degeneration. These cysts can also grow in the intestine, small bowel, and esophagus.

Cardiovascular Degeneration

Fatty degeneration also has a large impact on the cardiovascular system as well. Deposits of fat and cholesterol along artery walls are known as atherosclerosis, which is a potentially lethal condition. This condition is found in all patients to some degree, but large and numerous deposits become a major problem. If these deposits become too large, they may clog the vessel, preventing blood and nourishments from reaching all of the tissue the artery feeds. When this occurs it is known as an infarction, and if it occurs in the coronary arteries of the heart, it is known as a myocardial infarction, or heart attack. This deposit can also break off from the artery wall and travel, and an embolus may form, eventually blocking a new area of the vessel it reaches. Sometimes, the vessel may grow outward to allow blood flow past the deposit. However, this can result in an aneurysm or local dilation of the vessel wall, which may eventually rupture. Atherosclerosis is the most common underlying cause of heart disease and stroke. Treatment may include widening the affected vessel by inserting a stent or bypassing it using the patient's own vessels harvested from elsewhere in the body.

Calcium deposits may also contribute to arteriosclerosis and have strong implications in valvular diseases. Calcareous degeneration is any disease that is characterized by deposits of calcium in the tissues, the underlying cause of which may include problems with the parathyroid gland, which controls calcium concentration in the blood. Calcium is often deposited on plaque deposits in atherosclerosis, which helps to stabilize them within the vessel. This is known as Mönckeberg's degeneration or a form of angiolithic degeneration, in which mineral deposits coat vessel walls. When calcium is deposited on any of the four valves in the heart, it may narrow the opening, resulting in a condition known as valvular stenosis. The symptoms of this vary according to the valve the calcium is deposited on. For example, in aortic stenosis, narrowing of the aortic valve, the left ventricle must work harder to pump blood through the narrow opening and is thus larger in size, or hypertrophied. As the muscle thickens it needs more and more blood flow, most of which it is already not receiving. If this is not corrected, the hypertrophied muscle may become ischemic, resulting in chest pain. Syncope, or fainting, is also a common symptom, as less blood is being distributed throughout the body due to a decrease in cardiac output. One of the most serious implications of aortic stenosis is the possibility of congestive heart failure, in which the backflow of blood can cause shortness of breath, dizziness, widespread swelling or edema, and eventual heart failure. Pulmonary valve stenosis is characterized by a decrease in blood flow to the lungs. Patients have symptoms that are much less severe and may include hypertrophy of the right ventricle and cyanosis due to a decrease in oxygenated blood. Mitral stenosis by calcification is characterized by a decrease in blood flow between the left atrium and left ventricle. This results in a reduction in cardiac output and backflow of blood that can result in congestive heart failure and pulmonary hypertension. To compensate for the decreased cardiac output, the patient's heart rate may increase, a condition known as tachycardia, and may enter dangerous rhythms such as atrial fibrillation. Tricuspid stenosis usually is caused by rheumatic fever and rarely caused by calcareous degeneration. The treatment of all valvular diseases includes medical management, balloon valvuloplasty (which expands the valve), or valve replacement. Valve replacements may include mechanical, homograft valves from cadavers or heterograft valves from animals such as pigs. Mechanical valves last the longest; however, the patient must be on blood thinners for the rest of his or her life to avoid clotting.

Nervous System

Degenerations of the nervous system, or neurodegenerative diseases, are among the most widespread and the most debilitating. One of the best-known and most common degenerations of the nervous system is found in amyotrophic lateral sclerosis (ALS), or Lou Gehrig's disease, which develops in 1 to 2 people per 100,000 every year. ALS is characterized by the degeneration of motor neurons, which facilitate voluntary muscle movement. The net result of this degeneration is general muscle weakness, difficulty with movement (ataxia), muscle twitches (fasciculations), and an ultimate loss of voluntary movement (except for the eyes). Most patients ultimately die of respiratory failure due to an inability to breathe without the assistance of a ventilator. The majority of ALS patients (90%–95%) develop the disease sporadically or idiopathically, with no known cause. The remainder of the ALS patients show a genetic basis to the development of this disease. There is no known cure for ALS, although a new drug, Riluzole, was recently approved to slow the degeneration of motor neurons.

Another common and well-known neurodegenerative disease is Parkinson's disease, which is characterized by the degeneration of dopamine-secreting cells in the brain. This greatly affects motor control and results in tremors, rigidity, slowness in movement (bradykinesia), and postural instability or a difficulty with balance, among many other symptoms. Cognition is affected as well and may ultimately lead to dementia as the disease progresses. The majority of all individuals with Parkinson's disease develop the disorder idiopathically with no known cause. A very small number have shown a genetic basis to this disease. Most treatments focus on drugs that replace the lost dopamine in the patients. However, generally only 1% to 5% of the drug given produces the desired effect on the target area of the brain, with the rest being metabolized throughout the body, creating adverse side effects. Also, due to feedback loops, these treatments actually further the degeneration of dopamine-secreting cells, which are no longer needed due to the replacement therapy. Other treatments include dopamine agonist drugs and monoamine oxidase B inhibitors, which inhibit the breakdown of dopamine. Many treatments focus on treating the symptoms; these treatments include speech therapy, physical therapy, and deep brain stimulation, which acts as a "brain pacemaker," reducing tremors. Currently there is no known cure for Parkinson's disease.

Alzheimer's disease is also a very common neurodegenerative disorder and is the leading cause of dementia worldwide. This disease is characterized by a progressive loss of cognitive ability, including mood and behavioral changes, loss of language organization, and ultimately dementia. Plaques of amyloid beta, a misfolded peptide form within the brain, along with Alzheimer's neurofibrillary degeneration, in which protein aggregates form in neurons of the brain. This disease is also idiopathic in origin; however, early-onset Alzheimer's disease (before 65 years of age) has shown a genetic link. There is no known cure for Alzheimer's disease, and most patients die within 7 to 10 years after the onset of the first symptoms. As of 2004, Alzheimer's disease was the seventh leading cause of death in the United States. Treatments generally focus on treating the symptoms socially and include occupational and lifestyle therapies as well as psychosocial interventions. Other treatments, such as acetylcholinesterase inhibitors and ginkgo biloba supplements have shown to slow the progression of the disease, but they do not reverse its effects and do not slow it completely.

Special Senses

The loss of the special senses—taste, smell, hearing, and sight—is a normal part of aging. The number and sensitivity of taste buds on the tongue decrease over time from normal wear and tear. Thousands of tiny hairs within the cochlea of the ear are damaged over time, decreasing hearing sensitivity. However, these special senses also may degenerate prematurely, secondary to other disorders, especially those that affect nerve function, including the aforementioned Parkinson's disease and Alzheimer's disease, both of which affect smell, taste, and hearing.

Macular degeneration is characterized by the degeneration of the macula area of the retina and is the leading cause of blindness in the United States in patients over 50 years of age. In macular degeneration, yellow deposits called drusen form between the retinal pigment epithelium and choroid. This leads to atrophy of the retinal pigment epithelium resulting in a loss of photoreceptors in the offended area, generally the center of the eye. This is known as the "dry" form of macular degeneration. The "wet" form is caused by the formation of a small blood vessel within Bruch's membrane, the innermost layer of the choroid. This leads to blood leakage and scarring near the macula, destroying the photoreceptors, resulting in vision loss. Macular degeneration that forms at a young age (juvenile macular degeneration) is usually genetically linked and is found in many forms, including Best's disease (congenital macular degeneration), Doyne's honeycomb retinal dystrophy (Doyne's honeycomb degeneration), Sorsby's disease, and Stargardt's disease (Stargardt's macular degeneration). Treatments focus on slowing the progression of vision loss and incidence in high-risk patients and include dietary changes, drugs that reduce cholesterol, and, in individuals with wet macular degeneration, drugs that reduce the formation of new blood vessels.

The sheer number of degenerative diseases is considerable; volumes could be filled classifying and discussing the various degenerative diseases, as only the most common were briefly discussed in this entry. As modern medicine progresses, it is hoped that treatments will be discovered for many of these conditions. However, short of discovering the Fountain of Youth, with the passage of time all of us remain subject to the effects of aging.

DIVINATION

Divination is an attempt to connect to a supernatural power in order to retrieve information. It is intended to allow participants to learn about the future or secret, hidden matters. Thus, divination is a process of gaining information through rituals with a specific intended outcome. The word can be traced back to *divinity,* which indicates a relationship to the gods. Anthropologists have debated whether the rituals surrounding divination should be classified as religious ceremonies or magical invocations; however, it is recognized that participants of divination do not make this distinction. In fact, it is an important component of both religion and magic. In the absence of scientific knowledge, early humans used divination to attempt to understand and manipulate their environment. Vital information concerning weather patterns, such as rainfall or drought, and animal migrations were "read" from their surroundings in "signs" that would indicate the future. Some of these included the flight of birds, the position of pebbles in a stream, or reading the entrails of small animals. Another notable use of divination was its prevalence in healing ceremonies. Historically, diviners were diagnosticians who were concerned with maladies put in a sociocultural context. They used psychosomatic and physical symptoms, everyday encounters, and supernatural influences to determine the source and therefore the treatment of illnesses. Divination also provided people with a map along their spiritual journey. People then, as now, wanted to know about paths to love, money, careers, and power. It is human nature to want to make the "right" choices and divination was, and is, regarded as a tool to see into the unknown.

Divination in History

Some of the best-known forms of divination include astrology, numerology, palmistry, runes, and tarot. Astrology is the oldest method of fortune telling; it developed as people followed the cycles of the stars. Though the Greeks and Romans were credited with the stories attached to the zodiac, by 3000 BCE the Babylonians and the Chaldeans were recording movements of constellations. In the Americas, indigenous astrologers used the stars to predict individual destinies. Today people still use birth charts and the movements of stars in everyday life; avid believers in these signs check their horoscopes to daily. Numerology uses numerical systems to discover the pathways that connect all things. This practice is almost universally evident and is concerned with understanding present circumstances. Pythagoras, a Greek of the 6th century BCE, believed that everything encompassed in the human experiences was related to the first nine numbers. His theory of harmonics is astoundingly similar to 20th-century wave theory.

Forms of Divination

Palmistry, also known as chiromancy, is the discovery of how a person's character, "read" through the unique lines on the palm, will influence his or her destiny. Modern palmists can trace their roots back to the Roma (gypsies) and Indian mystics, but again, the names and stories are derived from Greek mythology.

Another common form of divination is reading ancient German and Scandinavian runes. These hearty northern tribal groups left behind symbols that were carved into pieces of wood and stone that were cast to settle disputes, to ask for the gods' assistance, and to see into the future. Today, people still cast the runes as a form of divination. Booklets for interpreting meaning along with pouches of runic tiles are sold. The runes resemble letters but are not an alphabet; each figure has a meaning unto itself. Each represents a literal meaning such as "cattle," "gift," or "joy" and a prophetic deeper meaning like "wealth," "rewards," or "harmony." The most commonly used runes today are from the Germanic *futharks,* which contain 24 runes.

Reversed (upside down) runes indicate a blockage or frustration. Runes are read in 3 or 5 spread and in a Celtic cross pattern much like the tarot. The tarot deck was used in Europe to play card games as early as the 14th century and later became a deck for divination. Arthur Edward Waite is attributed with developing the most commonly used tarot deck, the Rider-Waite deck. Tarot meanings are variable and can be interpreted in a number of ways depending on the card reader. There are many less-familiar varieties of divination. Alectoramancy is divination by a rooster and involves a cock "spelling" a message by pecking at grains of wheat placed on different letters. Cleidomancy is the interpretation of movements of a key suspended by a thread from the nail of the third finger of a young virgin while a Psalm is recited. Omphalomancy is the analysis of the belly button.

Function of Divination

During the 19th century a divide existed between what were considered "primitive" and "modern" religions for those who analyzed the existence of religion. This approach was mostly rejected by social scientists in the 20th century. Social scientists such as Karl Marx, Max Weber, and Émile Durkheim were more concerned with studying how religious beliefs and practices are a part of a particular social, political, and economic force and what purpose they serve. They found that there were patterns of cultural universals among diverse groups. A spirit world existed, sometimes in the form of ghosts, spirits, or deities. Magic could be used to influence and manipulate the spirit world. Also, divination made it possible to connect with the supernatural as a means of discovering knowledge. This was believed to help people feel that they have some control over aspects of their lives over which, in fact, they have no control.

Today, there are many popular forms of what is referred to as "spontaneous divination." This includes the art of placement or Feng Shui, reading the energy field ("aura") that surrounds a person, or opening the Bible to a random page to receive a relevant, divine message. Some people also use "fairy" or "angel" cards to receive guidance and reassurance.

DNA

DNA (deoxyribonucleic acid) is a fascinating and compelling molecule that is responsible for expressing, storing, and replicating all of the genetic information in eukaryotic (nucleated) cells. This marvelous molecule is nothing less than a chemical history of all living things on our planet; its span extends throughout organic time and contains chemical documentation of the course of evolution in all species.

Ideas About Inheritance

In 1857, Gregor Mendel (1822–1884), an Austrian monk and biologist, was the first to illustrate that inheritable characteristics (such as height and color) were distributed from parent to offspring in a mathematically predictable pattern. He did these experiments using pea plants. As he analyzed his results, he noted that each character had variations (such as tall or small, and purple or white) that again were expressed in a mathematically predictable pattern. These predictable patterns could be expressed graphically. (Later, British geneticist Reginald Punnett arranged such patterns of inheritance in grids, which are now referred to as "Punnett squares"). Mendel's work stimulated much interest in the study of genetics; as a result of his work, he is known as the father of genetics.

Mendel had illustrated that characteristics are inherited through particles in a predictable fashion, but how does this happen? In 1928, biologist

Frederick Griffith theorized that a molecule for inheritance must exist. His experiments involved injecting virulent and nonvirulent strains of bacteria into mice. These experiments never assisted Griffith in his quest to discover the inheritance molecule, but they did prove that a characteristic (in this case virulence) could be passed on from one type of bacteria (which was virulent) to another type of bacteria (which originally was not virulent). He called this "transformation." Griffith's research on transformation proved that an inheritance molecule existed.

During this time, there were two prevalent theories on what the inheritance molecule was. The first theory was that it was a protein, which was a popular candidate because there were 20 amino acids. The second theory was DNA, which was a less popular theory because it was composed of only four nucleotides and because scientists could not yet conceive how a molecule composed of only four types of nucleotides could account for the complexity of an organism. Some theories proposed that other proteins were the inheritance molecules.

Identifying the Inheritance Molecule

Fourteen years later, a scientist named Oswald Avery attempted to identify the inheritance molecule based on Griffith's findings. In Avery's experiments, he used the same types of bacteria from Griffith's work. However, with newer technology and a deeper understanding of the knowledge of cellular biology and structure, he was able to use a different approach. Avery decided to selectively destroy different types of molecules (e.g., carbohydrates, proteins, lipids, and ribonucleic acids) in the virulent bacteria. He then administered the samples to mice to test for virulence. The results showed that all the bacteria maintained their virulence except for the bacteria whose ribonucleic acids were destroyed. Avery had identified the inheritance molecule, which was composed of nucleic acids: DNA.

Even though Avery had clearly illustrated that DNA was the molecule of inheritance, most scientists at that time rejected the idea. Many still found it too perplexing to understand how a very uniform molecule was responsible for the advent of something as complicated as a human being. In addition, this began to raise eyebrows in religious circles that a molecule, and not direct action by God, was at the root of an individual's inherited characteristics.

It took almost 90 years from Mendel's illustration that characteristics were passed on from parent to offspring in a predictable pattern to the idea that DNA, a molecule, was solely responsible for the occurrence of genetic diversity among all species. However, at this time, no one knew what DNA was—neither its structure nor how it worked.

Discovering the Structure of DNA

In 1953, biologists James Watson and Francis Crick, working in Cambridge, United Kingdom, accurately proposed a working model of the structure of DNA. They were able to do this based on results from two very important works. The first important work was research done by Erwin Chargaff, in which he proved that the DNA molecule was composed of four nucleotide bases: adenine (A), guanine (G), cytosine (C), and thymine (T). He demonstrated that adenine and thymine occurred in equal amounts, as did guanine and cytosine. Based on these findings, he postulated that adenine paired with thymine (A=T) and that guanine paired with cytosine (G=C).

The second important work that assisted Watson and Crick was the photography of X-ray diffraction patterns of crystallized DNA, which were completed by Rosalind Franklin and Maurice Wilkins. Their research showed that the DNA molecule had a helical shape made up of two strands connected by ladder-like rungs.

Based on these two studies, Watson and Crick proposed that the DNA molecule was a double-stranded helix and that those two strands were made of a sugar-phosphate backbone. They also concluded that the "ladder-like rungs" that were holding the two strands together were alternated A=T and G=C pairs. Watson and Crick were also able to utilize current molecular knowledge to discover that the reason why adenine and guanine paired together was because they both had two available hydrogen bonds, and the reason why guanine and cytosine paired together was because they each had three available hydrogen bonds.

They proposed that because one of the DNA strands was an opposite complement to the other (because of the pairing bases), the DNA molecule was composed of two "antiparallel" strands.

Now the inheritance molecule was identified, and a structure of its model was established. This changed the way scientists viewed genetics and heredity. The next perplexing questions were How does this molecule replicate itself? and How does it work to make a cell or an organism?

How Does DNA Work?

At this time it was generally accepted that DNA must replicate itself in order to reproduce new cells and for organisms to produce new offspring. In 1958, Matthew Meselson and Franklin Stahl utilized research involving radio-labeled nitrogen bases (which are what A, T, G, and C are composed of) to demonstrate that DNA replicated itself using what is known as a semi-conservative model. This model helped to illustrate that the two strands of DNA actually unzip, and one of the DNA strands serves as a template to reproduce another strand of DNA by pairing nucleotides. The template and new strand of DNA are separated, the original strands of DNA are reconnected (or zipped back together), and the newly created strand has a complementary strand attached (using Chargaff's rule) to it in place of the original template. This replication of DNA happens during cell replication, a process in which a cell makes a copy of itself, DNA and all. However, it must be noted that a cell cannot replicate an infinite number of times. A cell can undergo cell replication only a limited number of times while maintained in tissue culture; this phenomenon was illustrated in 1965 by Leonard Hayflick and was called the "Hayflick limit."

Besides replication, the DNA molecule is responsible for storing the information necessary to synthesize the basic building blocks called amino acids. There are 20 amino acids, which in different combinations make up proteins, enzymes, and other constituents that compose all cells and organisms. The DNA molecule achieves this by a process called transcription. During transcription, the DNA molecule unzips a small portion of itself and a messenger RNA (mRNA) molecule is made. This mRNA molecule will ultimately assist in the production of a protein molecule, a process called translation. Therefore what types of proteins are produced is determined by all the different sequences of DNA. These proteins are the basic building blocks for the cell's structure and organelles. The same cells conglomerate to form tissues, which become structured organs that can form organ systems. The organ systems (such as the digestive system and the skeletal system) are what make more complicated organisms, like human beings.

Understanding Human DNA in the Future

The DNA molecule exists today as a product of time. It is responsible for organic diversity and genetic evolution, in addition to accumulating and accelerating all human evolution. In the year 2000, after almost 10 years of research known as the Human Genome Project, scientists completed analyzing more than 3 billion chemical "letters" that make up all human DNA (which is referred to as the human genome code). This accomplishment will eventually revolutionize the diagnosing and treatment of disease and is one of the greatest scientific milestones. The concept of inheritance and what makes up all organisms has changed over time. This began as the idea of an inheritance molecule and evolved into attempting to understand and decipher the vast complexities of the DNA molecule, a task in where we are only just scratching the surface.

Dogen Zen

Japanese Buddhist tradition gives Dogen (1200–1253) credit for founding the Soto Zen school following his return from China after having attained enlightenment under the tutelage of Jü-ching (1163–1268) and having previously studied under Japanese Zen master Eisai (1141–1215). After being frustrated trying to spread Zen in Japan, Dogen settled in present-day Fukui Prefecture where he founded Eihei-ji. He spent the remainder of his life training monks and writing *Shobogenzo* (*The Treasury of the Eye of True Dharma*) and other works. It is especially in the *Shobogenzo* that he expounds his nondualistic philosophy and understanding of time.

To illustrate his notion of time, Dogen first discusses the conventional view of time by using an example of a person who lives in a valley, travels over a river, and climbs a mountain to its summit. Once the traveler attains his goal, there is a human tendency to relegate the valley, river, and mountain to things of the past that have no relation to the present moment. This suggests that time is measured by the movement from the valley to the summit of the mountain by now-points that are connected in a linear series. And when a person thinks that time flies away, that person separates himself from time as directly experienced.

In contrast to this everyday comprehension of time, Dogen substitutes primordial time, which he calls being-time (*uji*). He defines being-time as nonsubstantial, which means that it is not objective and forms a transpersonal basis for all activity without reference to an ego, subject, substance, or object. Being-time is also nonreductionistic, which suggests that it is a unity. Moreover, it is nonanthropocentric and nondifferentiated, which means in the initial instance that temporality is not limited to human experience because it encompasses both human and the natural, whereas the latter characteristic means that time is a unity of time and existence, truth and time, and is not independent of existence or beyond it.

Dogen identifies two perspectives, or basic individual responses to the presence of one's situation, of being-time. Each of these perspectives is an authentic reflection of the temporal mode of experience stimulated by a situation, and neither is more primary than the other. What Dogen calls *nikon* (right now) represents the now moment that is a completely spontaneous making present of being-time. This nikon extends simultaneously throughout past, present, and future. The second perspective is *kyoryaku* (totalistic passage), which refers to the nondirectional, continuing, and connected aspect of time that refers to an experiential continuity. This aspect of being-time engages all aspects and dimensions of the past, present, and future here and now and allows for their diversity, variety, and differentiation. Kyoryaku refers also to the continuously creative and regenerating dimension of being-time. Neither of these perspectives possesses priority over the other.

The difference between right-now and total passage is a matter of viewing either the surface (nikon) or the cross-section (kyoryaku) of a total temporal phenomenon. If one returns to the metaphor of mountain climbing, the now-moment (nikon) designates the act of ascent, whereas totalistic passage (kyoryaku) suggests the entire context of human events and the universe. This means that each moment is complete because it includes the full range of multiple perspectives and situations.

Being-time possesses important consequences for Dogen because things and events within the universe are time. Thus Dogen claims that mountains, oceans, and grass are time. It also means that time is both temporal and spatial, which implies that they inseparably interpenetrate each other. Moreover, each absolute now moment constitutes a unique whole of actuality, which suggests that the now moment is realized contemporaneously with activity. It can also be asserted that time is activity and activity is time.

If being-time is applied to the Buddha-nature (a nondual reality for Dogen), both future and past signify the present. This suggests that the Buddha-nature is not a potentiality to be actualized in the future, but it is rather an actuality in the present. According to Dogen, the being of Buddha-nature is time. This implies that every moment of illusion and every moment of enlightenment contain all of reality. Thus both enlightenment and illusion are Buddha-nature.

Dogen raises an interesting question: Can a person experience being-time? His answer is that we experience neither time nor being in themselves but rather temporal existence. What Dogen means is that we overcome the perception of things in terms of the three moments of time—past, present, or future. This suggests that we experience a phenomenon just as it is. With such an experience, we encounter a stream of ever-changing phenomena, which means necessarily that prereflective consciousness involves change. This change is located neither in the self nor in the object; rather, it is an aspect of phenomena as they are prereflectively experienced. By accepting the experience of change as it is without projecting anything onto it, there is simply an unending experience of flux. But when we project our experience of change onto some external self, we falsely assume the experiencing self to be unchanging. For Dogen, things cannot be experienced independently of change or time, which means that all things and all beings are impermanent, and Buddha-nature is the experience of impermanence.

Dogen's notion of time possesses important implications for his grasp of body and mind, which he also equates with time in a nondualistic way. According to Dogen's nondual position, mind, body, being, world, and time form a unity. Not only are entities time, and not only is time in me, but activities are time. Thus jumping into water or a pool of mud is equally time.

The unity of time is evident most lucidly in his grasp of Buddha-nature, whose being is time itself. Within the Buddha-nature, both future and past signify the present. Dogen stresses the now moment because there is never a time that has not been or a time that is coming. Therefore, time is a continuous occurrence of "nows." This makes the Buddha-nature a present actuality and not simply something potential to be actualized in the future. And if every moment of illusion and enlightenment contains all reality, Buddha-nature is both illusion and enlightenment. In summary, Dogen radically temporalizes being, opposes a quantitative view of time, views time as a lived reality, and contends that things and events of the universe are time.

Donne, John (1572–1631)

John Donne is considered one of the finest poets in the English language. His works include a wide range of forms, including sonnets, love poetry, religious poems, epigrams, elegies, songs, satires, and sermons. Compared to the other poets of this period, Donne's work shines due to the language style he used and his expertise in using metaphors. One major theme in his poetry is the passage of time, as is evidenced in "Death Be Not Proud," in which he discusses how death is akin to sleeping and how it will be banished forever, due to God's bestowal of eternal life.

> And poppy or charms can make us sleep as well
> And better than thy stroke; why swell'st thou then?
> One short sleep past, we wake eternally,
> And death shall be no more; Death, thou shalt die.

Donne studied at Hart Hall, now Hertford College, Oxford, beginning at age 11. After 3 years at Oxford, he was admitted to the University of Cambridge, where he studied for another 3 years. He never obtained a degree nor did he graduate from either university; he declined to take the Oath of Supremacy, a requirement for all wishing to graduate. In 1591, Donne decided to study law and entered law school (they were Inns of Court at that time), and gained admittance to Lincoln's Inn, another "law school" of 16th-century England.

Donne longed for a career in diplomacy and by age 25 he was well prepared. He received status when he became chief secretary to Sir Thomas Egerton, the Lord Keeper of the Great Seal, and took up residence at Egerton's home, York House, which was in close proximity to the Palace of Whitehall, the most prominent social focal point in England. At some point during the next 48 months, he became romantic with Anne Moore, Egerton's niece, eventually marrying in 1601 (to his superior's consternation).

His early poems indicated a dazzling awareness of British culture attached to biting censure of its problems. His satires centered on ordinary themes, such as dishonest politicians and pedestrian writers, yet they maintain their comic strength even to this day. His early elegies were strikingly erotic, and he used eccentric metaphors (a biting flea is symbolic of marriage). A serious transformation occurred during the adverse years (1600–1610). He suffered financial setbacks and his closest friends died, leading to a more melancholy, but devout, poetic tone.

When he was young, Donne was skeptical of religious faith, but his views changed and he became pious. Although born a Roman Catholic, he converted to Anglicanism and eventually sought a position as a preacher. Soon thereafter, he grew prominent, and he was eventually appointed dean of St. Paul's Cathedral in London.

His later works challenged death, with the belief that those who die are sent to heaven to live eternally and thus, death should not be feared. Donne was expert in using the conceit, a figure of speech joining two opposite ideas into one, often using metaphors. His works are often witty, using literary devices like paradoxes, puns, and analogies; likewise, his works are frequently ironic and cynical, especially regarding the motives of humans and love. Donne used universal topics like love (more prevalent when he was young), death (primarily after his wife's demise), and religion.

In 1631, Donne preached his final time, giving a sermon detailing his belief in the Creator. Afterward, he returned to his bed and died quietly on March 31, 1631.

Dostoevsky, Fyodor M. (1821–1881)

Fyodor M. Dostoevsky was a Russian novelist and short story author whose writings often focus on the psychological aspects of deep human emotion and suffering. His work is widely regarded as highly original and profound and has earned him a worldwide reputation as a literary artist. Dostoevsky's works profess extreme philosophical and psychological insights, including theories and practices in psychoanalysis. His writings are often categorized as existentialist. His characters face moral dilemmas and endure challenges as if their moral actions have no significance in terms of an afterlife. In the nihilist tradition, Dostoevsky's characters also struggle against all forms of tyranny and hypocrisy, negate all moral principle, and struggle to support personal and individual freedom. In this existential and nihilistic genre, the characters feel the only time they have is the time in which they are alive on Earth.

Dostoevsky was born to a middle-class family. His mother died before he was 16, and, allegedly, the household servants murdered his father while Dostoevsky was away at school. As a young man, Dostoevsky was arrested and convicted of political subversion because of his involvement with a political and intellectual discussion group. Although he was sentenced to death, his punishment was later commuted to 4 years hard labor and imprisonment in Siberia, followed by 4 years in military service. While imprisoned, Dostoevsky studied the New Testament, which led to his belief that redemption is achieved through extreme faith, suffering, and pain, a theme that occurs throughout his literary work.

His first major novel, *Crime and Punishment,* was published in 1866. This story is a psychological thriller in which its central character, Raskolnikov, a young, poor, and monomaniac student heinously murders an elderly pawnbroker and moneylender, whom he deeply despised as being a threat to the great moral and economic good.

The novel begins in medias res, 2 1/2 days before the murder, and it continues in time for approximately 2 weeks after the event. The story is told through a juxtaposition of events that occur at different times, thus creating connections between these events without intrusive explanations or detailed narrations. Time in the novel is felt through Raskolnikov's consciousness; it is a flow of time that exists through his personal experience or perception of time, rather than time measured on a clock. This narrative technique became widespread later in the century, as a result of Dostoevsky's influence. His influence also extended to philosophy, as a precursor to Henri Bergson's theory of the fluidity of time. He also profoundly affected philosopher–writers Friedrich Nietzsche and Franz Kafka.

Dostoevsky also uses an objective chronology of time, or *fabula,* a Russian formalist term used to describe time sequences as they are recreated for the novel. This motif helped compound and later illuminate or clarify Raskolnikov's motive for murder. Using a double time, Dostoevsky allows the actions occurring in present time to clarify the events that happened at a time in the past. For instance, in examining the novel, during present time, we begin to see that Raskolnikov had radical notions on crime and accountability as much as 6 months prior to the novel's beginning, when he wrote the significant article "On Crime." In this article, he tells of the ordinary and extraordinary personalities who are capable of either accepting the established order or those capable of mass destruction in the name of creating something better. These great men, such as Napoleon and Muhammad, Raskolnikov writes, possess a capacity to do moral atrocities for the sake of duty. Another example of a time-lapse technique in the novel includes the 3-day time period in which Raskolnikov falls into a semiconscious and feverish delirium, awakening in terror to wonder if he may have given away clues to his murderous act while suffering from his illness.

Doyle, Arthur Conan (1859–1930)

Sir Arthur Conan Doyle was a Scottish writer and physician who popularized the detective genre of literature with his creation of the Sherlock Holmes character and pioneered science fiction with tales such as *The Lost World.* Much of Doyle's work reflects his personal interest in, and unconventional approach to, the subject of time.

Conan Doyle was one of the most popular and prolific writers of his generation. His work spans several genres and includes both fiction and nonfiction. He is perhaps best known for his creation of the character Sherlock Holmes, the clever detective who appears in a series of novels and short stories along with his assistant, Dr. John Watson. Although many of the Sherlock Holmes tales, such as the *Hound of the Baskervilles* (1902), remain in print and are widely read today, Conan Doyle considered his historical scholarship to be his most important work.

Conan Doyle's interest in time is evident in *The Lost World* (1912), an adventure tale in which four men travel to a remote region of South America to investigate claims that dinosaurs inhabit a plateau there. On their journey they encounter dinosaurs and other prehistoric creatures, as well as quarreling ape-men and hominids. The notion of surviving dinosaurs and early hominids intrigued audiences then as it does now. By the early 20th century, even the most inaccessible regions of the earth were finally being explored by scientists and adventurers, and excitement and speculation were widespread as to what might be found. Conan Doyle's famous character Professor

Challenger makes his first appearance in the story, along with another scientist, Professor Summerlee; a journalist, Edward Malone; and nobleman adventurer Lord John Roxton. The characters Malone and Roxton were inspired by E. D. Morel and Roger Casement, founders of the Congo Reform Association, which Conan Doyle supported through his book *The Crime of the Congo* (1909).

Conan Doyle was born in Edinburgh, Scotland, in 1859; was educated in Jesuit schools in England; and studied medicine at Edinburgh, where he took his M.D. in 1885. Initially receiving few patients, Conan Doyle increasingly turned to writing, applying his medical training and deductive reasoning to his literary work. His first novel, *A Study in Scarlet* (1887), began the Sherlock Holmes series for which Conan Doyle is most celebrated, though he soon grew tired of the character. Conan Doyle was knighted by King Edward VII in 1902 for his scholarly defense of British involvement in the Boer War, as well as for other writings. During his later years, Conan Doyle increasingly supported spiritualism, including the belief that the living can contact the spirits of the deceased; he also became a strong defender of the existence of fairies, or "little people." It has been pointed out that these beliefs contrast sharply with the logical pragmatism of Conan Doyle's fictional characters, as well as with his own approach to historical writing. But this apparent inconsistency may also reflect the elusive and mysterious nature of time itself, which Conan Doyle approached by means of art as well as science.

Dracula, Legend of

Count Dracula is the fictitious yet infamous vampire who lives a timeless and eternal life. In Bram Stoker's gothic horror classic *Dracula* (1897), Stoker created his vampire Dracula from various vampire folklore, myths, legends, and historical accounts of the vicious and blood-thirsty warlord Vlad Dracula, Prince of Wallachia. Stoker's story is the classic piece of literature that created a vampire legend that has only gained popularity and recognition over the past 100 years.

The popular legendary vampiric tale begins when the reclusive and aristocratic Count Dracula of Transylvania purchases real estate throughout London and meets Jonathan Harker, the law clerk sent to finalize the real estate paperwork. Dracula is described as an old man, clean-shaven, except for a long white mustache that nearly hides his ever-protruding long canine teeth. The Count's complexion is colorless, and he is dressed in black. His grip is firm yet icy, with hairy palms and long pointed fingernails. The Count's touch is like the touch of a dead man. His breath is foul and nauseating. Harker notices the Count casts no shadow, can enter and exit a room unnoticed, and has no reflection in a mirror. In a very short time, Harker becomes fearful for his life.

The story describes other legendary characteristics. Dracula must sleep in earth that is "unhallowed" or taken from his birthplace or native land. He is immortal, living forever, and unable to succumb to mortal wounds. Garlic, religious icons, and holy water can be used to repel vampires but not to kill them. Vampires such as Dracula become stronger as they age. Although a nocturnal creature, the Count can move in daylight, but his powers are somewhat diminished. He also can better tolerate Christian icons than novice or young vampires. In addition to transforming himself into beasts of the night, such as wolves and bats, Dracula can also force these beasts to do his will. He cannot enter a home unless invited. He can travel as mist or fog but is reluctant to cross a body of water, taking special care while traveling to and from London and Transylvania.

On its initial publication in 1897, *Dracula* was considered ordinary by the standards of that genre. It competed with several other superb tales of Englishmen conquering villains and monsters. To create the character of Count Dracula that has become a timeless icon, Stoker studied factual historical accounts of one of the best-known Romanian historical figures, Vlad Dracula, otherwise nicknamed Vlad Tepes (Vlad the Impaler). This Prince of Wallachia ruled in 1448, from 1456 to 1462, and again in 1476, the year of his death. Tepes was also called Vlad the Impaler because of his brute force and diabolical manner of impaling enemies, political dissidents, and Romanian citizens and criminals on long wooden stakes, where they would wither and die. He preferred to display his victims prominently, raising them in the town square for public viewing. Stealing was equally as offensive as murder, and in each case, the criminal faced public impalement. Under his rule, crime and corruption ceased to exist. Simultaneously, commerce and culture thrived, and Vlad Tepes became a highly regarded hero who fiercely demanded integrity and order in Wallachia.

The legend of Dracula is deeply rooted in vampire legends and folklore that spread from the Far Eastern trade routes, through India, the Mediterranean, Romania, and Transylvania. Belief in such legends of the undead was abetted by the lack of medical expertise that by modern standards diagnoses and treats illnesses. The spread of plague could wipe out entire communities as victims wasted away. An uneducated and unscientific populace rationalized that vampirism was the cause of such unfortunate deaths.

The spirit and appearance of Dracula have metamorphosed through time into countless derivatives. One of the earliest and most haunting vampire films, *Nosferatu: A Symphony of Horror* (1922), was a silent film and the German interpretation of vampirism. The legend of Dracula began haunting popular film and fiction during the 20th century, beginning with the Hollywood film release of *Dracula* (1931), staring Bela Lugosi. Films starring actors such as Frank Langella, Christopher Lee, George Hamilton, Brad Pitt, Tom Cruise, and Gary Oldman all showed a departure from Dracula prototypes. The undead creatures whose existence defiled all living souls would become transformed in the 1980s and 1990s and replaced with a sexier and more alluring Dracula. Hollywood film incorporated the American epitome of success into its later 20th-century film versions of Count Dracula. He is a sultry, debonair, aristocratic, and seductive man. Film vampires became beautiful, virile, and sexually irresistible. A modern Count Dracula is a distinguished, well-mannered, and youthful aristocrat who can show human emotion, including love for a woman and remorse for the inevitable death of those he feeds upon.

Although vampire stories existed before Stoker's novel *Dracula,* it has become the premier literary work or story that recorded the most widely held beliefs. The novel *Dracula* is a tale told through the letters, journals, diaries, and phonograph recordings of the novel's major characters, Jonathan Harker, his wife Mina Harker, Dr. Seward, and Lucy Westenra. The novel's characters all contribute to the legendary definitions of vampirism, in fact, doing a superb investigation and compilation of the facts each had learned through interactions with the Count, his servant Renfield, and his first female victim, the beautiful and seductive Westenra, who was later resurrected into vampiric life.

Dr. Van Helsing's expert knowledge, investigative techniques, and medical credentials help the cast untangle the mystery of Lucy's death, followed by the temporary disappearance of several small children who claimed that they had been playing with the "bloofer lady," the undead Westenra. Collaboratively, their observations of vampire characteristics and lifestyle habits later assist them in creating their plot to assassinate the Count.

Dreams

Time plays a pivotal role in dreams. Much of the fantasy, incoherence, inaccuracies, and ambiguities of dream contents is owed largely to continuous weakening of the strengths of connections (synapses) between nerve cells of the brain over time. Considerations here relate mainly to this weakening influence. Emphasis is on the dreams of children, which are expressed in their purest form, minimally encumbered by the complicating influences that accumulate with age.

Dreams are the accompaniments or by-products of certain essential activities of the brain during sleep. They primarily occur as neocortical circuits (the most recently evolved brain circuits) become activated by spontaneous, self-generated, complex electrical oscillations. Superficially, these oscillations are expressed as the slow and fast scalp-waves of electroencephalograms (EEGs). A major role of dreams during sleep is the processing of phylogenetic and experiential memories, that is, inherited memories and memories of past waking events.

Memory Consolidation and Reinforcement

Regarding this processing, during nonrapid eye movement (NREM) sleep, recently acquired short-term memories stored temporarily in the hippocampus become converted into long-term memories stored in the neocortex by a process known as hippocampal replay. In addition, enormous numbers of already-stored fragments of memories in the neocortex become reinforced (strengthened). During rapid eye movement (REM) sleep, many already-stored, long-term memories in the neocortex also are reinforced to maintain their authenticity.

Because dreams usually are highly visual, the storage process for visual memories is used here for illustration, though essentially the same principles apply generally. Storage of memories in both the hippocampus and neocortex is sparse and distributed, sparse in the sense that only a fragment of the memory is represented at any one of the distributed physical locations. In the visual neocortex, sets of neurons having different response properties (fragments) for colors, textures, distances, orientation, positions, and so forth, are clustered together at the various distributed locations.

As an example of memory consolidation by hippocampal replay, consider the process for a new declarative memory, that is, for the conscious recollection or explicit remembering of a new scene or event. During replay, fragments of the memory, already sparse and distributed and stored in the hippocampus for the short term, become similarly established in the neocortex for the long term, by a repetitive interactive process. Such replay in humans might continue for as long as 3 years.

Spontaneous reinforcement of memories stored in neocortical circuits during sleep involves electrical activations by both fast and slow brain waves. Reinforcement often is accompanied by an "unconscious" awareness of the corresponding memories in the forms of static dreams, that is, isolated thoughts or perceptions. Narrative dreams are assembled from these thoughts or perceptions but, on any given night, only from a small fraction of them.

It is an intrinsic property of synapses of memory circuits that they need to be reinforced periodically. Otherwise the synapses weaken and the encoded memories deteriorate, in days, weeks, or little more than a month. Synaptic strengths (weights) persist for only limited periods, primarily because the macromolecules that are essential for synaptic function break down continuously (molecular turnover). Because sufficient numbers of these molecules are needed to preserve the specific synaptic strengths that encode given memories, if "lost" molecules were not replaced periodically, these strengths would gradually decline and the memories would deteriorate.

Dedicated Synaptic Strengths, Brain Waves, and Dream Contents

Dedicated (functional) values of synaptic strengths for a given memory become established and maintained by the memory's use or periodic activation. But for memories that are used only infrequently during wakefulness, most synaptic reinforcement has to occur spontaneously during sleep. The functions of such spontaneously reinforced circuits that would disturb sleep usually are not triggered because of decreased or absent muscle tone or temporarily reduced behavioral responsiveness.

Circuits for dedicated functions remain labile to the extent that they are susceptible to being updated (reconsolidated) in response to related new experiences. Whereas the updating process drives existing synaptic strengths to new dedicated values, mere repetitious synaptic activity in the course of a dedicated function, or reinforcement during sleep, merely maintains existing strengths.

During REM sleep, spontaneous gamma oscillations (30–100 cycles per second) trigger a process known as temporal binding (binding by synchrony). In this process, neurons of distributed neocortical memory fragments are activated synchronously by gamma oscillations. The different embedded stimulus features of the fragments constituting a specific memory are brought together transiently in this way. By this process, first advanced by Christoph von der Malsburg, memories presumably are recalled. These include the thoughts and perceptions of waking as well as dream memories.

It seems likely that certain slow brain waves of REM sleep—the hippocampal theta waves (4–8 cycles per second)—trigger the serial linking of individual memories, recalled as described earlier, to form connected, narrative dreams. Reinforcement of memories during REM sleep and of enormous numbers of memory fragments during NREM sleep presumably occurs continuously. On any given night, however, only a small fraction of the reinforced circuit contents rise to the level of unconscious awareness, that is, enter dreams.

For memories, this limitation probably is because too many of them exist to be accommodated in one night's sleep. For memory fragments, it is because the content of an isolated fragment is essentially meaningless. The existence of such limitations in the information conveyed by unbound fragments in the visual realm is illustrated by the "blind sight" of brain-damaged patients. Fragments of visual information are received and registered in the visual cortices of these patients, but because the fragments do not become bound, they are not accompanied by visual awareness.

For example, although certain patients cannot see a moving object in their visual field, they nonetheless become aware that movement is occurring there. In this connection, the activation of enormous numbers of memory fragments without temporal binding or awareness probably is how synaptic strengths in the vast majority of memory circuits become reinforced during NREM sleep.

Dream contents give clues to the brain's priorities for circuit reinforcement during sleep. High priority goes to consolidation of recent occurrences, particularly significant events of the same and previous days. Highest priority is given to recent emotional events and/or actions and perceptions with significant survival value.

Illusory Contents of Dreams

From 85% to 95% of REM dreams are ordinary and mundane, with authentic, highly visual, and dynamic contents. Waking perceptual experiences reappear with remarkably lifelike details. G. W. Domhoff asserted that the waking mind and the dreaming mind seem to be one and the same. The main thesis of this entry is that many failures of our minds, as exemplified by illusory dreams, also have "one and the same" immediate cause—defective synaptic strengths.

Defective synaptic strengths have their origin in two broad categories of disruptive influences. The first category includes failures of intrinsic origin, owing simply to system complexity. Such failures are common even in much simpler cellular and subcellular systems. Also included is a normal weakening of synaptic strengths in neocortical networks with time (normal processes of decay). The second category of disruptive influences, which is not treated here, is due to pathologically altered brain waves.

It is most relevant, then, to ask what occurs when the strengths of a small fraction of the synapses—of the millions that may encode a given memory—are weakened slightly from their dedicated ranges. In answer to this key question, one would not expect a scene, for example, to be degraded beyond recognition as such. Rather, novel, unpredictable, probably relatively minor alterations would be expected—distortions, background or location ambiguities, altered identities, and so forth. A face, for example, still would be a face, but the alterations might make it unrecognizable.

Synaptic strengths in some memory circuits, even though adequately reinforced during sleep, probably accumulate chance errors in their records of dedicated strengths with time. This would place our general forgetting of our oldest memories over the years on a firm foundation, probably owing to the accumulation of these synaptic defects. Such an imperfection might even be favored by natural selection, as it would tend to eliminate useless memories of the distant past, freeing otherwise encumbered cortical tissue for the storage of new memories.

Static and Continuous Dreams

Most frequently, compatible circuits addressed by dream-producing mechanisms have overwhelmingly authentic contents. Temporal binding of small numbers of circuits with weakened synaptic strengths might lead merely to such discrepancies as unrecognized people and places, altered times, slightly altered thoughts, and so on. These dreams would not be considered illusory.

Illusory dreams, on the other hand, probably trace to the inclusion of older, variously incompetent memories and their fragments, often harking back to childhood experiences. These would contain greater numbers of defective synapses, leading to the incorporation of faulty thoughts and perceptions (beyond the mere minor discrepancies mentioned earlier). But such direct effects are unlikely to be the only cause of illusory dreams. Disruptive indirect effects probably also occur when flawed memories become serially linked, which inevitably would lead to incoherent connectivity.

When memories remain isolated in dreams (i.e., unlinked), the dreams are said to be "static" or "thoughtful." Such memories typically occur in many dreams during adult NREM sleep, in children's dreams up to about 5 years old, and in the dreamlike experiences that accompany some seizures and artificial brain stimulation. The means by which the unlinked memories of static dreams become serially linked to form dreams with narrative continuity can be dealt with only in broad outline.

Consider a dream that begins when gamma waves temporally bind certain memory fragments into an initial memory. Activation of a second memory would be expected not to be random but to be biased toward including other memories formerly associated with the first one and similarly for subsequent selections. Serial linkages between these memories, then, would possess narrative continuity.

One expects biases to exist in the activation of memories being bound and serially linked. In forming some "day residues" of dreams, in particular, the linkages conferring continuity would have been in effect only hours earlier, while awake. Accordingly, serial links must leave traces (temporally fortified connections) that guide subsequent binding and linking mechanisms.

The same reasoning would apply to old memories in long-term storage. Their ordered arrangement in narrative dreams implies that great numbers of much older, favored memory associations also persist. But any influence that tended to randomize the activation of fragments to be temporally bound, and the serial linking of the resulting memories, would be expected to favor the production of illusory dreams.

The circumstances in which temporal binding and serial linking mechanisms are subverted, leading to illusory dreams, occur only rarely during waking. This is to be expected, as few circuits employed during waking are for very old memories. Were it otherwise to any significant degree, dreamlike hallucinations, bizarre thoughts, and false memories—such as those that occur in certain pathological states—might not be uncommon in normal, awake individuals.

To further consider the basis for activation of memories whose fragments enter dreams, the process is treated as a three-step affair. In the first step, NREM slow waves (up to 14 cycles per second) address and activate circuits containing fragments of memories, thereby reinforcing the strengths of their internal synapses. However, the contents of the vast majority of these fragments do not necessarily enter dreams. Such nonentry is the probable primitive condition in animals that sleep. Dreaming takes place only if the second step occurs. In this step, proposed to be the more advanced condition in sleeping mammals and birds, REM gamma oscillations temporally bind the fragments together to yield memories.

Were the process to terminate with the second step, only a static dream, an isolated thought or perception, would occur, as is typical in NREM dreams. In the third step, the building blocks become serially linked by the actions of REM theta waves, thereby producing continuous, often narrative, and authentic dreams.

Vital Clues From Children's Dreams

The conclusion that temporal binding can occur without serial linking has a compelling basis. Whereas bound memories always exist in dreams and dreamlike experiences, serial linking of them may fail. For example, up to the age of 5 years, the dreams of children consist largely of isolated occurrences, described as static thoughts and images (often of familiar animals). This finding suggests that serial linking mechanisms are not yet fully developed at 5 years. Because theta waves are present at earliest ages, some additional mechanism, perhaps functional completion of nerve-fiber myelinization, may be necessary for serial linking to occur.

Inasmuch as David Foulkes reported dreams by the typical child of 3 to 5 years old, in only 15% of awakenings from REM sleep and in none from NREM sleep, it appears that even the temporal-binding mechanism is only infrequently present at these ages during REM sleep and is absent during NREM sleep.

In a dramatic change, a "storylike" format in which characters move about and interact in a dynamic dream world closely modeled on the real world, often with the dreamer participating, begins to appear in children 5 years old. This format contrasts with the earlier static dream content, almost wholly lacking in social interactions and the presence of the dreamer. These changes accompany the well-known "5 to 7 shift" in children's cognitive competence and functional completion of nerve myelinization—probably also when the serial memory-linking mechanisms mature. These also are roughly the ages when sufficient competence for formal schooling develops.

The other major time of prevalence of dreams without connectivity is during adult NREM sleep, when only 5% to 10% of dreams are indistinguishable from REM dreams. The other 90% to 95% of NREM dreams (themselves of infrequent occurrence) often are described as less visual, less vivid, less emotional, less bizarre, or as static or thought-like, and containing more day residues. The finding that only 5% to 10% of NREM dreams have connectivity presumably reflects the very low level of oscillations in the theta and gamma ranges.

Young children's dreams portray activity of the same general kind that waking children perform or observe. Their dream maturation proceeds in an orderly manner, both reminiscent of and temporally associated with the unfolding of their other complex mental operations. With weakened or otherwise defective synapses accumulating with age, there should be relatively few weakened synapses in young children, whose dreams should reflect minimal or no memory-recall failures.

These deductions conform to Foulkes's findings with children 3 to 15 years old, as they reported no illusory dreams. But dream distortions—dreams containing unrecognized people, animals, and places—were common. These did not begin to occur until 5 to 7 years of age. Earliest dreams, at 3 to 5 years old, were constrained and impoverished by cognitive immaturity. Almost without exception, however, dream contents at those ages were authentic, containing some few recognized family members and familiar settings, but mostly animals familiar from fairy tales and cartoons.

Dreams containing highly authentic memories at 3 to 5 years of age can be understood in terms of the existence of relatively few weakened synapses. These years also are times of intense synaptic pruning, as circuits become fine-tuned for dedicated functions. Mere dream distortions at 5 to 7 years reflect the expected minimal weakening of synaptic strengths. The frequency of occurrence of unknown people and places generally increases with age through (and beyond) adolescence, doubtless reflecting the accumulation of defective synapses.

Evidence of small numbers of weakened synapses also characterizes adult dreams, for which unknown people and places are a hallmark. Subjects typically describe objects or persons that have specific unidentifiable visual features. In one study, for example, people were recognized and recalled in only 20% of dreams—usually the familiar face of a relative, friend, or colleague.

Some fanciful explanations proposed by Freud and others for children's dream distortions were discounted by Foulkes's studies. However, his alternative explanation appears no less fanciful. He regarded the distortions as tracing to children's increasing ability to imagine unfamiliar people and places as their cognitive processes mature. A more firmly grounded explanation would hinge simply on the presence of increasing numbers of defective synapses—the greater the numbers are, the older the child will be.

It follows that children experience less interference with the dream process than do adults because children have had less time for interfering influences to develop—the younger the child is, the less time and the less interference there will be. In consequence, time can be seen to play a crucial role in the authenticity of children's dreams as compared to those of adults.

Dreamtime, Aboriginal

The Dreamtime, also commonly referred to as the Dreaming, constitutes the core of traditional Australian Aboriginal religion. It is the story of how animals, humans, and natural terrain came to be and why they have the particular behaviors and characteristics that they have; it is a code of conduct for all time. Before the period known as the Dreamtime, the earth was an endless, featureless plain devoid of all life. During the Dreamtime the Spirit Ancestors arose from under the ground and descended from the sky realm, creating human and animal life while journeying across the land. In doing so, they left behind evidence of their activities in the markings and contours of the natural landscape before disappearing back into the land and sky realms. The Dreamtime continues as an eternal moment that is accessed today, as it was in the past, through recounting the stories of the Spirit Ancestors, singing sacred songs, creating various forms of art, performing rituals, and totemism. The concept of time as neither linear nor cyclical, but rather as atemporal, is at the heart of this oral tradition.

Australian Aboriginal Culture

Numerous distinct cultural and linguistic groups span Australia, but with significant overlap in cultural practices and beliefs. The native people of Australia likely have the longest continuous culture of any group on earth. Archaeological sites throughout Australia provide evidence that indigenous people have occupied the continent for as long as 60,000 years. For most of this time they existed exclusively as hunters and gatherers. Men hunted animals such as kangaroos, emus, and turtles while women and children gathered fruits, berries, and plants. To prevent the overuse of any area of land and its resources, groups were mobile within a wide territory. According to Australian Aborigines, traditional lifestyles associated with existence as nomadic hunter and gatherers, as well as a newer way of life resulting from centuries of European contact, can be explained by reference to the actions and laws established by the Spirit Ancestors during the Dreamtime.

The Spirit Ancestors

The term *Dreamtime* is often misleading to Western thinkers who view time in a linear fashion and so mistakenly regard it as an event that was concluded in a distant past. But neither should the Dreamtime be thought of as time comprised of vast cosmic cycles, as found in many of the Eastern traditions. Rather, the Dreamtime may best be described with the term *everywhen,* coined by anthropologist and historian W. E. H. Stanner or, similarly, as the "all-at-once-time," in so far as past, present, and future coexist in an eternal now.

The Dreaming originated with the journeys of the Spirit Ancestors, who temporarily left their abodes under the ground and in the mystical sky realm to travel across the earth, creating the natural landscapes and living things that we see today. Taking a variety of human, animal, and other forms, the Spirit Ancestors endowed certain places with a particular power or sacredness while providing form to the landscape. These self-created Spirit Ancestors are not considered to be gods, but they do have significant power that can be used for either good or harm. For example, the Mimi spirits are described as tall, thin, stick-like figures that resemble humans. They live in rocky areas and although they may be mischievous at times, they are also credited with teaching the ancestors of today's Australian Aborigines how to hunt and cook as well as how to create rock paintings. Some indigenous groups maintain that particular rock paintings were left by the Mimi themselves.

After completing their journeys, many of the Spirit Ancestors transformed themselves into objects such as rocks, stars, or animals, and their powers still inhabit these objects. The journeys of the Spirit Ancestors still have relevance for today's people, with direct implications for why things are as they are. Explanations for how and why people and animals do the ordinary activities that they do, such as dancing, hunting, gathering food, and falling in love, are sought in stories of the Dreamtime that have been passed down orally for countless generations.

Stories of the Dreamtime

Knowledge of the Dreamtime was originally passed from older to younger generations in the form of oral stories rather than through the written word. Dreamtime stories are accounts of the journeys of the Spirit Ancestors as they moved across the landscape forming the natural geography and establishing the laws. Aboriginal groups who share a totem and territory are considered to be the owners of specific stories, songs, and ceremonies that pertain to the actions of the Spirit Ancestors in that territory. An individual's totem affiliation is derived based on the territory in which that person was conceived. Totems are animal or plant representations of a given Spirit Ancestor that link individuals to the group of other individuals who share that particular totem but also link the totemic group as a whole to the Dreamtime via their totemic Spirit Ancestor.

Dreamtime stories cover a wide range of themes and topics that vary from one group of people to the next, but they often contain significant overlap across the territories that span the continent. They tell of the period of the Dreamtime when all was created and so give reasons, for example, as to why we see particular geographic formations, why indigenous animals behave the way they do, why there are seasonal weather patterns, why we suffer, how people first learned language, why kangaroos have pouches, why and how the sun rises every day and retreats every night, how flat country came to have hills, and even how death came to be a part of human's lives.

The Rainbow Serpent is one of the most widespread figures throughout Aboriginal Australia. It is a large snakelike creature associated with the creation of watercourses such as rivers and lagoons that it formed while twisting and winding its way across the continent during the Dreamtime. The Rainbow Serpent is also attributed with producing the rain and storms of the wet season. As water is such an essential element throughout Australia, we see the Rainbow Serpent is revered as the source of life. However, if not respected, it can be a destructive force as well.

Another example of how Dreamtime stories explain the various contours of the landscape is found in the legend of a small lizard known as the Tatji and his actions at Uluru (Ayers Rock). At this site Tatji threw his kali, a curved throwing stick, which became embedded in the surface of the rock. In attempting to remove it by scooping it out with his hands, he left behind a series of hollows that continue to mark the rock face. Unable to remove his kali, he died in a cave where today his bodily remains appear as large boulders on the cave floor.

Given the importance of fire for traditional hunting and gathering groups across Australia, it is not surprising that another common theme found in Dreamtime stories is the origin of fire. Some Aboriginal groups attribute its origin to a strike of lightning or a small bird that brought it from a volcano. Others say that it was a gift from one of the Spirit Ancestors. One group traditionally located on the north coast of New South Wales claims that the Aboriginal people first discovered the benefits of fire for cooking and warmth long ago when the Spirit Ancestors accidentally set fire to the land. At this time in the distant past, only the Spirit Ancestors knew how to control fire, as they lived in the sky between two bright stars from which they could light fire sticks.

On one occasion the Spirit Ancestors faced a shortage of game in their sky world and were forced to seek food on Earth. During the hunt, two brothers carelessly left their fire sticks on the ground, whereby the two sticks began to chase one another leaving trails of fire in their wake. As the fire spread and overtook the cache of meat that had been hunted by the Spirit Ancestors, the people became excited by the wonderful smell of the cooked food and the warmth of the fire and so took the fire sticks for their own.

Ceremonies, Songs, and Art as Means of Accessing the Dreamtime

In addition to recounting stories, there are numerous means of invoking the Dreamtime and the Spirit Ancestors. Aboriginal religion is not centered on worshiping the Spirit Ancestors as gods but on reenacting the archetypal paradigms initiated by them. For this reason, Aboriginal beliefs about the creation of life and landscape on Earth and the laws set out by the Spirit Ancestors are conveyed in stories that are not only told but are enacted in ceremonial performance, art, dance, and song that allow participants to continually access the Dreaming. For example, people may perform ritual ceremonies at places in the natural environment that hold particularly potent power left by the Spirit Ancestors. Or, in different territories throughout Australia, such as Ayers Rock, we see rock art depicting the actions of the Spirit Ancestors that date back hundreds and, in some cases, thousands of years. These are typically painted with natural pigments of red, yellow, black, and white and may take a wide variety of unique stylistic forms. As Aboriginal culture continues to change to meet the demands of the 21st century, art associated with sacred totemic rituals endures but in addition to the traditional medium of sand, rock, or ground paintings, it can increasingly be found today in modern media such as acrylic and photography.

Duns Scotus, John (1265–1308)

John Duns Scotus, *Doctor Subtilis,* the Subtle Doctor, was a Franciscan theologian of the Middle Ages renowned for his defense of the Immaculate Conception and his writings on the soul. He also stands as an intermediary between Thomas Aquinas and William of Ockham. Although he sometimes is confused with Johannes Scotus Eriugena because of the similarity of their names, Duns Scotus lived at the end of the 13th century (1265–1308), whereas Scotus Eriugena lived in the 9th century (c. 810–c. 877). There is some debate as to Duns Scotus's origins, which may have been Irish, Scottish, or northern English. The English claim can be found in Duns Scotus's several years of service as a professor at Oxford. Part of the confusion stems from *Scotus,* which meant Irish in the Middle Ages. Some sources claim that Duns refers to a place in either Ireland or Scotland; *dun* is a Gaelic word for "fort," and it is a common prefix in place-names. It is perhaps significant in this regard that the Scotist school, of which he was the founder, found its greatest favor among Irish Franciscans. In the library of Saint Francis of Assisi, Duns Scotus is described as *de provincia Hiberniæ,* from the province of Ireland. Nonetheless, his grave inscription in Cologne says "Scotland bore me . . ." He is believed to have received his doctorate, titled *Quæstiones Quodlibetales,* at the Franciscan college in Paris, and from there he took up a professorship in Cologne prior to his death while still in his 30s.

The Scotist school, or the Later Franciscan school, is a theological and philosophical style that is derived from the Old Franciscan school of Augustinian theology (Platonism) and that combined the writings of Aristotle with those of Plato. Duns Scotus employed Aristotelian thought and Peripatetic ideas to a greater degree than had his predecessors, disagreeing with Saint Thomas Aquinas on some points, for example, the doctrine of necessity and the distinction between form and matter, yet he remained firmly entrenched within the Old Franciscan school.

His first work probably was his commentaries on Aristotle. Some of his other writings include *Reportata Parisiensia* and *De perfectione statuum.* The sobriquet *Doctor Subtilis* comes from his complex and subtly suggestive lines of thinking on subjects such as will, human freedom, universality, metaphysics, and theological language. This is evident in his *Opus Oxoniense,* his Oxford commentaries on Peter Lombard's 12th-century *Sentences* (*Quatuor libri Sententiarum*), which united the facets of theology from the Blessed Trinity through judgment to heaven and hell, into a unified whole. Duns Scotus's commentaries, although mainly theological in nature, cover the gamut of metaphysical, grammatical, and scientific thought and serve to display most of his philosophical system. Although Duns Scotus appears to have changed his position from his earlier acceptance of prevailing theology to his later individual insights, this cannot be certain because many of his essays remain incomplete, and he did not produce a *Summa.* His talent appears to have been criticism more than self-expression, or perhaps more accurately, self-expression through criticism.

Nonetheless, a philosophical system exists within the work of Duns Scotus. He distinguishes among pure intellectual distinctions, distinctions that are based in reality, and formal distinctions that lie between intellectual and realistic distinctions. This leads to the soul, the intellect, and the will, each with its own faculties and realities, yet which are different aspects of the same existence.

The Blessed Trinity exist of themselves regardless of externalities. It is in its wholeness as three persons in one existence that they create by their unified thoughts and will. Likewise, existence is not the same thing as substance; an accident can exist within substance yet not have substance of its own. Only things that actually exist have being. Prior to being, things have only essence but not existence, yet within the essence is contained the possibility of existence. Only God is perfect enough to exist without the need for material creation. Thus, when God gives existence to essence by his will, he makes it good and real because it comes from God. God's will is not limited by the laws of nature. Thus, being beyond the laws of nature, God is not bound by time, but he exists outside of it, making him eternal. Yet time itself exists solely dependent upon God's will, as he gives it existence. We measure time relative to lunar and solar movements put into motion as an expression of his will. From this we can infer God's infinity from his finite creations.

Ironically, the term *dunce,* someone who cannot learn, comes from later followers of Duns Scotus who were tied to his sophist teachings and would not accept the rise of humanism. Duns Scotus was elevated to Blessed by Pope John Paul II.

Duration

The word *duration* refers to a length of time and can be broadly categorized into two types. A *filled* (or *full*) *interval* is the length of time of a single event (such as a speech). An *unfilled* (or *empty*) *interval* is the length of time between two successive events (such as two knocks on a door).

Human perception of time is sometimes referred to as involving both duration and succession. In this case, succession is defined as the fact that two or more events are perceived as different and occurring in a sequence. Duration is defined as the interval between the successive events. Duration is not a thing by itself, but it is a quality or characteristic. Without succession, there is no duration.

For events having an extremely brief duration, the perception of instantaneity is created. In this case, the perceiver is unable to distinguish between the beginning and the end of the occurrence. Studies have found differing thresholds at which humans can perceive a duration, but the minimum threshold is usually around 130 microseconds.

A number of variables can affect how humans perceive a specific duration, as shown in many clinical studies. Circumstances that cause strong negative emotions seem to last longer, because of the additional attention focused on processing the emotional stimuli. This effect is known as the *filled interval illusion.* Other factors that may make an event appear longer include using auditory (rather than visual) stimuli, greater intensity of a sound or light stimulus, and use of filled intervals (rather than unfilled intervals).

The theory of cognitive orientation states that events with greater variability and unpredictability also appear longer. This is because the participant is not able to anticipate what is coming next, and it takes longer to become oriented to the situation.

It should be noted that perception of duration differs from estimation of duration. When humans estimate a duration, they are considering an event that has already occurred and is in the past. When humans perceive a duration, they are considering an event that is presently occurring.

Duration in Music

In musical notation, *duration* refers to the length of time that a note is held. In this case, a note's duration is not absolute but rather relative to the whole note. For example, a half note has half of the duration of a whole note. The absolute duration of each note in a given piece is determined by the metronome marking (if given) and time signature. The time signature is made up of two numbers, one showing the number of beats per measure, and the other showing which note gets one beat.

The metronome marking is listed as a single number, indicating the number of beats per minute. In place of a metronome marking, some composers may use a tempo mark, which is a word or phrase indicating how fast or slow the music should feel. With this type of marking, the tempo is somewhat open to the interpretation of the conductor or performer.

Long Durations

Although much research about duration involves small periods of time, the word *duration* can also refer to lengthier events. For example, the age of the universe has been estimated at 13.7 billion years. One could see this time period as a filled interval (i.e., the duration during which the universe has existed). In this case, as the universe continues to exist, the duration will become longer, as there has not yet been an end point.

Durkheim, Émile (1858–1917)

Émile Durkheim, a French sociologist and anthropologist, is often credited with having established sociology as a distinct science. Much of his work is meant to explain how sociology is unique within academia and thus must be recognized as its own academic discipline. Consequently, he paved the way for sociologists and anthropologists of the

20th century. His major works include *Division of Labor in Society, The Rules of the Sociological Method, On the Normality of Crime, Suicide,* and *Elementary Forms of Religious Life*. Durkheim holds a special place in the historical development of social thought. Furthermore, he viewed human values from a temporal perspective; his investigations viewed the development of societies, institutions, and human beings over the course of time.

Durkheim was born in Lorraine, France, into a devoutly Jewish family; his father, grandfather, and great-grandfather had all been rabbis. Émile's outlook, however, was essentially secular; he was interested in studying religions objectively and thus never affiliated himself with any formal religion.

As a child, Durkheim was a bright and diligent student. He was awarded numerous prizes and distinctions. He earned his baccalaureates in letters (1874) and sciences (1875) at the Collège d'Epinal, as well as high distinction in the Concours Général. This facilitated his acceptance to the Lycée Louis-le-Grand in Paris. However, he was not content with having been accepted there and he studied fervently to be eventually accepted, after three tries, to the École Normale Supérieure, one of France's most elite schools.

At École Normale Supérieure, Durkheim studied alongside other scholars who would attain fame, such as Jean Jaures, Pierre Janet, and Henri Bergson, and he often discussed with them the Republican cause, of which he was a strong proponent. Durkheim admired Léon Gambetta, one of the founders of the French Third Republic, and Jules Ferry, who introduced the anticlerical reforms that made education mandatory, free, and secular throughout France. It was also in college that he read Auguste Comte and Herbert Spencer. Thus, he was exposed to the fathers of social science even though no such discipline was recognized by academia at the time. He majored in philosophy but was bored by the humanities that his college required him to study and therefore graduated second to last in his class.

Despite his apparent underachievement in college, he was not dissuaded from pursuing knowledge throughout the rest of his life. His own interest in education centered on teaching methods, which had long been literary but which he felt needed to be scientific, and it was this issue that drove him. He traveled to Germany, where social science was more accepted, and studied there for a year.

Durkheim received his first employment in 1887 in Bordeaux, teaching pedagogy and social science, which was still quite new and not fully legitimated within French academia. The social science part of the appointment had been tailored to fit his new ideas, and thus, sociology became part of the French academic curriculum.

Durkheim introduced several important concepts to the vocabulary of sociology. For one, he differentiated between two ideal types of society: the mechanical and the organic. Mechanical societies were small, simple, and traditional societies in which labor was not differentiated and in which norms were well regulated by collective consciousness and repressive corporal punishments. Organic societies were larger, more complex societies in which labor was differentiated and punishments for deviant behavior were aimed at rehabilitation. Durkheim also introduced the concept of *anomie,* which describes a lack of clear norms, leading to deviant behaviors within society. Also worth noting, Durkheim was one of the first to rigorously study and speculate upon the human phenomenon of suicide; he described anomie as the primary cause of one type of suicide (thus named anomic suicide), the three other types being egoistic, altruistic, and fatalistic, each with its own set of properties. Furthermore, he developed the religiosociological concept of collective effervescence, by which he theorized that humankind's belief in God emerges from wonder at society.

Perhaps most importantly for the future of sociology, however, he rigorously advocated an empirical method applied to sociology so as to differentiate sociology from the other sciences. Consequently, he introduced the concept of a "social fact" to justify the new science, a concept he said denoted the existence of some institution in society that was not dependent upon particular individuals for its continued existence.

Durkheim's thought, descended from that of the Enlightenment, helped to shape a new understanding of time and history. He made a point throughout his work of describing history as a process resulting from an intermingling of factors. He helped to further establish within Western society the scientific way of understanding time as a chain of cause and effect. For instance, Durkheim connected religious with social phenomena, suggesting that religious beliefs and practices, by influencing the way humans behave, also shape time. Social facts, in the form of large institutions such as religions or states, which span generations and exist independently of individuals, come to influence and shape not only individual lives but also the way time is viewed by human societies as a whole.

Dying and Death

Dying is a process of time that all organisms undergo. From a biological standpoint, dying is synonymous with the concept of aging and metabolic degrading. The biological state or process of aging is known as *senescence*.

A phenomenon known as *cellular senescence* is a cell's apparent ability to divide (reproduce via cellular division) only a limited number of times in culture, negating the concept of perpetual cell replication. This phenomenon was illustrated in 1965 by Leonard Hayflick and was called the Hayflick limit. The aging process of an organism is known as *organismal senescence* and is typically quantified in terms of what is called a life span. A life span is defined as a length of time that an individual organism is expected to live. In humans, a life span is typically measured in years.

Death is the permanent end of the life of an organism. The principal causes of death are typically aging-related processes that cause a decrease in, and consequently the cessation of, metabolic actions. Other causes of death could include predation, environmental changes, and decreases in the availability of food. Overall, death is the inevitable consequence of aging. Although death may be viewed as undesirable, it is actually a natural part of the cycle of life.

Several factors influence the process of dying, thus slowing down or speeding up the process. Environmental factors most notably can affect the life span of an organism. A favorable environment can provide an organism with the proper food sources and ideal living conditions for it to attain a maximum life span. An unfavorable environment with insufficient food sources and hostile conditions (such as extreme temperatures) could directly cause an organism to die much sooner than its anticipated life expectancy.

Diet, or what an organism consumes for metabolic demands, can influence the rate of dying. For example, if an organism requires proteins and sugars to survive, where and how those two things are attained could have a positive or negative effect on that organism. If this food source is hazardous to procure or contains additional hazardous chemicals, then this could possibly increase that organism's rate of dying. However, if the food source is found in different forms that are safer to procure and/or contain less or no additional hazardous chemicals, then this would decrease that organism's rate of dying.

What type and how many predators an organism has can also affect its life span. An organism's ability to survive against predators depends on its genetics (inherited) and learned behavior. These two things give an organism a better chance of evading or fending off predation.

In essence the abilities of an organism to obtain food and avoid becoming food can increase its life span and prolong the dying process. These abilities would be favored by natural selection, a natural process by which favorable traits or genetics (that are inherited) become more common (by way of survival) in a population of reproducing organisms and, consequently, unfavorable traits that are also heritable become less common or eventually extinct.

Factors Affecting Human Life Expectancy

In humans, life expectancies (or the average life span of a group of organisms) have steadily increased. In the United States, the average human life expectancy was only 47 years in 1900, compared with 77 years in 2000. That is an average increase of 30 years. The global life expectancy in 2000, however, was 67 years, which is lower than in the United States and other industrialized nations but much higher than the global life expectancy in 1800, which was about 37. Five major factors are believed to have contributed to this increase in the U.S. and global life expectancies: improvements in general health, decrease in infant mortality, the advent of modern medicine, increased availability of food, and natural selection.

First and foremost is the improvement in general health, particularly the conditions of cleanliness and hygiene among large populations. In fact, one of the largest increases in life expectancies coincides with the advent of sewer systems. This greatly decreased both the spread of communicable diseases and the development of plagues that had wiped out massive numbers of people in the past.

Second, and often regarded as the most important factor in the increase of life expectancy, is the decrease in the number of infant deaths. This is more noticeable in industrialized countries, where the near elimination of infant mortality has been attained owing to improvements in prenatal health and medical obstetrics. From a mathematical standpoint, if you eliminate the number of zeros from your group of infant numbers, then the calculated results of your average life expectancy increases drastically.

Third, improvements and advancements in medicine have contributed to the prolongation of human life. For example, vaccinations against diseases like rubella, polio, and tetanus have allowed more individuals to survive beyond adolescence. In addition, improvements in diagnosing and treating diseases have also contributed to the increase in life expectancy. More interesting is that with the completion of the Human Genome Project, the physiology of aging may be better understood, and aging may perhaps be genetically halted or even reversed. This, of course, raises scientific, philosophical, and religious speculations.

Fourth, the increase in the availability of food has increased the life expectancy because of a decrease in the number of individuals dying from starvation. Just a century ago food was much scarcer and had to be grown or hunted if not bartered for. In those fragile times, if a crop failed or other unforeseen disasters took place that caused a shortage of food, people died of starvation. In modern times, hundreds of restaurants and grocery stores can be found in a single city, and in industrialized nations there is actually an overabundance of food. This could in turn have an adverse affect on life expectancy. Because of this overabundance of food, and the fact that much of this food is high in fat, cholesterol, and calories, industrialized nations like the United States are developing epidemics of obesity, diabetes, and increases in coronary artery disease. It has been postulated that in the near future we can expect to see a decrease in life expectancy for the first time in over 200 years.

Fifth, natural selection, in a theoretical way, may have improved human life expectancy, but perhaps only initially. In a given species, stronger individuals that live longer have more of an opportunity to reproduce, whereas genetically inferior members of the species die sooner and thus have less opportunity to reproduce. So initially when our species lived in more dangerous conditions, natural selection worked to improve the life expectancy, in general, by providing favorable genetics. However, there are newer philosophical speculations that have developed with regard to natural selection contributing to the improvement in life expectancy. Because our environment is not as hazardous as it once was, genetically weaker individuals are able to survive and reproduce, sometimes in large numbers. Therefore, because there are not as many natural factors to pressure the species to improve genetically, the gene pool is beginning to decrease in quality. This idea is known as "failure to improve the species" from a natural selection point of view.

Changing Views on Dying and Death

From a cultural standpoint, attitudes toward dying and death have changed over time. One major topic that has catalyzed moral and ethical thought about death and dying is euthanasia. There are two definitions of what euthanasia is. Passive euthanasia is the withdrawing or withholding of life-prolonging medical treatment, which in turn increases the rate of dying. This is typically done in what is believed or assumed to be in that patient's best interest because of the expected decrease in the quality of his or her life as a result of a current medical condition. Active euthanasia is the intentional act to end the life of a person who would otherwise suffer from a painful or incurable medical condition. Active euthanasia is illegal in most countries, whereas passive euthanasia is gaining more acceptance. Another factor influencing the acceptance of euthanasia is the cost of keeping terminal patients alive with little or no chance of their having a normal quality of life.

Understanding and Dealing With Death

The acknowledgment of death is the realization that another individual has ceased to exist. Mourning is the grief that an individual experiences as a result of the death of someone close or special to that individual. During this experience, an individual will undergo what is known as the grief cycle. The grief cycle, as originally outlined by psychiatrist Elisabeth Kübler-Ross, consists of five stages: denial (This can't be happening), anger (Why me?), bargaining (Please let me live to see [a particular event] happen first), depression (What is the point of going on?), and acceptance (He [or she] is in a better place now).

As we live, we witness the deaths that happen to others, but how do we come to terms with the fact that we too eventually will die? An organism's ability to comprehend that it is dying and will at some point cease to exist is known as death consciousness. This appears to be specific only to humans. Although some animals are reported to experience grief, it is uncertain if they are conscious of the fact that they too will eventually die. An animal's avoidance of death is driven more by instinct than by realization of a definite end.

In all likelihood, death consciousness was the driving force that motivated most religions to hypothesize the concept of the afterlife, which refers to the immaterial continuation of life or life after death once the physical processes of life have ceased. Every culture and religion has its own beliefs concerning what happens after an individual dies. For example, Christianity professes that when you die, your soul, which is immortal, goes to heaven if you were a good person or to hell if you were a bad person, based on the commandments of that religion. In many Asian philosophies or religions, it is believed that when you die, you are reincarnated into another type of life form. Other religions, such as Zoroastrianism, believe that the dead will be resurrected at the end of time. On the other hand, atheists and agnostics do not believe that there is life after death. However, all ideas about what, if anything, happens after death must remain speculative in the absence of proof or even of a universal agreement about what would constitute such proof.

Whatever religion or philosophy a person believes in, there is a general human tendency to want to remember loved ones or to be remembered after death. This is the purpose of a funeral, the ceremony that marks the death of an individual. In some cases, a monument is erected in remembrance. The burial of the dead is hardly a new concept. In fact, evidence discovered in the Shanidar Cave (in Iraq) establishes that Neanderthals buried their dead and adorned them with flowers. Some people, however, prefer not to be buried and choose to have their remains cremated instead.

Eternal Recurrence

The concept of eternal recurrence is a cosmological speculation based on the premise that the expanding universe has a limit, based on the current scientific assumption that there is a finite amount of matter. Once this limit is reached, it is believed that the universe may contract back to its origin, only to expand once again, then again to contract, and so on. Because the number of changes proposed through this model of expanding and contracting is believed to be infinite (which is another scientific assumption), there is a possibility that an exact state can occur an infinite number of times. In other words, this life may recur again an infinite number of times and may have already occurred an infinite number of times. In physics, an oscillatory model of the universe could illustrate and explain how the universe could cycle through the same events infinitely. Therefore the concept of eternal recurrence, from a scientific account, would be a function of energy and time. This also provides a model that death is not a permanent end.

The concept of eternal recurrence has its roots in ancient Egypt (c. 1600 BCE). The ancient Egyptian alchemy symbol, the *ouroboros,* which in Greek means "tail biter," is typically represented by a snake or serpent-like creature devouring its tail to form a circle. This also represents the concept that time is cyclical as opposed to linear. The idea of eternal recurrence was revisited by the German philosopher Friedrich Nietzsche, most notably in his works *The Gay Science* and again in *Thus Spoke Zarathustra.* Philosophically, eternal recurrence is a cosmological form of life after death.

E

Earth, Age of

About 75 years ago, the best guess for the age of Earth was about 100 million years before the present. About 50 years ago, the best estimate was approximately 2 to 3 billion years. Now, the best estimate is that the earth was formed 4.75 billion years ago. In cosmic time, it may have taken another 14 billion years for the gases in the universe to coalesce into a liquid or plastic form. Scientific research and technological advancement improves with time, but how can such a huge amount of time be put into an understandable perspective? The archaeologist D. J. Mahony made an analogy with a walk down the avenue of time into the past, covering a thousand years at each step. The first step would take us back to the battle of Hastings, the second to the beginning of the Christian era, the third to Homeric Troy, the fourth to Abraham, and the seventh to the earliest traditional history of Babylon and Egypt. About a quarter mile would lead to the origin of the oldest stone tools found in Europe. To continue until we encountered the most ancient fossil organisms would mean a journey of more than 250 miles.

James Hutton, in the 18th century, was a farmer, a doctor, and, many believe, the father of modern geology. He perceived, from what he viewed and understood of the soils and the rocks, that the formation of the earth took a much longer period to happen than that postulated by Archbishop Ussher in the 17th century, who proposed that the earth was created on the evening of October 22, 4004 BCE. Charles Lyell, in the 19th century, using earlier works as well as his own observations, indicated that the earth was not only of great age but that its processes in the present could be used to illustrate the changes of the past. Early in the 20th century, Alfred Wegener presented the concept of continental drift, now known as plate tectonics, to his peers and to the world. These concepts by Hutton, Lyell, and Wegener were not readily accepted. But now we know that Pangea was truly a single continent about 200 million years ago and that that continent has become no fewer than six: Africa, Antarctica, Australia, Eurasia, North America, and South America. The geologic processes that we observe today have been recurring again and again. Some of these events and processes can be viewed in the geologic timescale in Table 1.

The study of Earth's origin is a work in progress. A multitude of geologists and other scientists for the past 500 hundred years or so have built the body of knowledge we have currently. Today, scientists are using new technologies to piece together how the earth was formed. It some ways, it is like building a structure from the top down, or as Hutton put it more than 200 years ago, "The present is the key to the past." Speculation concerning Earth's origin and its formation runs rampant. This continues today regarding Earth's formation, but with developing technologies, new, vivid, and more exact evidence has begun to appear.

Astronomers, seismologists, physicists, chemists, and biologists, among others, are accumulating the evidence necessary to reveal the history of Earth and its age. The interior of the earth, its core, consists of hot, molten material. The core is surrounded by a

Table 1 Geologic Timescale

Geologic Periods	*Time (YBP)*	*Major Events*
Quaternary	2–3 million	ice age, emergence of humankind
Tertiary	65–70 million	Cascadian orogeny, carnivores, mammals
Cretaceous	136 million	Laramide orogeny, some extinction, ice age
Jurassic	190–195 million	first birds and mammals, Nevadian orogeny
Triassic	225 million	first dinosaurs, Palisades disturbance
Permian	280 million	Appalachian orogeny ends, ice age

Mississippian	345 million	Appalachian orogeny begins, conifers, ferns
Devonian	390 million	first amphibians, Acadian disturbance
Silurian	430–440 million	first plants, Caledonian disturbance
Ordovician	500 million	first fishes, Taconic disturbance
Cambrian	570 million	ice age, submergence, trilobites
Precambrian		Appalachia, Grand Canyon disturbances
Proterozoic		primitive marine plants, ice age
Archeozoic	4.75 billion	Laurentian orogeny, no life
Primeval gases		

mantle of more viscous material with variations in its fluidity. On top is the less hefty crust of the earth in two parts: the lower magnesium-silicate layer and the upper alumino-silicate layer, or the present landmasses. The crust consists of rigid materials such as silica (SiO_2) which is almost 95% of the total volume, followed by aluminum (Al), iron (Fe), calcium (Ca), sodium (Na), potassium (K), and magnesium (Mg), all of which add up to 98.59% by weight. In the core, below the crust, heat is generated and convected through the mantle. The heated material pushes forth and tends to weaken the crust, slowly moving it laterally, sometimes allowing molten material to ooze out, as in sea-floor spreading. This process of deformation has continued through time.

Landmasses built by volcanism, faulting and folding, and upheavals related to the collision of continents become exposed to the atmosphere, and they contribute sediments that are carried to lower elevations by moving water, moving air, moving ice, and currents and tides in bodies of water. Deformation of the crust has occurred repeatedly, producing a complex crustal surface.

Geological Eras

The Precambrian is divided into eon: the Archeozoic, which is characterized by primeval conditions, and the Proterozoic, considered to be the very beginning of primitive life. However, additional distinct eras during the Precambrian may emerge with the greater understanding afforded by newer technologies. During the Precambrian eon, considerable deformation has been noted with no fewer than three major orogenies and subsequent long periods of erosion and deposition, in addition to two ice ages. Every continent has Precambrian shields, many of which contain a wealth of minerals, including iron, copper, nickel, silver, and gold.

The Paleozoic era consists of the Cambrian through the Permian periods. This era begins with the appearance of trilobites and other marine fossils in vast shallow seas that came with climatic warming at the end of the Proterozoic ice age. The Ordovician was the greatest of all submergences, with reef systems and an abundance of marine fossils stretching from the tropics to the arctic regions of today. It must be remembered that the landmasses had different shapes and locations until about 200 million years ago. The rocks of this period offer gas and oil, as well as building stone such as marble, slate, limestone, and dolomite, and ores like hematite, lead, and zinc. The Silurian times were relatively calm as terrestrial life began, with the first air-breathing animals such as scorpions and millipedes, and marine life continued to develop. During the Devonian, which was relatively calm, some disturbances can be noted, as with other periods. Land plants flourished as did marine invertebrates; the ascendancy of the fishes began, including air-breathing fishes. The Mississippian and Pennsylvanian mark the millions of years of the carboniferous system with swamp vegetation, interspersed with sediments of clay, silt, and sand. The Permian marks a crisis in Earth history with major mountain building. Although deserts were widespread during this time, so were vast areas in the southern hemisphere covered with ice, and the decline of carboniferous floras can be noted.

The Mesozoic era includes the Triassic, Jurassic, and Cretaceous periods, during which the reptiles emerged. This was the age of dinosaurs measuring about 65 feet in length and more than 18 feet high at the hips. Also, smaller dinosaurs, birds, and mammals appeared in great quantities. The end of the era came with orogenic forces and a colder climate, with evidence of glaciers in Australia. It must be remembered that continents were not the same shapes or in the same locations as they are today.

The Cenozoic era is that of the modern world of the past 65 million years or so. The Mesozoic lasted about twice that long and the Paleozoic about five to six times longer. An appreciation for the magnitude and duration of the events of the Cenozoic era—including the birth of numerous volcanoes, the vast mountain ranges, the occurrence of earthquakes marking the faults, the array of hills, plateaus, and plains, the evidence of the great ice ages, and the broad expanses of oceans—brings into sharper focus the scale of time against which the existence of humankind can be understood.

Earth, Revolution of

Planets are continuously "falling" toward the sun due to the gravitational effect of solar mass and the constant centripetal force that allows planets to remain at a consistent distance from the sun. Earth, like every planet in our solar system, orbits the sun elliptically. German mathematician and astronomer Johannes Kepler, collaborating with Danish astronomer Tycho Brahe, first noted this trend in 1605, when together they plotted the orbit of Mars. At that time in history, the geocentric model of the universe was common belief, although their discovery led to its ultimate demise some 40 years later by Galileo Galilei. As Earth progresses in its orbit, there are climatologic impacts on the surface.

Revolutionary Characteristics

Earth's orbital plane is known as the ecliptic plane. It is also the same apparent motion of the sun across the terrestrial sky on any given day. It is taken as the point of perspective from which all other planetary orbital inclinations are derived. Its name is derived from the occurrence when the lunar orbital plane intersects at new and full phases, causing an eclipse. Based on the definition of celestial north, the ecliptic is used as a reference point, and therefore all solar system objects revolve around the sun counterclockwise.

Earth's orbital position affects its surface as a result of its proximity to the sun and its axial tilt, or

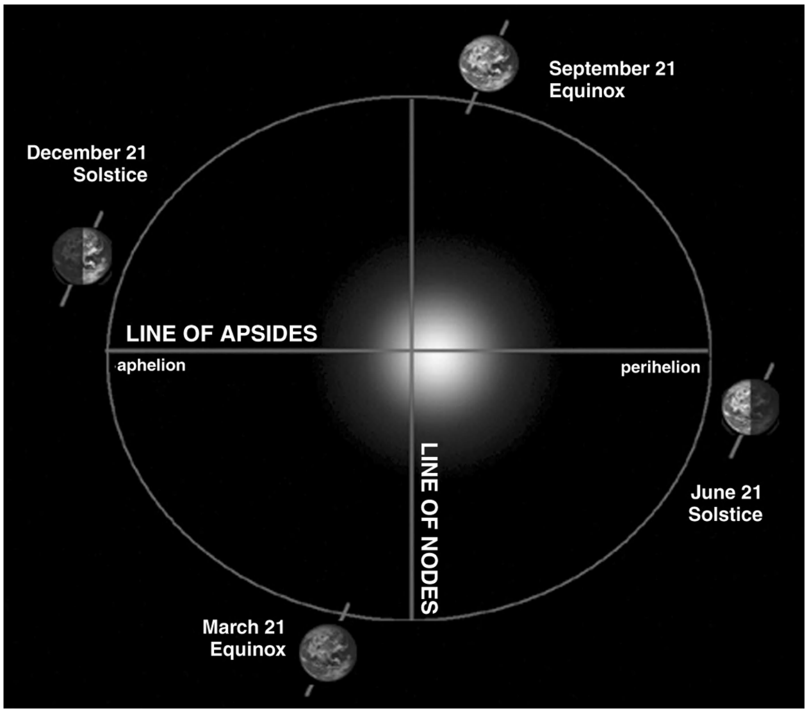

Figure 1 Generalized orbit of Earth around the sun

inclination. As a result, the sun is not at the true center of revolution but rather displaced from the elliptical center at a point called the focus. As part of his research, Kepler made this well known and discovered that orbiting objects in space exhibited predictable behavior. This research led in turn to Isaac Newton's discovery of modern physical laws.

Effects of Revolution

Climatologic effects on the surface of Earth are tied directly to its 23.5° axial tilt. Because the sun is not central, Earth then has points of closest and farthest distance from the focus, known as *perihelion* and *aphelion* (helio refers to the sun), respectively. Connecting one point to the other through the center of the ellipse yields a line of interest called the line of apsides. The line of apsides is the semi-major axis of any ellipse. Likewise, a similar line drawn across the semi-minor axis yields the line of nodes. The line of nodes is the point where the ecliptic and celestial equator intersect. These are the vernal and autumnal equinoxes.

Expectedly, Earth is most temperate at perihelion and, due to its angular inclination, the southern polar axis is pointed toward the sun during the southern hemisphere summer. Correspondingly, the northern polar axis slants away from the sun, so the northern hemisphere experiences winter. At aphelion, the seasonal reverse is true, and as a result, Earth's southern hemisphere tends to have warmer summers and colder winters than the northern hemisphere. At the nodes, Earth's axis is not a factor in climatology and a relatively equal temperature exists at the nodes (see Figure 1).

A common misconception is that because Earth is at its closest to the sun, a summer solstice is occurring for the warmer southern hemisphere. This is not necessarily the case. The points of perihelion (and aphelion) tend to precess over time because Earth's axis is subject to influence by other gravitational forces in our solar system, chiefly that of Jupiter. The net effect is that there is a cycle of where each solstice occurs.

Most planets tend to maintain their orbits and their order, except in the case of Pluto (which, as of August 2006, is technically no longer classified as a true planet by the International Astronomical Union). Every 228 years, Pluto falls inside the orbit of Neptune as it did between 1979 and 1999. However, each planet has differing distances across both the semi-minor and semi-major axes. The net effect of this event yields an eccentricity, or flattening, of the planetary orbit.

Earth, Rotation of

The rotation of the earth refers to the earth's spin around its own axis. The earth makes one complete rotation in 24 hours, during which the side of the planet facing away from the sun experiences night and the side facing the sun experiences day. The earth's axis of spin is inclined from the plane of its orbit, which causes seasons on the planet. The time required for one rotation has changed over history and is predicted to change in the future.

Characteristics of Rotation

Although Earth appears stable to humans, it is actually spinning rapidly. The velocity of a point on the equator is 465.1 meters per second, which is faster than the speed of sound at 335 meters per second. Objects stay on the earth's surface—despite the rapid rotation—because of gravity, a force that attracts objects toward the center of the planet.

The axis around which the earth rotates is not perpendicular to the plane of its orbit around the sun. It inclines from the perpendicular by 23.5 degrees, a geometric configuration that causes seasons on Earth. When the earth's axis points away from the sun, the northern hemisphere experiences winter because the sun's light hits the hemisphere at an angle. At the same time, the sun's rays are shining more directly at the southern hemisphere, which experiences summer. The seasons in the hemispheres reverse when the axis of rotation points toward the sun.

Astronomers have discovered that the position of the earth's axis is not constant over time. Every 14 months, the earth passes through a cycle known as the Chandler Wobble. A wobble, or precession, occurs when Earth's axis of spin oscillates around another axis; Earth resembles a spinning top that begins to slow down with its axis tracing a cone around a vertical axis. Scientists hypothesize that the 6-meter wobble is caused by changes in ocean currents or the atmosphere.

The Milankovitch cycles are patterns of rotation that occur over much longer periods. The axis inclination of the earth experiences a 41,000-year cycle, during which the axis moves from 21.5° of inclination to 24.5° and back again. Astronomer Milutin Milankovitch also identified a 21,000-year cycle during which the axis of spin wobbles and a 96,000-year cycle during which Earth's orbit becomes more and then less elliptical. Some astronomers hypothesize that the Milankovitch cycles caused the ice ages because when in conjunction, the cycles can vary sunlight reaching the northern hemisphere by as much as 20%.

Changes in Rate

Earth used to rotate more than twice as fast as it does in the 21st century. During the Archaean eon, 2,500 to 4,000 million years ago, the earth completed a rotation every 10 hours. One of the forces that slows Earth's rotation is the moon's gravity, which causes tidal activity. The friction of ocean tides actually acts as a brake on the rotation of Earth, causing the length of 1 day to increase by an average of 2.3 milliseconds per century. In the past 2,500 years, day length has increased by 42 milliseconds.

Ecclesiastes, Book of

Ecclesiastes is the English designation for a book of the Old Testament, known in Hebrew as *Koheleth* (variously spelled). The canonical Hebrew Bible, or Old Testament—also part of the Christian Bible—is generally divided into three sections: the Law (or first five books, called the Torah); the Prophets; and the Writings. Ecclesiastes falls into the latter group and, along with Job and Proverbs, is considered wisdom literature, containing reflections on the meaning of life and righteous living. It is also described as poetic writing, characterized by parallelism and thematic refrains that repeat much like the rhythms of nature. In particular, Ecclesiastes compares the fleeting essence of human life with the everlasting nature of God and Earth. "One generation passeth away, and another generation cometh; but the earth abideth for ever" (1:4). Humankind is time-bound, but God is eternal. Ecclesiastes is traditionally read during the Jewish harvest festival of Sukkoth (Tabernacles) as a reminder of the transitory nature of life and an admonition against overreliance on material possessions. In this context, Ecclesiastes foreshadows a similar message of the New Testament warning against attachment to earthly matters, which pass with time.

Underscoring the ephemeral quality of life, the book begins, "Vanity of vanities, saith the Preacher . . . all is vanity" (1:2). The term *vanity,* translated from the Hebrew through the Greek, does not suggest the English understanding of self-absorption but variously the concepts of futility and meaninglessness, based literally on the Hebrew *hebel* (or *hevel*), meaning vapor, or mist. Life is, therefore, no more than a breath that forms quickly, evaporates, and is gone. The passage of time is an overriding theme: "To every thing there is a season, and a time to every purpose under the heaven" (3:1). There are no less than 45 direct references to "time" in the 12 chapters of Ecclesiastes and at least 6 admonitions to enjoy life in the present, not in the hedonistic sense but rather accepting both life and death as gifts from God. The present, then, takes on paramount significance, with the past forgotten and the future uncertain.

When the canon of the Hebrew Bible was defined at the Council of Jamnia (c. 90 CE), many Jewish scholars opposed the admission of *Koheleth* to the sacred, or inspired, collection of writings because of its pessimistic outlook; however, although not a book of praise, it ultimately affirms faith in God, God's Creation, and the Hebrew law. The English title of the book is derived from the Greek *ekklesia,* originally denoting a secular gathering. The term became associated with religious gatherings and then was exclusively applied in a religious context referring to "church" or church-related (ecclesiastical) matters. The Hebrew title *Koheleth* is also based on the Hebrew root meaning "to gather or assemble"; however, the English translation has come to be understood as "preacher," an honorific title referring to one who conducts or leads a religious assembly.

Some elements in the Jewish tradition hold the author to be King Solomon, who ruled Israel from approximately 970 to 928 BCE, as implied in the first line: "The words of the Preacher, the son of David, king of Jerusalem" (1:1). Tradition also attributes two additional Old Testament books to Solomon: the Book of Proverbs and Song of Songs. However, other scholars believe the opening of Ecclesiastes to be calling upon the credibility of Solomon's wisdom rather than identifying him as the writer and believe its style and language place authorship about 250 BCE in the post-Babylonian exile era, when most Jews lived under Greek rule and exercised no real political power. The skeptical tone of the book may also reflect the prevailing Greek philosophy and antipathy of the Greeks toward Judaism. Despite the author's viewpoint, he does not yield his faith in the face of adversity. The autobiographical first person is employed throughout from the perspective of a wise man who has lived fully and wishes to share his perspective on the purpose of existence. The maxims he advances are based on his own observation, but he is nonetheless cognizant of the limitations of human reason when he poses the question, "For who knows what is good for man in life, all the days of his vain life which he passes like a shadow?" (6:12).

Ecclesiastes comments on the futility of human accomplishments and the cyclical pattern of history over time: "What has been done will be done again; there is nothing new under the sun" (1:9). The narrator makes no reference to a hereafter, since the lives of both the righteous and the foolish end in death: "All go unto one place; all are of the dust, and all turn to dust again" (3:20), which echoes the words of Genesis (3:19). Similarly in the Book of Job, divine justice remains a mystery: "The race is not to the swift, nor the battle to the strong . . . but time and chance happenth to them all" (9:11). The meaning of life, then, must be found in the temporal sphere and living the brief interval of life to the fullest within the Hebrew law. Despite the seemingly hopeless tone of the book, the narrator affirms the existence of God and recognizes and encourages enjoyment and pleasure as divine gifts. "There is nothing better for a man, than that he should eat and drink, and that he should make his soul enjoy good in his labor. This also I saw, that it was from the hand of God" (2:24). The author cautions against pleasure becoming the goal of life, however, since he himself experienced wealth, luxury, and privilege but found them unfulfilling. While human endeavor appears futile, there is recognition of the value of life no matter how brief the interval: "For to him that is joined to all the living there is hope: for a living dog is better than a dead lion" (9:4–5).

In questioning the purpose of human life and endeavors, the author of Ecclesiastes expresses a practical ethic for the present, but without assurance of future justice. With the passage of time comes the inevitability of death: "For man also knoweth not his time: as the fishes, that are taken in an evil net, and as the birds that are caught in the snare; so are the sons of men snared in an evil time, when it falleth suddenly upon them" (9:12). This tone is in contrast to the more traditional books of the Old Testament, particularly the Torah, which place great importance on law and ritual as the guiding principles of a righteous life. But the universality and timelessness of the message of Ecclesiastes has made it an enduring source of allusion, especially in Western culture and literature. The acceptance of the cycle of life does not reinforce hopelessness but recognizes the balance in all things in observing that there is a time to weep and a time to laugh, a time for war and a time for peace. The inexorable passage of time and the cycles of life, death, and rebirth place a particular value on life for all its brevity and uncertainty. Life remains a mysterious gift to be enjoyed to the fullest but never completely understood. Accepting the infirmities of old age and his own imminent death, the narrator advises, "Rejoice . . . in the days of thy youth" (11:9), but to find fulfillment, "Let us hear the conclusion of the whole matter: Fear God, and keep his commandments: for this is the whole duty of man" (12:13). Only righteous living in the here and now, regardless of station in life, gives meaning to an otherwise unexplainable existence.

Eckhart, Meister (c. 1260–c. 1327)

Dominican, philosopher, theologian, and mystic, Meister Eckhart was born outside of Erfurt, Germany, in Hochheim. His given name was Eckhart, yet became known as Meister Eckhart owing to an academic title he gained in Paris. Eckhart's ideas relate to a wide range of ideas and individuals, such as Immanuel Kant's critical idealism, the Eastern mystics, and pantheism. Eckhart's appeal is based mainly on his unorthodox understandings of how God works and interacts with creation; his unique view of time and God are foundational to this understanding.

Not much is known of Eckhart's early life. He entered a Dominican order in Erfurt and eventually attained the degree of master in Paris in 1302. He was evidently an exceptional preacher; some sermons are extant. He also gained fame as a teacher and author.

Later in life, Eckhart was accused of heresy. By 1309 Pope Clement V had decided to live in Avignon, France, and so Eckhart's heretical charge came to light during a contentious period within the Catholic Church. The Archbishop of Cologne wanted to try Eckhart in 1326, yet Eckhart appealed to Pope John XXII (who lived in Avignon). Eckhart affirmed his obedience to Catholic teaching in a letter dated February 13, 1327. He apparently died soon afterward because no further knowledge of his actions is recorded. John XXII issued a bull on March 27, 1329, in which he listed 28 heresies of Eckhart. The Dominican Order over time has attempted to reestablish Eckhart's Catholic orthodoxy. Although Pope John Paul II wrote favorably concerning Eckhart, the matter is still unresolved.

Eckhart's concept of time was counterintuitive to his milieu. From a medieval viewpoint, God worked within physical time and space. Yet Eckhart believed that time and space worked against a true understanding of God because it limited God to the physical world of time and space. He wrote, "For while the soul is occupied with time or place or any image of the kind, it cannot recognize God." Therefore, to Eckhart a true understanding of God must begin with God and not the Creation.

Eckhart believed in the importance of the union of the individual and God. Examples follow:

"Divine light enlightens me in everything I do." "Only God flows into all things, their very essences. . . . God is in the innermost part of each and every thing, only in its innermost part." "God . . . is the being of all beings." In each of these statements, Eckhart attempted to explain the mechanics of a union with God.

Since at least the time of John Climacus (d. 649), Christian mystics have attempted to explain how to grow in union with God; Eckhart attempted to explain how it worked.

Eclipses

Eclipses are astronomical events during which light from the sun or reflected light from the moon is blocked from reaching the earth, causing temporary darkness. A solar eclipse occurs when the earth and the sun are in alignment with the moon positioned between them, and the moon casts its shadow on the earth. A lunar eclipse occurs when the moon and the sun are aligned with the earth positioned between them. In this case, the earth casts a shadow onto the moon. The timing of solar and lunar eclipses can be determined based on astronomers' knowledge of the orbits of the earth and the moon.

Periodicity of Eclipses

The earth completes an orbit of the sun in approximately 365 days, and the moon completes one orbit around the earth in 29.5 days. Both orbits are elliptical, but the moon's orbit is more elongated and the plane of its orbit is tipped by an angle of 5° from the plane of the earth's orbit. This configuration means that the moon is closer to Earth at some times during the year, and for most of the year, the moon is slightly above or below the sun as viewed from Earth. The nodes are the two points where the two orbits' planes intersect. Solar eclipses occur when the moon nears the node closest to the sun and comes into alignment between the sun and the earth. Lunar eclipses occur when the moon nears the node farthest from the sun, and Earth is aligned in between the sun and the moon.

Astronomers can predict eclipses forward and backward in time based on knowledge of the earth's and moon's orbits. In the 1880s the Viennese astronomer Theodor von Oppolzer calculated all of the eclipses that did and will occur between 1208 BCE and 2161 CE. Based on his calculations, solar eclipses occur 238 times per century and lunar eclipses are less frequent at 154 times per century. With current knowledge, astronomers have determined that the minimum number of eclipses per year is two solar eclipses, and the maximum number is seven eclipses with the ratio of solar to lunar eclipses being 5:2 or 4:3.

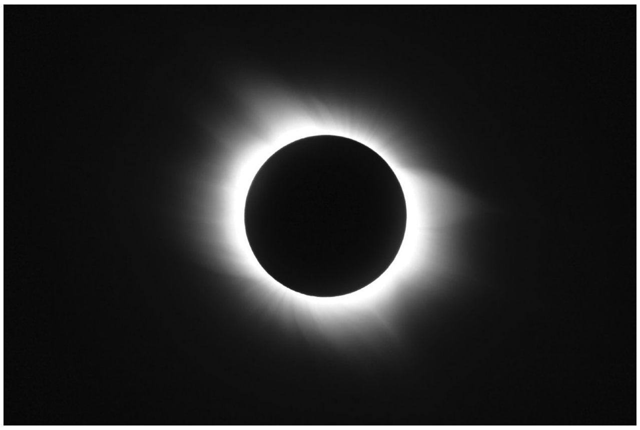
Another pattern in eclipse frequency is the *saros* series, which was first identified by the Babylonians. Any one solar eclipse has a specific geometric arrangement between the sun, the moon, and the earth, which determines its length and the location on Earth where it is visible. That precise arrangement repeats itself every 18 years and 11 1/3 days, meaning a solar eclipse of the same length results. However, the location is different because Earth has rotated for an additional 1/3 of a day. The eclipse will be at approximately the same latitude but will occur 120° west of where the solar eclipse did 18 years and 11 1/3 days earlier.

Solar Eclipses

There are three types of solar eclipses: total, partial, and annular. The first two depend on where an observer is in relation to the moon's shadow, and the last depends on the moon's distance from the sun. During an eclipse, the moon casts a total shadow, or umbra, over the earth in an area that is 60 to 100 miles in diameter. The penumbra, the area of partial shadow, encircles the umbra and has a much larger diameter of 4,000 to 4,500 miles. A person observes a total eclipse only when located within the umbra and when the moon is at one of its closest points to Earth. The moon appears to completely blot out the sun in this case, turning day to night. While the sun is about 400 times bigger in diameter than the moon, it is also 400 times farther from the earth than the moon; thus the perception is created that the sun and the moon are the same size. The frequency of total solar eclipses is one per 1.5 years, and the longest recorded period of total darkness is slightly more than 7 minutes. Although solar eclipses happen every year, a total eclipse can be observed in any one particular location on the northern hemisphere approximately only once every 330 years, and in the southern hemisphere only once every 540 years.

An observer sees a partial solar eclipse when located in the penumbra of the moon's shadow. The moon appears as a black disk moving over only part of the sun, so a partial solar eclipse does not have the dramatic darkness characteristic of a total eclipse. However, many more people can observe a partial eclipse because of the greater diameter of the penumbra. The frequency of partial solar eclipses is approximately 84 per century, or one partial eclipse per 1.2 years.

An annular eclipse occurs when the moon is aligned between the earth and sun and is approaching or leaving its apogee, the point in its orbit that is farthest from the earth. Then the moon appears to cover the sun only partially because it is closer to the much larger sun than it is during a total eclipse. When the moon and sun line up during an annular eclipse, the moon appears as a dark disk centered over the sun and ringed by its bright light.



Total solar eclipse, March 29, 2006. Eclipses occur when the sun, earth, and moon are in alignment. They are rare because the moon usually passes above or below the imaginary line connecting the earth and the sun.

Source: Petr Mašek/iStockphoto.

Lunar Eclipses

Lunar eclipses also can be total or partial depending on whether the moon passes through the earth's umbra or penumbra, respectively. The frequency of lunar eclipses is 1.5 eclipses per year. They are less frequent than solar eclipses at 2.4 per year because the moon is a smaller target for the earth's shadow to hit than vice versa. However, lunar eclipses have a longer duration than solar eclipses, lasting up to several hours, including total coverage of the moon for as long as 1.5 hours. This phenomenon occurs because the earth's shadow is much larger than the moon's, therefore it takes the moon longer to traverse the shadow than the earth does to cross the moon's shadow.

Ecology

Ecology is a scientific discipline that focuses on the distribution and abundance of living organisms and how this distribution and abundance are affected by interactions between organisms and their environment. The term is derived from the Greek words *oikos,* meaning home, and *logos,* meaning study. Therefore, ecology might be described as the study of the home life of living organisms. The environment of an individual organism is composed of biotic factors, including other animals, plants, fungi, or microbes living in the same habitat, and abiotic (physical and chemical) factors, for example, local climatic or hydrologic conditions.

Ecology is commonly considered a branch of biology, but it might be better characterized as a multidisciplinary science. Because it also focuses on the interactions between organisms and their abiotic environment, many other scientific disciplines that help to explore environmental relationships contribute to ecological knowledge, like anthropology, chemistry, climatology, geography, geology, and physics.

Regarding distribution and abundance of living organisms, ecology deals with three levels: the individual organism; the population, consisting of individuals of the same species; and the community, comprising all populations living in the same habitat. Additionally, ecologists study the pathways followed by energy and matter through the interacting biotic and abiotic components that compose the so-called ecosystem and the relationships across multiple ecosystems. According to these levels of examination, the subdisciplines of ecology are commonly classified into autecology (also called species ecology), population ecology, synecology (also called community ecology), ecosystem ecology, and landscape ecology. Nevertheless, ecology can also be subdivided according to other categories. Different kinds of this scientific discipline can be defined, for example, by organism of interest (e.g., plant ecology), by habitat (e.g., urban ecology), or by application (e.g., conservation ecology).

Although ecology as a scientific discipline does not dictate what is right or wrong, the term *ecological* is also used as a synonym for environmental concern; because of this, it has acquired a positive connotation regarding moral judgments about human action in the nonhuman natural world. This meaning, tending to mix up results of scientific research and ethical values, emerged with the transformation of the ecological movement in the 1960s. For an exact distinction between ecology as a pure scientific discipline and the ideas and goals of the political movement of nature preservation, it is helpful to speak of ecology and environmentalism. Nevertheless, both try to see nature as a whole, and they continue to influence one another. Ecological knowledge provides a scientific basis for expressing and evaluating the aims of the environmental movement. Ecologists themselves also respond to the call of the environmental movement in directing much of their research to the environmental problems that have become increasingly pressing.

The concept of time is an increasingly important theme within the field of ecology, including both the science and the political movement. Both have their own history of development, which at some points are intertwined. Further, the history of ecology shows that for a long time, nature was thought of as being inherently balanced, wherefore it was largely ignored that history as one conception of time is applicable to the ecosphere. Such ideas were increasingly questioned after World War II, and nowadays it has become widely accepted that the natural world changes continually through time and that ecological and evolutionary processes affect each other. On this basis, the discipline of evolutionary ecology started to develop in the 1950s. But time does not only play a role in ecology in its historical sense: All organisms are embedded within the cyclical structure of the natural world. Ignoring the timescales of natural cyclical processes, like the flux of energy and matter through ecosystems, is thought to be a causal factor in the present environmental crisis.

History of Ecology

Ecology is generally spoken of as a new scientific discipline that has gained in importance in the second half of the 20th century and the beginning of the 21st. Nevertheless, prehistoric cultures probably passed down forms of ecological knowledge from generation to generation as a way of increasing their chances for survival. Information about the interactions between organisms and their environment was probably gathered from everyday experiences and closely intertwined with religious beliefs and myths.

The birth of modern natural sciences took place during the period of Greek antiquity. Presocratic philosophers (c. 600 BCE) went beyond myths in their attempt to explain nature. By studying phenomena of nature, they searched for the natural laws behind them and developed the first scientific theories. Later, Aristotle (384–322 BCE) developed biology to an independent scientific theme. Though ecological aspects can be found in his writings and in the writings of other philosophers and scientists of the ancient (e.g., Theophrastus, 371–287 BCE), medieval (e.g., Albertus Magnus, c. 1200–1280) and early modern (Carolus Linnaeus, 1707–1778) periods, the birth of ecology is generally dated to the year 1866. In this year, the German zoologist Ernst Haeckel (1834–1919) published his book *General Morphology* and with this the first definition of the term *ecology:* "By ecology we mean the body of knowledge concerning the total relations of the organism to its environment, to that we may reckon all conditions of existence. These are of both, organic and inorganic nature" Basically, the same definition is used today. Haeckel's definition was strongly influenced by the proto-ecological view the great naturalist Charles Darwin (1809–1882) provides in his 1859 book *On the Origin of Species* (1859). The theory unfolded here replaced the conception of the natural world as an enduring system with a conception of it as an open-ended historical process. Without using the word *ecology,* Darwin shows the ecological orientation of his thinking insofar as he refers to the impact of the inorganic and organic conditions of life on natural selection and therefore on the development of new species. The very fact that Haeckel's definition of ecology refers specifically to Darwin's theory of evolution indicates that time is an important factor in the study of ecology.

Haeckel did not elaborate the concept, and therefore the term *ecology* became an independent and established scientific discipline only after the publication of *Plantesamfund* in 1895 by the Danish botanist Eugen Warming (1841–1924). It is no surprise that this first significant textbook on the subject focuses exclusively the ecology of plants, because a second important strand in the development of ecology has been plant geography. Here ecological thinking can be recognized at least since Carolus Linnaeus published his writings, but the most important name in this context is Alexander von Humboldt (1769–1859), who explained the geographic distribution of plants with respect to geological data and went into the question of plant communities. For this reason, like Haeckel, he is called the father of ecology.

In the light of Darwin's theory of evolution and of plant geography, ecology developed into an independent scientific discipline in the second half of the 19th century. Around 1900, the first books were published under the headline ecology. Still, animal and plant ecology were explored separately in independent disciplines of zoology and botany, hindering a more synthetic understanding of their interdependence.

The first comprehensive works of ecology evolved within the field of hydrobiology—probably because a freshwater lake, for example, can easily be seen as a system. Therefore it is no surprise that the term *biocoenosis* (all interacting organisms living together in a specific habitat) was coined in 1887 by the German biologist Karl August Möbius (1825–1908). He was the first to describe in detail the interactions between the different organisms in the ecosystem of the oyster bank. In the same year, Stephen A. Forbes (1844–1930) published his paper "The Lake as a Microcosm." Two important ecological terms developed in response to Möbius. First, in 1908 the German zoologist Friedrich Dahl (1856–1929) introduced the term *biotope,* which means an area of uniform environmental conditions. Then, in 1935 the British botanist Arthur G. Transley (1871–1955) introduced the term *ecosystem,* which comprises "not only the organism-complex, but also the whole complex of physical factors forming what we call environment." Another important term not only in ecology but later on also within the theory of evolution, the *ecological niche,* was coined by the English animal ecologist Charles Elton (1900–1991) in 1927: "the 'niche' of an animal means its place in the biotic environment, its relations to food and enemies." The most important contribution to the development of a comprehensive ecology was made by the German biologist August Thienemann (1882–1960), who argued that autecology and synecology are just different steps of the ladder to ecological knowledge. Nevertheless, throughout the 1940s, 1950s, and 1960s, the debate continued regarding whether ecology is not more than autecology, or alternatively is not more than synecology. Intensive research under the title "ecosystem" began only in 1960, with the synthetic understanding of animal and plant ecology. It incorporated the advances from many scientific disciplines, such as pedology and climatology, but also statistics and informatics, expanding the options for ecological research by computer-aided modeling.

Already in the 1920s, some ecologists were aware of the fact that humans are a major ecological factor and advanced the view that ecology could help to solve environmental problems in the future. A conservationist movement also developed in the 20th century, parallel to ecology as a scientific discipline, inspired by such figures such as the American author and philosopher Henry David Thoreau (1817–1862). Thoreau argues in his 1854 book *Walden; or, Life in the Woods* that people should become intimately close with nature. Another American, the ecologist Aldo Leopold (1887–1948), claims in his famous and influential book *A Sand County Almanac* (1949) that humans should morally respect their natural environment. Nevertheless, environmental ideas reached public consciousness only after the 1960s, when the changes in the natural environment due to human influence began to be understood as the environmental crisis. At this time, the environmental movement was transformed, especially after the publication of Rachel Carson's (1907–1964) book *Silent Spring* in 1962. It emboldened a new generation of thinkers searching for an ethical basis for preserving the environment. This question has remained an issue within the philosophical subject of environmental ethics. The public desire for a better environment led to increasing financial support for ecological research, and the 1960s and 1970s were a period of rapid growth in both fundamental and applied ecology. Other indications of the developing public interest in ecology and environmentalism are, for example, the publication "Limits to Growth" (1972), commissioned by the Club of Rome; the research program "Man and Biosphere," which was launched by UNESCO in 1972; and the first international conference on the human environment, which was held by the United Nations in Stockholm in 1972. At the same time, in some countries political groups that are self-identified as ecological parties and environmental organizations, such as Greenpeace, were founded. The highly visible public support for the environmental movement declined during the 1980s, but recently it has been renewed by the concern over the effects of global warming. The increasing dangers of the greenhouse effect were recognized internationally at a conference in Kyoto in 1997.

In response to the interests of the environmental movement, the application of ecological thought to societal problems is one important direction in ecology today. This goes beyond the scope of ecology as a scientific discipline, but understanding human social behavior plays a role in some ecological research programs. To distinguish ecology as a pure scientific discipline from all other sciences that help to explore human environmental relationships, the term *environmental studies* is proposed. Nevertheless, the attention to scientific rigor is still an important direction in current ecology, in addition to a continued interest in interpreting ecological phenomena in terms of evolution.

Evolutionary Ecology

"Nothing in Biology Makes Sense Except in the Light of Evolution," the title of a 1973 essay by Theodosius G. Dobzhansky (1900–1975), applies to all disciplines of biology and therefore also to the study of ecology. However, whereas ecology is the field concerned with interactions between living organisms and their abiotic and biotic environments, evolutionary biology deals with the question of how populations change through time, split, and go extinct. So, how are ecology and evolution linked? Ecological and evolutionary processes affect each other. Interactions between organisms and their environment drive the evolution of populations by the pressure of natural selection, and this again leads to changes of the interactions and of the environmental processes themselves. Therefore, evolutionary and ecological biologists have a lot to say to each other, and the field where they meet is called evolutionary ecology.

Evolution, and therefore change though time, is one theme that tends to unite the different subdisciplines of ecology. Nevertheless, the use of the concept of evolution is not of equal intensity. Whereas it is strongly integrated into autecology, population ecology, and synecology, in ecosystem and landscape ecology the concept of evolution is a peripheral theme.

Balance of Nature, or Change Through Time?

The conception of ecological balance long precedes the development of ecology as a science. The ancient Greeks had ascribed balance to the natural world, whereas stability was thought rarely true for human societies. In most cases, this idea has its basis in the belief that this ordering is the work of a divine agency, but in some cases, the condition of equilibrium is described as an internal feature of nature itself. In Western cultures during the Middle Ages, the belief in divine order strengthened the belief in natural order and became a background assumption. Later, expressed in the metaphor of the great "chain of being," 17th-century rationalists continued to hold to the notion of a well-balanced nature but believed that laws accessible to human reason, and not a divine power, governed nature. Carolus Linnaeus assumed that harmonious relations between species according to the divine plan create order and stability; this he called the *economy of nature.* His hypothesis was later adopted by modern ecologists, who usually discuss the issue of balance of nature—using the term *ecological equilibrium*—in connection with segments of the natural world identified as communities or ecosystems. These terms indicate the existence of a certain structure ensuring order and stability. This seems surprising in light of Darwin's revolutionary theory of natural selection, which shows how the hereditary characteristics of a population change over time due to their differential reproduction arising out of their struggle for life. Though the emergence of a historical view on nature challenged the traditional belief of a divinely created world, even Darwin went along with Linnaeus's assumptions and considered equilibrium in nature. He wrote in *Origin of Species,* "Battle within battle must be continually recurring with varying success; and yet in the long-run the forces are so nicely balanced, that the face of the nature remains uniform for long periods of time, though assuredly the merest trifle would often give the victory to one organic being over another" The Scottish moral philosopher and pioneering political economist Adam Smith (1723–1790) contributed the idea that competition can lead to equilibrium in a community. From this point of view, Darwin's theory serves to explain the balance of nature and leaves intact the confidence that even in the evolution of life, order would prevail at last, and out of the tangled history of competitive struggle would come progress, harmony, and stability. The knowledge about periods of rapid changes within the course of evolution did not disturb the belief in the overall stability of the system, given that these are externally caused. Additionally, evolutionary change was sufficiently drawn out to leave the relatively stable world of ordinary experience intact.

In the 19th century, plant biologists began to focus on the roles of change and history of plant communities on smaller timescales. In 1899 the American botanist and ecological pioneer Henry Chandler Cowles (1869–1939) published a description of the patterns of vegetation change on sand dunes surrounding Lake Michigan. In his book *Vegetation of Sand Dunes of Lake Michigan,* he formalized the idea of dynamic vegetation succession. Nevertheless, his ideas did not lead to the notion that community change is an unceasing process. Influenced by Cowles's work and his own observations of prairie ecosystems, Frederic E. Clements (1874–1945) developed a comprehensive theory describing the mechanisms and patterns of successive change. This theory of succession, which was widely accepted by ecologists until the 1960s, hypothesizes an orderly sequence of changes in plant communities. One central assertion was that regardless of the types or varieties of disturbances that initiate successive change, succession inevitably leads to a single stable climax community whose composition is determined by the characteristics of the region's climate and has the potential to remain essentially unchanged forever. Though this theory postulates that plant communities change through time, it tends to support the conception of nature as balanced, because the changing occurs according to ascertainable laws and results in a steady state. Furthermore, it indicates that chance historical accidents and past disturbances in a community are erased by succession, whereas the composition of later successive ecosystems contains little or no information about their past history.

After the brothers Howard Odum (1924–2002) and Eugene Odum (1913–2002) developed and formalized the ecosystem theory in the 1950s, nature was conceived as an interlocking series of self-regulating and self-organizing hierarchically ordered ecosystems at various stages of development. Mature ecosystems—characterized by greater stability, increased diversity, and minimal loss of minerals and nutrition—were distinguished from immature ecosystems. Howard Odum even assumed a strategy of development in all ecosystems that is directed toward a world of mutualism and cooperation among organisms living in the same habitat. This goal, which is characterized by a no-growth economy, he called "homeostasis." His idea reappears in John Lovelock's (b. 1919) Gaia hypothesis, which proposes that biotic and abiotic parts of the earth form a complex interacting self-regulating system. This system can be viewed as a single organism promoting life, which Lovelock named after the Greek goddess of Earth.

Though reporters and even scientists persist in using words like *ecosystem, ecological equilibrium, balance,* and *fragility,* and many nonscientists still believe in the balance of nature, after World War II ecological thinking started to shift away from assumptions of order and stability. Until then, the few ecologists who were aware of the possibility of nonequilibria were ignored, but in the past several decades, a revolution has occurred in the worldview of ecologists. Soon after Clements published his influential works on plant succession, a few scientists challenged his theory of a stable climax. One of them was the American ecologist Henry A. Gleason (1882–1975), who worked largely within the theoretical structure of Clements's ideas, before he began to doubt his organic theory of the climax community. Gleason rejected the existence of balance, equilibrium, or steady state in nature and offered, as an alternative, "The Individualistic Concept of the Plant Association" (1926). In this article, Gleason argued that every plant association is nothing but a temporary gathering of strangers, a clustering of species unrelated to one another, and he advanced the view that we live in a world of constant change over time. Clements never responded in print to Gleason's objections and they were largely ignored elsewhere, but gradually some ecologists came to realize that the available data were not sufficient to support Clements's major assumptions. Research by a number of ecologists, for example, the American scientist Robert H. Whittaker (1920–1980) in 1953, supported Gleason's thoughts. In the 1950s, palynologists showed that the vegetation of North America has been in continual flux for at least the past 40,000 years, and the first serious contributions to the discipline that is now called evolutionary ecology were published. Increasing evidence suggests that succession may be governed more by external than by internal factors and that past events influence the properties of current ecosystems. Now it is generally recognized that natural disturbances are a normal part of most landscapes and that the evolution of a population or a species is not the necessary product of any natural laws but rather the outcome of a concatenation of chance events. In 1973 William Drury (1921–1992) and Ian Nisbet challenged not only Clement's but also Odum's theory seriously and rejected completely the assumption that there is a progressive development in nature and that organic nature tends toward order. Many ecologists will now admit that even the ecosystem concept is only a human construct. None of them ever succeeded in isolating one in nature. It is suggested that nature should be seen as a landscape of patches, a patchwork quilt of living things, changing continually through time and space, responding to an unceasing barrage of disturbances.

Scientists after World War II have been finding that contingency plays nearly as big a role in natural history as it does in human history, and instead of seeing a world in balance, most scientists nowadays see a world of flux and uncertainty and regard disturbances as the rule rather than the exception. This raises some questions: Why do the new ecological models seem more plausible to the scientific community than the former equilibrium models? And why do ecologists like Clements and Odum tend to dismiss disturbances as threats to the order of nature? Understanding these questions requires an understanding of how scientific concepts are culturally determined. One reason for the paradigmatic shift—besides empirical data that cast a scientific description of the natural order into doubt—could be the rapid political and cultural changes since World War II. Uncertainty today may seem more plausible than harmony. In addition, among ecologists, Social Darwinists are back on the scene generating new directions for ecology. For them a nature characterized by individualistic associations, unceasing disturbances, and permanent changes may be more ideologically satisfying. A third reason for post-Odum ecology could be the attempt of many ecologists to disassociate themselves from the environmental movement and some branches of environmental ethics, whose supporters still cling to the notion of natural balance as a last bastion of certainty, as a major argument for nature conservation, and as one last source of metaphysical absolutes.

The truth probably lies somewhere in between. Nature works in more than two modes, balanced and unbalanced, and some ecological systems persist in spite of centuries of disturbances—eluding ecologists' models and understanding. One important insight of modern ecology is that landscape patches have different levels of resilience to disturbances. Resilience relying on ecological relationships does not mean the absence of change, for it is defined as the ability to undergo change and then return to a similar but not exact configuration. If ecological relations are broken beyond a certain threshold by a major disturbance, the system may lose resiliency and form a new community. Finally, it has to be stressed that scientific attempts to answer whether nature is balanced or dynamic depend on the selected perspective and the scale of an analysis.

Temporalities of Nature and Culture

The passage of time is a basic experience of human existence; as such, it has been of concern to those interested in religion, philosophy, and science. As discussed previously, however, temporal aspects of the natural world had long been ignored while the focus of attention was on the role of time in human societies. Within the 20th century, the idea that history is not only a feature of human societies but also of the natural world became widely accepted.

Biological processes of change fundamentally entail cyclicalities, such as metabolic cycles, metamorphic processes, and life cycles. They range from the very fast to the very slow. Empirical studies of chronobiologists demonstrate the cyclical behavior of all living organisms, from single cells to mammals, including humans, and with this the importance of this temporal patterning of life. The varied cycles of the body's physiological activities, such as respiration, digestion, or activity–rest cycles, are orchestrated into a coherent whole and function as biological clocks. However, as Barbara Adam (b. 1945) declared in 1990, this "body symphony" of internal time programs is not played in isolation. It is—because of evolution according to the direction of the pressure of natural selection—embedded in the cycles of its environment. It exists as a kaleidoscope of different but connected timescales, constituted by the movement of the earth and its moon in relation to the sun. Therefore, it is the cyclical structure of the physical world that constitutes the cycles of organisms, populations, and ecological relationships. It appears, for example, in the form of circadian, lunar, or seasonal cycles.

The cyclical structure of nature seems to support the notion of an ahistorical natural world, but—contrary to the rhythm of a metronomic beat—cyclical does not mean invariant repetition. Rather it is in the very nature of those cyclical processes to differ in their recurrence. Something similar returns, instead of something identical, based on context-dependent adaptations. It is suggested that this openness of natural cyclic processes to variant repetition allows the evolution of the ecosphere. According to Barbara Adam, precisely these cycles of change, whereby past, present, and future can be experienced by humans, constitute time.

As with all organisms, human life is also ordered and regulated by internal biological clocks and external natural cycles. However, since the invention of mechanical clocks and notably since the use of electricity for industrial applications, social time has become more and more disconnected from the ecological choreography of planet Earth. This cultural decoupling from the cycles of nature in contemporary industrial societies, according to the time-is-money-principle based in the speeding up of social life and economic processes, is supposed to be associated with the current environmental crisis. Nowadays human action is structured not by the cycles of nature but by the context-independent and invariant metronomic beat. The 24-hour schedule of the machine dominates not only the temporal patterns of industrial work but also agricultural food production. One striking example is the acceleration of evolutionary processes by means of genetic engineering of plants.

Facilitated by the exploitation of nonrenewable resources such as fossil fuels, the speedup of production and consumption does not only affect human health but also has potent ecological implications, for it results in an increase of energy use and material flows. The industrial way of life and its approaches to time stand in conflict with the cycles of the natural environment, because renewable resources are used at rates incompatible with the rates of regeneration. One example is the degradation of soils, caused by erosion, salting, compaction, pollution, acidification, and sealing. Because soil takes thousands of years to develop, the recent human action on soils—literally the basement of life on Earth—converts this renewable resource to a nonrenewable one.

Additionally, the vast production of often toxic chemicals results in environmental pollution when those substances introduced into nature cannot be readily decomposed. The process of global warming is an example currently being debated. This process, also called the greenhouse effect, is thought to be the outcome of an increased concentration of carbon dioxide in the atmosphere, based on combustion of fossil fuels associated with accelerated industrial activity and other human activities, like tropical deforestation. Nitrous oxide is another gas that absorbs infrared radiation and, therefore, also contributes to global warming as human activity increases its concentration in the atmosphere. To date, humans have roughly doubled the input rate of fixed nitrogen into the ecosphere by combusting fossil fuels, planting nitrogen-fixing crops, clearing land, draining wetlands, and producing fertilizers. This not only has severe implications for the atmosphere. Nitric oxide is a principal cause of acid rain, which results in declines in soil fertility and acidification of freshwater lakes and streams. Nitrogen washed into aquatic systems has caused blooms of toxic algae and die-offs of fish associated with eutrophication.

These few examples indicate how economical timescales endanger ecological timescales. There are further consequences for ecological relationships. If the environment changes slowly enough, populations can ride with the tide of change by, for example, adapting via evolution or by migration. However, if the anthropogenic environmental changes exceed the maximal speed of adaptation, severe disturbances will follow. Ecological relations may be broken to the point that resilience of systems is lost and adaptation of the ecological processes to the new situation is no longer possible. Therefore, fast changes may destroy communities in a flash. This already takes place, as we have observed in the mass extinctions of species.

The environmental movement reacts to this acceleration of social life with its claim to conserve imperiled species and places. But this goal of conservation—though comprehensible given the fast anthropogenic changes of the natural world—may ignore the dynamic structure of nature as well as the industrial way of life. Environmental changes are the norm and occur across all timescales. Even natural catastrophic changes, such as triggered by volcanic eruptions or asteroid strikes, are able to destroy human resiliency. Nevertheless, the anthropogenic disturbances seem to be of a new quality and quantity. This raises an important question: What rate, quantity, and quality of change can be accepted? This is not an ecological but rather an ethical question.

To systematically recognize and establish the relevance of the temporal dimension of cultural time for the so-called ecological crisis, the Time Ecology Project was initiated 1991 at the Protestant Academy of Tutzing in Germany. One member, Barbara Adam, is the author of numerous publications on cultural and natural time and the founding editor of the journal *Time and Society.* In her monographs on time, she charts the importance of recognizing the multiple time frameworks of nature for our daily lives. The field of *time ecology* focuses on the mutual implications of time and ecology as one step toward ameliorative action with respect to environmental matters. In search of a time politics that shifts concern from the pursuit of total time control to the appreciation of the cyclical structure of nature, proponents of time ecology search for approaches to time that are sensitive to the temporalities of the environment. Human intervention into a natural system should allow a development of this system in its own timescale. Therefore, it calls for a balanced relationship between human technological interventions and environmental processes; it seeks a balance between the human timescale of consumption and resource depletion on the one hand and the environment's capacity for regeneration and reproduction on the other. This shift in human attitude toward nature, associated with awareness of the ecological significance of time, is a step toward achieving sustainable development, minimizing environmental degradation, and halting or reversing the process of exhausting natural capital faster than it can be replenished.

The Concept of Time in the Field of Ecology

In summary, the history of ecology as a scientific discipline shows that from its beginning, the concept of time played a central role. Early ecological thinking was especially influenced, for example, by Darwin's theory of evolution and his protoecological view. Nevertheless, for a long time most scientists ignored that history as one conception of time is not only applicable to human societies, but also to the ecosphere. They clung to the notion that nature is inherently balanced. It was thought that ecological communities have the potential to remain essentially unchanged forever and that serious changes occur only because of external disturbances. Even then, if climatic conditions persisted, a succession would lead inevitably to the former climax community. In this way, chance accidents of historical events were thought to be erased. Such ideas were increasingly questioned after World War II. Within the scientific community more recently, it has become widely accepted that the natural world changes continually through time and that evolutionary and ecological processes affect each other. On this basis, the discipline of evolutionary ecology developed.

Time plays a role in ecology in more than a historical sense as well. The evolution of the ecosphere is influenced by the cyclical structure of the natural world. Time-consuming cyclical processes, like the flux of energy and matter through ecosystems, exist as different but connected timescales. All organisms, including humans, are embedded within these cycles. Nevertheless, after the Industrial Revolution an increasing decoupling of social time from the cycles of the natural world can be observed. Ignoring the ecological timescales in favor of economic timescales is thought to be one important reason for the environmental crisis. The claim of the environmental movement to conserve imperiled species and places is a reaction to the fast anthropogenic changes of the ecosphere. Nevertheless, environmental changes are the norm and occur across all timescales. The extent of acceptable anthropogenic changes is an increasingly pressing question—not only for ecological scientists but also for environmental ethicists.

Economics

The term *economics* is derived from the Greek words *oikos* (house) and *nomia* (law). In ancient Greece, it was used to describe the management of the household. Today, the word is used in a much broader sense and describes the complex interactions of economic systems, including the production and exchange of goods and services. Economic evolution through time represents the different transitions from a subsistence economy, where people tried to satisfy only their basic needs, to today's highly industrialized and globalized economy. The evolution of economics as a social science attempts to describe the most influential persons, concepts, and theories in order to give some fundamental answers to the basic question: Why did it happen? Economic evolution, from prehistoric roots to the modern world, has been a multilinear process. However, complex developments may be broken down to several main milestones in human economic history. The starting point is the prehistoric developments that began the step-by-step economization of human life.

Prehistoric Developments

About 1.6 million years ago, the emergence of *Homo erectus,* a predecessor of the modern human, can be considered as the initial point for prehistoric economic development. *Homo erectus* was the first human who was able to use fire, which changed the life of prehistoric humans in a tremendous way: Apart from offering a better and a new method of hunting animals, fire also allowed for cooking meat. This then resulted in better nutrition because it made meat easier to chew and to digest. In addition to the use of fire, the creation of different tools made of stone and wood was an important characteristic of *Homo erectus* life. This reflected the ability to adapt to different needs and to the changing climate conditions of the Ice Age. Because they were foragers, their economic life consisted of hunting wild animals and gathering wild fruits and roots for only their own needs (subsistence economy). At this stage, there was no private property, and mobility was the key to consistently supplying the members of the community with food. It can be assumed that the foragers were already able to develop hunting strategies, which were realized in small groups of about 30 people. Tasks like observing, hunting, and carving could then be allocated among the different group members; this can be considered as an early form of the division of labor. Another advantage of organization in small groups was the possibility of hunting bigger animals to gain more meat with less effort. Hence, foragers already had to be efficient, productive, and innovative to survive.

The First Agricultural Revolution

From about 15,000 BCE to 10,000 BCE another economic transition took place: Specialized economic forms emerged in different geographic areas as a response to the various climate conditions marking the precondition for the development of early civilizations. Tools and weapons became more sophisticated, making hunting easier and more efficient, for example, with the use of bows and arrows, lances, or other long-distance weapons. Moreover, the foragers started cultivating plants or domesticating animals, and overproduction was stored. Hence, the economy changed slowly but consistently from subsistence to bartering and from a possessive to a productive economy. The improvements in food production led to higher population densities and to a change from nomadic to a more sedentary life. As a result, humans were no longer restricted solely to the locally given resources of nature but also created the environment themselves. Fostered by temperate climatic conditions about 8,000 years ago, fertile soil was created, and agriculture became the dominant economic form. Additionally, grazing land and water promoted the development of a high population density, which was the starting point of early civilizations. Food production was no longer driven by coincidence but by the cultivation of plants and the domestication of animals. The advantages of having a meat supply are obvious. Besides meat, other products could be gained, like wool, skins, and bones. However, agriculture was a seasonal activity, and the increasing demand for food due to the growing population resulted in strategies to stabilize the food supply. This resulted in new types of storage, transportation, and the development of lasting agricultural techniques. Consequently, the exchange of goods (e.g., nutrition, tools, and raw materials) was no longer limited to the immediate vicinity; the first interregional trade routes can be determined by archaeological findings. One example is the Fire Stone Route between Bohemia and Bavaria, dated about 7,000 years ago with a distance of 250 kilometers. However, these trade connections were, for the time being, of small importance. The revolutionary steps were to take place in agriculture.

The invention of irrigation systems and the plow, about 6000–5000 BCE in Mesopotamia and Egypt, can be seen as the First Agricultural Revolution (sometimes still called the Neolithic Revolution, even though it had been neither neolithic nor a revolution in the view of many prehistorians). The farmers were now able to dig up the soil, and the use of axes enabled them to clear the fields of wild plants and brushwood, which increased the efficiency of agricultural production. New technologies of storage were invented, like grain bins or jars, that allowed the people to retain the surplus of a harvest for lean times or to trade it against other goods and services. Pottery also played an important role for storage, plates, mugs, cooking tools, and art. Pottery was produced as early as 8000 BCE, but the invention of a fast rotating potter's wheel about 4000 BCE made pottery products one of the earliest mass products. Another innovation was animal domestication. Even though it is not quite clear how the domestication of animals began, the domestication of wolves to dogs, of wild to domestic goats and sheep, of aurochs to cows, and wild cats to domestic cats can be estimated to have occurred about 10,000 to 7000 BCE. A few millennia later, about 4000 BCE, horses and donkeys were domesticated. Not only were domesticated animals used for meat, wool, or milk supply, but they also played an important part in specialized tasks, such as plowing or transporting. As a result, agriculture and animal production became an important driver for the emergence of chiefdoms and the world's first states. Building permanent houses instead of using temporary camps as in of earlier times, resulted in stronger social links among the villagers, enhancing the development of human social complexity. Reciprocity and kinship ties became more important in agricultural societies, as it was no longer possible to move away in cases of social disputes. Additionally, the reciprocal networks of a clan's members helped them to survive in cases of crop failures or other emergencies, knowing that they would get assistance in turn if they would need it one day. The farming societies relied also on trade and exchange, as many commodities were not locally available.

Thus people who controlled the exchange networks were able to gain power and to become chiefs of the interconnected village societies. Whereas early forms of farming societies have been egalitarian without a social hierarchy, the new and more complex societies were under the control of the chief and his family, creating an elite. Inequality, with usually two or sometimes even three tiers of hierarchy, became common for these prestate societies. However, chiefdoms were a relatively unstable form of social organization, as leadership did not necessarily pass from one generation to another. Consequently, it was often a system of collapse and renewal. Chiefdom societies (e.g., Thy in Denmark/Northern Europe about 2300 BCE) emerged almost everywhere in the world, but none of them was able to gain control over more than a local or regional area. Thus state-organized societies must have had some institutional advantages, being economically superior to chiefdoms over time.

The Urban Revolution

Another technological breakthrough was the invention of metallurgy (e.g., copper, bronze, and iron) in approximately 4500 to 3000 BCE, making possible the invention of a wide range of new, improved tools, thus enhancing efficiency even further. New professions, such as craftsmen, arose, and the division of labor advanced. However, the new exotic raw materials were not accessible everywhere; this resulted in an intensification of long-distance trade. All this was the fruitful environment of what is sometimes called the Urban Revolution. The increasing complexity and the growing interactions would have required a certain form of organization to be efficient. This resulted in the formation of cities and, later, state-organized societies.

The first cities and state-organized societies came into existence between 4000 and 3000 BCE in Egypt and southern Mesopotamia, which is commonly referred to as the origin of civilization and was later the home of the Sumerians. Characteristic of civilized societies are literature, religion, and monumental structures (e.g., the pyramids). Being central in their respective regions, a city had the task of providing services to its citizens and to the surrounding area, being itself dependent on the food production of the rural area. Centralized institutions were necessary to organize the different needs, such as infrastructure or security. Whatever the complex factors that led to state-organized societies, they changed the way of life in a tremendous way. Development was not limited to new inventions such as complex irrigation systems, the wheel, or transportation by water, but led to institutional changes like state religion, taxation, and legislation. People such as priests, state executives, and soldiers could be taken out of the production process to serve society. Capital could be accumulated, which could then be spent for monumental architecture, for military purposes, or for the infrastructure. States therefore played an important role in the new economies. They purchased goods and services with tax revenues, employed people, and regulated commerce.

Additionally, pictography as a form of script was first used in Mesopotamia and was the basis for the cuneiform writing developed later by the Sumerians. Writing was another cornerstone in the economy, as it allowed formal record keeping and advances toward science and mathematics. Thus class societies evolved with some people forming the elite, accompanied by an increasing demand for luxury goods, which were often exchanged by long-distance trade (e.g., gemstones sourced by the Sumerians from the Indus Valley civilization). A famous ancient trade route was the European Amber Route, which led from Northern Europe to Italy. As important as these trade connections were for increasing wealth and enhancing economic growth, the instability in terms of the rise and fall of ancient states and cities resulted in unstable trade connections, both in domestic markets and in foreign trade.

Despite the remarkable progress made by these early civilizations, the subsequent era of classical antiquity, with its unique features, nevertheless represents a major shift toward civilization and has been most influential for the evolution of the Western world.

Economy of Classical Antiquity

The beginning of ancient Greek and Rome society, about 800 BCE up to the fall of the Roman Empire in 476 CE, marked the era of classical antiquity. Between 750 and 500 BCE the Greek states Sparta, Corinth, and Athens were on the rise, and democracy as a new form of state organization came into being. Even though democracy played only a rudimentary role in ancient Rome, the Roman Empire is known for establishing a code of law as the basis for a legal system and—when further developed—a constitutional state. Democracy and a trustworthy legal system are the foundations of modern civilization and economic growth, as they guarantee political, legal, and economic stability. Additionally, the first coin in ancient Europe was embossed about 650 BCE in Lydia (China had been using coin money since 2000 BCE). Earlier, noncoined forms of money of various kinds, like shell money, salt, or crops, were used to pay for goods and services. The advantages of exchanging goods for money instead of other goods include easy countability, less transportation, and suitability for storage. As a result, money facilitates transactions in the economy and is therefore a driver of economic development.

Philosophy evolved in ancient Greece, with Socrates, Plato, and Aristotle as its most famous exponents. Philosophers reflect human thinking and behavior with the aim to explain why the world and human beings exist. The theories of the ancient philosophers therefore built the basis for the worldview of the occident so that they developed even up to now. But, philosophy can also be seen as the earliest predecessor of economics as a social science. Aristotle, for example, gave economics its name (*oikonomia*). In his view, economics has the task to ensure the survival or subsistence of human beings. Thus it has only an assisting function for the well-being of a society. Besides expounding the importance of economics for a society as a whole, Aristotle also developed a monetary theory. Money, he recognized, can be used as a medium of exchange, as a measure of the value of a certain good, and as a measure for the intensity of wants and needs. According to his theory, money also has an intertemporal function, as it is possible to save it for future investments. It allows for the taking out of loans, which means that people can satisfy their needs now and pay for them later. Last but not least, Aristotle attributed a social function to money in the sense that without trade money, neither barter nor community is imaginable. Aristotle's seminal work on justice is likewise notably for economics. He was one of the first to develop a comprehensive theory of justice. His concepts of distributive justice (in Latin, *iustitia distributiva*) and commutative justice (*iustitia commutativa*) continue to influence social thinking. He realized that economic growth and fair distribution are the cornerstones of social living, thus linking economics and morality.

In classical antiquity, highly differentiated empires emerged in Greece, Rome, and China and were associated with an intensified intercontinental long-distance trade. The Silk Road, for example, an 8,000-kilometer ancient trade route on land and sea between China and the Mediterranean, shows that various goods like spices, gold, gemstones, ivory, glass, porcelain, and—where the name comes from—silk were traded bidirectionally. Not only were goods exchanged but also aspects of culture, religion, and information. Silk was nevertheless the most demanded luxury good by the Roman elite. However, safety was a crucial issue in ancient times, as pirates held up the caravans. Despite harsh conditions concerning safety, climate, and geographic barriers, the Silk Road was an important achievement of the ancient world, especially in terms of economic growth for the connected states, and it can be seen as an early form of globalization.

Besides, the early Romans recognized the benefits resulting from a good infrastructure. The construction of roads helped link together the far-reaching provinces of the growing empire, which accelerated the flow of information and supplies and facilitated the relocation of troops.

From the Middle Ages to the Scientific Revolution

After the fall of the Roman Empire, political and economic instability were the dominant features of the early Middle Ages. Those people who lived in a city for a certain period lost their status as serfs and were released from doing compulsory labor. Searching for liberty, many people migrated into the cities, fleeing from their lords and seeking better working conditions in the 13th and 14th centuries. In return, cities had to organize their markets and ensure safety. However, the intensified creation of marketplaces, which brought together supply and demand for goods, had helped boost trade connections among the medieval cities. The right to hold markets ("market rights") was usually restricted to cities with town status, that is, cities with certain privileges. Both market rights and privileges boosted the attraction of cities as working and living environments. Because of the growth of cities, the increasing demand for goods had to be satisfied. Thus certain occupation groups, like craftspersons and salespersons, syndicated into guilds. Guilds limited the access to their professions, as professionalism depended on the membership of the appropriate guildsman. As a consequence, guilds were able to restrict competition and keep prices high, which contradicts the economic concept of free markets. Accordingly, guilds succeeded in building power as they participated in municipal councils, which were responsible for trade legislation or regulation. In some areas the economic and political power of the guilds was used to create monopolies or even to take over the control of some cities. Famous examples are the Hanseatic League or the Fugger dynasty; both were able to dominate the commerce in northern Europe from the 13th to the 17th centuries. During that time, the city-states in northern Italy, like Venice, Florence, and Genoa, became the center of economic power in Europe. Their seaports were important trade connections between the Occident and the Orient, and to Africa, so that they could act as intermediary traders. Venice, for example, established a power monopoly with salt, which was a highly demanded good, as it was used for conserving meat and fish. While wealth and capital accumulation increased dramatically, the need for banks as an intermediary was also growing. Thus the foundations of a modern banking system with bookkeeping, cashless transactions, and new institutional structures were set in northern Italy in the late Middle Ages.

The era of transition from the Middle Ages to modern times is generally called the Renaissance, which took place between late 14th century and the 16th century, depending on the country. Art and education flourished as rich patrons supported artists like Rafael, Leonardo da Vinci, and Michelangelo Buonorroti. It was now feasible to draw more natural images and to paint more realistic copies of reality. Humanism became the leading idea of the Renaissance, driven by the thought that each human being is responsible for his or her own fate. Additionally, in 1450, the invention of movable-type book printing by Johannes Gutenberg is also considered one of the preconditions for the transition to modern times. It now became possible to print large numbers of books, thus driving the acceleration of knowledge transfer in Europe. Simultaneously, huge efforts were made to discover new land and resources by sea, driven by increasing imperialism. In 1492 the explorer Christopher Columbus discovered the New World (in fact, the Vikings landed on American ground around 1000 CE, and there is some evidence that 12,000 years ago Asiatic clans migrated over the Bering Strait and all the way to South America). However, all these events took place in the 15th and 16th centuries, which is sometimes called the Commercial Revolution.

Seeking economic expansion, European states tried to found colonies throughout the world and to link them together for international trade networks. Some historians argue that globalization, a concept used today to describe intensified international cross-links, can be attributed to developments in the 15th century. The discovery of the sea route to India by Portuguese explorers is another example of expanding international trade. Spices like pepper, cloves, and cinnamon, which were unavailable in Europe but of high value not only for flavoring food but also for medication or for conservation of food, were conveyed directly through the new sea route. From an economic point of view, the sea route broke the Venetian monopoly as an intermediary, which then resulted in lower prices. Demand and supply increased, enhancing economic growth. Lisbon and Antwerp were especially able to benefit from the new sea routes, establishing them as the new financial and commercial centers of Europe. Consequently, the first stock exchange was established in Antwerp in 1531. Later, Amsterdam became the new economic power and financial center until the Industrial Revolution.

Besides trade, important advances took place in the field of science around 1600, which is now referred to as the Scientific Revolution. The prevailing theories about physics and astronomy were revised, supported by inventions like the microscope and the telescope.

All of the previously mentioned developments were results of the so-called preindustrialized civilization, as they are based mainly on manual labor rather than the use of industrial techniques run by fossil fuels. The Second Agricultural Revolution prepared the ground for a drastic change in production techniques, which is known as the Industrial Revolution.

Second Agricultural Revolution

Not until centuries later did advances in agricultural techniques in Britain prepare the ground for the modern world. Taking place in the 18th century and also referred to as the British Agricultural Revolution, a series of developments resulted in an enormous increase in agricultural productivity. The selective breeding of livestock, enclosure (i.e., the conversion of common land to private ownership), and new farming systems such as crop rotation instead of the three-field system (e.g., wheat and barley in two, with the third fallow) and the cultivation of higher-yielding crops boosted the output of food. Furthermore, in 1840, the invention of mineral fertilizer by the German chemist Justus von Liebig also enhanced agricultural productivity. Thus the food surplus was now remarkably sustainable and able to keep pace with the expanding population, contradicting the influential views on population growth by the British economist Thomas Robert Malthus. In his "Essay on the Principle of Population" (1798), Malthus developed the theory that population increases at a geometric rate (1, 2, 4, 8, 16, etc.), whereas the food supply grows only via an arithmetic sequence (1, 2, 3, 4, 5, etc.). Hence, population growth, if uncontrolled, will unnecessarily lead to famine. However, Malthus failed to recognize the human ability for substantial technological advances, which took place as described earlier. As food output rose, fewer workers were needed for agricultural production, making them now available for industry.

Industrial Revolution

Technological improvements in agriculture enhanced industrialization and vice versa. This transition from an agricultural to an industrial society is also known as the Industrial Revolution, which had its starting point in Britain in the late 18th and early 19th centuries. Even though the complex factors that caused the Industrial Revolution are still a topic of debate, it can be assumed that changes in the social and political system were also helpful for the emergence of the industrial economy. The end of feudalism; colonial expansion; advances in medicine, accompanied by lower infant mortality and fewer epidemics; and local resources of coal, iron, and copper all resulted in excellent conditions for the development and expansion of the industrial sector. Thus Britain could be considered a relatively open society, allowing for the formation of a large middle-class society with the opportunity of social advancements. Entrepreneurship and the willingness to invest were high as capital accumulation rose. Additionally, a Protestant work ethic (or Puritan work ethic) influenced by Calvinism emphasized the necessity of an ascetic lifestyle. Economic success and the accumulation of wealth were seen as signs of personal salvation. The theoretical framework for the Protestant work ethic was later developed by the German sociologist and economist Max Weber (1864–1920). Liberalism became the dominant principle for the economic order, influenced by the seminal work of the Scottish moral philosopher Adam Smith (1723–1790). His influential treatise "An Inquiry Into the Nature and Causes of the Wealth of Nations" (1779) is commonly referred to as the rationale for capitalism and as a precursor to the academic discipline of economics, also called political economy. According to Smith, free trade and free markets will, in time, lead to the most efficient outcome in the sense that the right amount of various goods will be produced. There seems to be an "invisible hand" that brings together supply and demand, keeping prices low and therefore maximizing society's welfare. The economic concept of capitalism requires the private ownership of resources (i.e., labor, capital, land), assuming that everybody strives for profit maximization. Then, the allocation and distribution of goods is accomplished efficiently only by the market itself. Smith was opposed to guilds and government interventions (e.g., tariffs), even though he believed the state must play an important role by setting the legal and political frameworks for free markets and by providing goods, like public education or an army.

The complex interactions of geographical, economic, political, and social structures provided a fruitful base for the British Industrial Revolution. Here, it started with the mechanization of textile industries, especially the processing of cotton. In 1733 the clock maker John Kay (1704–1780) invented the flying shuttle, which carried the weft yarn mechanically from one side to the other with more speed and higher accuracy than it was previously done by hand. Hence, the speed of weaving accelerated and worker productivity more than doubled. As a result, the production of yarn posed a bottleneck problem, as it could not keep pace with the accelerated speed of weaving. New spinning machines were therefore necessary to solve this problem. First, James Hargreaves with his hand-operated spinning jenny (1764) and later Richard Arkwright with his water frame (1771)—a water-powered spinning machine—revolutionized the fabrication of cotton yarn. But it was Samuel Crompton who achieved a breakthrough in industrial yarn production by inventing the spinning mule in 1774—a combination of the spinning jenny and the water frame. These inventions marked the beginning of industrial mass production. Instead of small spinning and weaving companies, multilevel factories emerged. The cotton industry became the crucial sector and set the pace for economic expansion. Additionally, the factory as a new working environment was established. Although the textile industry played an essential role in driving the economy, other inventions and developments were important: First, the discovery of bituminous coal led to improvements in iron making. Second, both growing demands for resources and increasing trade required the expansion of roads, canals, and, later, railway networks (the first steam locomotive began operation in 1804). Last but not least, technological improvements in the steam engine were also a major source of economic growth. In 1769, James Watt succeeded in stopping the enormous energy loss inherent in early types of steam engines, thus improving the effectiveness and power output of these machines. Initially employed in mining to pump out water, the Watt steam engine was then used in other industries such as mills, breweries, and all kinds of factories, as it was able to produce mechanical work to a virtually unlimited extent. It is worth noting that industrialization occurred worldwide—even though at different times and with variations in length and process—and represented a major shift in human history. The gradual replacement of human hands by fossil fuels changed not only the technological but also the social and cultural conditions. More and more people migrated into the cities to find jobs; this resulted in an excess supply of labor, forcing workers to accept low wages and poor working conditions. Thus women and even children had to work for starvation wages to support their families. Moreover, the high migration into the cities caused a housing shortage and fostered the formation of slums.

Driven by these social grievances, the German philosopher and political economist Karl Marx (1818–1883) developed the economic concept of communism. In his theory, capitalism leads to an exploitation of workers, as entrepreneurs are able to make profits by paying low wages to their workers. As a result, workers feel alienated. The divergence of interests between owners and workers would inevitably result in a revolution. In the long run, communism would become the new order, including a classless society and the public ownership of resources. Even though Marx's ideas were controversial, debated, and commonly rejected, they initiated government intervention for the sake of improving the working conditions for the poor and, later, for bringing about social security legislation. However, the Industrial Revolution was the starting point for a sustainable period of enormous economic growth never seen before.

Today, historians prefer the term industrialization to describe the period of technological advancements lasting up to now, whereas the term *industrial revolution* generally refers to radical innovations within the process of industrialization leading to an accelerated growth in these industries. Hence, the control of electric power, groundbreaking advances in chemistry, and the invention of the automobile are also regarded as industrial revolutions.

Since 1911, these developments were also assisted by the efficiency movement. The American engineer Frederick W. Taylor (1856–1915) started analyzing workflows with academic methods to enhance worker productivity and is therefore credited as the founder of scientific management (or Taylorism). He thought that any workflow should be split into its separate components. Then, according to the "one best way" principle, precise work instructions are needed to assist the workers with the most efficient way to perform their task. For this purpose, Taylor conducted several comprehensive time and motion studies to find the least number of motions for a given task—a technique that is often cited in management textbooks. A few years later, the American entrepreneur Henry Ford (1863–1947) brought these concepts to perfection by inventing the assembly line in 1913 and thereby setting a new standard for mass production, particularly for large-scale manufacturing processes. With the standardization of production processes, less-skilled workers were needed, and it was the management's task to control and plan the working steps efficiently. Besides the advances in production technology and processes, two other inventions revolutionized not only the working environment but also the way of modern life: the digital computer and the Internet.

Digital Revolution

In contrast to analog technology, where signals can have infinite valences, digital technology can be used to transform analog signals into a binary combination of ones and zeros. Greater flexibility, lower cost, and the prevention of error propagation made digital technology superior and promoted the development of computers. The earliest digital computers can be dated back to the 1930s, but the most important developments were made in the 1970s, when the microprocessor and the personal computer were invented. Additionally, the invention of computer networking and the Internet, as well as digital broadcasting, also induced the Digital Revolution. The Digital Revolution marked the beginning of the Information Age and enhanced the emergence of new businesses and professions, such as software developers, computer technicians, and companies such as Google, eBay, and Amazon, whose business models rely on only the Internet. In contrast to the industry sector, the Internet-based and Internet-related businesses (the "dot-coms") are often summarized with the term *New Economy.* The Internet hype in the late 1990s caused a high demand at the stock markets for these companies' shares even though many of them had never made any profits. As a result, market capitalization of many New Economy firms far outreached their book value. However, the dot-com publicity peaked in 2000, at which time the speculative bubble at the stock markets burst, putting the whole world economy in trouble for years.

The Future

Today, the question remains: What might be the next revolution? Nanotechnology is a promising field as it allows the production and control of devices on a scale smaller than 1 micrometer. Further, new forms of generating energy, such as solar, wind, water, and biomass, could lead to an energy revolution. Colonization of space with interplanetary transportation is imaginable. This would probably require new social, political, and legislation structures and new innovations, resources, and professions for the space age environment. Even machines that accomplish all the work for us might be another revolutionary step in human economic future. Time will tell.

Education and Time

What is the never-ending task of education? This question has been asked and answered by inquiring minds throughout history. Not surprisingly, the responses have been complex. A credible reply is found in the autobiographical *Education of Henry Adams:* "From cradle to grave this problem of running order through chaos, direction through space, discipline through freedom, unity through multiplicity, has always been, and must always be, the task of education" The task does not change. The means to accomplish it are, however, many and varied.

In considering the task of education over time, it is well to examine how education has progressed over the years in representative nations across the continents. This entry considers the earliest vestiges of educational pursuits, as well as adaptations over the past 150 years, in Africa, Australia, the Americas, and Eurasia. Attention is given to the human and material price of progress.

Republic of South Africa

Historically, education in South Africa was centered in each village, where children were taught the survival skills necessary to subsist in a subtropical climate that is home to "The Big Five": buffalo, rhino, lion, leopard, and elephant. Early African education was not institutionalized, and black African families were multigenerational. Women were considered subservient and were often subject to spousal violence. For centuries, both boys and girls learned their roles from their elders in the language spoken in their own regions.

With the 17th century came white dominance. White Afrikaners (Dutch South Africans) reigned supreme, and in the mid-1800s ethnic-specific boarding schools were established with the dual purpose of producing laborers and precluding uprisings among the natives. Literacy was not a priority in these schools, cost was a factor to poor families, and children from rural areas had little opportunity to attend. In contrast, white children were educated in private schools, many of British origin. The disparity between black and white schools increased with the institution of apartheid in 1948. The Christian-based National Party denied blacks access to any white-only areas, particularly schools, and imposed Christianity on students regardless of their religious affiliations. Blacks were not allowed to travel freely. In 1953, the Bantu Education Act was passed, further discriminating against blacks and resulting in only 1% of all funding to reach black schools. Students were coerced into learning the Afrikaans language, and they continued to be educated to do manual labor. In 1976, while the United States was celebrating its bicentennial, 600 South African students were massacred in riots while protesting against inferior schools and the unwelcome heavy use of Afrikaans in the school system.

Since the fall of apartheid in the late 1980s, measures have been taken to integrate the schools and to revise the curriculum to include literacy, mathematics and science, life skills, history, and geography. Lessons began to be taught in English and in a native language of choice: Ndebele, Sepedi, Zulu, Setswana, Xhosa, Venda, Swazi, Xitsonga, Tsonga, or Sesotho. Budgets for educational improvements were astronomical. With the election of Nelson Mandela as president in 1994, marking the official end to apartheid, school populations grew to over 12 million black and white students in more than 30,000 schools. Presently, 87% of males and 86.7% of females over age 15 can read and write. Desmond Tutu coined the phrase "the Rainbow Nation" to illustrate the diversity of the South African people. And, so that they did not die in vain, President Mandela's new government declared June 16 as Youth Day in memory of the 600 protestors who died in Soweto.

Australia

Prior to the arrival of the English settlers in Australia, the Aboriginal people who populated the continent lived a pastoral life. Boys learned to hunt and to plant from their fathers, and girls learned to rear children and to maintain the home from their mothers. Institutional education did not exist until the early to mid 1800s when early English settlers and clerics established private schools for the purpose of domesticating the tribes. By the late 1800s each Australian state had passed public education laws that funded public governmental schools and, to a lesser degree, private denominational schools. Funding for private schools was fully guaranteed in 1964 when Parliament affirmed the practice. As the Commonwealth developed, there were major efforts to unify states in terms of common goals for education, but the outcomes of the conferences were only with regard to schools remaining free, compulsory, and secular in nature, with authority and funding to remain the responsibility of the states. Only in the Capital Territory, in and around Canberra, near Sydney, did the central democratic federal-state government determine educational processes and practice.

Australia is made up of six states and two territories; most people live in and around the large cities and work mostly in the manufacturing and tourist industries. Only 5% of the total workforce is involved in farming. Over time, interest in educating Aboriginal and other agricultural populations has become keen. An important innovation, facilitated to expand educational opportunities to the native people and to people in the remote areas of the outback, is a system of schooling named School of the Air. To communicate, two-way radios are used by teachers and students. Follow-up is carried out via the Internet, facsimile, or the mail. Instruction is done in an Aboriginal language and in English, and, in both the School of the Air and in city schools, Japanese is studied. Australia is a mecca of cultural diversity, and more than 200 languages are currently spoken there.

Unlike schools in the northern hemisphere that traditionally begin in September and end in June, schools in Australia begin the academic year in June and end in September. Students wear uniforms sewn of cotton, and children wear hats with a neck flap to shield their necks and shoulders from the sun. Sunnies (sunglasses) and sunscreen are required for students. Sometimes children are rewarded for their hard work and compliance to rules with little treats called *lamingtons,* small sponge cakes that are drenched with chocolate and topped with shredded coconut.

Throughout history, education has been strongly influenced by Western educational philosophy. Continual reformation has brought about dynamic and progressive change. Australia's literacy rate is currently 100%, and there are 20 colleges and universities on the continent. Australia is ranked high on the international stage for exceptional schools.

Mexico

Education in Mexico has changed dramatically over the years. Mexico has entered the 21st century with a national system of education dedicated to meeting the needs of all Mexico's children from the rural Mayas in the south to the Mestizo miners in the north. These ideals, however, have not as yet been fulfilled. Emanating from a society where only the elite attended school and education was the sole responsibility of the Catholic Church, a secular system of education was extremely costly and difficult to establish. The country was largely illiterate. Initial credit goes to President Benito Juárez. Juárez rose from poverty by way of a sound education. He focused on increasing the number of schools in Mexico, and by 1874 there were 8,000 schools, and public education was declared a universal right.

José Vasconcelos, director of education in the early 1900s, popularized the notion of education for the masses, and through his efforts, the education budget was more than doubled between 1921 and 1923 to 35 million pesos. Vasconcelos dispatched teachers, agriculturalists, home economists, and artists to remote villages to teach literacy, numeracy, and technology. Opportunities were advanced to women. A lively and enduring Mexican identity and cultural nationalism took hold.

For a time, the third article of the Mexican Constitution was amended to proclaim "State education will be socialist in nature." New curricula were written to emphasize the leading roles of the workers during the Mexican Revolution. Catholic education was basically tolerated, but great opposition was mounted against powerful landowners and foreign property owners. Revolution bore industrialism, and prosperity followed. Money became available for education, and literacy rates rose to 57% before World War II. The word *socialist* was removed from the Constitution. Catholicism remained, and still remains, the religion of 95% of all Mexicans.

Education continued to be a priority throughout the 20th century. Cost-effective prefabricated schools, furnished with teacher residences, were built to attract teachers to the rural villages. Free textbooks and workbooks, some in the 50 or more indigenous languages of Mexico, allowed more children to remain in school. Mexico became the first country in the world to offer *telesecundarias* (distance learning), and by 2004 the overall literacy rate reached 92%. This is significant because only one quarter of all students remain in school until age 16. Poverty plagues the society, and many poor Mexican families harbor detrimental anti-intellectual attitudes. Only a small percentage of high school graduates go on to higher education. Despite these problems, amazing progress has been made in the federal republic. Mexico City University, founded in 1551, is the oldest and largest university in all the Americas. Nonetheless, until students from the Mexican countryside have an equal opportunity with their counterparts in the cities to attend college or university, the absolute success of the Mexican educational system will not be realized.

Iraq

Iraq has a magnificent history of intellectual pursuit. What other country can boast the invention of the wheel, utilization of the first alphabet, or rank among the first to study mathematics and astrology? Indeed, the oldest university in the Arab world, Mustansiriya University, founded in 1234, is located in Baghdad. Relatively modern educational practices were introduced to Iraq by the British in the early 1900s, but student enrollment was low and the literacy rate was only 20% of the Iraqi population. Upon Iraq's becoming a republic in the late 1950s, great strides were made by the new government to construct schools, raise enrollment, and more than double the literacy rate. From kindergarten level to university level, tuition was free. The government provided all materials and texts. Teachers were paid well, and schools were in very good condition. More boys than girls attended Iraq's gender-segregated schools. Age-old gender bias existed, and Muslim women wore the *hajab* or the *burka*. It was believed that separating the sexes resulted in children's being better able to concentrate on their studies. Also of note is that more children from the populous areas went to school than those from rural areas. The nomadic and seminomadic people raised sheep, goats, cattle, poultry, and horses. School-age children were needed by their families to tend the livestock. Education was a luxury for them, not a priority.

According to Roger Wright, UNICEF representative to Iraq, "Iraq used to have one of the finest school systems in the Middle East." That is no longer the case. From 1979 to 2003, the pan-Arab and socialist policies of the Baath Party were enforced by Saddam Hussein. Iraq became a dictatorship where the people had little influence on the government. During this time, the Iraqi economy and its exemplary system of schools were adversely affected by neglect, underfunding, and war without end. The fall of Saddam Hussein in 2003 did little, however, to alleviate the deterioration of the schools and the school system. Harsh economic conditions caused some of the youngest children to drop out of school and beg on the streets of the cities. Parents feared sending their children to school. In Baghdad, alone, bombs destroyed, damaged, or burned hundreds of schools, and thousands of them were looted.

Even today, children who do attend school find the buildings in disrepair, with broken windows, weak foundations, and leaking roofs. Running water and sanitation facilities are defunct. Furniture, equipment, and materials are scarce. Teachers are disillusioned. They teach two and three shifts per day, and teacher salaries are at an all-time low. There is, however, reason for optimism. Much of the Baathist ideology has been removed from the curriculum. Reconstruction is slowly being carried out with the help of UN agencies, private sector companies, and the U.S. military.

Russian Federation

Education does not exist in a vacuum. It reflects the social, economic, cultural, and political posture of a nation. This is especially true in the former Union of Soviet Socialist Republics. The recently formed Russian Federation is the largest country in the world, spanning two continents. The land west of the Ural Mountains is located in Europe and the land east of the Urals is in Asia. In early times, Russia was an imperial state ruled by a hereditary monarchy. Education was reserved for royalty and the upper echelon of society. The masses were uneducated, poverty stricken, and subject to the restrictions of the czars. The abolition of serfdom under Alexander II in 1861 brought the Zemstvo reform. Rudimentary public schools were built in the countryside for the children of peasants. Twenty years later, the Russian Orthodox Church was granted jurisdiction over education, and by the dawn of the 20th century 50% of all school-age children attended the parish schools.

With revolution came innovation. The new phase of Russian education coincided with the rise of the Bolsheviks and the establishment of the Soviet Union in 1918. Led by Vladimir Lenin, and under the leadership of the Commissariat of Education, schools were deigned to become child-centered, interactive, and progressive. Instruction was to be rooted in students' interests. However, Lenin's idealistic vision for education was not well received at the local levels. Little change occurred, and tradition was defiantly maintained.

During the Joseph Stalin years (1931–1953), the schools became a vehicle for dispensing Soviet ideology. Schools were administered by the Politburo, the main organ of the Soviet state, and strict allegiance to the state was enforced. As often happens in a totalitarian regime, the curriculum was rewritten, in this instance painting Stalin as the Father of the Revolution. Suppression, fear, and numbing routine characterized the state and school. Yet the literacy rate under Stalin was reported to have risen to 95% by 1939 and was maintained throughout the century.

The year 1991 marked the fall of the Soviet Union and the foundation of the Russian Federation. With this came great hope and optimism among average citizens who believed that the far-reaching political upheaval would bring prosperity with democracy. Their hopes were dashed. Political and societal uncertainty and a weak economy prevailed. Schools were underfunded, teachers were underpaid, and conditions continued to deteriorate over time. Today, schools are in disrepair. Major heating, plumbing, and electrical repairs, as well as technological advances, are needed. New school construction is necessary to alleviate overcrowding and double sessions. New curricula must be designed, and "communist mythology" removed from textbooks. At this moment in time, Russian students are not encouraged to enter college or university because they can earn more money by entering the workforce. With hopes for immediate reform dashed, many Russians look to their current leader, Dmitry Medvedev, upon whom they depend to improve conditions in both society and in the schools.

Egypt, Ancient

The concept of time was an essential part of life for the people of ancient Egypt because they believed that all things are connected in a continuous cycle of life, death, and renewal. This belief was a natural response to the phenomena that they observed in the world around them. They could depend on the annual flooding of the Nile River to renew the fertility of the soil. Ra, the sun god, was resurrected every morning following his nightly passage through the underworld, to continue his perpetual voyage across the skies. All around them was proof that the cycle of life was continuous.

This idea of continuity led the Egyptians to the belief that the world had been created in a state of perfect order that would never be changed. They worshipped the goddess Ma'at, who stood for order, balance, justice, and equality. This reverence led to the development of a moral code called *ma'at,* which served as a guide for everyone, beginning with the pharaoh and extending down to the common people. The goal for all Egyptians was to lead a sinless or virtuous life in order to be judged worthy of living on in the afterlife.

Development of Religion

As was the case in most primitive cultures, the earliest inhabitants of Egypt based their religious beliefs on the natural world. Before the unification of Egypt, each city-state worshipped its own local god, usually in the form of an animal. One example of this practice was the cult of the god Apis (or Hap) of Memphis. A single bull would be selected to be the sacred Apis bull on the basis of certain markings or coloring. The temple priests maintained the bull in luxury throughout its life. When the sacred bull died, it was mummified and received a royal burial. This cult existed well into the Ptolemaic period, so there were many tomb complexes where these bulls were interred. One such tomb is the huge underground cemetery called the Serapeum of Saqqara. Other animal burial sites have also been uncovered at Saqqara, with each tomb containing a different animal species.

Another animal cult, which originated in the city of Bubastis, was centered around the worship of the cat goddess, Bastet. The oldest known statues of Bastet represent her as a lioness. Her worship persisted and, over time, spread throughout Egypt. Around 1500 BCE, cats were first domesticated in Egypt and came to be considered sacred animals. They were greatly favored as pets, and mummified cats have been found in many tombs. Following the Roman conquest of Egypt, the worship of Bastet spread as far as Italy.

Beginning with the First Dynasty, the animal itself became less of an object of worship but continued to serve as the personification of the god. During this time, Egyptian gods also began to take on human attributes. Statues of the gods dating from this period portray them with a combination of both animal and human features. Assigning human features to a god or an animal is called *anthropomorphism.* An example of this is found in later representations of the goddess Bastet, in which she was depicted as a woman with a cat's head.

Many local gods were adopted as state gods as local beliefs were incorporated into a more formalized religious practice. The ruling pharaoh would often build temples in honor of his favorite god in order to promote the worship of that god, but Egyptian temples were never intended for public worship. They were constructed to house the image of a god and a staff of priests to serve the needs of the god. The full-time priests were the only permanent residents in the temple complexes. They were also the only ones who could perform the required rituals. However, all Egyptian men were required to work in a temple for 1 month out of 4 to fulfill their duty to the gods.

Daily temple rituals were performed beginning at sunrise. The statue of the god was usually housed in an inner chamber of the temple inside a sealed cabinet. At dawn, a priest would enter the chamber, unseal the cabinet, and remove the statue, offering incense and prayers before it. The figure would then be washed, clothed, and adorned with jewels. A meal was prepared, and the food was offered to the god. This ritual was repeated several times during the day until the image was retired for the night. The priest would then return the statue to the cabinet and reseal it with wax, sweeping away his footprints as he left the chamber. None of the general population was allowed to participate in these daily rituals at the temple, but small shrines in private homes were not uncommon.

The only time that the public was allowed to participate in religious observances was during a festival. Each of the primary gods had his or her own festival, and as there were many gods, there were multiple festivals throughout the year, usually at least one per month. Festivals were celebrated as holidays, days when no one was required to work. At the start of the celebration, the god's statue was brought out from the temple and carried to the Nile River by a procession of priests. This was the only time that the common people were allowed to see the god's image. The statue would be installed on a luxurious barge for the journey to the capital city, stopping at towns and villages along the way where the people celebrated with feasting and entertainment. When the statue reached the capital city, the pharaoh would assume the duties of high priest, ministering to the daily needs of the statue.

Not only was the pharaoh ruler over the civil workings of the country, but he was also designated as the high priest for all of the gods. Because he could not possibly fulfill his function as high priest at every temple, chief priests were appointed to serve as proxies in his place, and the pharaoh fulfilled his duties as high priest only during religious festivals. In addition to his birth name, pharaohs always carried multiple names and titles, both secular and religious, as did all high-ranking officials. The Egyptians believed that the pharaoh was not just a representative of the gods but the incarnation of the gods. Most importantly, the pharaoh was the incarnation of the sun god, Ra.

Beginnings of the Calendar

It was essential that these festivals take place on the same day of every year to ensure the goodwill of the gods who sent the yearly floods to sustain the land. To accomplish this, the Egyptians found it necessary to find a way to measure the passage of time. Temple priests first used the movement of the stars to mark the passing hours. They observed the stars nightly, appointing priests called "hour watchers" to monitor the heavens throughout the hours of darkness and record the movements of the stars in relation to a fixed point. Around 1500 BCE, the priests at the temple of the god Amon (or Amun) in Karnak began to use water clocks, or clepsydra, to determine set intervals of time for recording their astronomical observations. Over time, these observations revealed predictable patterns in the movement of the stars and planets, allowing the priests to predict the exact moment when the sun would rise and the daily temple rituals could begin. Another result of these nightly surveys was the division of the visible sky into 360°. Names were assigned to 36 star gods, or decans, each of whom occupied a 10-day period on a star chart that was similar to a horoscope. The first recorded use of star charts in Egypt has been dated to about 2100 BCE. Star charts became so important to the Egyptians that they inscribed them on the inside of a sarcophagus, or coffin, for use by the deceased in the afterlife.

The use of star charts led to the first calendar, which was used by temple priests to record religious observances. It was based on the lunar year of 12 months of 30 days with 5 additional, or epagomenal, days added at the end of the year to bring the total to 365 days. Epagomenal days were designated as birthdays of the gods and were celebrated as special holy days. Months of the lunar calendar consisted of 3 weeks of 10 days and were named for the god whose festival was held during that month. The Egyptians were the first to use a day that consisted of 24 hours, with 12 hours designated for daylight and 12 hours for darkness. Because the length of a day varies with the seasons, an Egyptian hour was not a set amount of time.

Instead, it was measured as 1/12 of the hours of daylight or darkness.

The first solar calendar came into use in Egypt around 2900 BCE. It was based on the appearance of the star the Egyptians called Sothis, which also signaled the imminent appearance of the annual flood. The solar year, like the lunar year, consisted of 12 months of 30 days plus the 5 epagomenal days at the end of the year. This was to become the civil calendar of Egypt and was used for all official business, such as recording the dates that grain was harvested on government land or how long workers served at civil building projects during the annual floods. Ancient Egypt had three seasons of 4 months each that coincided with the annual cycle of the Nile River. The season of Inundation would occur from June through September and was the time when the Nile River flooded the land. Because no work could be done in the fields, the people could make use of this time to work on civil building projects. The season of Emergence was the season when the fields emerged from the waters. The receding water was captured in holding ponds for later use, and seed was sown for new crops. Emergence lasted from October through February. Drought was the season of the harvest and took place between March and June.

Both lunar and solar calendars were inaccurate and, over time, the two calendars became asynchronous. Neither of them accounted for the full 365.25 days in a year. Using the lunar calendar, the first day of the New Year was the first day of the Nile flood. A year based on this calendar was problematic because it could vary by as much as 10 days, either shortening or lengthening the year, depending on when the start of the flood occurred. When the discrepancy between the two calendars became severe enough to cause religious festivals to be celebrated during the wrong season, the use of a lunar-solar calendar that combined the best features of both types was introduced.

In 239 BCE, Pharaoh Ptolemy III issued the Decree of Canopis to institute the use of a leap year. The Egyptian priests, however, refused to change their calendar. It was not until 23 BCE, when the Roman Emperor Augustus decreed that the Egyptian calendar was to be reformed, that the changes were actually made. This calendar became known as the Alexandrian calendar and was adopted in many areas of Africa and Eastern Asia. The calendar that we use today originated from the Roman calendar, which was heavily influenced by the Egyptians. When Julius Caesar initiated reforms to the Roman calendar in 46 BCE, he used the recommendations of Sosigenes, an Egyptian astronomer from Alexandria.

Beginnings of Astronomy

In their astronomic observations, the Egyptians noticed that certain stars and constellations remain stationary while others change their position in relation to the earth. Some of these stars disappear below the horizon for a predictable amount of time. When they reappear in the east, they are usually visible for a few moments just before the rising of the sun. This is called the heliacal rising of a star. If a star does not make its heliacal reappearance as expected, but remains invisible below the horizon for an extended period of years, the phenomenon is called precession. Both of these phenomena are caused by the rotation of the earth.

One of the most important heliacal stars for the Egyptians was Sothis, the star now known as Sirius, which is the brightest star in the constellation of Orion. Sothis was important because its heliacal rising signaled the immanence of the annual Nile River flood. It was also used to determine the beginning of the New Year for the civil calendar. Sothis and the constellation of Orion are closely linked with Osiris, god of the underworld. Osiris is one of the most important Egyptian gods because of his influence on Egyptian religious beliefs.

Osiris was one of the local gods who had moved up to the status of state god. He was a fully anthropomorphic god, being portrayed in human form, usually pictured as a mummified figure. The origin of the story of Osiris is unknown, but it seems to be a combination of a number of stories that have been found in various funerary texts that were discovered in Egyptian tombs. Plutarch, a Greek writer who lived in the 1st century CE, has left the only existing version of the story that brings together all of these myths. According to Plutarch, the story begins with Osiris, who is Pharaoh over all of Egypt. His brother Seth becomes jealous and plots against him. Seth lures Osiris into a sarcophagus, which he closes and throws into the Nile River. Isis, Osiris's wife, searches for and locates the sarcophagus. When Seth learns of this, he is so enraged that he cuts the body of Osiris into 14 pieces and distributes them throughout Egypt. Isis travels across the country to gather all of the pieces and, with the help of Thoth, the god of embalming, puts the pieces back together and embalms the body. Through the use of magical spells, Isis resurrects Osiris, who fathers a son with her and names him Horus. Osiris must then descend into the underworld, leaving Isis to rear the child in secrecy to protect him from Seth.

In the next portion of the story, Horus has reached adulthood and sets out to hunt for Seth. A battle ensues, during which Seth removes Horus's eye. Horus later retrieves the eye from Seth through trickery and the help of his mother. Horus descends to the underworld to present the eye to Osiris, who is granted eternal life because of it and, as a result, becomes ruler of the underworld. After these events, Horus rules over lower, or Northern, Egypt and Seth becomes ruler over upper, or Southern, Egypt. Horus, however, brings his case before the council of the gods, declaring that he alone is Osiris's rightful heir and should be the ruler over all of Egypt. The gods vacillate between the two claimants for 80 years before Horus is finally declared supreme ruler of Egypt.

What could be the significance of the 80-year court case of the gods? One modern researcher has advanced a theory. Using a computer simulation, he has discovered that the constellation Orion disappeared below the horizon of ancient Egypt for 80 years. Because the Egyptians believed so strongly in the divine order of the world, the extended disappearance of Sothis would need to be explained. This event may have been the source of the story of Osiris.

Burial Practices

One belief that may have originated from the story of Osiris involves the embalming process that is known as mummification. It was believed that if the pharaoh's body were embalmed in the same manner as Osiris had been and the correct magical spells were invoked, his immortality would be ensured. During his lifetime, the pharaoh was the person who was responsible for the welfare of the Egyptian people. He was supposed to continue to intercede with the gods on their behalf in the afterlife, making it imperative that the pharaoh achieve eternal life.

Was the story of Isis embalming her husband, Osiris, based on the practice of embalming, or did the embalming process originate with the story? Whatever the case, the process of mummification followed a strict ritual process. First, the body was cleaned and the internal organs were removed, with the exception of the heart. The brain was removed through the nostrils with no effort to preserve it because the Egyptians considered the heart to be the seat of knowledge. The four most important organs were stored in clay jars called Canopic jars. Each jar stood for one of the four sons of the god Horus, with each jar bearing a likeness of the head of its patron on the top of the lid. Imset was represented by a human head, and this jar contained the liver. Hapy was signified by the head of a baboon; he guarded the jar that held the lungs. Qebhseneuf watched over the intestines and was symbolized by a falcon's head. Duwamutaf protected the stomach and was denoted by a jackal's head. Each of these was watched over by a goddess from one of the four directions of the compass. After the removal of the organs, the body cavity was filled with resin or sawdust. Finally, the entire body was covered with natron, a salty substance, and was left to dry during the 70 days of mourning.

While the body was being prepared for burial, the tomb was being prepared and stocked with necessities. A tomb was thought of as the dwelling place of the deceased for eternity, so it needed to be equipped with everything that the deceased would need to live in the afterlife. This would include furniture, household utensils, a miniature funerary boat, food and drink, as well as small clay figures called *shabti.* Scenes depicting special times in the life of the departed one were painted on the tomb walls, and a statue of the deceased was nearly always placed in the tomb to serve as a replacement home for the *ka,* or spirit, in the event that the mummy was destroyed.

After 70 days, the body was removed from the natron, washed, and wrapped in linen cloths. When the entire process was complete, the funeral service was held. Cemeteries were usually placed on the west side of the Nile River and when a person died, they were said to have "gone west" where the sun "died" each day. The western horizon was thought of as the borderline between the land of the living and the underworld, the kingdom of Duat that was ruled by Osiris. Just prior to placing the body into its final resting place, which was usually a stone sarcophagus, a ritual called the "opening of the mouth" took place. In this ceremony, the priest would touch the mouth of the mummy with two special instruments while reciting magical incantations. The first was thought to give life and breath back to the body. The second was believed to enable the deceased to receive nourishment from the food offerings that were left in the tomb. In addition, it was thought that these incantations would enable the miniature funerary boat to enlarge for use by the deceased in the journey through the underworld. The spells were also supposed to animate the shabti figures to become the person's servants in the afterlife and were believed to enable the tomb paintings to come to life to serve the departed. This is the reason that tomb paintings always included everyday tasks, such as the harvesting of grain, the baking of bread, and the brewing of beer.

After a person died, it was believed that his or her soul must descend to the underworld to pass through certain tests and trials. Those who had lived a good life and had the proper answers to the questions of judgment would move on to an eternal existence. In the Old Kingdom, texts were written on the interior walls of tombs and pyramids to serve as a guide for the deceased. These are referred to as Pyramid Texts. During the Middle Kingdom years, these texts were written on the inside of the sarcophagus and are called Coffin Texts. Scrolls of papyrus with instructions for the deceased to use in facing the tests of the underworld were placed between the knees of the mummy in New Kingdom burials. These scrolls are known collectively as the Book of the Dead. One thing that was contained in the Book of the Dead was a recitation of the sins that had not been committed by the deceased. In addition to responding correctly to all of the questions posed by the gods, the individual's heart would be weighed against a feather in the Hall of Ma'at. If the scales balanced, the person would go on to eternal life. If the scales did not balance, it was believed that the heart would be eaten by Amment, the "devourer of souls." If this happened, there was no chance for an eternal existence, and it is likely that this was one of the reasons that the Egyptians devoted themselves to following the principles of truth and fairness that were expressed by the philosophy of *ma'at*.

During the early years of the Old Kingdom, only the pharaoh was expected to achieve eternal life. Smaller tombs for nobles and courtiers were usually constructed around the tomb of the pharaoh in the hope that they would be allowed to serve the pharaoh in the afterlife as they had during his lifetime. By the beginning of the Middle Kingdom, burials of nobles and courtiers reflected their expectation to live on in the afterlife in the same manner as the pharaoh. By the start of the New Kingdom, these beliefs seem to have included anyone who had the means to pay for embalming and an appropriate tomb.

The temple complexes that were commonly built around the tomb or pyramid of the pharaoh during the Old and Middle Kingdoms served a double purpose. Regular attention would keep his name alive, and the priests would continue to supply his mummy with regular food offerings. For everyone else, relatives were expected to visit the tomb with food and drink offerings to sustain the departed one. Those who were wealthy enough could hire priests to ensure that their loved one would have the necessary offerings in perpetuity. As time passed, it was not unusual for these agreements to be forgotten. If the food offerings were not forthcoming, it was believed that the needs of the deceased could be supplied by the tomb paintings that had been magically animated during the ceremony of the "opening of the mouth."

Another belief tied to the story of Osiris is the idea that a person who was deceased would have eternal life as long as his name was remembered. Tomb texts containing the name of the deceased were meant to ensure that the person would live on in the afterlife, just as Osiris had done. This belief, combined with the responsibility of the pharaoh for his people's welfare, made it important to record the pharaoh's name many times within his tomb, particularly on the sarcophagus. Carrying this belief one step farther, the Egyptians believed that if the departed pharaoh took on the name of Osiris, his name would be remembered forever, ensuring his immortality. Writings found in the tomb of Pharaoh Unas, who ruled from 2375 to 2345 BCE identify him as Unas-Osiris, showing that the funerary customs of that time were based on beliefs that had originated from the story of Osiris. The importance of keeping the name of the deceased alive also led to the construction of extensive temple complexes around the tombs of the pharaohs during the Old and Middle Kingdoms.

Tombs and Pyramids

The Egyptians practiced the worship of multiple gods, but the central principle in Egyptian religion was a belief in the continuation of life after death. To achieve eternal life, a person must have a properly prepared tomb where his or her *ka,* or spirit, would live forever. Consequently, temples, tombs, and pyramids were designed to last for eternity, and they were the only structures in Egypt that were constructed of stone instead of the traditional mud brick.

Sandstone was the stone of choice because it was easily worked with the available stone tools. However, sandstone's limitations include the fact that it cannot be used to span a large distance without support. Limestone came into use because, like sandstone, it was easy to work with, but it is also strong enough to withstand the stress of being incorporated into an arch. Everyday structures, such as houses, shops, and even the palaces of the pharaohs, were constructed of mud brick that has long since weathered away. As a result, most of what is known about ancient Egyptian civilization has come from the art and funerary goods that have been discovered in tombs.

At the beginning of the Old Kingdom, pharaohs were buried in mastaba tombs. These consisted of an underground vault, sometimes a suite of rooms, with a shaft to the surface. Above the tomb, a rectangular structure of mud brick was constructed to afford access to the vault below. A chapel was usually built inside the mastaba to provide a place for relatives to bring offerings for the deceased. Small funerary chapels slowly gave way to temple complexes.

In the 3rd century BCE, the style of tombs was changed forever when Pharaoh Djoser commissioned his chief architect, Imhotep, to design a tomb for him at Saqqara. Imhotep was an extraordinary man who served as the king's vizier but was also a priest, physician, astronomer, philosopher, and a gifted mathematician. The project began with preparations for a large, raised mastaba tomb. However, this tomb differed from those of previous kings in that it was built entirely of limestone bricks instead of the traditional mud bricks. In imitation of the former tradition of using organic building materials, the outer surface of the stone was carved to represent bundles of reeds and grass mats. After completion, the tomb underwent a radical addition. A second, smaller layer was added on top of the first, with two more added to form a step pyramid. Another addition followed the first, enlarging the base and adding two more layers to form a rectangular step pyramid of six layers. It was the first structure of its kind to be built in Egypt and was the largest stone structure in the world at the time of its completion. Tombs from this time period, including Djoser's step pyramid, had a north-facing entrance, pointing toward the polar stars, where it was believed that the deceased would spend eternity.

Pharaohs who followed after Djoser built tombs in a variety of styles. Some built step pyramids, but several of the kings who succeeded Djoser ruled only a short time and did not undertake such massive building projects. It was King Sneferu of the Fourth Dynasty who began planning an ambitious project for his tomb shortly after coming to power. The first attempt, built at Dahshur, resulted in the bent or rhomboidal pyramid. The second attempt, also built at Dahshur, resulted in the first classic pyramid, and became Sneferu's tomb. Its outer surface is covered with pink limestone that appears red at sunset, so it has been given the name Red Pyramid.

The largest of the Egyptian pyramids is the Great Pyramid at Giza, which was built by Sneferu's son, Khufu. Its base covers 13 acres. It measures 451 feet in height and its sides are aligned with the four directions—north, south, east, and west. Khufu's son, Khafre, built the second pyramid at Giza. Although it is smaller than the Great Pyramid, it seems larger because it was built in a higher position. The third pyramid was started by Khafre's son, Menkaura, who died before it was finished. His successor, King Shepseskaf, completed the building of Menkaura's pyramid.

Why did the Egyptians feel the need to build the pyramids? Pyramids, like the mastaba tombs before them, are thought to be symbolic of the primeval mound that was the first creation of Ptah, one of the creator gods. The entrance to the pyramid always faced to the east, where the sun god, Ra, rose every morning. It is thought that this practice reflected an emphasis toward the worship of Ra. The prevailing belief of the time concerning the afterlife was that the deceased would continually journey across the sky in the boat of Ra.

Pyramid construction occurred for a relatively short time during the Old Kingdom. In the Middle Kingdom years, tombs reverted to the mastaba style but were constructed of stone instead of mud brick. By the start of the New Kingdom, tombs were constructed entirely underground with a hidden entrance. This is the type of tomb that is found in the Valley of the Kings, which is located on the west bank of the Nile near Thebes. These tombs consist of extensive passageways and chambers that have been tunneled into the cliffs with the entrance hidden after the burial, most likely to discourage tomb robbers. This would be especially important to the Egyptians because they believed that if the tomb was robbed and the mummy was destroyed, the deceased could not continue to enjoy a life in eternity.

Conclusion

The Egyptians were a people who became obsessed with time and eternity. Although their religious beliefs changed over time, their belief in the afterlife came to dominate every aspect of life in Egypt. The primary purpose of the greatest Egyptian architecture and art was to construct a dwelling place for the deceased and the provisions that would be needed for life in eternity. Everyday life in Egypt was ruled by the tenets of *ma'at* in order to achieve eternal life. This obsession would eventually lead to the study of astronomy, the invention of timekeeping instruments, and the concept of a 24-hour day and the invention of the calendar. Although these discoveries were made thousands of years ago, the legacy of the Egyptians continues to influence people's lives today.

Einstein, Albert (1879–1955)

Albert Einstein was a German–American physicist who significantly changed the physical and philosophical view of time and space. The special and general theories of relativity are among his most seminal works. He also provided fundamental contributions to early quantum theory. For his quantum theoretical interpretation of the photoelectric effect, he was awarded the Nobel Prize in Physics in 1921. His most lasting contribution, however, is his theory of relativity, which changed our conception of time forever. As a pacifist, Einstein was actively involved with movements for peace, tolerance, and international understanding all his life.

Early Developments

Albert Einstein was born in Ulm, Germany, on March 14, 1879. His father was a moderately successful salesman in the electrical trade. The South German roots of Einstein's Jewish family reached back for centuries. Since 1880, the family had lived in Munich. According to Einstein, the experience that aroused his scientific curiosity occurred at the age of 6, when he was wondering about the invisible force aligning a compass needle. The stories often told about Einstein's underachievement in school are merely a myth. He earned average marks in most subjects but was excellent in the natural sciences. However, he showed a dismissive attitude toward dull authority from his early days on. Beyond school lectures, he was able to figure out the infinitesimal calculus on his own.

While his family moved to Milan, Italy, in 1894 for economic reasons, young Albert stayed back in Munich alone to finish grammar school. Ahead of time and without formal graduation, Einstein left school on his own decision when he became at odds with the school's authorities. "Your sheer presence corrupts the class's respect for me," his teacher remarked. On the basis of his attitude as a freethinker, he also resigned from the Jewish religious community. In 1895, he went to the Kantonschule Aarau (Switzerland) where he passed the Matura (the Swiss grammar school diploma), qualifying himself for the Confederate Polytechnical Academy Zurich (today's ETH). In 1900, he achieved the teacher's diploma for math and physics. He applied for an assistantship at the Zurich Academy, but his application was rejected, so he eked out a living as a substitute teacher at first. In 1901 Einstein submitted his dissertation on the theory of thermal equilibrium and the second law of thermodynamics to the University of Zurich; the dissertation was declined.

During his years of study, Einstein fell in love with his Serbian fellow student Mileva Maric. In 1902 she gave birth to their illegitimate daughter, Lieserl, at Mileva's parents' home in Serbia. The subsequent fate of the child is uncertain; it is stated in various sources that she was given up for adoption at Einstein's insistence in order to preserve moral standards; some sources state that she suffered from trisomy 21 (Down syndrome) and died at the age of almost 2 years.

Annus Mirabilis: An Explosion of Creativity

In 1902, after a recommendation from his friend Marcel Grossmann, Einstein got employment as "third class expert" at the Swiss patent office in Bern. Half a year later, on January 6, 1903, he married Mileva. Their sons Hans Albert (1904–1973) and Eduard (1910–1965) were born from this marriage.

Along with his time-consuming but nevertheless regular work, Einstein concentrated on theoretical physics and prepared for his graduation at the University of Zurich. With his friends Maurice Solovine and Conrad Habich, he founded a sort of philosophical discussion circle, the Akademie Olympia. After leaving work, they would study and discuss the works of Immanuel Kant, Ludwig Boltzmann, Henri Poincaré, or Ernst Mach. Einstein's wife Mileva was among the intellectual discussion partners.

Einstein's ambitions, advanced beyond the academic establishment, first culminated in a scientific "eruption of genius" in 1905, often referred to as his annus mirabilis, or miraculous year. Within a few months, the 26-year-old Einstein published four papers of historical relevance in the prestigious journal *Annalen der Physik*. In mid-March, he explained the photoelectric effect and laid one of the cornerstones of quantum mechanics by ascribing a corpuscular nature to light; in 1921 Einstein would win the Nobel Prize for this work. Two weeks thereafter, he resubmitted a dissertation titled *A New Way to Determine Molecular Dimensions*. This work contained essential hints on the atomic nature of matter. With this publication, he succeeded in referring the Brownian motion in fluids to the thermal motion of molecules. He thus established the kinetic interpretation of heat.

Foremost, however, the name of Einstein is associated with the idea of relativity. The first and most constitutive work on this topic was the "Electrodynamics of Moving Bodies" paper, which he submitted on June 30, 1905. The paper is particularly remarkable in that it does not contain any academic references, unthinkable for a scientific paper today. Finally, in September, he provided a sort of extension to the electrodynamics paper culminating in the equation $E = mc^2$, the most famous physical formula in history. Both works set up the special theory of relativity, Einstein's revolutionary new theory of time and space.

Scientific Reputation

In January 1906, Einstein received his Ph.D. Shortly thereafter he was advanced to a "second-class expert" as a patent office employee. Until 1908, he made his living from passing expert opinions on patents. Later on, his weighty contributions would pave the way for a scientific career. Meanwhile, qualified as a professor and now possessing a certain reputation within the scientific community, Einstein delivered lectures beginning in 1908 and was appointed to an associate professorship at the University of Zurich in October 1909. During the following 5 years, he changed his academic affiliation several times. After working in Prague for a short period, he returned to Zurich. Finally, in 1914 he was enticed by his elder colleague, Max Planck, into going to Berlin, and he worked there without teaching commitments. Einstein's departure from Zurich was impelled by more than scientific reasons; his marriage to Mileva was breaking up, and in Berlin, he had begun an extramarital relationship with his second cousin Elsa Löwenthal in 1912.

After the outbreak of World War I on August 1, 1914, Einstein began to care about political concerns more intensely. He joined the group Neues Vaterland (New Fatherland), which was based on a decidedly pacifistic attitude. Despite lucrative offers by other German and international universities, he would stay in Berlin until his emigration to the United States in 1933.

Quanta and Relativity

Einstein's 1905 works provide not only the general basis of his theoretical framework but also, in particular, a radical new view of space and time. Until his death, Einstein would criticize the new quantum theory. "God doesn't play dice": With these words, he summarizes his pessimistic attitude toward the probabilistic "Copenhagen interpretation" of quantum theory developed by Nils Bohr and Werner Heisenberg in 1926, even though in 1905, Einstein had provided a fundamental contribution to the quantum concept. "On a Heuristic Aspect Concerning the Creation and Transformation of Light" is the bulky title of the very paper postulating the particle character of light. In a letter to his friend Konrad Habicht, Einstein announced his own work to be "revolutionary."

The quantum concept had been introduced 5 years earlier by the physicist Max Planck, also in the context of electromagnetic radiation. However, Planck was referring only to the radiation energy being emitted and absorbed in discrete packets, denoted as quanta.

Around the mid-19th century, the French physicist Alexandre Edmond Becquerel discovered the effect that an ultraviolet-irradiated, negatively charged metal plate emitted negative charge carriers in a characteristic manner. The energies of the individual electrons emitted do not depend on the radiation's intensity, but only on its wavelength. Moreover, the effect sets only in as soon as the radiation wavelength drops below a certain limit. These observations were not compatible with the conventional and established wave picture of electromagnetic radiation.

Einstein took on the challenge and postulated that both light and electromagnetic radiation consist of tiny portions of "light" particles called *photons*. However, the wave properties of light had been proved experimentally in Newton's era. In this respect, Einstein introduced the duality of light, which is still considered valid today: Though excluding each other, both natures obviously coexist in electromagnetic radiation. Many years after Einstein's work, the concept of duality was applied to any kind of matter when two beams of electrons were observed to interfere. This is considered as conclusive proof of waves acting.

Einstein would apply himself to quantum theory all his life. After the publication of his light-quantum hypothesis, however, his investigations on the nature of space and time came to the forefront.

Around 1900, the classical disciplines of physics had been completed in their main features. What one knows as classical mechanics today was provided as a complete theory by Isaac Newton (1643–1727) more than 300 years ago. Meanwhile, it turned out to be a valid border case of Einstein's theory of relativity. James Clerk Maxwell, on the other hand, united the broad domains of electric and magnetic effects within a single theory of electromagnetism, based on four fundamental equations that provide the undisputed classical frame to this day.

After the turn of the 20th century, insurmountable problems arose at the borderland between mechanics and electrodynamics. Elegant attempts at solutions were suggested by Hendrik Antoon Lorentz and Henri Poincaré, but these turned out to be mathematical gimmicks rather than plausible physical explanations.

Again, it was Albert Einstein who brought about a rebound in 1905. To conserve the universal validity of the principle of relativity (PR, the equivalence of any uniformly moving frame of reference), and without further ado, he ascribed physical reality upon the Lorentz transformations (Lorentz's mathematical gimmick). At the same time, he declared dispensable the concept of the ether that had been postulated centuries earlier; this substance was believed to pervade all space and bodies though it had never been detected. Light and electromagnetic waves should propagate through this ether like sound waves through the air. Last but not least, ether was to provide an absolute frame of reference in Newtonian space.

Together with the universal validity of the PR, the new ideas called into question the classical Newtonian concepts of space and time. They individually lose their rigid, absolute characters and turn from passive subjects to active objects depending on the physical circumstances. Simultaneity becomes relative and depends on the observer's state of motion: Two events, appearing simultaneous to a (say) resting observer A, happen successively to a moving observer B. Following the theory of relativity, clocks run differently for two observers moving with respect to each other; likewise, spatial length measures are different. "From now on space and time apart shall reduce to shadows and only a kind of a union shall keep autonomy," the German mathematician Hermann Minkowski stated. This bizarre issue is frequently illustrated using the twins paradox. An astronaut says good-bye to his twin brother prior to his interstellar flight. In his spacecraft, he would travel through space at 99.5% the speed of light. He returns 10 years later and is greeted by his brother, whereupon both brothers realize they have aged unequally. While the earthling is older by 10 years, there passed only 1 year for the space traveler!

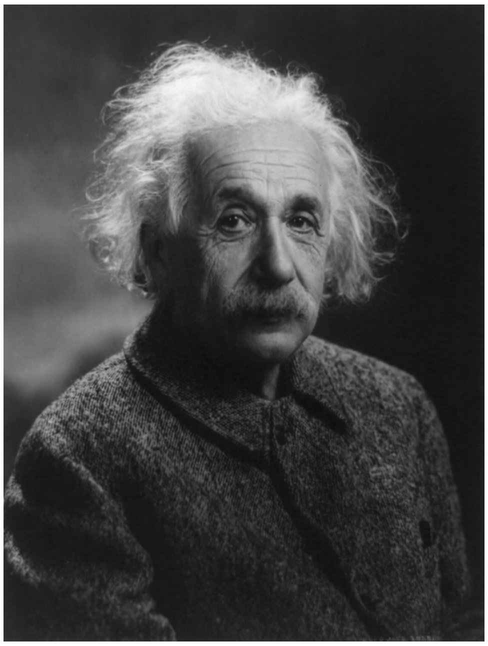
Furthermore, Einstein showed that the new theory implies that the mass and energy content of a body are equivalent. This is expressed in his most famous equation, $E = mc^2$. The relativistic effects of length contraction and time dilation are proved by many experiments today.

Starting in 1907, Einstein tried to generalize the PR for accelerated frames of reference. The PR in the special theory of relativity says it is not possible for an observer to distinguish whether he is placed in a resting or a uniformly moving frame of reference. As a generalization, Einstein introduced the principle of equivalence, the "most felicitous idea in [his] life." An observer in a closed room, such as an elevator or a windowless spaceship, is strictly unable to tell whether he is accelerating in free space or resting in a gravitational field (like on the surface of the earth).

From this principle, Einstein finally overthrows the concept of time and space even more radically than before. Gravitation turns out to be an intrinsic curvature of spacetime. This curvature is in principle comparable to a spherical surface but, beyond any human imagination, in three dimensions instead of two. The curvature of spacetime is caused by the presence of mass-afflicted matter. Vice versa, the curvature causes a body to accelerate. A direct and verifiable implication of the general theory of relativity (GTR) is the deflection of a light beam passing near a massive body (like a star). Einstein's article "The Foundations of the General Theory of Relativity" was published in the *Annalen der Physik* on March 20, 1916.

Three years later, following the war's end, a British expedition led by Sir Arthur Eddington left for West Africa to observe and measure the exact positions of stars appearing close to the obscured sun during a total eclipse. Einstein remarked that his theory would be incorrect if it were not able to correctly predict the deflection of light (and thus the shifted positions of the observed stars). It turned out that the deflection of the starlight passing the gravitational field of the sun was in close agreement with the predictions of the GTR. This verification of Einstein's theory was the onset of his international fame and myth. One week after the confirmation of his theory, Einstein married his cousin (the daughter of his father's cousin), Elsa Löwenthal. In December 1919, he published a popular science book titled *The Special and General Theory of Relativity, Generally Understandable.*

During the following years, many physicists and mathematicians attempted to find solutions for the GTR field equations. Particular significance in this context was achieved in the works by Georges Édouard Lemaître (1894–1966) and Alexander Friedmann (1888–1925). Their solutions



At 16 years old, Einstein tried to imagine what it would be like to ride on a beam of light. Could he travel as fast as light or could he travel faster? In 1905, nearly a decade after this first "thought experiment," Einstein answered these questions with his special theory of relativity.

for homogenous and isotropic spaces constitute the foundation of the cosmological standard model to this day.

Berlin and Princeton

Einstein left Switzerland the year before he submitted his GTR. In Berlin, he was accorded respect by the Prussian Academy of Sciences and given a professorship. He would never re-enter Germany after his emigration in 1933, and he expressed disgust with the "brutality and cowardice" of the Nazi Germans. He states about Berlin: "There's no city ever, I'm more associated to by human and scientific connections."

Though he was exempted from lecture commitments in Berlin, Einstein gave numerous public talks. Sometimes there was such an enormous crowd of attendees that only the largest auditorium in the university could accommodate it. Among his various leading positions within the academic community, perhaps the most noteworthy was his being the chair of the German Physical Society, a position he held as the successor of Max Planck from 1916 to 1918.

In the year of his move, Einstein was sensitized to politics through the outbreak of the Great War. Contrary to the initial national enthusiasm for the war, he pleaded in public for international understanding and called for an immediate end to the war. He campaigned for democracy and pacifism and engaged himself for the Bund Neues Vaterland (New Fatherland Alliance), later renamed the League for Human Rights. After the war, he embraced the anti-monarchic German November Revolution and the ensuing Weimar Republic.

In a famous statement that offended many, Einstein expressed his contempt for war and soldierhood:

> If someone feels pleasure marching lock-step to music in rank and file, he has already earned my contempt. He has been given a big brain by mistake, since for him a spinal cord would be quite enough. This disgrace to civilization should be done away with at once. Heroism on command, senseless violence and deplorable "fatherland" blubbering, how passionately I hate it, how mean and ignoble war seems to me. I would rather be torn to shreds than take part in so base an action! It is my conviction that killing under the cloak of war is nothing but an act of murder.

Being more in the public eye and as a committed advocate of humanistic values, Einstein more and more became a focal point of anti-Semitic hostilities, which occasionally arose even from his circle of colleagues. In particular, Philipp Lenard and Johannes Stark excelled with subjective debates against "Jewish physics" and declared the theories of relativity "degenerations of common sense." As anti-Semitism flourished in Germany and elsewhere in Europe, Einstein reflected on his Jewish roots and joined the Zionist movement. Together with its leader Chaim Weizmann, he traveled across the United States for 2 months. In a show of solidarity in the face of hostility and persecution, he rejoined the Jewish religious community, which he had quit in his earlier days. In 1921, Albert Einstein was awarded the Nobel Prize for his light quantum hypothesis (not for his theories of relativity).

Einstein undertook three more extensive, scientifically motivated journeys to the United States. During his last one, starting in December 1932, Adolf Hitler came into power; immediately Einstein declared that he would not return to Germany. After a trip to Europe, he moved to his adopted city of Princeton in the United States, where he would work at the Institute for Advanced Studies until the end of his life.

In 1939, alerted by the outbreak of the war in Europe, Einstein wrote a letter to the president of the United States, Franklin D. Roosevelt, and advised him to develop a nuclear bomb, in anticipation of the Germans' attempt to do so. Thereupon, Roosevelt initiated the Manhattan Project, culminating in the dropping of two nuclear bombs on the Japanese cities of Hiroshima (August 6, 1945) and Nagasaki (August 9, 1945).

After the end of World War II, shocked by these terrible incidents, Einstein intensively campaigned for armament control and suggested that a world government be established. In November 1952, the Israeli President Chaim Weizmann died. Einstein was immediately offered the presidency, but he declined: "Equations are more significant to me. Policy is for the present but equations are for eternity," he was said to have explained. As one of his last contributions for a peaceful world, he signed a manifesto, written by the British philosopher and mathematician Bertrand Russell, calling for all nations to abstain from nuclear weapons.

On April 15, 1955, Albert Einstein was taken to Princeton Hospital because of internal bleeding. He died on April 18 at the age of 76. In keeping with his wishes, his body was burned to ashes on the same day, but not before a pathologist purloined Einstein's brain during the autopsy.

"God Doesn't Play Dice": Criticism of Quantum Mechanics

In 1926, the young German physicist Werner Heisenberg had published the so-called uncertainty principle. It is the preliminary climax in the evolution of quantum theory, initiated by Max Planck (1900) and Einstein (1905). With the uncertainty principle, Heisenberg expressed the innermost character of quantum mechanics: the turning away from classical strict determinism and the wave–particle duality, which Einstein prepared the ground for with his light-quantum hypothesis. A year later, Heisenberg and his Danish mentor Niels Bohr developed a probabilistic interpretation of the theory (the Copenhagen interpretation), accepted by most physicists today.

Einstein disliked this idea from the beginning. During the Fifth Solvay Meeting, he led a legendary series of lively disputations with his friends and colleagues Niels Bohr and Max Born, but both of them emerged victorious in each case. Some of Einstein's objections to quantum theory Bohr could parry using Einstein's general theory of relativity. But until his death, Einstein was unwilling to accept the dual character of matter, the renunciation of determinism, or the introduction of randomness into physics.

Search for a Unified Theory

The pursuit of structural unity in physical theories arose with the birth of theoretical physics itself. In his historic work *Philosophiæ Naturalis Principia Mathematica* (1687), Isaac Newton had developed a single unified theory to explain the fall of an apple and the journey of a planet around the sun. Another great success of theoretical physics was the unification of electric and magnetic phenomena, developed around 1864 by the Scottish scientist James Clerk Maxwell.

Of the four fundamental forces that physics now recognizes, only two were known in Einstein's time: the electromagnetic and, exhaustively investigated by Einstein, the gravitational force. After the publication and experimental confirmation of his GTR, Einstein for the first time addressed the problem of describing both within a common scheme. He provided a first paper in 1922 and a second one in 1929, accompanied by high expectations within the scientific community.

Like his lifelong but unsuccessful criticisms of quantum mechanics, Einstein's enterprise was to lead to a scientific dilemma that Carl-Friedrich von Weizsäcker called the "tragedy of his late years." Neither Einstein nor any other physicist ever succeeded in unifying gravitation with any other fundamental force. Three of the four forces known today (including the weak and strong interactions) are so far unified in the so-called grand unified theory. To this day, gravitation, with its completely different mathematical structure, resists any such attempt at being unified with the three other forces.

Nature of Time in Relativity

It is by far the most significant effect of relativity that space and time lose their absolute and independent character. *Absolute* means that time intervals do not depend on the observer's state of motion and the presence of gravitational fields. In particular, the term *simultaneity* loses its meaning beyond the context of a certain frame of reference (i.e., a certain observer). Because there is nothing like one frame of reference in the universe being superior to any other, there is no absolute, universally valid measure of time, but only some observer's inherent time or proper time. The loss of independence means that time cannot be considered as a physical quantity independent of space. Rather, time and space generate a four-dimensional coordinate system called spacetime, providing the stage for any physical phenomena.

The twins paradox in principle demonstrates the possibility of time travel to the future in terms of special relativity. However, this would require technical conditions (far out of reach today) for traveling at almost the speed of light over a significant period of time. Furthermore, it would not be possible to travel back to the present, which would require superluminal velocities.

Finally, going back to the general theory of relativity, one insight is that time has (at least) one universal border. Within the framework of the big bang cosmological theory, time begins with the big bang event, which is held to have occurred about 13.7 billion years ago. There is no moment "prior" to the big bang, just as, according to Stephen Hawking, there is no point "north of the north pole." Today, cosmologists maintain that there will be no end to time in the form of a big crunch, as the "reversal big bang" is frequently called. In fact, there are many hints pointing to an eternal, even accelerated, expansion of the universe.

Einstein and Newton

Albert Einstein (1879–1955) and Isaac Newton (1642–1727) are scientists best known for their contributions to the field of physics in relation to space, time, and other forces within nature. To Newton, space and time were constants, and his philosophy formed the basis of classical physics. Einstein, however, in his famous theory of relativity, proved that space and time were not so easily defined.

Isaac Newton

Isaac Newton was born on Christmas Day, 1642. Newton grew up on his family's agricultural estate, Woolsthorpe, and spent his time working the farm land when he was not in school. Under the supervision of a local apothecary near his boarding school in Grantham, Newton studied Latin, and he constructed wooden models, clocks, and sundials in his spare time. Though he sometimes neglected his schoolwork, his analytical intellect landed him a place at Cambridge's Trinity College in 1661, relieving him of the daily tedium of rural life.

At Cambridge, Newton devoted much of his time to independent study. He read books by René Descartes and Galileo Galilei, reflecting on them in handwritten notebooks. His study of Descartes also led him to read about "analytic geometry," and before long he received a scholarship to continue his studies at Cambridge until he received his B.A. in 1665.

Later that summer, Cambridge shut down because of an outbreak of the bubonic plague, and Newton was forced to return to Woolsthorpe. It was here that he made the discoveries for which he is most famous. The observation of fruit falling from trees let him to deduce that a force attracted them to the earth. From this he pieced together the laws of universal gravitation and developed corresponding formulas for these laws based on the assumption that space and time were unchanging absolutes. Newton used these formulas to estimate the relation between objects in the universe, including the gravitational forces that keep the planets in orbit.

Newton had difficulty proving his calculations to the scientific community, and it was nearly 20 years before he published his findings. He first achieved renown through his experiments with prisms, light, and color. Once accepted as a notable scientist, he published his famous *Principia Mathematica,* and his laws of universal gravitation finally received the acclaim they deserved. Newton also used his knowledge to assist the astronomer Edmund Halley, who utilized Newton's formulas to predict the arrival of the comet that is now named after him. Newton retained a noble status in the scientific community until his death in 1727. Before he died, he was working to find a unified theory to explain matter in relation to the universe.

Albert Einstein

Albert Einstein was born in Ulm, Germany, on March 14, 1879, to a middle-class Jewish family. One of his earliest memories was of his father, showing him a compass with its precise dials and needles, and Einstein wondered about the invisible forces that imparted motion to the magnetized needle. However, he was temperamentally unsuited to submit to the harsh discipline and rote memorization required in the German education system of the day and ended up dropping out of school and leaving Germany at the age of 15.

He joined his parents in Milan, Italy. Einstein thrived in Milan, which was much more open to his free thinking, and it was here that he first formulated visualizations of what would later become his theory of relativity. Although he failed his first attempt at the entrance exam for the prestigious Swiss Federal Institute of Technology in Zurich, he passed the examination a year later and was accepted. At the Swiss Federal Institute of Technology in Zurich Einstein excelled at physics, but he was still a poor student in French and history and only graduated with the help of his classmates.

Einstein was unable to find steady work until 2 years after he graduated. He finally found a stable job in a patent office in Bern, Switzerland, which allowed him spare time to test his physics theories. Einstein worked on his ideas constantly and would even record his thoughts in a notebook when taking his son out for walks.

His efforts soon paid off. He published six papers by early 1905, particularly impressive considering his unsuccessful postgraduate stint. The year 1905 is known as his "miracle year," when his publications changed scientists' ideas of both the Brownian movement (how particles move within water) and the photoelectric effect. In the latter, Einstein proved that light travels as both waves and particles, giving the first evidence of the existence of atoms and earning him the Nobel Prize in 1922.

Einstein's final two papers of 1905 are his most famous; these papers enabled him to expand on what Newton had already discovered. For instance, Newton's laws were able to predict the precise movements of all the planets except Mercury. Einstein's theory of relativity revealed that because Mercury is the planet closest to the sun, it is more affected by the sun's gravitational pull, which causes distortions of space and time within its orbit. These calculations proved that space and time are relative, and they helped astronomers better predict the movements of various objects in the universe. Einstein verified that gravity is also relative, demonstrated in his famous $E = mc^2$ formula, which proves that larger objects have more energy and gravitational pull than smaller objects.

Due to persecution by the Nazis in pre–World War II Germany because of his Jewish heritage, Einstein was forced to relocate to the United States, where he was offered a professorship at Princeton University. Afraid that the Nazis were constructing a powerful bomb, he wrote a letter to U.S. President Franklin D. Roosevelt and encouraged him to launch efforts in building a similar bomb. After U.S. military forces dropped an atomic bomb on the city of Hiroshima in 1945, however, Einstein was emotionally devastated by the terrible loss of human life, and until his death he spoke out passionately against the use of nuclear weapons. He died in 1955, absorbed until the end in his efforts to construct a unified field theory to explain the behavior of all matter within the universe.

Though Newton's findings were based on absolute motion and Einstein's were based on relativity, the two scientists led similar lives. Both had "miracle" years during which they formulated theories that explained the complexities of the universe in a way that enabled scientists to better predict its various phenomena. Both also tried but failed to find a unified theory to explain the behavior of matter within space and time. Most importantly, their theories are still used by scientists to examine the universe's history and nature.

Eliade, Mircea (1907–1986)

As philosopher, historian of religions, novelist, professor, and editor, Mircea Eliade was an extraordinarily erudite scholar whose writings, methodology, and personal biography continue to generate debate in various academic disciplines. Several of his well-known books reflect a fascination with the concepts of time and history, in particular, and still influence the contemporary discussion.

Born in Bucharest, Romania, where he also received his university education, Eliade's interest in philosophy led him to study for 4 years in Calcutta and to spend several months in a Himalayan ashram. These experiences helped to make Eliade an expert on yoga—the subject of his 1933 doctoral dissertation and later book—and broadened his comparative horizons; other writings reflect Eliade's study of Eastern religions, including the Hindu and Buddhist concepts of time and history. His political affiliations caused him to leave Romania after World War II began. Following the war, Eliade taught comparative religion for 10 years in Paris, where he developed many of his seminal ideas. In 1957, Eliade came to the United States and began teaching at the University of Chicago, where he exercised tremendous influence as chair of the history of religions department for nearly 3 decades. By all standards, Eliade was a gifted and prolific writer; he published over 1,300 items, including a number of popular and influential books—two of which incorporate his major treatments of time and history, namely, *Cosmos and History: The Myth of the Eternal Return* and *The Sacred and the Profane: The Nature of Religion.* Creative and energetic, Mircea Eliade's life and wide-ranging scholarly perspectives remain provocative and controversial.

Repeated use of a technical vocabulary, some of whose terms Eliade created or used in an idiosyncratic manner, reflects his fascination with the concepts of time and history. Among the world's ancient (or "archaic") and modern cultures, he identified two different perspectives on time. On the one hand, a religious person (*homo religiosus*) divided time into two categories: "sacred" and "profane." The former refers to time associated with religious festivals and other occasions (hierophanies) that recall and regenerate (or "reactualize") the mythical time of origins. On the other hand, a modern, nonreligious person does not experience this sacred time but lives in the mundane world of ordinary historic time. Members of this secular (or profane) society do not have access to *illud tempus,* the mythical, ideal time that gives meaning to life. In Eliade's analysis, myths reach across time and provide explanations of what took place and how things came into existence at the beginning of time (*ab origine*) and provide examples for human behavior. Eliade also emphasized the distinction between cultures that perceived time as cyclical and allowed for periodic reoccurrences of sacred, primordial time ("myth of the eternal return") and those that did not. The latter saw history as linear and irreversible, and Eliade emphasized the special place of history in the noncyclical perspective of the Judeo-Christian tradition.

Time—its passage and our experience of it—is also a major theme in Eliade's fiction, as seen, for example, in the character Stephane in *The Forbidden Forest.* Eliade advocated a new humanist agenda and wanted his readers, who live in a desacralized world, to rediscover the sacred in their lives—including its manifestations in space and time.

Eliot, T. S. (1888–1965)

Anglo-American poet and critic, Thomas Stearns Eliot exerted a major influence on modern English poetry and became a prominent literary figure during the post–World War I to World War II period. His poetry opposed the major intellectual worldviews of modern Europe, going against the current of modernism in philosophy. Eliot's concept of time develops and plays a prominent role in several of his most popular poems: "The Love Song of J. Alfred Prufrock" (1917), "Gerontion" and *The Satires* (1920), "The Waste Land" (1922), "The Hollow Men" (1925), "Ash Wednesday" and the *Ariel Poems* (1930), and *Four Quartets* (1943). The themes of time, timelessness, and eternity, as they relate to the Christian concept of salvation, reappear in his works as he questioned the disintegration of modern European culture and approached the concept of time according to his own faith. Eliot also founded the journal *Criterion* in 1922 (which he edited until 1939), worked as an editor for the London publisher Faber and Faber, and wrote plays and literary criticism. His most popular drama, *Murder in the Cathedral* (1935), depicts the events surrounding the death of Saint Thomas Becket.

Born in St. Louis, Missouri, in September of 1888, Eliot received his education and training as a writer from Harvard University and Merton College, Oxford, and during brief studies abroad in France and Germany. Eliot studied the French symbolists, the English metaphysical poets, Elizabethan drama, and Dante. In September 1914, Eliot became friends with the American expatriate writer Ezra Pound, who supported Eliot as a rising poet and helped him to publish some of his earlier poetry; Eliot would later dedicate *The Waste Land* to Pound. In 1915, Eliot married a British woman, Vivien Haigh-Wood, and he became an British subject and member of the Anglican Church in 1927. The marriage was troubled and ended in separation; the couple had been apart for several years at the time of Vivien's death in 1947. Eliot received the Order of Merit and Nobel Prize in Literature in 1948. In 1957 he married again, to his long-time secretary, Valerie Fletcher.

Throughout Eliot's poetry, one can see a transformation in the treatment and interpretation of the concept of time. The characters in his earlier works were conscious of the passing of time and the recurring patterns of monotonous daily routines. For Eliot, the modern temporal world offered no hope or salvation, and these early poems reflected that despair, loneliness, and sense of meaninglessness. He perceived 20th-century Europe's concept of progress as offering people false hope and deceiving the world about the reality of life beyond the temporal. Therefore, his later works explore the possibility of transcending earthly existence and finding timeless eternity, full of meaning, purpose, and hope.

One of Eliot's most complex works, *Four Quartets,* offers the best expression of his concept of time. *Four Quartets* is a collection of poems that offer a different and changing perspective on time and how humans experience that time. In "Burnt Norton," time is eternally present with no beginning or ending; in "East Coker," time represents cycles with seasonal and life changes; in "The Dry Salvages," the mood shifts to a meaningless view of time without purpose or direction; and in "Little Gidding," the theme of time reappears as eternity but is seen as past, present, and future time. In Eliot's personal experience, the faith of Christianity offered hope and gave meaning to the temporal world. Although he did not openly identify Christianity in his poetry, the language and ideas reflect Eliot's emphasis on humanity and God, timeless eternity, and the Incarnation of Christ.

ELIXIR OF LIFE

According to legend, the elixir of life is a potion created through alchemy that grants immortality and perpetual youthfulness or creates life. The word *elixir* comes from the transliterated Arabic *al-iksir* meaning "essence." The concept of the elixir of life is associated with Eastern traditions, namely, those of China and India; the Western traditions are more closely associated with the concept of the philosopher's stone.

There is some uncertainty as to where alchemy began, but in China and India the elixir of life was the primary object of alchemical research. Although the focus was on life extension, the transmutation of base metals (mercury and lead) to higher or noble metals (gold and silver) was a by-product in these countries. This was probably due to the culture: Although acquisition of wealth was discouraged, the extension of life was considered a dignified pursuit and could therefore be researched.

Within both the Eastern and Western traditions there are two perspectives: internal (spiritual or philosophical) and external (via elixir, potion, etc.). In China, Taoism influenced both perspectives, and over time the internal perspective became more important. This has been attributed to the rise of Buddhism and the failure to find a less-than-dangerous potion of immortality.

As in all alchemy, metals and other substances were transformed, transfigured, subsumed, and converted into other metals and substances. At this time in China, consuming precious metals or minerals, such as gold, cinnabar, and even jade, was thought to extend one's life. Other substances were added to these mixtures, some dangerous (like lead, arsenic, or quicklime) and others that are not (such as gold and silver). Owing to its various properties, mercury was a highly prized metal that was added to many elixirs, potions, and other alchemical mixtures. We know today how highly toxic mercury is to the human body, and with large doses sometimes added to potions that were eventually consumed, these elixirs actually had an effect opposite to the intention.

In India, as in China, the quest for the elixir of life combined both the internal and external perspectives. But because many Indian alchemists were also priests, they were familiar with the Vedas (the sacred texts of Hinduism), which describe *soma,* a sacred drug that was believed to impart divine qualities to those who drank it, including immortality. Because the Vedas discuss soma at length, the external perspective concentrated more on medicinal herbs and mixtures for healing and rejuvenating. Such experimentation eventually led to the modern science of pharmacology and the global pharmaceutical industry. (In recent decades, with the rise of "alternative" medicine, herbs and other natural remedies have become the focus of renewed interest.) It has been suggested that the elixir of life in India was soma, which today is believed to be caffeine, ephedra, ginseng, or one of many other botanical extracts.

The search for the elixir of life declined in these two countries when the focus turned inward, to the spiritual and philosophical, based on a growing belief that the path to immortality was not achievable through an external source but only through an inner transformation.

Emotions

Although emotions did not play a significant role in modern philosophical discussion up to the 1970s, today they form an important subject of philosophical inquiry. If one considers a broader historical context, however, this discovery of emotions in practical philosophy turns out to be a rediscovery. From antiquity to the Middle Ages, a discourse on "passions" and "affections" was an integral part of moral philosophy and ethics. Although Aristotle, the Stoics, Saint Augustine of Hippo, and Saint Thomas Aquinas had widely diverging opinions about the role emotions should play in ethics, they all agreed upon the importance of emotions for the moral life. Up to the 18th century, when the English and Scottish moralists (Shaftesbury, Butler, Hume, and Smith) centered their moral philosophies around "moral sentiments" and when Rousseau traced back any sort of moral behavior to the pure feeling of "commiseration," emotions continued to be at the core of morality. Yet, with the triumph of positivism in the social sciences and the birth of scientific psychology in the 19th century, emotions were reduced to mere biophysiological phenomena that had to be dealt with in a purely functional sense. Against the background of the Cartesian distinction between spirit and matter, emotions were categorized as belonging to the body without having any cognitive content. Emotions as a whole were thus reduced to what the classical discourse on emotion had classified as "appetites" and "passions." From such noncognitive drives, the classical discourse had distinguished more subtle emotional phenomena like "affections" or "sentiments" that belonged to the higher parts of the soul.

The contemporary revisionist discourse on emotions has taken up this strand of thought. The now-prevailing cognitive approach to the emotions distinguishes emotions proper from mere physical drives like bodily appetites by their cognitive content. From the cognitivist's viewpoint, emotions are individuated by reference to their characteristic beliefs. One cannot describe the pain that is peculiar to fear without saying that it is pain at the thought of a certain sort of future event that is believed to be impending. It is this intentionality, or "aboutness," of emotions that sets them apart from mere biophysiological reactions to an external or internal stimulus.

This new conception of emotion as a cognitive phenomenon has several consequences for the conception of the interplay of emotionality, sociality, and morality. First, because emotions are no longer seen as mere passive responses to given stimuli, their productive role in shaping and constructing social reality can be addressed. Second, emotions do not only structure social interactions but are, in turn, shaped by social circumstances. They are social constructs. Third, the question of how development and emotionality are linked on the personal and societal level arises. Fourth, the role of emotions in rational decision making and moral reasoning has to be reconsidered. In all of the four points, special emphasis is put on the relationship between emotions and time.

Emotions and the Social Construction of the World

Mainstream sociology stresses the role of cognition and action in the social construction of the world. With a cognitive conception of emotion in mind, however, an emotional construction of the world becomes no less plausible. How emotions structure our apprehension of reality can be made clear by reference to the first cognitive theorist of the emotions, namely, Aristotle. In Book Two of his *Rhetoric,* Aristotle treats emotions (*pathé*) as "that which causes people to change with respect to their judgement." For example, becoming ashamed of a person involves being led to view that person as involved in misdeeds that bring dishonor. Anger involves the view that somebody has insulted one, and so on. To be moved to a certain emotion involves making the judgment constitutive of the emotion and excludes other judgments. Being moved to envy does not allow one to be moved to pity toward the same person at the same time. The judgment implicit in an emotion influences the way in which we view the world.

In addition to this cognitive modulation of our worldview, emotions affect our perception. As common experience shows, one is easily deceived about perceptions when one is in emotional states. What something is perceived as differs for people moved by different emotions. Ronald de Sousa thus compares emotions to paradigms, which are how we see the world.

This insight in the role of emotions as partly constitutive of our way of viewing the world is most clearly expressed in Martin Heidegger's *Being and Time,* in which he refers to Aristotle's *Rhetoric* as the first account of our necessarily emotional being-in-the-world. For Heidegger our "affectedness" is constitutive of our cognitive and performative ways of being in the world. Hence, for Heidegger, the emotional construction of the world is the most fundamental one.

If our emotions are at the core of the social construction of the world, what then is their relation to time? Three points can be made. First, emotions shape our subjective experience of time. While we are depressed or bored, for example, things seem to be stretched in time. On the contrary, our being angry, stirred up, or stressed results in an acceleration of time-experience. Second, emotions can be differentiated as to their relatedness to the past, the present, or the future. Past-directed emotions like gratitude and guilt relate to something that occurred in the past. By contrast, present-directed emotions like love, hatred, courage, anger, joy, and sorrow are feelings that relate to something that, although it may have happened in the past, continues to affect us. Although, as in past-directed emotions, one may love somebody in part for what he or she did in the past, love also demands that we love the person as he or she presently is. Future-directed emotions, such as hope, despair, and fear, refer to states of affairs that have not yet happened but that are expected to come about with more or less likelihood (fear, hope) or with certainty (despair).

According to Heidegger, a third claim can be made. Because emotions have a temporal structure, it is through the experience of emotions that the temporality of time is grasped. Emotions make accessible to us the fact that our being-in-the-world is in principle embedded into temporal horizons. Experienced time necessarily has an emotional quality.

Emotions as Cultural Concepts

On the noncognitive scientific account, emotions are biologically determined reactions that are (more or less) universally dispersed among humans and primates. Charles Darwin and other 19th-century biologists and psychologists tried to conceptualize emotions as biologically determined patterns of instinctive behavior. Recent anthropological and ethnological research, however, has uncovered the cultural diversity of emotionality. Darwin and his fellows were right insofar as some basic emotions, like hunger, fear, anger, sorrow, and joy, seem to be universal and in fact do have an innate type of bodily expression. But more sophisticated emotions like envy, compassion, and guilt are clearly socially shaped and differ from culture to culture. Opinions diverge on whether these culturally shaped emotions retain a robust essence untouched by social and cultural context or whether they are socially constructed through and through. Yet, no matter whether the emotions themselves or only the emotion-triggering stimuli are culturally determined, it is well established that emotive cultures vary strongly over time. Every culture establishes certain "feeling-rules," which regulate the expression of emotions and which have to be accommodated by "feeling-work."

Emotion and Development

It is a commonplace that an individual's life is emotion-laden in its earlier stages and becomes calmer as one gets older. This is one reason why wisdom is usually attributed to old people. In developmental psychology, the formation of our cognitive capacities is associated with the balancing of our emotions. In Piaget's genetic epistemology as well as in Freud's psychoanalysis, the development of our cognitive structures goes hand in hand with the formation of affect-control.

Sigmund Freud, the founder of psychoanalysis, applied this conception of individual development to the evolution of collective entities. According to Freud, civilization may be understood as a collective process in the course of which affect-control is established on the level of society and its institutions. Whereas for Freud this process is a fragile one, because the natural drives cannot be fully tamed, Norbert Elias develops a much more optimistic view in his influential work on the *Civilizing Process*. According to his interpretation, Western history since the Middle Ages can be reconstructed as a progress in the history of manners and morals. For Elias, the state's monopolization of the use of legitimate physical force and the emergence of a capitalist economic system bring about the gradual abandonment of the emotional laissez-faire that was characteristic of the medieval warrior societies. Already in the high court society (*höfische Gesellschaft*) governed by a code of etiquette, the unstable emotional life is partly overcome by regulations of civility. The absolutist society of the 17th century and the modern nation-state are further steps in the process of civilization, which is marked by the internalization of constraints and the strengthening of affect-control.

Elias's teleological and overly optimistic account of history has been criticized from various perspectives. Some contemporary sociologists maintain that at least since the 1970s, the process of civilization as defined by affect-control has been reversed. The liberalization of sexual morality, the stirring of emotions by mass media reporting, and the emotionalization of politics have reintroduced emotions into public and political life. Whereas critics urge that this trend toward re-emotionalization be seen as a process of de-civilization, cognitivist theorists of emotion argue that this need not be so. To judge whether the resurgence of emotions poses a threat to the current state of civilization, the relationship between emotions and rationality must be explored.

Emotion and Rationality

The reconstruction of occidental history as a process of progressive civilization rests upon the underlying assumption that emotions are irrational forces that have to be suppressed, canalized, or transformed by rational institutions. In Max Weber's terminology, the "rationalization" of society presupposes the mastery of reason over emotion. In this perspective, the civilizing process can be seen as a process of rationalization precisely in that it involves the strengthening of affect-control. Rationalization, then, is coextensive with the de-emotionalization of public conduct.

The view that emotions are the opponents of rationality is one of the constitutive tenets of occidental philosophy. Even Plato and Aristotle, although more attentive to the positive roles of emotions, put forward a reason versus passion dichotomy that has been deeply influential ever since. Yet, whereas in the reason/passion dualism, the passions were still seen as properties of the soul (if only of its lower part), the emotion/cognition dichotomy employed by current mainstream psychology is even sharper. On this account, emotions are bodily disturbances without any cognitive content whatsoever.

The presumptive irrationality of emotions that is implicit in this dichotomy can be put down to emotion's relationship to time. According to Aristotle's *On the Soul* (III, 10), the supremacy of reason over passion is established by virtue of its broader temporal horizon. Because reason, unlike emotion, takes into account the future benefits that rational action may bring about, rationality entails the capacity to distance oneself from the present emotional states.

In Hobbes's *Man and Citizen* (*De homine*) this argument is taken one step farther. According to Hobbes, humans are rational animals to the degree that they are capable of transcending the present. Thus they are rational animals only because they are providential animals.

By contrast, emotions seem to have an urgent, pressing character (they are, however, not entirely contained in a present-related point of view, as has been pointed out earlier). Because of their shortsightedness, emotions are treated as impediments to rational decision making in classical rational choice theory. As urgent and pressing, they affect the probability and credibility estimates of the agent. Consequently, they lead to irrational belief formation and interfere with the cost–benefit calculation of the agent.

The claim that emotions always hinder rational decision making has been cast into doubt by modern theorists of emotion. De Sousa points out that emotions can actually promote rational behavior. In situations of rational indeterminacy or in cases of indifference, they serve as tiebreakers and promote decisions where no decision could be made by rational deliberation alone. According to de Sousa, emotions are "patterns of salience" that help us find out what is rational at a given moment because they represent to the actor his or her preferences. If it is required that the action be chosen quickly, emotions offer a guide to rational decision making.

The neurologist Antonio Damasio has offered an argument that heads in the same direction. He draws on findings from patients with specific brain lesions that render them emotionally flat. Although these patients retain their other cognitive powers, along with their capacity to react emotionally, they lose their ability to make decisions. Based on these findings, Damasio makes the strong claim that "reduction in emotion may constitute an important source of irrational behavior."

In Damasio as well as in de Sousa, rationality cannot be separated from the emotions. Rather, in order to be rational in a meaningful sense, rationality has to draw upon emotion's capacity to represent to the agent his or her preferences (de Sousa) or to give meaning to otherwise senseless cognitive operations (Damasio).

Emotions and Morality

The relation between emotions and morality can be addressed from the three following perspectives. First, on the *epistemic level,* emotions take part in the formation of moral knowledge. De Sousa's characterization of emotions as patterns of salience and his proposal to illustrate the function of emotions with reference to the role that paradigms play in the formation of theoretical knowledge suggest that only emotions allow us to recover what is morally required. One can even go so far as to maintain that emotions constitute the moral context of our actions. On this account, one does not become angry because a comment is offensive. Rather, the comment appears offensive by virtue of its being an object for anger.

Second, on the *axiological level,* emotions influence our moral evaluations. With a view to the history of ethics, this claim can be illustrated by pointing to the Scottish moralists of the 18th century, David Hume and Adam Smith, whose ethical systems center on the notion of moral sentiments. Critics of this tradition of ethical thought argue that although emotions may serve as the basis of moral evaluations in communitarian contexts, they are incapable of instructing moral action in more complex situations and de-localized contexts. This criticism is in part inspired by the idea that emotions have a narrow temporal horizon and thus cannot transcend the here and now. However, this need not be so. Consider once again the case of past-directed emotions like guilt or future-directed emotions like fear, which play an important role in the contemporary ethical discourse on collective guilt or the rights of future generations.

Third, on the level of the *theory of action,* emotions constitute an important subgroup of motivations for action. The crucial question here is whether emotions as motivations are stable enough to constitute a reliable ground for moral behavior. Two types of emotions can be distinguished by virtue of their timely dimension. Short-lived emotions (mere affects) may instigate a single moral deed. However, they cannot be relied upon because they depend on a situation that serves as a trigger for the emotion. By contrast, a standing emotion (passion) is characterized by its continuity in time: It is a permanent disposition for certain attitudes. For Aristotle, insofar as an emotion is part of a permanent state of mind (*hexis*), it may become part of what he calls "ethical virtues." In his account, a virtue is a "mean" (middle ground) disposition with regard to both passions and actions. Because the right emotional state is an integral part of an ethical virtue, an apparently correct action would cease to count as a virtuous action if it were chosen without the appropriate motivating and reactive emotions.

Empedocles (c. 495–435 BCE)

Empedocles was a Presocratic philosopher, poet, and mystic whose theory of cosmogenesis marks his fame. He was born in the ancient Greek city of Akragas (recently renamed Agrigento) on the coast of Sicily. Popular lore claims that Empedocles was offered the kingship of Akragas after having overthrown the previous oligarchy. Though Empedocles is often cited as being extravagant, and even making claims that he was immortal, he refused the kingship in order to support a democracy. His ideas embraced a temporal framework.

Empedocles was a pupil of Pythagoras and a disciple of Parmenides, two other major Presocratic figures. Borrowing heavily from Parmenides' concepts of the nature of reality and theory of being, along with the Pythagorean theory of opposites, Empedocles applied these principles to his cosmogony and the universe's cyclical nature. Owing to Empedocles' belief in the transmigration of souls, which also stemmed from Pythagorean tradition, he remained a strict vegetarian, believing meat-eating to be a sin, an act of cannibalism. In fact, Empedocles believed his fall from being a potentially divine being (or daimon) stemmed from a past life's sin of eating meat. To complete his catharsis, Empedocles is forced to journey the earth through continuous reincarnations, being rejected by the various combinations of elements, until one day being reunited with the gods, free of pollution.

According to Empedocles, all matter is composed of four primal elements (*stoicheon*). These elements—Earth, Air, Fire, and Water—are each attributed to a god: Hera, Aidoneus, Zeus, and Nestis, respectively. The elements are timeless and indestructible and therefore can be considered divine. To explain the creation of the universe, Empedocles introduces two cosmic forces known as Love (Philia) and Strife (Neikos), which in turn are likened to the gods Aphrodite and Aries. Love is responsible for the unity of the elements, while Strife is responsible for the division of the elements. Because the elements can never be annihilated, only separated and united, all things are eternal, including life. Death, as one knows it, is merely a separation of the elements by Strife, which will soon be rearranged and united by Love.

This elemental theory applies to all aspects of the universe and is undoubtedly what led to Empedocles' evolutionary theory and ideas of natural selection, in anticipation of later philosophers and naturalists such as Herbert Spencer and Charles Darwin, respectively. Empedocles claimed that Earth was responsible for the birth of living creatures, each imbued with portions of Water and Fire. In the beginning, however, all were masses of disembodied organs. Through the force of Love, the organs would join together in different combinations. These combinations would result largely in mutation, filling the world with beings with two heads and human-faced animals, though sometimes perfect combinations would result and would survive and multiply.

Empedocles delivered these postulations in the form of epic verse, which can be found in his two extant works, "On Nature" (*Peri Physeos*) and "Purifications" (*Katharmoi*), the largest body of fragments that remain from any Presocratic philosopher. Whether or not these two works are separate entities has long been a source of scholarly debate, though a recent find of papyrus fragments at the University of Strasbourg may link the two works as part of one larger work.

In addition to being a philosopher, poet, and crude scientist, Empedocles was well known for his mystical feats. There are many accounts of Empedocles performing miracles, healings, and even being consulted for cures. Although these ideas may originate from Empedocles' poems, where he describes himself as a celebrated mystic, one cannot help but believe that Empedocles was often consulted for help because of his knowledge of cosmic affairs. His skill in the art of rhetoric was, without a doubt, another impetus for him to be well received.

To prove his immortality, according to a much celebrated tradition, he threw himself into an active volcano on Mount Etna, the mythical forge of the Greek god Hephaestus, leaving nothing behind but a sandal, which revealed the farce. Most likely a legend, this particular account of Empedocles' death has been dramatized in a play by Friedrich Hölderlin and in the poem "Empedocles on Etna" (1852) by Matthew Arnold. Though Empedocles may not have proved his immortality to his contemporaries, his ideas and notions remain immortal and timeless.

End-Time, Beliefs in

As stories of the beginning are provided by any number of religious or secular belief systems, so too are stories of the end. End-time beliefs broadly understood are those things believed about the eschaton, or the end of things: the end of an individual life, the end of a community, the end of the universe, or the end of time itself. End-time beliefs reflect a cultic system's explanation of how the end

This is the third and most famous woodcut from Dürer's series of illustrations for The Apocalypse. (c. 1497). *The* Four Horsemen *presents a dramatically distilled version of the passage from the Book of Revelation (6:1–8).*

of things will come about. These beliefs are based on canonical sources, folk sources in the absence of canonical sources, or creative reinterpretation, willful denial, or simple ignorance of received wisdom whether from folk or canonical sources.

Doctrinal beliefs often differ from popular beliefs. For example, often in the popular Christian imagination the death of the saved is directly followed by their heavenly welcome. However, in the canonical Christian account found in the Book of Revelation, the death of the saved is directly followed by their long wait, along with the damned, for the worldwide bodily resurrection, final judgment, and arrival of God's heavenly city into which the saved are only then finally welcomed.

Varieties of End-Time Beliefs

Literature that reflects end-time beliefs that describe a final catastrophe resulting in the general destruction of life on Earth is generically, though somewhat imprecisely referred to as "apocalyptic" literature. However, the word *apocalypse* is simply an artifact of the Christian influence on world culture. The Book of Revelation (or the Apocalypse of Saint John) in the Christian Bible contains an end-time narrative in the ancient Near East tradition that the writer (or writers) inherited from the Hebrew Bible's Book of Daniel. The word *revelation* rendered in Greek is *ἀποκάλυψις*, or "apocalypse." Based on the influence of this book on Christian and therefore Western literature, a text that follows the style or content of the Book of Revelation, whether written before, during, or after the closing of the Jewish and Christian canons, became referred to as "apocalyptic." The Jewish–Christian form of apocalyptic literature properly includes particular identifying elements such as angelic visitation, numerology, catastrophe, judgment, and final punishments and rewards. Yet narratives that lack one or another apocalyptic element still have been considered apocalypses in the generic sense as long as they include catastrophic events that are to accompany the end-time.

Canonical and noncanonical end-time literature presents a diverse array of end-time beliefs, not all of which contain catastrophe and ultimate destruction. Zoroastrian Persia developed rich and complex end-time scenarios. Here the writers of scripture produced two apocalyptic narratives that provide examples from two decidedly different historical moments. The writers of the more ancient apocalypse recorded in the *Greater Bundahišn* described a general cataclysm that would result in general happiness. Mountains would empty themselves of molten lava enough to cover everything on a newly flattened Earth. "Followers of truth" would experience the molten rivers as a bath of warm milk. "Followers of evil" would experience them as molten rivers but with miraculous results: First, everyone would survive, and second, the experience would occasion a transformation not only of the entire earth but of all humankind. All would begin to speak the same language. All would become followers of truth. Worldwide apocalypse would be followed by worldwide bliss. This particular narrative developed during a time of relative strength and security in the Persian Empire. After the Roman conquest, however, Zoroastrian end-time narratives themselves became more menacing. Writers of the *Oracles of Hystaspes* revealed the catastrophe and chaos that would reign as the end-time drew near; but rather than a worldwide transformation resulting in a happy family of an egalitarian humanity, this end-time scenario resulted in a devastated Rome, an ascendant Asia, and rewards and punishments meted out by a just, mighty, and decidedly pro-Zoroastrian God.

This latter type of end-time belief resembles more the end-time narratives of another kingdom of little strength and even less security: ancient Judah, the seat of Judaism. The appearance of Jewish apocalyptic literature followed the conquest of Judah by the Persian Empire, whose state religion was Zoroastrianism. The apocalypse in the Hebrew Bible's Book of Daniel provided a standard for apocalyptic visions that later Jewish and Christian writers were to emulate. In this likely pseudonymous book, Daniel, the famed Jewish hero, saw visions, received angelic visitations, described fantastical images and events ripe for interpretation, invoked numerical and quizzical secrets, and, like the latter Zoroastrian narrative, ended the scenario with punishments for the evil and rewards for the good.

Over time, a variety of Jewish sects gathered in the hills around Jerusalem and in the Near East, some complete with their own messiahs and all evidently anticipating impending doom. Apocalyptic communities included those at Qumran and the Dead Sea who are known because they left records that have survived. Common end-time beliefs among such groups included the rain of destruction on establishment temples and the divine formation of a new regime and new temple of which the sectarians themselves would be the primary beneficiaries.

During this era, the newly founded Christian sect developed similarly heightened end-time expectations. Early Christian canonical and noncanonical end-time and apocalyptic texts from Matthew to Paul to John the Revelator included the almost immediate return of Jesus, their messiah, who would inaugurate the end-time. But whereas some of the texts referred to the return as happening within the lifetime of the writer or reader, other writers avoided more precise dating than that. Medieval Christian end-time anticipation saw the occasional popular apocalyptic deadline come and go. In the European settling of North America, the Puritans saw the Christian conquest of the continent as proof of the impending end, so they evangelized accordingly in order to speed the apocalypse on.

Islam developed its own apocalyptic narrative that, like the Christian one, owed much to its Jewish prototype. Here again there would be a general resurrection, judgment, and punishments for the evil and rewards for the good. But unlike the many canonical and noncanonical Christian apocalyptic texts, there was little by way of timing the event, much less characterizing it as "soon."

End-time beliefs include a variety of expectations that exist apart from a unifying narrative, written or oral. In Hinduism, for example, although there are certainly texts that include scenarios of the end-time, Hinduism itself contains within it such diverse belief systems that it is virtually impossible to speak of a single Hindu end-time belief. Some Hindu end-time visionaries described cataclysmic ends to the current universe; some, an all-consuming fire; some, an avenging Kalki who would ride on a white horse to transform a holy remnant of humanity and begin a new golden age referred to as the *Krta yuga*. Other, though not mutually exclusive end-time beliefs focus more sublimely on the cosmic closing of Vishnu's eyes that would bring the resolution of the current universe, just as the next opening of his eyes would inaugurate yet another new universe through the "Golden Embryo" that is Brahma. Commonly included in most of these end-time beliefs has been the notion that, of the *yugas* (time units that last hundreds of millions of years) of this universe, the world currently exists in its last and most corrupt phase, the Kali yuga. Precisely how many solar years a yuga includes and where the universe lies in the span of this yuga has provided a source of considerable speculation. Because of this lack of agreement on when the end-time may arrive, Hinduism's long history has been punctuated by incidents of apocalyptic fervor whenever believers have expected that the end was at hand.

Buddhist end-time beliefs have been established primarily among Mahayana Buddhism and have focused primarily on the Maitreya Buddha. Writers of Mahayana Buddhist scriptures looked forward to the Maitreya Buddha, who would bring in his wake the end of the world as we know it, with or without a catastrophic prelude. End-time beliefs of Mahayana Buddhism do not appear to necessitate widespread immorality or decay but do anticipate the complete abandonment of Buddha's teachings or *dharma*. In the wake of a world that would completely forget Buddha Shakyamuni's (also spelled *Sakyamuni*) dharma, the Maitreya Buddha would arrive as the new and final Buddha. Some of the end-time visionaries anticipated that the final Buddha would be the world's ruler, who would teach pure dharma that would bring an end to war, disease, and even death, effecting a transformation of the world as we know it but not its end.

End-time beliefs exist not only within universalizing cultic systems but also within the religious imagination that is more local in scope. Local or regional cults, however, offer the added interpretive challenge of distinguishing between indigenous and colonizing beliefs. Native American end-time narratives, for example, stubbornly frustrate attempts to separate original elements from Christian incursions. End-time beliefs that have incorporated obvious influences from the colonizing cult of Christianity include, perhaps most famously, the multitribal Ghost Dance of the late 19th century. This apocalyptic cult developed from the vision of a Paiute shaman named Wovoka, who prophesied the final coming of Christ, a new Earth that would be inherited by Indian peoples, and, in some accounts, the obliteration of all white peoples.

Other end-time beliefs appear to have less explicitly Christian influence. Originators of the White Buffalo Calf Woman legend of the Lakota Sioux, for example, spoke of the promise of her return. Far from being apocalyptic, this "return" would encourage transformation through human, cultic, or environmental renewal on the rare occasion of the birth of a white buffalo. Yet, although centuries-old versions of the story lack any accompanying end-time expectation, the mere fact of the explicit "return" narrative has fueled end-time speculation when white buffalos have been calved.

Modern end-time cults offer a blend of secular anxiety and New Age interpretations of traditional religion that results in the cult's particular recipe for apocalypse. Rather than developing their own end-time narratives, these cult systems have usually accepted the inherited end-time narratives of the predominant religious tradition and have modified that narrative depending on the cult's own doctrinal particularities. In this sense they can be seen as amalgam cults that not infrequently include conscious or subconscious accommodation to modernity. Examples include Japanese end-time cults based in Buddhism, Shintōism, Christianity, new religious movements, or combinations thereof; and American end-time cults being based in Christian apocalypticism onto which New Age elements can be grafted. Like their historic Christian predecessors, non- or quasi-Christian cults such as Heaven's Gate, People's Temple, and the Branch Davidians of Waco, Texas, have had immediate end-time expectations. Some of these expectations have been realized through cult members' own actions, for example, when People's Temple or Heaven's Gate members realized their own communal end-time through mass suicide.

In addition to explicitly religious end-time beliefs, nominally secular environmental activists have taken on quasi-religious fervor in their beliefs that the end-time is near. These beliefs have included the idea that humanity actively perpetuates the species' own demise or even ecocide. Such beliefs have inspired some to work to interrupt or reverse the environmental degradation. Others have sought to promote the environmental decay, hastening the decimation or destruction of the human species in order to save the planet for other, more benign life forms.

Apocalypticism

Fervent belief in the apocalypse, no matter its religious or secular origin, can take on characteristics of being a religion itself. A belief system that focuses on an apocalyptic end-time is sometimes referred to as apocalypticism. In a world where end-time books and films have proliferated and record numbers of Americans have believed that some Christian apocalyptic vision would be realized in their lifetime, apocalypticism carries tremendous cultural, social, and political power.

Throughout the history of apocalyptic movements, the marginalized, colonized, and persecuted have been attracted to apocalypses that could promise the destruction of the persecutors and the reversal of the social hierarchy. Ancient Persian Zoroastrians provided a classic example of end-time beliefs from both of these divergent cultural contexts: An ascendant Persia produced an end-time narrative resulting in blissful global family reunion, and an occupied Persia produced an apocalypse ending in bliss for the Zoroastrian faithful but doom for their Roman invaders. Currently, however, it has been leaders and significant numbers of people in the wealthiest and most powerful countries who have been vigorous promoters of apocalypticism, with some of these leaders controlling the military wherewithal to create an apocalyptic reality. This makes understanding apocalypticism a serious if not urgent area of study.

American Christian apocalypticism has continued the tradition inherited from early Christianity, the medieval church, and the Puritans that the end-time is near. Two thousand years figures prominently in the mythology of the Christian eschaton, based on the most liberal interpretation of the end-time timeline in the Book of Revelation. After the year 2000 CE arrived without the anticipated apocalypse, some Christian apocalypticists extended that 2,000-year marker, revising it to some time within a generation of the turn of the millennium. Due to some perceived problems with the accuracy of the Christian calendar, some have extended the coming apocalypse to centuries in the future.

Concluding Remarks

Topics common to end-time beliefs have included (1) timelines; (2) speculation on the origin of the end-time; (3) dualistic elements of (a) particularity versus universality, (b) bliss versus punishment, and (c) global transformation versus annihilation; and finally, (4) the appropriate cultic responses to the coming end.

Timelines of end-time beliefs vary from "soon" to "far in the future." Rare is the end-time vision that has provided precise names and dates. And when that has occurred, their followers have been prone to find room for interpretive liberality once that date has passed or the history of the named person has failed to fit the prophecy.

Speculation about the ultimate source of the end-time itself varies in connection with the theological commitments of the believer. End-time beliefs of theistic cults favor divine or semidivine retribution. Nontheistic cults such as Buddhism and secular beliefs such as those of environmentally committed activists often invoke themes of a humanity that would bring about its own destruction.

Dualistic elements such as universal bliss versus universal punishment abound between competing narratives as well as sometimes within the same end-time scenario. The writers of the Book of Revelation, for example, seem to have invited various and self-contradictory interpretations regarding whether sinners would be permanently tortured, fatally extinguished, or miraculously renewed and made ready to enter a new Earth where the only distinction between the renewed sinner and the saint would be the inability of the former to enter the heavenly city. Thematic elements also vary such as whether the apocalypse would result in a complete or a partial catastrophe and whether the destiny of the planet would include total destruction on one extreme versus complete renewal on the other, with interim possibilities including partial renewal or partial destruction.

Finally, end-time beliefs have inspired various responses from their believers in the form of cultic or social action. Some end-time beliefs simply demand that their particular end-time story be read or told. Others encourage cult members to ritually enact the main elements of the narrative. And, rarely, still other belief systems encourage the instigation of actions to effect the conditions for the beginning of the end-time itself. Some believers act to forestall the end-time. Others work to speed the end-time along.

Engels, Friedrich (1820–1895)

Friedrich Engels was born on November 28, 1820, in Barmen, which was, at that time, part of Prussia. Engels's father was a prosperous German industrialist. Young Engels attended the *Gymnasium* (secondary school) in Elberfeld in 1834. Liberal freethinkers directed the school. By 1837, Engels openly expressed sympathy with radical humanism and militant democratic ideas. In 1838, Engels moved to Bremen, Saxony, to train as a factory manager for the firm of Heinrick Leupold. Engels found that liberal ideas were more openly articulated in Bremen.

In 1839, Engels published an article that attacked the absurd mysticism of pietism. Engels claimed that this ideology was closely linked to the major social ills of Germany and that it justified the wealth of the moneyed elite. Owners who were deeply religious were morally responsible for the pain of child labor. It was justifiable to blame the owners for the poverty and suffering of the working class.

In November 1842, Engels moved to Manchester, England. He went to work at the Victoria Mill office of Ermen and Engels in Manchester. This operation manufactured yarn and sewing thread. During the working day, Engels was a hard-working industrialist. At night, he became a social researcher and labor militant, hanging around the grimy, perilous streets of the Manchester working-class slums. Manchester was, at this time, a major center of the most revolutionary elements in the Chartist movement. Though born into a capitalist family and working as a manager in his family's business, he openly sided with the revolutionary proletariat. Engels began his famous study on the conditions of the English working class. This became the data for his book *The Condition of the Working Class in England in 1844*. This book detailed the life of the industrial proletariat in an advanced industrial capitalist nation. Under such conditions, antagonisms with the bourgeoisie were open and strong. The Industrial Revolution converted tools into machines. Tools, which were extensions of the workers, distorted the worker into an extension of the machine. Because of the dehumanization of the industrial proletariat, the middle class, which became the new ruling class, found that its enemy was no longer the feudal aristocracy but its own workers.

Next, Engels began a serious study of the history and evolution of the sciences. The philosophy of the 18th-century materialist philosophers of France and England provided the connection between philosophy and science. However, the materialism of the 18th century was seriously limited. Materialism needed to be merged with the dialectical logic of Georg Wilhelm Friedrich Hegel. Engels, along with Karl Marx, also wrote in refutation of both the young Hegelians and their master Ludwig Feuerbach. This radical secular humanism would not provide the ideology needed to organize a working-class movement in its struggle for socialism.

The Thesis

This was the thesis of the emerging German ideology: The real history of humanity begins with people providing for their material necessities of life through their practical activities of taking care of their physical needs. It is through labor that people connect with nature and with each other. This link between the forces of production and the relations of production set into motion all the changes in history. When forces and relations of production no longer support each other, revolutionary changes in society take place. The production of material life defines the possibilities of the social, cultural, and political life of a people. In a stratified society, all ideas have class content. The ideas of the ruling class are the ruling ideas. These ideas reinforce the economic and political power of the ruling class. Private property and a market economy come together over time to concentrate the resources and products of production under the control of a very few wealthy owners. The majority of the population of direct producers is forced, by fear of hunger, to sell their labor power in order to survive. The workers can end this oppression by abolishing private property.

It was at this time that Engels and Karl Marx became close colleagues and partners. Over the next 50 years, Engels would carry out his close collaboration with Marx. Engels's contribution to the intellectual traditions of Marxism was based upon his initial proficiency in economics and science.

Engels wrote about science and social science. The writing of *Anti-Dühring* was a defense of historical materialism against not only a watered-down eclecticism but also an insipid assortment of idealism, materialism, and fabrication. The study of an object or event in the context of its larger historical and environmental setting, scientifically and methodically, was central to materialism. This study recognized that change is always happening and that it can be understood dialectically. The unity and conflict of opposites and the transformation of quantity into quality were Engels's explanations of how all this was achieved.

Materialism states that physical matter is reality and humans are a historical product of the environment, both social and physical. However, if one does not recognize the dialectical nature of everything, the research will miss the mark. Constantly changing reality, with a material basis, is true for history, sociology, biology, or physics. Through historical materialism, it is possible to understand the conditions that were elemental for the origins of capitalism. It now becomes possible to understand the subsequent development and changes of capitalism as a world system.

Capitalism expanded from its homeland to the rest of the globe, demolishing, integrating, or containing preexisting economic systems. Class conflict, economic crisis, colonialism, and nationalism were natural consequences of private property, expanding markets, production for profit, and the culture of individualism. Industrial markets expand and transform every nation. Private ownership and competition in a world market lead to increased productive resources being concentrated into fewer hands. When companies become larger, more people are stripped of their resources; with the exception of their ability to work for wages. This leads to the majority of the world's population being controlled by a socially organized system of production and exchange. Historically, the social role of the capitalist changes over time from entrepreneur to investor and from innovator to parasite. The contradictions between the forces of production and the relations of production lead to a revolution not only in technology and social organization but also in the culture of everyday life.

Dialectical Materialism, Science, and History

Engels was seriously interested in advances made in all the sciences. Knowledge of mathematics and the natural sciences was essential in order to comprehend a materialist method that would also be dialectical. It was implicit that anything studied was in a process of change, coming into existence and ceasing to exist at the same time. Matter in motion is seen everywhere. The universe itself is changing, evolving, dying, and being born at every moment. In the process of change, what exists is being replaced by something new, fashioned out of what went before.

Because of this, science itself is founded upon philosophical materialism. As science evolves, teleological arguments are harder to justify. Interconnections can be observed and then presented as facts. Problems like biological evolution, conservation, the transformation of energy, and new discoveries in organic chemistry are better understood from a model that is both dialectical and materialist.

Science best matures as an interaction between theory and practice. From observation, we derive scientific experiments, and then we develop theories that have practical applications. From these applications, new observations and experiments are conceived. Philosophy is never superseded by science, but science itself is historically and culturally embedded in a set of specific historic preconditions. Freed from religion and magical beliefs, science is founded on materialist philosophy that uses the dialectical logic of understanding.

In *The Part Played by Labor in the Transition From Ape to Man,* Engels argues that human evolution had a long historical development in which labor and early use of tools, once being established among our hominoid ancestors, played an important role in further human biological evolution. This interaction between human creation and the physical evolution of humans demonstrates the importance of using a research model based on interaction of parts rather than simple unidirectional cause and effect.

Engels gathered a copious amount of notes on what was current in natural science. These notes would become *Dialectics of Nature,* posthumously published in 1924. Following is a summary of the book's argument.

Central to the evolving universe is a conflict of opposites merging continuously into something new. Objectively, these movements follow law-like patterns. Subjectively, these patterns are interpreted and reflected in a people's ideology and consciousness (culture). At any time everything is coming into being and ceasing to exist. The subjective reflection of this, while seen as absolute and unchanging "truth," is in fact continuously reinvented and reinterpreted.

The universe consists of matter in motion, changing through time and space. The earth and all the bodies in the cosmos arose from a random collection of atoms, acting in the course of objective law, like patterns that can be discovered by the use of the scientific method. Because all parts interact and modify all other interacting parts, change is constant everywhere in the universe. Thus, any method of inquiry should be both materialist and dialectical.

People evolved from less-developed biological organisms. Because human consciousness is a function of the human brain, consciousness is also a function of human evolution. Ideology and culture result from this consciousness and are a part of human evolution. Slowly, the transition from simple neural response to external stimuli to complex cultural awareness evolves.

Engels would claim that walking upright was central to the evolution of the highly complex human consciousness necessary for human society. An effect of freeing the forelimbs was to make tool-making easier. With more comprehensive tools, a more multifaceted consciousness naturally evolved. The human brain evolved from a common ape ancestor. Humans, through their collective labor, created humanity in a natural environment.

Forces of production, as in technology, environment, and population pressure, are always in conflict with the relations of production, which is the social organization of a society. Conflict in competing ideologies reflects this. Struggles within a society are expressed as opposing values, which reproduce competing interests over production and distribution. Production and redistribution are needed resources of subsistence. Each class within society has its own interpretation of the dominant ideology.

Specifics of history reflect changing historical trends, because of these conflicts. With the constant disintegrations of the old, the raw material for the construction of the new is constantly being created. Small changes accumulate until there is a rapid break with the old order. There are small quantitative changes until there is an abrupt qualitative transformation. This is completed by natural causes, though the ideas of cause and effect are only intellectual tools to understand these changes. Something fundamentally new is created out of the leftovers of the old; these occasions are called "nodal points." Motion arises from this continuous interaction of elements of divisions of a larger whole.

Humans are biological, social, and cultural animals. The production of the means of subsistence at any point in history is the foundation for the creation of culture or ideological superstructure. This being said, the histories of most societies are mapped out by class struggle. Political tussles arise over political control of economic resources. The older classes try to maintain domination of society, and newer emerging classes attempt to obtain that power for their own benefit. The fight is over control of material resources and how they are used in the productive process of a society.

This is an ongoing struggle. The relationships between classes are always in flux. Because of the continuing struggle, changes in the social organization of society reflect the varying ideas. Ideas change to reflect the changing economic needs and relative strength of the competing classes in society. In this evolving culture of conflict, social and political relations in turn change to reflect changing economic relations between the various groups in a society. Given this context, religion, philosophy, art, and culture are produced within a historical context.

In any class society, it was the "small privileged minority" that controlled both the means of production and distribution. The minority benefited from the productive activity of the majority. The wealth of the minority was created by the poverty of the majority. Because of this, control over the direct producers was the primary issue of government and law. All of history is the history of class struggle. Each government reflects a specific mode of production (economy) and the needs of a small ruling class. This is the real foundation of all political, religious, and social conflicts and change.

When people make fallacious assessments about the world, those assessments are not based on rational assumptions that are in turn based upon correct data. When these same people inescapably arrive at goals that are contradictory to a chosen purpose, then no matter how we protest that their decisions were based upon rational assumptions and empirical data, they always lead to unforeseen consequences. It is those choices that lead to the experience of a world beyond our control.

In *The Origin of Family, Private Property and the State,* Engels came to the conclusion that the type of family in any society reflects the property relations and class structure of the society being studied. The family type is, then, historically determined. The type of state that develops when a state society is formed also reflects the specific property relations and is also historically determined. The state is the real meaning of oppression. Each new ruling class overthrows the previous ruling class and creates an all-new state to reflect its interests. The state, then, is always the instrument of oppression. This is true even though every state claims to represent the interests of all people.

Enlightenment, Age of

The Age of the Enlightenment describes a time and a movement rare in history because of the fact that the movement's thinkers actually gave the title to their own period of time. Roughly, the Enlightenment covers the period from 1750 CE to 1800 CE. Enlightenment thought emanated from Europe, especially France, but its consequences spread throughout the world and, pertinently at the time, to the colonies of North America that were to become the United States of America. The changes wrought by the Enlightenment include a rejection of traditional religious and metaphysical ideas, as well as the insistence upon the virtues of freedom, equality, moral dignity, science, and reason. Tied in with these Enlightenment values, however, was a particular conception of time as a continually unfurling process by which progress was made. Thus, time was of crucial importance to Enlightenment philosophers because the passage of time would bring progressively superior ideas about religion and metaphysics as well as greater freedom, equality, moral consciousness, ethical action, and understanding of the universe.

Early Enlightenment

To understand the Enlightenment one must first acknowledge its antecedents. The Enlightenment could not have occurred if not for the historical foundation that buttressed it. This historical foundation includes the accomplishments of reason and logic dating back to ancient Greece. It was in ancient Greece that logic had been used to turn traditional beliefs upside down, and the thinkers of the Enlightenment sought the same outcome in Europe.

Most emblematic of the Enlightenment is the appreciation of reason. Thus, the roots of the Enlightenment in Europe can be traced back as far as Saint Thomas Aquinas, who reinvigorated the ancient Greek logic of Aristotle, attempting to demonstrate harmony between reason and faith. It was at this point in the 13th century that reason began to vie for center stage in European thought, rivaling the religious faith that had been venerated since the fall of Rome and throughout the Dark Ages. The conflict may be seen not just in the philosophy of Aquinas but in literature as well, particularly in Dante Alighieri's *Divine Comedy.*

From the 13th century on, reason vied to sway the European mind, as can be seen by the unfolding of European history afterward. The 14th and 15th centuries saw the rise of the Renaissance and particularly the humanist thinkers who fueled this movement. The humanists defied traditional power structures not just by championing reason but by taking a new attitude toward God, humanity, and the universe. Instead of gloomily dwelling on original sin, they took a more positive and cheerful attitude, arguing that to worship God one must worship his creation, the most beautiful of which was humanity. In fact, the new humanist paradigm envisioned humans as being like God not only in literal image but also in his image in the sense that they too had creative powers. Thus, the outpouring of intellectual and artistic achievement during the Renaissance was rooted in the idea that such works were not sinful but were means of worshipping God.

Also demonstrating a new appreciation of humanity were the changes that came during the Reformation, which followed the Renaissance. The primary change was the appreciation and acceptance of human interpretation of the Bible. This new insistence upon human powers to create and interpret formed the foundation upon which the Enlightenment could unfurl. Furthermore, the emphasis on worshipping God through worship and appreciation of his creation evidences the roots of deism, which was the religion embodied by the Enlightenment.

Finally, the third major social transformation that allowed for the Enlightenment after the Renaissance and the Reformation was the Scientific Revolution. The Scientific Revolution marked a new method of thought, aptly named the scientific method. It was the method advocated by Francis Bacon (1561–1626). It involved observing, questioning, hypothesizing, and experimenting. The Scientific Revolution's impact was felt first in the realm of physics. Nicolaus Copernicus, Johannes Kepler, and Galileo Galilei successfully changed the way that humans thought about the earth and about their relationship to God. No longer was the earth at the center of the universe as had been taught throughout the Dark Ages. It merely revolved around the sun, which was situated in the center. These first scientists who established the heliocentric model as humanity's universal paradigm were followed by Isaac Newton, who made yet another grand leap for science, uncovering natural laws that governed the universe, the most important of which was gravity. Once Newton established the existence of natural laws determining the movements of the universe, humans reasoned that natural laws might govern not only celestial bodies but human populations as well. Thus, the search was on for natural laws that could guide the development and progress of human society.

The Value of Reason

The stage was set for the Enlightenment over a number of centuries that preceded it. New values were championed, such as appreciation of the individual and human power to create, choose, interpret, and act freely. It was only a matter of time before these changes inspired a large and organized movement for social reform. Optimism about the human condition and the grand undertaking to discover natural laws that ordered and directed the progress of society are what would come to characterize the Enlightenment.

Thus, the Enlightenment was an optimistic period marked by the belief in reason, secularism, and progress. The Enlightenment was characterized by the belief that there was a logically deducible reason for everything and that humans could unravel the mysteries of the universe by using the faculties of their own minds. It was believed that with time, the accomplishments of humankind in science and morality would be limitless. Through the use of reason, humans could learn how to manipulate the universe to their every advantage and thereby make the world the most optimal place for human existence. It was believed that through the employment of reason, humans could perfect society and could subsequently perfect themselves as individuals as well. According to Enlightenment thought, human potential was limitless, and in the world there was a correct answer for everything; it was only a matter of time before the answer was found. Thus, a belief in the inevitable fulfillment of people's potential to govern themselves and the world characterized the Enlightenment.

With the Enlightenment came the embrace of subjectivity and freedom as well. Attached to these came a decline in the power of traditional religion and monarchical state authorities. After the Reformation, modern individuals could stand alone in the world, independent and self-reliant, in the sense that they could directly mediate their own relationship to God, bypassing the previous mediator that had existed in the Catholic Church. The Enlightenment marked a leap even grander than this, as many began to abandon Christianity completely in favor of more rebellious ideas such as those of deism, or even naturalism, in which assumptions of divine intervention and guidance are laid to rest. In addition to the religious shift came an economic shift as well, as people during the Enlightenment stood to gain greater economic freedom. Rational theories of self-interest guiding the economy, such as Adam Smith's theory of the invisible hand, worked to erode mercantilism and justify capitalism. Thus, people came to be free and self-directed not only in their religious beliefs but in economic adventures as well.

In many ways, the thinkers of the Enlightenment believed that they were involved in an act of creation: the creation of a new and better world order, based upon reason and the study of individuals and societies. As with any act of creation, this of course necessitated destruction. In the case of the Enlightenment, this meant the destruction of the church and the destruction of the monarchical state. Thus, the philosophers relentlessly scrutinized and criticized the dogmatic theology that buttressed both. Instead, they championed open inquiry and new forms of government. Some, such as Voltaire (1694–1778), believed enlightened despotism to be the ideal means of government. Much like Plato, Voltaire felt that only philosophers could rule in the most rational way, and thus the king ought to be informed by philosophers such as himself. Symbolizing his distaste for democracy, Voltaire is often cited as saying that he would rather obey 1 lion than 200 rats of his own species. In other words, one enlightened despot is better than a whole democratized country of uninformed fools. Thus, it was through a monarchy directed by philosophical reason that Voltaire thought progress and change would occur.

Enlightened Despotism

To understand the Enlightenment, one must understand the governmental models that its thinkers found ideal. Enlightened despotism, also known as benevolent despotism or enlightened absolutism, was championed by Voltaire, and its enactment was catalyzed by Voltaire's close contact with several monarchs of the time. Enlightened rulers identified themselves as such and differed from traditional rules in their emphasis upon rationality as a means to better government and their espousal of modern notions such as religious toleration, freedom of speech and the press, and the right to hold private property. Subsequently, these rulers often cultivated learning in their lands more than traditional rulers had.

Determining the enlightened despot from the mere despot is not a matter of black and white, however. Both tended to believe that their right to rule was granted by birth and thus were not apt to make unwarranted compromises such as the allowance of constitutions or the proliferation of legislative bodies that would serve to check monarchical power. Determining whether or not a ruler was enlightened depended in large part upon the judgment of the historian and upon a broad examination of a ruler's reign. For instance, Holy Roman Emperor Joseph II embraced the social contract, whereas Catherine II of Russia rejected the concept but demonstrated her enlightenment by sponsoring the arts and encouraging a committee revising Russian law to incorporate the ideas of Montesquieu. The two differed in the ways in which they showed themselves to be enlightened, yet both are regarded as such by historians.

Essentially, enlightened monarchs wished to improve the plight of their peoples without relinquishing their own hold on authority. It is no coincidence that serfdom was abolished during the Enlightenment. Emperor Joseph II encapsulated the ideology behind enlightened despotism by saying, "Everything for the people, nothing by the people."

While enlightened despotism was the preferred form of government for most Enlightenment thinkers, some, such as Jean-Jacques Rousseau, expressed a different opinion. Rousseau argued for something closer to democratic revolution. Unlike Voltaire, who took inequalities among men for granted, Rousseau believed all men ought to be equal under the law, obviously an underpinning of the democratic governments that followed the Enlightenment. Particularly, this type of thought materialized into the United States of America and the French Revolution.

Metaphysics and Ethics

Government was just one of the realms in which thought changed during the Enlightenment. Another realm was metaphysics and ethics. It was during the Enlightenment that some of Europe's first materialist atheists gained prominence and fame. One of these enlightened thinkers was Julien Offray de La Mettrie. He was the earliest materialist thinker of the Enlightenment and is credited with being the founder of cognitive science. He observed that bodily circulation was hastened upon thought, which led him to theorize that physical phenomena were caused by organic changes in the brain and nervous system in his books *Histoire naturelle de l'âme* (*Natural History of the Soul*), *L'Homme machine* (*The Human Machine*), and *L'Homme plant* (*The Human Plant*). In the ethics he derived from this, which he detailed in *Discours sur le bonheur, La Volupté* (*Discourse on Happiness, Exquisite Delight*) and *L'Art de jouir* (*The Art of Joy*), he concluded that the purpose of life was pleasure of the senses and thus that self-love was virtuous. He believed that the theologians had deceived humanity into believing in a fictitious soul and that humans ought to reject this metaphysics, instead opting for atheism and a morality based in hedonism. His earth-centered metaphysics and ethics exemplify the new paradigms espoused by many of the revolutionary thinkers of the Enlightenment.

Another thinker whose ideas closely mirrored those of La Mettrie was Paul-Henri Thiry, Baron d'Holbach. He was also a materialist and an atheist, and his morality would be described by most as hedonism, as he argued that if virtue made a person unhappy, then that person should love vice. In 1761 he wrote *Christianisme dévoilé* (*Christianity Unveiled*), in which he charged Christianity with being counterproductive to man's moral development. This was followed by an even more famous and controversial book, *Le Système de la nature* (*The System of Nature*). Unlike other Enlightenment thinkers, however, he did not call for revolution but rather warned the educated classes against it, arguing that reform was necessary to prevent mob rule.

While the Enlightenment marked changes in realms of thought such as government, metaphysics, and ethics, it also marked new achievements in academic production. Perhaps the greatest achievement of academic production was by Denis Diderot, editor of the world's first encyclopedia. The project began as something meager. Bookseller and printer André le Breton solicited Diderot to translate Ephraim Chambers's *Universal Dictionary of Arts and Sciences*. Diderot accepted the project, but after undertaking it, persuaded le Breton to allow him to undertake an original work, which was to be a compendium of all active writers, new ideas, and new knowledge of the day. Soon Jean le Rond d'Alembert joined Diderot as a colleague. The project was announced to the world in 1750, right at the commencement of the Enlightenment. By 1751 the first volume was published, and by 1765 the last was completed, although it was not until 1772 that subscribers received the final volumes of the *Encyclopédie, ou dictionnaire raisonné des sciences, des arts et des métiers* (*Universal Dictionary of Arts and Sciences*).

The encyclopedia was more than a mere academic work. The significance of the encyclopedia reverberated in social and political realms as well, which cost Diderot numerous friends. The supporters of the church opposed the encyclopedia, as it championed the very Enlightenment values that challenged ecclesiastical authority. The aristocracy opposed the project as well because it took for granted modern notions of justice such as religious tolerance, freedom of thought, and the value of science and industry. Furthermore, it asserted the democratic doctrine that the state existed to serve the people, not vice versa. Diderot's subscribers grew to 4,000 by 1757 and continued in the same direction afterward, a trend that offended and frightened the enfranchised classes of Europe. Resultantly, rumors were spread that the encyclopedia was the work of conspirators against society, and in 1759 the encyclopedia was formally suppressed, but by that time Diderot's mind was set to keep the project moving, although at a slower pace due to the complications of working in secrecy. Unfortunately, d'Alembert withdrew from the enterprise and other knowledgeable colleagues such as Anne Robert Jacques Turgot, Baron de Laune, declined to contribute further to a book that had developed a bad reputation. Stalwartly, Diderot completed the project himself, writing hundreds of articles and editing hundreds of others. In a final act of misfortune, the bookseller, in fear of the government, eliminated the passages he considered too dangerous, thus mitigating the uproar sparked by the encyclopedia, but also (in the mind of Diderot) defacing the masterpiece. Nevertheless, the publication of the work, even in mutilated form, marked an appreciation and treasuring of knowledge that was to characterize the Age of the Enlightenment.

Social Reform

The great academic production that characterized the Enlightenment was matched with striving for social reform. No description of the Enlightenment could be complete without discussion of one of the period's most ambitious reformers, Jean Antoine Nicolas Caritat, Marquis de Condorcet. After being appointed inspector general of the Monnaie de Paris in 1774, he defended human rights, particularly those of women and blacks. In fact, he was an abolitionist, active in the Society of the Friends of Blacks. He supported the ideals embodied by the United States and proposed projects of reform in France. In the realm of politics, he is famous for Condorcet's paradox, which describes one of the problems of democracy. This problem is that it is possible for a majority to prefer A over B, B over C, and C over A simultaneously.

The culmination of the Enlightenment was the French Revolution, in which Condorcet took a leading role. He championed many liberal causes and hoped the revolution would lead to a transformation and reconstruction of society. In 1791, he was elected as the Paris representative in the Legislative Assembly and then became secretary of the assembly. In this position he was able to advance enlightened ideas for a better France. These ideas included a state education system and a Bourbon Constitution for the new France. He also advocated women's suffrage in France.

Condorcet's defense of human rights could be seen by his opposition to the death penalty for King Louis XVI during the public vote at the convention. It is this that would lead to his own untimely death. As the parties advocating the king's execution gained power, Condorcet was branded a traitor and a warrant was put out for his arrest. Subsequently, he went into hiding and wrote *Esquisse d'un tableau historique des progrès de l'esprit humain* (*Sketch for a Historical Picture of Progress of the Human Mind)*. The text outlines the enlightened paradigm with regard to time and history. In it, the history of civilization is described as the progress of the sciences, intimately tied to the growth and proliferation of human rights and justice. Furthermore, like the work of many Enlightenment thinkers, it outlines an optimistic view for future society crafted upon scientific knowledge and rationalist principles.

In fact, Condorcet's conception of time was sufficiently rigorous that he outlined nine great stages of universal history. The first stage he defined as the time when hordes of hunters and fishers united in tribes. The second stage was that of pastoral peoples. The third stage included the development of agriculture up to the invention of the alphabet. The fourth stage he described as the progress of the human mind in Greece up to the division of the sciences. The fifth stage he then described as the progress of these sciences until their eventual decline, followed by a sixth period, roughly the Dark Ages in which intellectual life stagnated. The seventh stage he saw as the reawakening of science and the innovation of printing in Europe. The eighth stage he characterized as the time when science and philosophy diverge from the auspices of traditional religious and monarchical authority, and finally the ninth stage he saw as the time spanning from Descartes until the emergence of the French Republic.

Having described these nine stages, his tenth stage is what is most emblematic of characteristic Enlightenment thought. This was the future stage of equality and freedom, which would be achieved by means of scientific achievement leading to, and/or partnered with, social reform. In this stage Condorcet foresaw a holistic perfection of humankind in physical, intellectual, and moral aspects, resulting in the eradication of war, prejudice, superstition, and disease. In fact, his faith in the scientific perfectibility of medicine led him to believe that humans would become virtually immortal, saying that death would be due only to extraordinary accidents and that the time between birth and death would have no assignable value.

Also working for social reform was Claude Adrien Helvetius. He is among the privileged writers whose work, *De l'esprit* (*On the Mind*), was deemed so heretical by the church and state that it was burned. Like Condorcet, he was interested in advancing human rights and increasing the general welfare of France. He made a fortune quickly at a young age as farmer-general (a tax-collecting office), but when his wealth was sufficient, he retired and employed his capital in the relief of the poor, as well as the development of agriculture and industry. The controversy surrounding his book actually helped to popularize it, and it was quickly translated and disseminated throughout Europe. Historians have divided his book into separate discussions, all of which present well-known and agreed-upon Enlightenment principles. First, all human faculties may be reduced to physical sensation. Second, self-interest, inspired by the love of pleasure and fear of pain, is the motivating factor for all decisions and action. Any case in which this appears not to be so is only a case in which there is an unseen pleasure or pain motivating the actor. Consequently, there is no such thing as good and evil, as they are classically defined. Third, all intellects are equal, and subsequently all people are born of equal ability. Inequalities actually spring from the passions, which motivate people unequally to receive instruction. These ideas, put forth by Helvetius in his controversial work can thus be summed up as utilitarian and democratic, both of which were currents of thought that ran strongly through the Enlightenment.

Voltaire

While La Mettrie, Diderot, Condorcet, and Helvetius all made important contributions to the paradigm embodied by the Enlightenment, perhaps none of their contributions was as great as that made by Voltaire, who is thought by many scholars to singularly embody the Enlightenment better than any other thinker. His thought was crucial to the Enlightenment in France and throughout Europe. In Paris, the year 1694 CE, he was born François-Marie Arouet to a noble family from the Poitou province. Later, he took up the pen name Voltaire, which was a good idea, given the controversy his work stirred up. He defended civil liberties and human rights, insisting upon the importance of religious freedom and, in matters of state, the right to a fair trial. He stood for freedom of speech, as was evidenced by his frequent disregard for French censorship laws. He often criticized the Christian Church and the dogma it proliferated. Most generally, he worked for social reform. Voltaire's energy toward the reformation of France caused him to end up on the wrong side of those in power more than a few times. He was repeatedly imprisoned and exiled. During one such period he spent 11 months in the Bastille for writing satire about France's aristocracy.

Voltaire symbolized the Enlightenment not only because of his personal efforts to reform society but also because of the compendious nature of his work. His work was perhaps more varied than that of any other scholar during the Enlightenment. He wrote poetry as well as a number of plays that attacked the church, monarchy, or aristocracy. Furthermore, he wrote what may be considered ethnography. Voltaire spent 3 years in London and condensed his experiences into a work titled *Lettres philosophiques sur les Anglais* (*Philosophical Letters on the English*). In this work he was very critical of French society while extolling the virtues of constitutional monarchy and human rights that he experienced in England. As could be expected, the French aristocracy found his work distasteful to the point that copies of it were burned and he was forced to leave Paris.

His expulsion from Paris only led to a greater diversity in his work. He traveled to the Chateau de Cirey on the borders of Champagne, Alsace, and Lorraine. Here he performed many scientific experiments, including one to determine the properties of fire. He was particularly interested in Sir Isaac Newton, to whom he had been exposed during his exile in England. Voltaire was especially curious about optics and gravity. He was impressed by Newton's discovery that white light is comprised of every color in the spectrum, and he was inspired to perform several of his own experiments on the topic. Voltaire ended up writing a book on Newton's philosophies: *Éléments de la philosophie de Newton* (*Elements of Newton's Philosophy*).

Demonstrating the compendious nature of Voltaire's studies, he additionally examined history and, in the spirit of the Enlightenment, paid particular heed to concentrating on past people who had contributed to the growth and development of civilization. He wrote an essay titled *Essay Upon the Civil Wars in France* and a biographical essay on King Charles XII, in which he began to reject religion, expressing a fundamental tenet of the Enlightenment that human life is not destined to be controlled by any beings greater than humans, but by humans themselves. Voltaire continued to do work relevant to religion, analyzing the Bible, and philosophizing on metaphysics. He advocated separation of church and state, a staple of the Enlightenment, which lives on today, and went so far as to claim, "One hundred years from my day there will not be a Bible [on] the earth except one that is looked upon by an antiquarian curiosity seeker." This irreverence for tradition and grand vision of a very different future is characteristic of the paradigm.

This criticism of religion was a theme common in much of Voltaire's work. He personally identified himself as a deist, as did many other philosophers and scholars of the time. The deist believed in God and found it reasonable to do so by virtue of creation. Therefore, the deist felt that faith was not necessary. Deists felt that the beauty of creation suggested some sort of supreme designer. However, they denied the phenomenon of divine intervention. The deist envisioned a world that ran like clockwork, according to laws designed by the Creator but not subject to whimsical change by him. Thus, deists did not believe in any traditional book of authority, because God did not need to reveal himself through such a book when he revealed himself through the beauty and workings of nature.

Immanuel Kant

While Voltaire singularly embodies the Enlightenment better than does any other individual, the culmination and aspirations of the Enlightenment can be seen outside of France in the work of Immanuel Kant (1724–1804). Kant stated that the Enlightenment was humanity's exit from a self-incurred minority. By this Kant means that the Enlightenment is people's exit from the fear or lack of determination to employ their own intelligence. Hence, Kant said the motto of the time was, "Have the courage to use your own intelligence!" Kant proclaims that it is time for Europeans to stop letting others, such as the propagators of religion and monarchical rulers, to direct their thoughts and actions. Kant reasoned that it was essentially laziness that kept other Europeans from thinking and directing themselves, and Kant encouraged them to use their reason to be self-determining. This, Kant said, necessitated open inquiry and discussion in the public sphere. Exemplifying what he meant, Kant said that a military officer has a duty to obey the commands of his superior officers, but he also had a duty to the public to express it if he felt his superior officer had blundered, thereby submitting judgment to the public. Likewise, a good citizen pays his taxes but is obliged to publicly utter thoughts about the undesirability or injustice of a tax if it is so. Finally, a clergyman teaches the faith to his congregants, but has a duty to criticize errant beliefs or practices of the religion in his own writing. Thus, it can be seen that to Kant, Enlightenment meant, in addition to free use of individual reason, free presentation of reasonable thought in the public sphere.

Furthermore, in addition to the free use of reason by the people, Kant defines the Enlightenment as an age in which people are ensured the right to do this by protection from the government. Kant said that the monarch's only concern is to prevent one subject from hindering another by force, to work according to each subject's best ability to determine and to promote his salvation. Kant added that it detracts from the monarch's power if he interferes in the matters of his constituents, and subjects to governmental supervision the writings by which the monarch's subjects seek to clarify their ideas, especially those concerning religion. Thus, it can be seen that according to Kant, enlightenment also consists of a government that will allow citizens to use their reason freely, both privately and in public discourse.

Concluding Remarks

Since the Enlightenment, we have seen that reason and freedom are not the simple panacea that the thinkers of the Enlightenment envisioned. Two world wars and the failures of numerous democratic governments prove this to be true. In fact, tyrannical regimes have often existed in the name of freedom and have bent reason and logic to justify their own existence. Thus, interpretations of and responses to the Enlightenment have been varied. Counter-Enlightenment movements and particularly Romanticism as inspired by Jean-Jacques Rousseau followed the Enlightenment. Friedrich Nietzsche, in particular, questioned the values of the Enlightenment and criticized its lofty ideals.

Thus, the legacy of the Enlightenment is multifaceted. However, for the most part the Enlightenment is seen as a positive historical trend that forms the roots of modern democratic government and our modern appreciation of science and education. The underpinning axioms of democracy were postulated and put forth during the Enlightenment, and the importance of education was firmly advocated. This emphasis on education led to the growth and development of educational systems in Western society. Although society is still far from being perfect, most would argue that we have made steps toward better societies. Particularly we have moved away from totalitarian monarchical governmental systems toward republican and democratic ones in which the people have more power.

Moreover, the separation of church and state that we esteem in the U.S. today, along with the values of free inquiry, education, reason, and knowledge, all have their roots in the Enlightenment.

Finally, and quite pertinently, conceptions of process as progress remain with us today. Despite the tragedies that have befallen humanity since the Enlightenment, such as the two world wars, much of humanity still has an optimistic attitude about the future. The idea that science will resolve the problems humanity faces remains with us. In fact it is an implicit truth to many in the modern world that life continues to improve as scientific and governmental advances occur. It is this tacit approval of science and the notion of a continually bettering world that has its roots in those conceptions of time and history born in the Enlightenment.

Entropy

Entropy is a measure of disorder. This innocuous-looking definition indicates neither that entropy is connected closely to time nor that the road to an adequate understanding of entropy might sometimes wind its way through an area full of wrong paths and dangerous traps. To show the connection between entropy and time, and to dispel confusion, this entry provides a short tour of the history of the concept of entropy.

The concept of entropy was introduced in thermodynamics, the physical science that studies energy and how it is transformed. In the first half of the 19th century, the technological issue that drove thermodynamics forward was the problem of how to optimize the efficiency of steam engines. Efficiency is the ratio of the net work produced by a cycle of movements in a steam engine to the heat supplied to the engine during such a cycle. The higher the efficiency of a steam engine, the better it converts the supplied heat into work. What steam engine is the most efficient? In 1824 the French engineer and officer Sadi Carnot solved this problem by inventing an ideal steam engine, now called the Carnot machine. Its workings are completely reversible: A cycle in a Carnot machine can be made to go backward by an infinitesimal change in it because all forces that cause the cycle are only infinitesimally removed from balance. Someone viewing a motion picture of the working machine cannot decide whether the picture is being shown forward or backward. So it is impossible for the observer to distinguish objectively between different directions of time in Carnot machine cycles.

This result clearly contradicts our everyday experience: We know that heat is transferred only from a body at a given temperature to a body at a lower temperature. The German physicist Rudolf Clausius generalized this best-confirmed observation and stated the second law of thermodynamics: A transfer of heat from a body at a given temperature to a body at a higher temperature never occurs spontaneously, that is, without any other change in the state of the bodies at the end of the process. If the second law were falsified, it would be possible to construct a Carnot machine that could use heat transferred from the body at lower temperature to the body at higher temperature for the production of work. The latter body would give up and take in the same amount of heat, so that it would be in the same state at the end of the cycle as it was at the beginning. If the temperature of the colder body were kept constant, we would have succeeded in constructing a machine that is, for all practical purposes, a *perpetuum mobile:* Simply by cooling down its environment, it could completely transform thermal energy, of which there exists a practically unlimited amount in the environment, into work.

In 1865, Clausius introduced the term *entropy* (from the Greek verb *entrepein*, "to turn") to denote a mathematical function of the state of a physical system like a Carnot machine or an irreversibly working steam engine. The difference in entropy between two states of such a system is the integral, taken over a transformation from the first to the second state, of the ratio of the net heat absorbed by the system from its environment to the temperature of the environment. If the transformation of a thermodynamically isolated system (i.e., a system that does not exchange heat with its environment) is reversible, the difference in entropy is equal to zero; if the transformation of such a system is irreversible, the difference in entropy is greater than zero. Clausius could thus rephrase the second law of thermodynamics: *In a thermodynamically isolated system, the entropy can never decrease with time.* In case of an irreversible transformation, an observer can decide whether some state has occurred earlier or later than another state in the history of a system. One just has to calculate the difference in entropy between these states. After an isolated system has reached its state of maximum entropy, an irreversible transformation of energy cannot occur in it anymore. Clausius applied this result to our universe as an isolated system in which entropy tends to a maximum, too, and he called its final state "heat death of the universe": a state in which the whole of nature will be in thermodynamic balance.

Ludwig Boltzmann, one of the most important physicists of the second half of the 19th century, redefined Clausius's concept of entropy in statistical terms. Without going into the mathematical technicalities, *statistical interpretation* means roughly that thermodynamic concepts (like that of temperature as degree of heat in a system) are explained from an atomistic point of view (e.g., temperature as measure of the average kinetic energy of atoms in a system). Entropy then becomes a function of the number of atomic microstates of a system that can realize its present thermodynamic macrostate. Whereas the description of the microstate of a system contains information about the states of all atoms of the system, a description of its macrostate contains just such information that characterizes its overall thermodynamic properties.

The statistical interpretation of entropy can be illustrated by means of a thought experiment. Imagine that you have a box containing 1 million tiny red marbles and 1 million tiny blue marbles in your hands.

- At the beginning of your experiment, the red marbles are separated perfectly from the blue ones: All red marbles are in the right half of the box, and all blue marbles are in the left half. If this macrostate of the box is not be altered, then only such changes in the position of a marble (and, thus, in the microstate of the box) are allowed that let all red marbles stay in the right half of the box and all blue marbles in its left half.
- Now you shake the box violently. The longer you do so, the more the red and blue marbles will be mixed. The probability that a marble chosen randomly from, for example, the right half of the box, is blue will approximate the probability that it is red, namely 50%; before the shaking, the probability was 100%. The macrostate of an equal distribution of blue and red marbles to the halves of the box can be realized by many more microstates than the first macrostate: Any marble in, again, the right half of the box may interchange its position not only with any other marble in this half but also with any marble of the same color from the left half. The more microstates can realize one and the same macrostate of the system, the more disordered the system is and the higher its entropy is.
- The probability that, by shaking the box anew, the first macrostate will reappear is negligibly low. You might have to shake longer than the heat death of the universe will allow you. If you again start your experiment with another macrostate, your shaking will almost certainly transform this initial macrostate once more into increasingly probable macrostates, that is, into

> macrostates that can be realized by more and more microstates. Yet it is not completely impossible that your shaking will result in a less probable macrostate. The thermodynamical reason for such a decrease of entropy is that the box is not isolated: It absorbs the energy of your shaking.

Since the turn of the 20th century, the statistical concept of entropy has been used in many sciences other than thermodynamics to quantify the degree of disorder of a system. The most important of these applications is Claude E. Shannon's theory of information, which laid the foundation of modern communication engineering.

The concept of entropy attracted much interest also beyond science. The foremost reason for this is that the second law of thermodynamics not only implies the existence of an objective direction of time in nature but also has a pessimistic consequence from the standpoint that history is a process of unlimited progress. In the long run, the heat death of the universe sets an unsurpassable limit to the transformation of energy into work—even in a thermodynamically open system like the earth, which is currently fed with energy from the sun.

Thomas Pynchon's short story *Entropy* (1958–1959) is an intriguing literary document of the nonscientific reception of the entropy concept. Pynchon's narrative puts together, on a few pages, many of its facets: its thermodynamic sense, its statistical definition, its connection to information theory, its cultural interpretation as a natural boundary of human progress, and its psychologically disastrous misunderstanding by individuals who short-circuit their experiences with the general tendency of the universe toward heat death. Pynchon effectively contrasts a party that, in danger of ending in a state of total disorder, is prevented from reaching it by a constant energy input of the host, with the ordered everyday life of an isolated couple that has resigned itself to consider any event as a depressing symptom of the universe's growing entropy. Thermodynamics cannot tell us which ethics we should choose.

EPISTEMOLOGY

The theory of knowledge emerges bearing several names: epistemology, gnoseology, noetics, or simply the theory of knowledge. Any attempt to precisely define these terms requires looking for equilibrium between two extremes. On the one hand, there is a danger of shifting to questions in infinite regression: How do we know that our knowledge is really correct, and how do we know that this precise knowledge is correct and not illusionary? On the other hand, we can be overwhelmed by bare historical description, because there are few themes like the problematic of knowledge that are interesting not only for all philosophers but also for many scientists, logicians, and mathematicians. We have no choice but to try to find a compromise solution and to rely above all on chosen intuitions that originate in our prephilosophical and prescientific behavior that need no theoretical justification. We trust these intuitions because they helped us to survive; we have nothing better to start with.

The different names for the theory of knowledge are often used as synonyms; in other cases, authors try to establish a certain differentiation in meaning. The term *gnoseology* usually accompanies an effort to describe the theory of knowledge as a set of questions and answers that define our cognitive dispositions, even before the beginning of the cognitive act itself. The terminology is moreover slightly complicated by the shifts of meaning and different application in main linguistic-cultural contexts.

Epistemology in Time Versus Time in Epistemology

The perspective of time can facilitate the classification of different approaches to the problematic of epistemology. An examination of the history of epistemology suggests a double sense: history of epistemology considered as a philosophical discipline and history of knowledge considered as our abilities to know ourselves and the surrounding world. This first approach can be called epistemology in time. The second line—time in epistemology—is dependent on the remarkable development of the natural sciences since the beginning of the 20th century, when many traditional philosophical notions—space, causality, determinism, movement, and time—appeared in the new context of modern physics. The category of time, in particular, is a frequent theme and subject of analyses and speculations. Time in epistemology is a prototypical problem of modern epistemology that exposes different approaches and a possible delimitation of the relation between philosophy and science.

The term *epistemology,* in use since the 19th century, has never been unequivocal. In Continental philosophy, epistemology—the study of knowledge—is often related to the philosophy of science, which focuses on scientific methods and the results of natural sciences especially. According to French philosophy, the term *epistemology* is often inappropriately identified with the theory of knowledge (gnoseology), considered as analysis and philosophical criticism of scientific knowledge. In their new thinking based on recent scientific discoveries, epistemologists try to describe the development of particular scientific disciplines from different points of view.

However, epistemology is not a theory of science. Epistemology does not deal with concrete problematics of particular scientific fields and their procedures; rather, it is concerned with questions that are *provoked* by these scientific procedures. When physicists search beyond their measured data—to discover something hidden, to explore to what extent their work is a conventional language game, or to wonder whether notions and concrete objects have something in common—they have left the field of natural science and have begun to deal with epistemological questions.

To move on to define the object and content of epistemology, various conceptions, according to linguistic-cultural spheres, must be distinguished.

The questions of epistemology are neither questions of science nor questions of traditional metaphysics. Metaphysical methods cannot be used to resolve the questions of epistemology, even if they may often touch on them thematically. That is why Pierre Duhem and Emile Meyerson try to distinguish metaphysics and science with its theory on the one hand and to find a common basis for both disciplines on the other hand. It follows that Duhem believes that logical order reflects the ontological order, whereas Meyerson is not content with simple description of phenomena and control over them but requires their explanation.

Logicians and mathematicians often deal with questions of intuition and abstraction, as well as the adequacy of their application in mathematical theory; many of them (e.g., Jean Cavaillès) find the central subject matter of their work in this field of epistemology.

The close connection between epistemology and science as such can be understood as a certain way to distinguish epistemology from the philosophy of science itself, which frequently deals as well with a larger problematic of scientific development and thus does not avoid economic, social, and institutional questions; it is often in touch with the sociology of science. In this perspective, epistemology is more "theoretical"—in contact with the theory of science, it approaches unanswered questions and doubts. At the same time, epistemology is more "practical" because it (much less often) enters directly into current problematics, as in the case of the question of determinism in connection to quantum mechanics.

Epistemologists rarely aim to create a general (the one and only) theory; rather, they look for variations by turning their attention to the past. The connection between epistemology and history of science thus results from the very basis of the problem and the logical process of its solution (see, e.g., the work of Pierre Duhem and Michel Serres). The close connection between history and epistemology gave birth to the new term *historical epistemology.*

Basic Issues

Epistemology can be characterized according to the basic issues it deals with, including the following:

1. *Crisis of the basis of science*—It does not matter which science, as long as it is natural or mathematical. For example, the crisis of formalism in logic, the crisis of mathematical essentials, and the crisis of basic physical principles are all events that provoke a continuous revival of the philosophy of science. The task is often undertaken by scientists active in particular scientific disciplines (e.g., Henri Poincaré, Meyerson).
2. *Mathematization of logic and attention to language* spurred philosophers to attempt to explain scientific assertions and to use formal analysis to verify or falsify those assertions (Poincaré).
3. *Specialization* of modern science leads also to the relative autonomy of *regional epistemologies,* that is, the study of the specificities of particular scientific disciplines (Gaston Bachelard).
4. The rapidity of development of science, especially in the past 2 centuries, is one of the main reasons for the emergence of historical epistemology, the study of the appearance of scientific theories and their successive changes (Duhem).
5. Epistemology also is influenced by efforts to obtain a better understanding of the *historical determination of changes in knowledge and scientific theories* and their individual and psychological sources (Jean Piaget, Michel Foucault).

In the European tradition as influenced by French philosophy, scientific *epistemology* is related especially to Gaston Bachelard and was developed consecutively by other French authors, such as Cavaillès, Georges Canguilhem, and Alexander Koyré. Scientific epistemologists typically connect the history of science to the epistemological problematic itself, but scientific epistemology should not be confused with the history of science.

Even though these features issue exclusively from the French domain, there is no "French epistemological school"; nevertheless, some French philosophers, including Bachelard, Canguilhem, and Foucault, have greatly influenced other European and American thinkers. Whereas Bachelard is interested in physics and chemistry, Canguilhem and Foucault concentrate more on biology or, more precisely, on the history of biological science. Foucault's research surpasses narrow specialization in many ways, whereas Canguilhem is profoundly interested in the same field of biology. As a specialist, Canguilhem offers a rather different perspective of the epistemological problematic; he provides a detailed view of specific scientific disciplines and, in this sense, approaches Bachelard. They both differ from the encyclopedic Foucault, who ventures into the fields of linguistics, economy, history, and biology.

Despite all differences, Dominique Lecourt finds some common traits—and not marginal ones—in the work of the Bachelard, Canguilhem, and Foucault. He starts with a comparison between French epistemology on the one hand and its equivalent in American and Russian philosophy on the other. Lecourt overlooks personal relations between the French philosopher-epistemologists (Bachelard was Canguilhem's teacher and Canguilhem was Foucault's teacher); nevertheless, he uncovers some relevant connections, for example, a common philosophical conception based on "nonpositivism," that is, an attitude that is in opposition to efforts to build "a science about science" or a technocratic variation of science organizing scientific work. Lecourt names John Desmond Bernal and Kernov among the proponents of "science about science"; he also mentions logical neopositivists (e.g., Hans Reichenbach), who talk about "the century of science" and seek to provide science about science and scientific criticism of philosophy at the same time.

Another approach to the theory of knowledge—again, called epistemology—derives from philosophers such as Bertrand Russell, Ludwig Wittgenstein, Rudolf Carnap, and Hans Reichenbach. It is mainly Anglophone philosophers who use the term *epistemology* to refer to a theory of basic themes in the theory of knowledge. These themes can be defined by general questions: What is knowledge: cognitive process, or fact? (This question focuses on trust, justification, truth, and their limits—the so-called Gettier problem.) What is the basis of justification, and what are its structure, sources, and limitations? (This question focuses attention on the principles and sources of knowledge and basic ways to work with them.) What are the basic cognitive attitudes? (Human knowledge can be extended in the form of principal attitudes in cognitive process, such as skepticism in various forms, cognitive optimism, relativism, etc.) What are the contributions of subject and object to the formation of knowledge, and what are the roles of empirical and rational (inductive and deductive) processes?

Epistemology, as a theory of knowledge in the broad sense, is the study of knowledge itself. This banal statement harbors considerable problems and many questions. Principally, the conception becomes gradually traditional; if not absolutely on the decline, it is certainly expanded by new themes. From a purely theoretical, often rather speculative level, it transforms into the methodological, empirical, or even "engineering" level. These changes are caused by the influence of the development of information technologies that necessarily demand a profound elaboration of formal cognitive processes, up to the level of research in artificial intelligence. From this perspective, the theory of knowledge is not considered only as a theory "for itself," that is, without the traditional impact on an object, because this object can stand for many scientific disciplines, under the influence of their rapid development; it is more often a discussion of aims. Many of these objectives are embraced by cognitive sciences that successfully develop contacts with special (often empirical) sciences, alternatively with or without engineering ambitions.

Traditional Approaches

Traditional approaches to the theory of knowledge follow at least three lines.

1. Epistemology is a theory of knowledge, in the sense of research on basic cognitive assumptions. What is the basis of our trust in the possibility of knowledge? Where do possible doubts about relevancy of obtained knowledge originate? Is there a historical model of knowledge? Does it make any sense to talk not only about knowledge as conceptual but also, in a larger sense, about the ways and methods of information exchange, that is, to take interest also in the animal world and even the nonorganic one? How long can we hold these (in most cases a priori) thoughts and resist the need to argue against the special sciences (e.g., biology and physics)? Are there any limits of knowledge? If we are willing to consider and seek them, should we turn to the external world to look for the laws of nature and physical connections that would determine these limits? Or should we turn to more subjective areas and take an interest in the possibilities of psychological, physiological, and historical determination?

The transitory state between a general epistemological problematic and its overlap with specific knowledge can be observed in the analysis of cognitive methods. The first rough division into empirical and theoretical, general, and special methods is a textbook case; any subtler distinction cannot stand without overlap to particular scientific disciplines. Analysis of simulation and modeling is mostly a study of concrete physical or mathematical models from selected domains: the atomic model, the universe model, models of *n*-dimensional spaces. Analysis of experiment is also intentional because real, physical experiments are genuine cases of empirical science. Theoreticians of thought experiments, who enjoy essentially a larger sphere of activity and avoid the aforementioned tendency, use numerous concrete illustrations. In view of the fact that the question of method is considered as a problem of theory of knowledge, epistemology can then participate in concrete scientific disciplines, but also—in the case of scientific experiment and methods related to modern technologies that open classic questions of mind (e.g., the question of artificial intelligence)—a shift from cognitive sciences to particular engineering procedures can be observed.

2. Beyond the limits of specialized knowledge is modern (regional) epistemology, often focused on one selected discipline of contemporary natural science, characterized by considerable empirical orientation. Narrowly focused epistemologies dealing with concrete problems (e.g., epistemology of theory of relativity, epistemology of evolution biology, etc.) are not exceptional. Another transgression of limits, this time toward practical application, or at least toward concrete considerations of possible applications (data collection and information exchange in expert systems, particular models of artificial intelligence, agents and robots, etc.), is a way toward the engineering approach to knowledge mentioned earlier.

3. Definition of the limits (albeit often imprecise) between an engineering approach and cognitive

sciences is not easy. Cognitive scientists provide their conclusions in the form of possible experiments in various shapes (from purely thought form up to completely realistic) or even directly in a concrete application.

Recognition of the content common to epistemology and cognitive sciences might be extended to other related disciplines—for instance, epistemological questions form part of the large field of thematic content of another specialized discipline: the philosophy of mind. Within the scope of philosophy of mind, attention is focused on problems related to identification of mental states, differences in the perspectives of first person and third person, and especially to the traditional problem of other minds.

The Philosophy of Science

This survey of possible approaches to the problematic of knowledge is certainly not exhaustive. A broadly conceived problem could embrace also a domain known as the philosophy of science. The theory of science usually defines critical analysis of the basis of scientific thought and proper scientific theories. However, if these bases are considered in the broad sense, they include also prescientific, philosophical, or metaphysical assumptions of science, which does not exclude possible overlap to the field defined earlier as gnoseology—namely, epistemology as a theory of a priori knowledge. Just as the philosophy of science cannot escape the history of science, it also approaches closely the content of particular scientific theories and overlaps the field of epistemology. Philosophy that shares with science itself some common characteristics—it is rational, constructive, it seeks veracity—cannot be an objective external perspective in all aspects. Besides, it is obvious that none of the mentioned approaches, not even the philosophy of science, can provide a universal methodology of science and scientific thought, even if such attempts can be found in the history of philosophy and science. Today, this ambition is consigned to the archives of unsuccessful ideas; nonetheless, its place has been quickly replaced by another effort, more poetically called dreaming—that is, dreaming about a final theory (Steven Weinberg) that would be the definitive theory. Dreams about the ultimate theory (theory of everything; unifying theory) were born in the field of physics as an effort to unify physical interactions. Nevertheless, some physicists would not protest against enthronement of this theory as the true Theory of Everything, to fulfill the ambitions of strict reductionism.

In conclusion, the traditional problem of the very possibility of knowledge studied by epistemologists has been divided into two lines. On the one hand, there are abstract, purely philosophical, analytical considerations of the essence of knowledge, the possibility of knowledge, and its foundation, justification, veracity with overlap to problems of language, role of subject (internal and external in knowledge), senses, and reason. On the other hand, there is discussion about physical, physiological, biological, and psychological limits, and it is predominantly particular disciplines that deal with the nature of these limits. Epistemologists (or philosophers in general) can express the pretheoretical basis of particular disciplines and touch on methodological problems. Even if epistemology cannot offer anything factual (in the sense of empirical fact), it is not without competencies. With respect to the factual aspect, epistemologists can ask questions of science, questions considered by philosophers of the first line of epistemology, that concern basic assumptions about the elaboration of scientific theories.

Equinoxes

An equinox is the actual point in time at which the sun crosses the celestial equator. The celestial equator is simply the projection of the earth's equator into space. An equinox is a particular point of time, not a full day as is commonly thought.

The word *equinox* is a translation of the Latin words *aequi,* meaning "equal" and *nox,* meaning "night." The equinox is commonly considered to be the day on which the day and night are equal in length on all parts of the earth, save for the poles. The poles will have either 24 hours of light or 24 hours of darkness. The word equinox, however, is a misnomer. Day and night are not equal on the day of an equinox, with daylight exceeding darkness by as many as 16 minutes. The days on which equal day and night occur are called *equiluxes* and usually occur either a few days before or after the date of the actual equinoxes.

Twice yearly, the sun crosses the celestial equator, the vernal and autumnal equinoxes. The vernal equinox, also called the spring equinox or the first point of Aries, occurs on or about March 20. The autumnal equinox, also called the fall equinox or the first point of Libra, occurs on or about September 22. The vernal equinox passes the equator from south to north, while the autumnal equinox indicates the sun is crossing the equator from north to south. The dates of each equinox are not fixed, however, because it takes the earth 365.25 days to orbit the sun. Although this is remedied, for the most part, by the addition of 1 day every 4 years, during the leap year, it does not allow a fixed date for the equinoxes to occur. As for the equinox, the sun crosses the equator at a particular point in time, which will occur approximately 6 hours later the following year, or 1 full day every 4 years.

Despite the occurrence of the equinoxes across the earth, both equinoxes are named in relation to the northern hemisphere. So, whereas the vernal equinox in the northern hemisphere indicates the beginning of longer days and the beginning of spring, it indicates shorter days and the start of fall in the southern hemisphere.

The equinoxes hold great meaning across cultures. Many celebrations and holidays are marked by each. Perhaps the best known is the calculation of the Christian holiday, Easter. Easter occurs on the first Sunday after the first full moon on or after the vernal equinox. Whereas Easter's date of occurrence varies greatly from year to year, the date of March 20 or March 21 is used as the date on which the spring equinox occurs, whether true or not.

Many calendars, including the Iranian calendar, utilize the vernal equinox as the start of the year. In Japan, both the vernal and autumnal equinoxes are national holidays—days to visit family graves and hold reunions. The autumnal equinox indicates the beginning of the harvest in many cultures and is celebrated as such in the United Kingdom.

Whether celebrated on a grand scale or simply observed in passing, equinoxes remain a natural, consistent indicator of seasons and an accurate measure of the passing of time.

Eriugena, Johannes Scotus (c. 810–c. 877)

Johannes Scotus Eriugena means "John the Scot born in Ireland" ("Scots" referred to the Irish in the early medieval period). Scotus Eriugena was one of the Peregrini—traveling Celtic scholars who established monasteries throughout Europe. Little is known of Eriugena's personal life; it is believed that he received his early training in one of the monastic schools in Ireland, possibly Clonmacnoise, or northern Britain that were established by an Irish monk, Saint Columba, after which some believe him to have studied in Greece. Others believe that he acquired his Greek training in Ireland, as scholars of Greek in the previous century often were assumed on the

Continent to be Irish. Although Eriugena preferred the teachings of the Greek theologians, he also respected the Latin works of Saint Augustine of Hippo. He is renowned as a theologian, poet (much of whose work was dedicated to his royal patron), philosopher, and translator of texts. He is considered by many to be the greatest mind of his era.

Eriugena arrived in France by 847, where, by 853, he served at the court of Charles II (the Bald; grandson of Charlemagne), as the translator of theological works. Eriugena served as rector of the University of Paris. He also may have spent time as head of the Irish scholastic community at Laon, France. There is no evidence of his having traveled to the Middle East or having settled in Malmesbury, England, as some sources claim. Among the works of Eriugena, possibly his greatest translation was the work of the early 6th-century mystic Pseudo-Dionysius the Areopagite from Greek into Latin. This work had a profound effect on European religious thought for some time. Others of his works, however, specifically his backing of the concept of free will and Neoplatonic denial of the existence of evil, earned Eriugena condemnation by church councils in 849 and 857.

Eriugena's six-volume *The Division of Nature* (*De Divisione Naturae*), written between 865 and 870, combined Greek and Latin scholarship to examine how God is revealed to thinking beings in terms of their own capacities to comprehend him through his three personalities. The pantheistic (some might say animistic) views in this book caused it to be prohibited by the Vatican in 1685.

It was in this work that Eriugena took on the concept of time and space as it related to the nature of the divine. Reality is created by and streams out from God, the Primordial Cause, who is the Center, through the Word, in which all things are eternal, through the levels of logic, and into the world of number (where the Word takes the form of angels); at this stage there is only the appearance of reality. It then enters time through Creation and exists in space, where the ideas become divided and subject to corruption and decay; they become material and the source of illness, discontent, and sin. Thus what we material beings see as matter, including ourselves, actually is thought to have originated ultimately from God. It is out of the eternal essence of God that all things are created. We are the ultimate completion of God's thought process. In our return to him through our redemption by our use of reason, we complete a divine cycle that was interrupted by original sin. It is in our return to God that we achieve timeless immortality with him, for, although God is in time (as it is part of him), he is not bound by it. God is eternal.

Erosion

The surface of the earth is continually being worn away by natural geologic processes. The displacement of this weathered material is called erosion. Agents such as water, wind, ice, and gravity work to level the land surfaces of the earth across vast expanses of geologic time. The shapes of continents constantly change as waves and tides cut into old land, while rivers deposit silt and build new land. Erosion eventually wears away mountains, but movements of the crust and volcanic activity raise new ones. Although erosion is generally a slow and gradual process that occurs over thousands or millions of years, human activity greatly increases the rate of erosion on fertile land. Farming, mining, and industrial development are all ultimately destructive processes.

Types of Erosion

There are two major categories of erosion: geologic erosion and soil erosion. Geologic erosion is initiated by the weathering of rock. Weathering can be caused by natural physical or chemical means. Heat from the sun may expand the uppermost layer of rock, causing cracking on the surface. Wind and rain then carry the particles away, completing the erosion process. In damp climates, minerals in the rock can react chemically with rainwater, causing the rock to gradually dissolve or decompose. Cold climates will cause water that has seeped into crevasses to freeze and expand, splitting rock at the surface. Roots of nearby plants may also grow into cracks and cause further breaking. Water is a very powerful erosional agent. Running water in streams and rivers not only wears away or dissolves rock but also can carry stones that cause further abrasion along the banks. Glaciers pick up and carry away all loose surface material. When the ice melts, only bare rock remains. Ocean currents and waves erode coastlines, sometimes carving into cliffs and other times depositing sandy beaches.

Soil erosion on uninhabited, untouched land is balanced by soil formation. Soil is protected by natural vegetation. Trees, shrubs, and grasses serve as windbreaks and protect the soil from the force of the rain. Roots hold soil in place. Unfortunately, many human activities involve removing the vegetation from the land. Agriculture, logging, construction, mining, and heavy animal grazing all greatly increase the rates of erosion. Some historians believe that soil erosion is partially responsible for population shifts and the collapse of some civilizations throughout history. Ruins of cities with agricultural artifacts have been found in arid deserts, demonstrating that farming was widespread in these areas in the distant past.

Rates of Erosion

Over geologic time, approximately the past 500 million years, there has been about 60 feet of erosion each million years. Currently, in areas of the United States being eroded by human agricultural activity, erosion is occurring at a calculated 1,500 feet per million years. The rate is even higher in other parts of the world. Soil formation varies, but it takes about 10,000 years for 1 foot of topsoil to form. Today, approximately 40% of the world's agricultural land is seriously degraded, The resulting in lower productivity and poorer crop quality. Virtually all arable land is in use.

Slowing Erosion Rates

Erosion is recognized as a serious problem. Judicious farming practices can greatly reduce erosion rates. Less disruptive tilling methods are being developed. Leaving plant debris in fields after harvest protects the soil and provides shelter for the creatures that assist in soil formation. Strips of land planted with trees and shrubs are left between fields to form windbreaks. Perennial crops that leave root systems in the soil over the winter also hold the soil in place. Contour plowing and terracing the land also help limit erosion. Urban developers can plan green space and replant vegetation after the construction process is completed.

A certain amount of erosion is both natural and healthy for an ecosystem. However, the huge population growth experienced in the past few centuries has put a great deal of stress on the surface of our planet. The availability of rich soil will be critical if we expect to feed future generations. There is unnecessary soil loss happening on every continent right now. Soil conservation programs can substantially reduce the loss of this basic, yet critical, resource. With careful planning, erosion can be minimized and the earth will remain a productive place for the generations to come.

Eschatology

Eschatology refers to a set of beliefs about the last things or the end-times. Derived from the Greek words *eschatos* ("last") and *logos* ("word"), a Latin form of the word (*eschatologia*) was first used by Abraham Calovius in the 1600s. The word appeared in German in the early 1800s and in English in 1845. Since then, it has been considered an important (and usually the last) component of Christian theology, but it can be applied more generally to any view concerning future events.

Eschatology is divided into two subject areas. *Individual eschatology* focuses on the fate of the person after death. *Cosmic eschatology* focuses on future events related to the end of the world. People who adhere to religions based on a linear view of history generally believe that certain events will precede the end of history and that a new, eternal age will replace the current, temporary age. Such would be the views of those who follow Zoroastrianism, Judaism, Christianity, and Islam. The new age is described in these religions either as the restoration of the world to its previous state of perfection or as the replacement of the world by a better, more glorious one.

Religions based on a cyclical view of history—such as Taoism, Confucianism, and Shintōism—generally do not teach any kind of cosmic eschatology. Asian religions such as Hinduism and Buddhism, however, teach that certain events will happen in the future to usher in the next cycle of history. Chinese Buddhists, for example, view current history as a period of decline at the end of which a messianic figure called Maitreya will establish a new age of bliss and salvation.

In the ancient Near East, eschatological schemes often depicted the arrival of an eternal political order ruled by an ideal king. In some versions, history is divided into four successive kingdoms followed by the fifth and final one. A shift away from this kind of this-worldly eschatology occurred in Zoroastrianism, whose proponents viewed history as a cosmic struggle between the forces of light led by Ahura Mazda (or Ormuzd) and the forces of darkness led by Angra Mainyu (or Ahriman). The end will come with the victory of light, the resurrection of the dead, judgment of individuals, and destruction of evil.

Historical Background

Earlier conceptions of eschatology in the Hebrew Bible were this-worldly in orientation. They envisioned Yahweh's deliverance and judgment as occurring within history to end poverty and injustice. Beginning in the 8th century BCE, the prophetic writings depict Yahweh as coming to Earth on the "Day of Yahweh" to subdue the enemies of Israel and establish his reign with Jerusalem as the center of the world. After the Babylonian exile, writings such as Isaiah 60–66 and the Book of Daniel began to present an otherworldly, apocalyptic eschatology in which a new heaven and new earth would replace the current world. These biblical depictions of the future often adapted the imagery of the ancient Near Eastern myth of combat between God and the chaos-monster.

Apocalyptic literature, which flourished from 200 BCE to 200 CE among Jews and Christians, recorded autobiographical narratives of visionary experiences during which the seer received insight into either the structure of the cosmos or the events of the end-times. The futuristic apocalypses envisioned a future intervention of God into the flow of history to inaugurate a new, more glorious age. Some apocalypses depicted the future in earthly terms, others described it as more transcendental than worldly, and others combined the two. The Dead Sea Scrolls also reveal the central role that eschatology played in the belief system of the Jews who lived at Qumran.

Greek writers such as Hesiod and Plato described history as the cycle of one epoch or kingdom replacing another. The Stoics envisioned the periodic purification of the cosmos in a future conflagration. Other thinkers such as Cicero and Philo posited that the world may be eternal.

During the Intertestamental period, Jewish writings associated the Day of the Lord with the coming of the Messiah and the resurrection of the dead. The Day of the Lord would be preceded by a period of intense suffering, often referred to as "the messianic woes." During the 1st century CE, Jewish writings referred to "this age" as dominated by sin and death and "the age to come" as the period of bliss inaugurated when the Messiah (or God) would come to earth.

Modern Theology and Scholarship

Since the late 1800s, New Testament scholars have debated the role of this Jewish eschatology in the teachings of Jesus and Paul. Theologians such as Albrecht Ritschl and Adolf von Harnack ignored the eschatological teachings of Jesus and focused instead on his moral teachings. In opposition, Johannes Weiss interpreted Jesus as teaching that the kingdom of God was a cataclysmic event of the near future in which God would intervene in history. Albert Schweitzer, building on the work of Weiss, also stressed Jesus's expectation of the imminent coming of the kingdom. Jesus surrendered himself to death so that history might end and God's kingdom would come. However, the end did not come as he expected, and he died as a failed prophet. Early Christians struggled with the fact that Jesus did not return and establish the kingdom. Paul responded to this "delay of the Parousia" by developing his concept of "Christ mysticism." The elect have entered into the resurrection mode of existence in the here and now and enjoy bodily union with Christ. Schweitzer's view is called "consistent" or "thoroughgoing" eschatology.

Throughout the 20th century, theologians struggled with Schweitzer's interpretations of Jesus and Paul. Scholars such as Karl Barth and Rudolf Bultmann accepted the centrality of eschatology in the teachings of Jesus and Paul but denied its continuing validity for contemporary Christians. For Barth, eschatology did not focus so much on a time beyond this one as on the eternal, uncontrollable action of God from above to below. Bultmann attempted to "demythologize" the eschatology of the New Testament by reinterpreting the apocalyptic imagery in existentialist terms as a radical call to authentic existence in the present. This project was continued in the "new hermeneutics" of his students Ernst Fuchs and Gerhard Ebeling. However, another of his students, Ernst Käsemann, stressed the central role of future eschatology in the teachings of Jesus and Paul.

C. H. Dodd (following Rudolf Otto) took an approach that differed from the approaches of Barth and Bultmann. He emphasized the "realized eschatology" of Jesus and Paul: The kingdom of God arrived in the ministry, death, and resurrection of Jesus and is now present and available. The coming of Christ will not be a future event in history but occurs beyond space and time whenever people believe that the Lord is near. His student John A. T. Robinson denied that Jesus expected an immediate and supernatural return from heaven after his death.

Oscar Cullmann developed the view known as "inaugurated" or "proleptic" eschatology, a mediating position between Bultmann and Dodd. Both Jesus and Paul adopted the Jewish dualistic framework of history, but they held the paradoxical view that the age to come has already broken into the present. The kingdom of God is both present and future. This view has also been developed by Joachim Jeremias, Werner Georg Kümmel, George Eldon Ladd, and Anthony Hoekema, and it has become the dominant view of New Testament theology, especially among evangelical Christians. In this view, the "already" and the "not yet" of the kingdom of God are held in tension. The followers of Jesus believed that the promises and predictions of the Hebrew Bible concerning the messianic age and the kingdom of God were fulfilled in Jesus and that his death and resurrection resulted in the turning of the ages. The age to come has broken into the present age so that Christians now live in "the last days" (Acts 2:17; Heb 1:2). Christians have tasted "the powers of the age to come" (Heb 6:5) and are those "on whom the ends of the ages have come" (1 Cor 10:11).

These interpreters argue that the references to the future consummation of the kingdom cannot simply be dismissed as the invention of the church. The New Testament writers awaited the consummation on "the last day" or "the day of the Lord Jesus Christ" when Jesus would return, raise the dead, judge all people, and replace this corrupted world with a new heaven and new earth (1 Thes 4:13–18; 1 Cor 15). Christians now live in the overlapping of the ages and await the culmination of the victory that Jesus won on the cross.

More recently, Marcus J. Borg and John Dominic Crossan have argued that eschatology was not central to the teaching of Jesus. In their view, Jesus was not an apocalyptic prophet but a Cynic sage whose teaching focused on proverbial wisdom. In contrast to this growing trend, other scholars, such as E. P. Sanders, John P. Meier, and Dale C. Allison, Jr., have argued that Jesus was an eschatological prophet who looked forward to the restoration of the Twelve Tribes of Israel. The debate over the role of eschatology in Jesus's mission and ministry continues to dominate research into the historical Jesus.

In systematic theology, the centrality and futurity of eschatology have been promoted by Pierre Teilhard de Chardin, Jürgen Moltmann, Wolfhart Pannenberg, and liberation theologians. For Teilhard, evolution will lead toward greater human progress until Christ descends in his Parousia and permeates the whole cosmos. In opposition to Bultmann, Moltmann emphasized that hope for the future was central to faith in the God of the Bible. The resurrection of Jesus offered the promise of a better future for the world that cannot be reduced to a timeless, historical encounter between God and the individual. Pannenberg stressed that the full meaning of history as God's history will be revealed only at the end. The resurrection of Jesus anticipates the future end of the world but also allows the power of the future to work in the present. Liberation theologians proposed that a better future can be actualized through political struggle for justice and equality in the here and now.

Christian theology eventually developed four different systems of eschatology, each of which contains numerous variations. The focus of their differences is Revelation 20:1–10, which contains the only reference to the 1,000-year reign of Christ in the New Testament. The earliest view is known as "historic premillennialism" or "chiliasm." This view was held by many church fathers, including Papias, Irenaeus, Justin Martyr, Tertullian, Victorinus, and Lactantius. According to this schema, the Antichrist will persecute the church during 3 1/2 years of tribulation. Christ will return, raise the dead saints in new bodies, and transform the living saints into their eternal bodies. Christ will judge the nations, imprison Satan in the abyss, and reign on Earth with his saints for 1,000 years (the millennium). Then Satan will be released to draw the nations into one last rebellion. Christ will throw him into the lake of fire, raise all people from the dead, and carry out the last judgment, which will determine the eternal fate of all individuals. The unredeemed will be thrown into the lake of fire, or Gehenna, and the redeemed will enjoy eternity in a renewed heaven and earth. Throughout the history of Christianity, millenarian ideas have been promulgated by numerous theologians and Christian sects, including Montanism, Joachim of Fiore, Thomas Müntzer, Seventh-Day Adventists, and Jehovah's Witnesses. "Historic premillennialism" is still defended by some evangelical Christian theologians such as George Eldon Ladd, George Beasley-Murray, Robert Mounce, Robert Gundry, and Grant R. Osborne.

Several factors led to the decline of chiliasm: (a) its association with Montanism, an early heretical movement; (b) the diminishing expectation of Jesus's imminent return ("the delay of the Parousia"); (c) the cessation of official persecutions of the church; and (d) the influence of allegorical interpreters such as Origen, Ambrose, Eusebius, Tyconius, Jerome, and Saint Augustine of Hippo. These theologians interpreted the 1,000-year reign as a spiritual reign of Christ through his church in the present age. Although they retained belief in a literal Antichrist, their teachings eventually resulted in the system of "amillennialism," which traditionally has denied a literal tribulation period, Antichrist, and millennium. The Council of Ephesus in 431 CE condemned as superstition the belief in a literal, 1,000-year reign of Christ on Earth. Amillennialism became the official doctrine of Roman Catholicism and is accepted by most mainline Protestant denominations.

In the 1700s, the system of "postmillennialism" was developed by Daniel Whitby and others and was held by Jonathan Edwards and Alexander Campbell. According to this view, the eventual acceptance of the gospel by all the nations will usher in a golden age of prosperity and peace. After the 1,000 years of bliss, Christ will return to raise the dead, carry out the last judgment, and usher in the eternal age. This view resonated with the optimistic views of progress promoted by the Enlightenment and Darwinism, but the tragedies of World War I caused it to fall into disfavor. Most postmillennialists adopted amillennialism, but some Presbyterian theologians have continued to promote it.

"Dispensational premillennialism" originated among the Irvingites and Plymouth Brethren in Great Britain in 1830 and was disseminated to the United States through the efforts of J. N. Darby. The *Scofield Reference Bible* popularized this view among fundamentalist Christians, and popular writings in America since the 1970s have increased its acceptance among evangelicals and Pentecostals. This view differs from historic premillennialism by teaching that Christ will come secretly before the 7-year tribulation to "rapture" living Christians from the earth. This view also places more emphasis on God's future plans for Israelites, who are still his chosen people. Because this system incorporates numerous passages from the Old Testament as well as the New Testament, it offers the most complicated and detailed of the four systems of eschatology.

Islamic and Secular Eschatology

Islam also offers various versions of eschatology. The central theme of Muhammad's eschatology was "the hour," the Day of Judgment and final catastrophe. After resurrecting both body and soul, Allah will reward individuals who acted justly by assigning them to paradise (Janna) and will punish other individuals by assigning them to hell (Jahannam). Near the last hour, Gog and Magog will devastate the earth, assault heaven, and be destroyed by Allah. In later versions, Gog and Magog will be led by the Antichrist (al-Dajjal). Some versions, especially among Shiʿites, also teach that a messianic imam called al-Mahdi (the "guided one") will return to establish a just society on Earth. The Antichrist, al-Dajjal, will usurp his reign until he is destroyed by ʿIsa (Jesus) or by al-Mahdi. Then will come the final judgment.

Secular versions of eschatology have also been proposed. Charles Darwin viewed natural selection as an ineluctable progress toward perfection. Karl Marx envisioned the future overthrow of the ruling capitalist class by the proletariat, resulting in a utopian, classless, and nonreligious society. Ernst Bloch argued that hope for a better future is a universal characteristic not only of humanity but of the whole universe. In contrast to the Christian view of eschatology, these secular versions propose a better future that is not dependent on the action of God. They criticize Christian eschatology for encouraging political passivity by denying the possibility of a better future within this age brought about by human efforts.

Eternal Recurrence

The engaging concept of the eternal recurrence may be traced back to cosmic speculations in ancient Greece and early thought in the philosophies of India. This idea focuses on time, maintaining that it is essentially cyclical (rather than linear) in nature. Over the centuries, some serious thinkers have held that this finite universe has been, and will be, returning in exactly the same way; thus for them, reality is an infinite series of identical universes. This assumption that our universe is forever a repeating circle of objects, events, and relationships has far-reaching consequences for science, philosophy, and theology. This intriguing concept of time has appeared in major works of world literature, and it is also referred to in modern lyrics and major films.

In antiquity, the eternal return may be found in the thoughts of the Pythagoreans and the Stoics, as well as in Hindu and, later, Buddhist speculations on time. Among the Presocratic philosophers, Heraclitus developed a version of the eternal recurrence. He taught that the flux of reality is endless, but within it everything returns forever in an infinite series of finite cycles: Night and day follow each other, as do the lunar phases and the four seasons of the year. Likewise, life and death are followed by rebirth. On the cosmic scale, the whole universe returns periodically. Heraclitus's dynamic view of the world greatly influenced several process thinkers who came later, especially German philosopher Friedrich Nietzsche in the 19th century.

If true, then the idea of an eternal recurrence of the same raises profound questions concerning metaphysics and ethics; for example, if our universe is strictly determined, then can there be human freedom in the world? This idea also challenges the concepts of identity, causality, and creativity. Even though it is an extreme point of view, the eternal recurrence remains a unique frame of reference for making value judgments.

In recent philosophy, Friedrich Nietzsche (1844–1900) grounded his own worldview in the eternal recurrence of the same, thereby reviving this perspective in serious thought. In fact, it is his central idea. This concept came to him as a result of a fortuitous summer visit to Switzerland. In early August of 1881, while staying in Sils-Maria of the Upper Engadine, Nietzsche took a walk through the wooded Swiss Alps and along the lake of Silvaplana. The philosopher tells us that, while walking alone in deep thought not far from Surlei, he unexpectedly came upon a huge pyramidal rock in his path. Suddenly, in a flash of intuition "6000 feet beyond man and time" (as he put it), the restless thinker experienced a new vision of reality far superior (so he thought) to those views that had been presented by all other philosophers. Nietzsche's instant grasp of the colossal idea of the eternal recurrence made him delirious with joy, as he claimed that this concept would justify his own iconoclastic interpretation of ultimate reality, a worldview that he had been developing over the previous years.

Nietzsche had undertaken a rigorous reevaluation of all values, with alarming results. His scathing criticisms of Western civilization (especially Christianity) concluded that those basic ideas and entrenched beliefs that underpin the modern sociocultural milieu are actually false and have therefore been responsible for reducing human beings to a pitiful mediocrity. Claiming that "God is dead!" but overcoming nihilism, Nietzsche now desired to give to humankind a new philosophy that focused on the value of affirming life in general, and he gave priority to those superior individuals who are capable of impressive creativity.

Concerning time, Nietzsche had embraced the Darwinian theory of evolution with its sweeping framework of time. Evolution awoke the philosopher from his dogmatic slumber, giving to him a scientific foundation for his dynamic worldview. Nietzsche now saw this universe as a pervasive driving force or the will to the power responsible for the creative evolution of all life; he saw our own species as a temporal link between the fossil apes of the remote past and the overbeings to emerge in the distant future. But, must there exist only this one evolving universe? Why not an endless series of cosmic evolutions, each cycle absolutely identical to all the others? Christianity taught a unique and unrepeatable history of this world from the Divine Creation to the Last Judgment. In sharp contrast, however, the eternal return is far more than just a single linear history of this world or a general periodicity of different worlds. For Nietzsche, time has no preestablished final state or predetermined end goal. Furthermore, in the ongoing circularity of this universe, each successive cosmic cycle is absolutely identical in all general and specific details. Each cycle will be trillions of years in duration. This philosopher hoped that advances in the natural sciences would offer sufficient empirical evidence to, one day, demonstrate the truth of the eternal return of cosmic reality.

Nietzsche attempted to give rational arguments to convince other thinkers that the eternal recurrence of the same is a viable interpretation of our dynamic universe. He made three crucial assumptions: Space is finite, but time is eternal, and the cosmos consists of a finite number of atomic units. Therefore, the number of objects and events that can exist in this universe is also finite, and the resultant sequence of things will occur in a finite series. Nietzsche concluded that if time is eternal, then the same cosmic sequence of things would repeat itself (no matter how long it would take). As such, the identical galaxies would return with their same stars, comets, planets, and moons (each object playing out its same history). Every snowflake, drop of water, blade of grass, and grain of sand that has ever existed will reappear in an identical series of events throughout all time. The earth will return, undergoing the same evolutionary sequence of organisms, with fossil apes giving rise to our species and human beings preceding the emergence of superior overbeings to come. In the distant future, the wise overbeings will joyfully accept the cosmic truth of the eternal recurrence, which guarantees for them that they will exist forever.

In fact, Nietzsche thought that this identical universe would return an infinite number of times! Thus, for him, the eternal recurrence of the same was the quintessential interpretation of this universe; one is reminded of the oscillating model for this universe in modern cosmology. Concerning human conduct, the eternal recurrence offers this existential imperative: One ought to choose to act only in such a way that every choice is a decision made forever. This duty to eternity follows from the cyclicality of reality and gives infinite value to each choice. But there is no recollection of any past cosmic cycle, and, because each cycle is identical, it is always as if a person is free to decide among the actions that may be taken. However, if the eternal return is true, then each and every choice has been determined for all time, and, consequently, there is no free will (freedom is an illusion).

If true, then the eternal recurrence gives meaning and purpose to all existence. Nothing, not even the human animal, will pass out of existence forever. Everything has returned, and everything will return over and over again, including Friedrich Nietzsche (who would, in Nietzsche's view, live to formulate his idea of the eternal return an infinite number of times). If it is better to exist than not to exist, Nietzsche argued, then it is better to return to live one's identical life over and over throughout all time than to never exist again. As such, the eternal recurrence offers to human beings a natural substitute for personal immortality outside of religious beliefs and theological assumptions.

Actually, one may see the eternal recurrence of the same as a philosophical replacement for the personal God of the Judeo-Christian-Islamic religious tradition. The cyclical universe itself is the eternal, necessary, and sufficient Being that gives endless existence to everything in material reality. No doubt, Nietzsche found enormous comfort in this comprehensive idea, because it offered him a form of personal immortality without the need for postulating a spiritual soul within his naturalistic standpoint. Nevertheless, it remains puzzling that he had devoted so little space to explicating his idea of eternal return in his writings. Nietzsche had planned to author a book exclusively on this concept, but his intention was never realized. Even so, the highly controversial idea of eternal recurrence is both unverifiable and unfalsifiable. Therefore, it remains only a metaphysical speculation, although a very powerful one.

Eternity

The idea of eternity has two meanings: eternity as timelessness and eternity as everlastingness. In Western intellectual history, both meanings have been principally connected with discussions of God, especially regarding God's relation to time. Ever since Saint Augustine of Hippo (354–430 CE) and Ancius Boethius (c. 480–c. 524 CE), the view that God is timeless has became the dominant one. However, those who stress God's immanence and activity within human history have at times preferred divine everlastingness, especially in more recent times. The debate has been sharpened by the use of John M. E. McTaggart's distinction between A-series and B-series accounts of temporal sequence. The idea of a timeless "eternity" has resurfaced recently in experiential claims by many New Age proponents.

The word *eternal* comes from the Latin *aeturnus,* which means everlastingness. Philosophical discussions lead, however, to the two meanings already mentioned: One of these equates eternity with atemporality; the other equates it with sempiternity or everlastingness.

Classical Discussions

Perhaps one of the oldest discussions of a timeless eternity goes back to Parmenides of Elea (5th century BCE) and surrounds his notion of the One, though scholars disagree about this. Clearly, however, in Plato's *Timaeus* (37E6–38A6) there is a contrast between eternal and timeless forms and the world of change and becoming (with time being at least the measure of change). Time is famously termed by Plato "the moving image of eternity." Eternity here is a "movingless" realm. Aristotle, in contrast, more modestly claims that the existence of necessary things (like a God) only requires that such necessary things be unbounded by time—but only in the sense that they cannot age (*Physics* 221b30). Aristotle could be viewed as being an early proponent of eternity as everlastingness. Later, Philo Judaeus (20 BCE–50 CE) ascribes, possibly as the first Jewish philosopher, timelessness to the Jewish God. Plotinus (204–270 CE) goes further in identifying timeless eternity and life. *Nous* (or soul) for Plotinus is eternal and beyond time, enjoying duration without succession.

Subsequent ancient discussion of eternity in Western philosophy and theology has centered on the manner of God's existence. Book XI of the *Confessions* of Augustine and Book V of *The Consolation of Philosophy* by Boethius are the most famous ancient sources.

Boethius distinguishes between timeless eternity, which only God enjoys, and the temporal everlastingness of the world itself. God's existence, however, being that of a living being could not be like the timeless existence of lifeless abstract objects like numbers or ideas. For Boethius, God has life, yet its life is all "at once," or simultaneous. This atemporal simultaneity helps resolve the puzzle of how God's foreknowledge of all events is compatible with humans' real free will. (If God knows my choices in advance, then how can I really have the power to avoid making those choices?) For Boethius this is not a problem, because God does not know anything "in advance" but knows what happens atemporally.

The puzzle that leads Augustine to agree with the atemporal view of eternity is this: How can God precede all times in order for God to create all times? After all, the notion of precedence is itself a temporal notion. Augustine concludes that only by being outside of time can God "precede" all times. God's type of eternity is "always in the present." This divine present, of course, is not a moment in time or of time. There is no temporal sequence in God's manner of existence. God transcends time. Unlike his creation, God is changeless and exists necessarily. Augustine shares this view with Plato, that is, the assumption that change is a mark of imperfection. God's perfection, therefore, rules out its being subject to change and thus to time. If God were temporal, then God could in principle change, and perhaps the changing of a perfect nature could only lead God away from perfection. God must exist as a finished and perfect unity. Unlike material objects, God cannot be spread out in time (or in space). God must exist all at once.

Anselm of Canterbury (c. 1033–1109), Moses Maimonides (1131–1204), and Saint Thomas Aquinas (1225–1274) propose similar views. For Aquinas and for John Duns Scotus (c. 1266–1308), God's timeless eternity is a correlate of divine simplicity, which is incapable of being defined or fully grasped by a creature.

Modern Philosophical Debates

Modern debates between eternalist and temporalist approaches to understanding God's eternity—and of God's relation to our time—have benefited from a distinction put forth by J. M. E. McTaggart (1866–1925). This is the distinction between an A-series view of time (where the temporal series is viewed from within and uses terms like *tomorrow, now, then, past,* and *future*) and a B-series view of time (where the temporal series is viewed indifferently as a series of moments or events placed as *earlier than, later than,* or *simultaneous with* other moments or events).

Some current thinkers, such as Paul Helm and Katherin Rogers, argue that for God, who exists timelessly, the temporal order is a B series. All times are equally present to God's mind. According to this view, God is in no temporal relation to this B series.

Other defenders of divine timelessness, such as Eleonore Stump, Norman Kretzmann, and Brian Leftow, insisted that God's eternity has some of the features of extension or duration, which they claim are not temporal but which critics have found objectionable.

Temporalist opponents, such as Anthony Kenny and Richard Swinburne, have argued that eternalism is incoherent. If God exists all at once, then God exists simultaneously with all the events that occur in the universe. They argue that since an event now and an event 2,000 years ago are each simultaneous with God, the two events must then be simultaneous with each other. But the latter is absurd. Thus, God's simultaneity with every temporal event must be impossible.

This argument is still the subject of debate, as it is not clear that God could not be "simultaneous" to separate temporal events in such a way that the two temporal events would not be forced to be simultaneous with each other.

Paul Tillich (1886–1965), in his book *The Eternal Now,* claims that a timeless and divine eternal now is required for our sense of temporal present now. For, looked at from the outside, time as a succession of moments does not exhibit any present or any "now," but only a chain of moments sequentially arranged. Yet we experience a now. The experience of a present now, Tillich claims, is made possible only by the breaking through of a timeless eternal present (of God and of our essential divine self) in the time sequence.

Common Analogies

A much repeated metaphor meant to shed light on the paradoxical relation between a divine eternal now and our successive time is the image of God as an immovable point at the center of a circle, a center point equally distant from every point on the circumference. The circumference represents the moving, successive, spread-out nature of time. Such a circumference would have to be imagined as infinitely long and as not necessarily returning to close upon itself. Also, in this image the distance between God, as center point, and each point on the circumference would have to be imagined as nonexistent—to establish the immediacy of God's presence in every moment of time.

A second analogy often used to convey the paradoxical relation between a divine eternal now and our successive time appeals to the possibility of a hidden macro dimension within which time is embedded. Imagine how a third spatial dimension would appear to a Flatlander (an inhabitant of two-dimensional space). A three-dimensional line perpendicular to a Flatland plane would have to be conceived as a stack of points piled on each other and yet each *in some sense* occupying *the same* Flatland place. Imagine how motion along this perpendicular line (as the motion of a missile or point going straight up) would have to be conceived by Flatlanders. Ordinarily for Flatlanders all motion is horizontal motion. Thus, they would have to speak of perpendicular motion as of a kind a spatial dynamism that is not really spatial. This could, by analogy, shed light on the paradox of nontemporal *yet dynamic* events. Just as the motion of a missile moving in a direction perpendicular to Flatland would be incomprehensible to Flatlanders, yet quite real, so too an atemporal fifth-dimensional divine observation of temporal events might be *dynamic* in a way that is incomprehensible to four-dimensional beings like us. Whether this spatial analogy can in fact shed light on temporal paradoxes has, of course, been disputed. A second question that has been raised is whether this extradimensional analogy points to a timeless God or to a hypertemporal god.

These debates between eternalists and temporalists are complicated by the new physicist notion of relativized spacetime—which denies that there is an objective temporal sequence of temporal events (i.e., which events happen before and which ones happen after depend on an observer's spatiotemporal standpoint).

Temporalists have also objected that eternalism relies on a false view of time, the B-series view—time must inherently be experienced from within. Whether this is true, however, is controversial.

Temporalists have further objected that eternalism would make God a "lifeless" being. Any personal living God, who is affected by the suffering of its creatures and who affects changes in this world, must be a temporal God. Of course, whether a God must be personal in this fashion is subject to dispute. In addition, whether a timeless God would be automatically unable to engage "timelessly" in such interactions is itself not completely obvious, particularly if there could be either nontemporal dynamisms or forms of hypertime totally foreign to our form of time. The appeal that is often made here—particularly by mystics—is that God's nature transcends, at least in part, our intellectual, linguistic, and imaginative powers.

Finally, philosophers like Swinburne find divine temporalism attractive because it is most compatible with the libertarian free will of creatures (and perhaps also of God itself). For the perfect omniscience of a timeless God might make alternative choices by agents impossible. However, a temporalist God might also be in the position of knowing human choices *in advance*—thereby possibly making alternative possibilities in human choices an illusion. Moreover, Boethius's type of defense of eternalism (that a timeless God does not know anything "in advance," hence its timeless knowledge might be in some sense simultaneous and thus harmless with respect to agents' free will) may remain still substantially sound.

It is worth adding that in Eastern thought, eternalists have dominated the characterization of the Ultimate Source. Among such eternalists, the account of Brahman by the Hindu Vedanta philosopher and theologian Shri Adi Sankara is one of the most influential. He characterized the ultimate Brahman—following, he claimed, older Upanishadic sources—as pure timeless awareness and bliss. Here too there have been criticisms that any pure divine awareness of all things, including awareness of the changing world of Maya or our apparent universe, would seem to require some internal structure and dynamism. The latter might be incompatible with timelessness.

Recent Accounts or "Experiences" of Timeless Eternity

There has been a recent resurgence of nonphilosophical and nontheological experience-based claims regarding some form of timeless eternity. These accounts derive partly from the New Age movement since the 1950s—a dispersed movement characterized by eclectic nontraditional mysticism-based spirituality. Similar claims derive also from the now widespread phenomena of near-death experiences.

The former movement includes a number of alleged spirit-channelers reporting on rather Eastern-like pantheistic claims to the effect that God is in everything and that by turning inwardly we can access God's and our own (and more real) timeless nature. This viewpoint advises that beneath our ordinary temporal realm there is another and more basic one, often characterized as a divine eternal now. The metaphysics underlying this claim seems to be that the ultimately timeless Divine Reality opts to manifest itself as the temporal and spatial multitude of things we call the universe (and perhaps as many other universes as well). Such metaphysics appear to have roots in ancient Indian thought. The popular "Seth" books by Jane Roberts may constitute the most sophisticated and serious example of this New Age account of reality.

There is, in addition, an extensive recent literature regarding the *experience* of some form of timelessness during alleged near-death experiences (experiences one has during certain traumas and sometimes in hospitals through moments while one is mistakenly declared clinically dead). During parts of such experiences—while reviewing one's whole life "instantaneously," or while engaging in some form of "instantaneous" thought-travel—many people claim that their sense of time slows down drastically, or stops altogether, while their awareness of countless events continues. Some claim that this represents the experience of an eternal now, and they often attribute this eternal now to a feature of the postlife divine environment.

ETHICS

Our time on earth has an exceptional value. It is valuable because with the death of one human being a whole world dies. In other words, the unique perspective of a person disappears with his or her death. This is one of the reasons why murder is considered such a horrible crime: It destroys "a whole world." An important task of every ethics consists in establishing a framework preventing us from killing or harming each other.

The term *ethics* was first coined by the philosopher and physician Aristotle (384–322 BCE) in his book *Ethika Nikomacheia* (a book on ethics for his son Nikomachos). *Ethics* has its roots in the noun *ethos,* which means "custom." Aristotle understood it as the rational study of customs, which as a practical science does not have the methodological exactness of, for example, mathematical science, but is nevertheless guided by principles. Today the term *ethics* is used in a manifold way. In everyday language, it is often used synonymously with moral behavior; that is, people are called ethical if they behave morally. In philosophy, ethics is synonymous with moral philosophy and deals with questions regarding how we can justify norms, distinguish good and evil, or develop consistent ethical theories. For some philosophers of the analytic tradition, ethics can only be metaethics, meaning that it is able to analyze ethical terms and principles but is unable to provide universally valid ethical norms. Others reduce ethics to a hermeneutic description of ethical attitudes, using it to interpret how it influences the world in which we live. For theologians of the Christian tradition, ethics is synonymous with moral theology, thereby reflecting the moral precepts of the Bible and Christian communities.

This entry begins with the fundamental question of whether or not there is free will and, subsequently, if moral obligation is possible. Next it explores why the concepts of time and space have a significant role in ethical theories by giving a short historical overview of ethical positions, which at the end focuses on the question that pits ethical relativism against ethical universalism.

The Question of Free Will

Neurobiological discoveries, in combination with modern genetics, have led some to the opinion that human beings are biological machines determined by their biological hardware. This is especially the case with human brains and genes, though outside influences play a role as well. In this case, there is no room for free will; the web of motivations that moves us to act is fixed. We simply do what we are predetermined to do. If ethics is supposed to develop moral norms that dictate what we ought to do, it now seems to be in contradiction with the assumption that we are determined. In other words, we need the ability to act in accordance or discordance with the "ought to" and, moreover, because we have free will and are not already determined. If there is no free will, the concept "ought to" becomes meaningless.

There are various solutions to this problem. Philosophers often suggest a version of free will in terms of modular brain functions that is compatible with determinism. Human beings are perceived as a complex, determined, neurophysiological system. Data are taken in, and alternatives are generated and ranked. Eventually an output initiates action, and this action is considered free, notes Simon Blackburn, if the following is valid: "The subject acted freely if she could have done otherwise in the right sense. This means that she would have done otherwise if she had chosen differently *and,* under the impact of other *true and available* thoughts or considerations, she *would* have chosen differently. True and available thoughts and considerations are those that represent her situation accurately, and are ones that she could reasonably be expected to have taken into account." Theologians tend to offer an incompatibilist version; that is, free will is not compatible with determinism. For strict Calvinists, for example, there is no free will. God predetermines what we do. The Roman Catholic Church explains freedom of the will by insisting that the human person can be reduced to a physiological, and therefore entirely material, reality. The moral self has a transcendent element, generally associated with the soul, and moral decisions reflect the complexity of that body–soul reality; that is, it cannot be a simply material determination. The question of how moral thoughts are evaluated, such that humans may or may not choose the "good" action, is answered by introducing the concepts of grace and sin and the mystery of evil.

A Short Overview of Ethics and the Importance of Time

Ethics can be either religious or philosophical. Some religious ethics require a belief that God reveals himself (Judaism, Christianity, and Islam), while others are more similar to secular ethics, for example, Buddhist ethics or Confucianism. Jewish and Christian ethics are based on the Ten Commandments: The first three commandments relate to the worship of God, that is, no graven images of him should be made and a day of worship should be set aside, whereas the other seven deal with relationships between human beings dictating that we should honor our parents (4) and refrain from killing other human beings (5), from breaking the vows of marriage (6), from stealing (7), from false testimony (8), from desiring the wife or husband of another (9), and from desiring the belongings of another (10). We follow these commandments when we love God, as well as when we love our neighbors as we love ourselves. The Five Pillars of Islam are (1) the declaration of faith, (2) praying five times a day, (3) almsgiving, (4) fasting during the month of Ramadan, and (5) making the pilgrimage to Mecca at least once in one's lifetime. All three monotheistic religions stress the importance of our time on earth and its relation to eternity. Whoever does not follow the commandments puts his or her eternal life and reward at risk and is faced with the threat of eternity in hell. For this reason, our time on earth is extraordinarily important.

In a similar sense, Buddhist ethics emphasizes the importance of our life on earth. Whoever does not follow the Eightfold Path, which can be considered a kind of virtue ethics, does not reach Nirvana. The elements of the Eightfold Path are the (1) right view, (2) right resolve, (3) right speech, (4) right action, (5) right livelihood, (6) right effort, (7) right mindfulness, and (8) right meditation. But instead of going to a hell, those who do not follow the Eightfold Path will be reincarnated into a life form that corresponds with the deeds in their former life. However, here we have to ask: When are the view, the resolve, and so forth, right? The answer is rightness exists when one follows the five principles: refraining from harming living creatures, from taking what has not been given, from sexual immorality, from speaking falsely, and from taking intoxicants. Confucianism also provides a number of practical principles for life here on earth instead of a focus on a future eternal life.

In Western philosophy, written ethical reflection in the philosophical sense begins with Plato (c. 428/427–348/347 BCE). Plato, Aristotle (384–322 BCE), and the Christian philosopher and theologian Saint Thomas Aquinas (1224–1274) believed that an objective, transcendent reality guarantees the good and the rightness of principles, norms, and corresponding actions. For Plato this is the idea of the Good; for Aristotle it is the unmoved mover, which is the first cause; and for Aquinas it is God as love, who reveals himself in history. Human beings touched by this reality will do good and avoid evil. Furthermore, this represents the fulfillment of human nature. Therefore, these ethical approaches are often called doctrines of natural law, even though they sometimes significantly differ in the concrete norms they establish. For example, Aristotle allows abortion, whereas Aquinas forbids abortion. The common bond, however, is the focus on virtues as good habits that foster a good life. Consequently, these ethical theories are sometimes called virtue theories. For Platonists, though especially for Neoplatonists and Aquinas, the good life does not end here on earth, but reaches fulfillment only in the presence of God.

A completely different class of ethical approaches is the class of contractarian theories. Religious wars destroyed people's trust that religion could bring peace and prosperity because all sides defended their actions by claiming to act in accordance with God's will. Hobbes (1588–1679), therefore, did not use a transcendent reality as the foundation for ethics. Instead, he developed a contract theory according to which the lives of all humans are guaranteed when they relinquish their freedom to an all-powerful sovereign. The sovereigns implement the contract, and they have all freedoms except one: They has to protect the lives and well-being of their subjects. Thereby, a contract, not the idea of "good" or a god, secures our lives and well-being. However, even today it remains unanswered how such a contract can be realized and implemented. A similar approach that focuses on a moral ideal rather than on securing life and well-being is called contractualism. John Rawls (1921–2002), the most famous contractualist, bases the contract on the moral ideal of justice as fairness. His main idea is as follows: On the basis of their common interests, people would rationally choose a democratic society based on the principles of freedom and justice as fairness (the option for the "least advantaged") if they did not know what their later position in society was to be. Contractarians and contractualists agree on the relevance of the life of every human being. Our lives are so important because death terminates every possibility of action here on earth for the respective person.

In contrast to Plato, Aristotle, and Aquinas, who focus on an objective good, and to contractarians and contractualists, Immanuel Kant (1724–1804) emphasizes the role of goodwill. The goodwill is realized by action guided by a fundamental commandment called the "categorical imperative," a principle of action that is a universal moral law. All rational beings endowed with freedom, regardless of their particular interests and social backgrounds, have to adopt this principle: "Act only according to that maxim [the determining motive of the will] whereby you can at the same time will that it should become a universal law" By using the term *universal law* Kant means that this principle does not allow for any exceptions like laws of nature do. Kant's ethics is called deontological (from the Greek to deon, meaning that which you have to do) because you have to follow this imperative for the sake of duty and not for any other reasons. The categorical imperative is not commanded from someone other than the agent—that is, it is not heteronomous (*heteros,* "the other"; *nomos,* "the law")—but rather it is a law that the practical reason of agents gives to them. Consequently, it is autonomous (*autos*, "self"). Thus, a fulfilled life is a life lived for the sake of duty. To a certain extent and in the tradition of Kant, the contemporary philosopher Jürgen Habermas has developed a discourse theory according to which norms are established by means of an ideal discourse situation. This is a situation free from the threat of violence, where every participant has an equal say in the process of establishing the necessary norms. As a result, all participants accept the norms they have agreed upon together. Like Kantian ethics, Habermas's discourse theory has no real relation to time and space. It is a universalist ethics beyond time and space.

Kant's and Habermas's ethics differ very much from all forms of consequentialism (Latin: *consequi,* "to follow"), which assess the rightness or wrongness of an action in terms of the goodness or utility of its consequences. Insofar as most religious ethics, though also the virtue ethics, assess the rightness or wrongness of actions in terms of goodness, that is, an eternal life, they can be called consequentialist. Nevertheless, these ethics are not utilitarian. Utilitarianism is a specific form of consequentialism. Though it has a long history dating back to Plato's time, its classical formula was coined by Jeremy Bentham (1748–1832): "by utility is meant that property in any object, whereby it tends to produce benefit, advantage, pleasure, good, or happiness (all this in the present case comes to the same thing) or . . . to prevent the happening of mischief, pain, evil, or unhappiness." The goal should be to maximize utility, which means the greatest happiness for the greatest number should result. Nowadays, there are a variety of utilitarian theories. However, most important is the difference between act utilitarians and rule utilitarians. For questions regarding applied ethics, Peter Singer's preference utilitarianism is of great interest. In contrast to utilitarians like John Stuart Mill (1806–1873), Singer emphasizes the importance of the preferences of humans as well as other animals.

Ethical Relativism Versus Ethical Universalism and the Importance of Time

Most ethical theories have to deal with an argument taken from social and cultural anthropology: Social and cultural anthropologists, up to the present day, have discovered huge differences among societies with respect to their moral evaluation of issues such as euthanasia, infanticide, sexuality, child support, the poor, the status of women, slave labor, and so on. The Greek historian Herodotus gives us one of the most famous examples. Darius, the king of Persia, once asked Greeks, who burned the bodies of their deceased relatives, how much he would have to pay them to eat the dead bodies of their family members. They refused to do it at any price. Then Darius offered a huge amount of money to some Indians, who, according to custom, ate the bodies of their parents, to burn their fathers' bodies. The Indians refused to do such a horrid act, which would have been in violation of their beliefs. Herodotus drew the obvious moral conclusion: Each nation considers its own customs as morally right and the customs of others as morally wrong.

Two very important questions arise from this conclusion: Does cultural relativism entail ethical relativism? Is morality only a matter of what is customary; that is, is it relative to a particular society? If this is so, then words such as *good* and *bad* just mean "acceptable in a certain society" or "unacceptable in a certain society." Even if there are common moral convictions across cultures, this does not mean that ethical relativism has been proven wrong. There was a time in which slavery was not questioned by any known society. Today we, of course, do not accept slavery as morally right. Although the nations involved in World War I were excited about going to war in 1914, we do not claim today that the war was morally "good."

From a logical point of view, ethical relativism cannot be proven wrong, but the examples of slavery and of World War I show that this ethical position is highly problematic: We do not accept slavery today because *our* society disapproves of slavery. We reject slavery because we are convinced that slavery was wrong and is wrong and will continue to be wrong. And we have good reasons to think so in order to defend human dignity and human rights, which through the experiences of the atrocities of the 20th century, have become the foundation of a common universal ethical bond among human beings. Alan Gewirth has developed a rational argument for an ethical universalism with respect to human dignity and human rights. His argument rationalizes the experience given in history and so given in time: I do (or intend to do) X voluntarily for a purpose that I have chosen. There are generic features of agency in a deep sense of the word *agency.* My having the generic features is good for my achieving the purpose I have chosen. I ought to pursue my having the generic features of agency. Other agents categorically ought not to interfere with my having the generic features *against my will* and ought to aid me in securing the generic features when I cannot do so through my own unaided efforts *if I so wish*. I have both negative and positive rights to claim that I have the generic features. If I have these rights, all agents have these generic rights, and I have to respect their rights. Whoever does not accept this reasoning contradicts him- or herself because then it is possible to interfere with his or her generic features against his or her will.

But even if this argument gives good reason for ethical universalism, it does not explain what exactly generic features are. Therefore, on the one hand, the various results of social, cultural, philosophical, and theological anthropologies do not necessarily lead to ethical relativism. On the other hand, they prevent us from quickly labeling a norm as universal, and they indirectly let us understand that we have our own lives to live, not just a kind of universal life.

Ethical universalism gives a framework for what we should do. This framework, however, cannot abolish the responsibility every human being has in living his or her true nature. Every human being as a being in time and as a being able to anticipate his or her death knows about the finitude of his or her time on earth. Ethics cannot substitute this individual responsibility of living the proper life. A human being may follow all commandments of a religious or secular ethics, but if he or she does not live his or her true nature, this life was not his or her proper life. So, it is the finitude of our time on earth that transforms every universal ethical approach into a personal way of life.

Event, First

A contemporary cosmology of the universe is based on the theory of general relativity, which includes a creation event, a first event. Using the equations of general relativity, it is possible to trace the origin of the universe backward in time to an estimated beginning point, a first event. The big bang as a first event is viewed as the beginning of the universe and more specifically as the beginning of time. As a result of the big bang, the universe is continually expanding and changing because galaxies are moving away from each other at high speeds. In the big bang cosmology, time is finite and has a specific beginning point and a possible ending as the expansion that began with the big bang comes slowly to an end due to gravitational forces. A series of photos collected from the Keck and Hubble space telescopes show the universe in the various phases of expanding from the time before galaxies existed to newly formed galaxies tightly packed together and still colliding, to the current stage of development when there are few new star formations, and galaxy collisions are less frequent. It is believed that photos have captured the moment in cosmic history when the universe was only 300,000 years old. At that moment, light is thought to have separated from darkness, a description that some contemporary theologians believe fits the biblical account of Creation.

The big bang theory was proposed in 1946 by George Gamow, a Russian scientist, who identified the big bang as an exploding, primeval fireball that contained the entire physical universe, including the dimensions of time and space. In 1965, observations at the Bell Telephone Laboratories of a ubiquitous background radiation provided convincing evidence of the validity of the big bang theory. In 1992 the NASA (National Aeronautics and Space Administration) satellite Cosmic Background Explorer provided additional evidence that placed the beginning of the universe at about 15 billion years ago. In the 1970s the work of Stephen Hawking and Roger Penrose helped to prove that time is finite in a universe with an identifiable beginning event and possible predictable ending. Using mathematical calculations to establish the presence of mass in the universe and the general relativity theory of Einstein to show how mass can be expected to behave, Hawking and Penrose established that time is finite and must have started when the universe began. Hawking defines an event as something that happens at a particular point in space and at a particular time. For Hawking, time and space begin together in the big bang and therefore are never truly separate. He refers to space and time together as spacetime. Hawking's description of the big bang as the "singular boundary" for space and time is known as the singular boundary theorem. For some philosophers and theologians, the spacetime theorem lends itself to the argument for the existence of God because the concurrent beginning of the universe and time make it necessary to find a first cause. For many theologians, the first cause can only be a deity who transcends time and all other dimensions of the cosmos, including space, matter, and energy. While it is not necessary to narrowly define the first cause as the God of the Christian Bible, many philosophers and theists agree that it is not possible for something to come out of absolutely nothing; therefore, the universe must have a cause that existed before the big bang. The big bang theory of the universe requires a transcendent force that is separate from the universe to bring the universe into being. Without endorsing any theological beliefs, many physicists acknowledge the need for a universe with a beginning and a pre–big bang first cause or superior reasoning power. Some members of the scientific community continue to argue for a static or steady-state universe where time and space are still absolute and separate according to the calculations proposed by Isaac Newton. However, for some cosmologists, this universe may be cyclical and therefore does not require a beginning in time or a transcendent ultimate force.

Evidence of Human Evolution, Interpreting

In the fossil human record, the most famous fossil discoveries have been those that provided evidence to either support a current theory, reject a previously supported theory, or that have created new theories about human history. The information that new discoveries provide comes more from the analysis and interpretation of the evidence than from its display in a museum and observation by the public. Although interpretations can vary based on the knowledge and opinions of an individual, they provide meaning for the object. The evidence holds the facts, and it is the interpretation of the evidence that exposes the facts. Over time, as new discoveries continue to fill in the fossil record of human existence, it is not the fossil skeletons and artifacts themselves but the interpretation of the evidence that allows for solution of the puzzle. A fossil, in and of itself, is nothing more than the preserved remains of an organism, but analyzing it and drawing a conclusion from this analysis reveal its true historical footprint. A large portion of our current knowledge is the result of this process of observation, then analysis, followed by interpretation, and finally assumption, deduction, hypothesis, and theory.

Generally, the more complete the specimen, the more information it reveals, but even small partial fossil remains can give an overwhelming amount of data about human history. A simple leg bone can help researchers date the characteristic ability of hominids to stand erect and walk upright on two legs. Even a fractured, partial skull bone can help prove if bipedal walking or the enlargement of the brain arose first in hominids. The morphology is what tells the story. But as interpretations are based on the perceptions and opinions of the individual investigator, they are not infallible. As a result, the theories created from these interpretations are always subject to change over time. As new evidence becomes available, the current theories are either rejected or confirmed; they evolve. It is not uncommon for several interpretations to exist that conflict with each other. Although the interpretation of evidence is not flawless, it is fundamental for the understanding of human evolution. As our only source of information about human evolution, every new piece of evidence is valuable and influential. This is especially true because only a small number of all the hominids that have ever lived on Earth became fossilized, and of those that were, only a fraction have been discovered. But as more evidence is found each year, we develop a better understanding of, and appreciation for, our human evolution.

Early Interpretations: Germany and Java

Even before the first fossil humans were discovered, many naturalists in the 19th century had already begun to recognize that the earth was much older than described in the Bible. Therefore, the length of existence of humans on Earth became open to interpretation, and the field of paleoanthropology was born. The first discovered human fossils were those of a Neanderthal in August 1856. Found in a limestone quarry in the

Neander Valley, the bones were brought to Johann Fuhlrott, who recognized them as both human and ancient. He gave the bones—consisting of a skullcap, two femora (thighbones), fragments of an upper and lower left arm, a partial pelvis, and several other small bones—to Hermann Schaaffhausen, an anatomy professor.Schaaffhausen's report described the anatomical features with great detail, and he concluded that they belonged to a strong, muscular individual. What most intrigued Schaaffhausen were the pronounced ridges above the eyes and the low, narrow forehead, which he said resembled the skulls of the large apes. From this, he concluded that "man coexisted with the animals found in the diluvium; and many a barbarous race may, before all historical time, have disappeared, together with animals of the ancient world, whilst the races whose organization is improved have continued the genus." His interpretation fit into the common idea of the time. Before Charles Darwin's publication of *On the Origin of Species* (1859), the dominant theory was one that proposed a variety of species had existed. This was a more fundamental approach, in which the thought was that all the species that exist today existed in the past, but some species have become extinct. So Neanderthals, Schaaffhausen concluded, were a "barbarous race" of humans that had coexisted with the ancient relatives of modern humans but had gone extinct sometime in the past. The human fossil record at that time was not seen as evidence for the idea of human evolution, only as evidence of human antiquity and diversity.

It took several years for the full scope of Darwin's idea of evolution as "descent with modification" to be realized. The leap to the thought that "species are the modified descendants of other species," as Darwin described, was a difficult one. Many did not want to accept an idea that proposed humans had descended from the same ancestors as the apes. Darwin's publication of *On the Origin of Species* laid the foundation for this change, but it was another decade until it emerged. In 1868 and 1871, Ernst Haeckel and Charles Darwin, respectively, published books that supported the idea that both apes and humans share a common ancestry. The first fossil evidence to support their ideas was not discovered until 1891 in East Java, Indonesia, by Eugene Dubois. The fossil remains, known as Java man, consisted of a skullcap, a femur, and several teeth. The femur was similar to that of a modern human femur, which meant that the animal had been bipedal. However, the skull showed apelike characteristics, most notably the pronounced ridges above the eyes. The size of the brain, 900 milliliters (ml) in volume, although considerably smaller than the brain of modern humans (which is around 1400 ml in volume), is much larger than those of the modern apes, around 400 ml. Therefore, because the brain was larger than that of modern apes, Dubois asserted that these remains were that of an ape-like man and not of a man-like ape. He named it *Pithecanthropus erectus,* meaning "upright apeman." Dubois claimed that it could be classified neither as human nor ape but was an intermediate between modern humans and the common ancestor of humans and apes. His evidence demonstrated that bipedality arose prior to the enlarged brain size; Darwin had proposed that a large brain preceded bipedality. Today this ancestor is classified as *Homo erectus,* and most anthropologists believe that the earlier ancestor of modern humans is the *Homo erectus* found in Africa, not in Asia.

Early Interpretations: South Africa and China

Another major discovery was that of the Taung skull in 1924. Found in a quarry in South Africa, the fossil consists of an almost complete face, a mandible with teeth, and an endocranial cast of the braincase. An endocranial cast is a cast of the cranial cavity showing the approximate shape and size of the brain. The fossil, among others, was given to Raymond Dart, an anatomist and anthropologist, who recognized it as the skull of a child of an unknown hominid species, intermediate between humans and apes. Dart named it *Australopithecus africanus,* meaning "southern ape of Africa." The brain was larger than that of an immature ape but not as large as that of a modern human child. This trend was also seen in the teeth, which were smaller and more human-like than those of the chimpanzee, which Dart's critics believed he had found. The skull also showed human-like characteristics such as a less robust mandible and a rounded forehead that lacked the pronounced eyebrow ridge. Dart was criticized at the time because most of the traits he described as human-like could be attributed to the fact that it was a juvenile and had not fully developed its facial features and secondary sexual characteristics. There was one feature, however, that his critics could not attribute to immaturity. What convinced Dart he had discovered a bipedal man-like ape was the position of the foramen magnum, the hole in the skull where the spinal cord attaches to the brain. It was positioned at the base of the skull, the same as in humans, not at the back of the skull, as in apes. This meant it had walked upright, on two legs. His interpretation was also criticized because, at the time, it was believed that the ancestors of humans would be found in Asia and not in Africa because of the discoveries of Java man and later Peking man in Asia. Also, because the earth was considered to be only around 65 million years old at the time, the Taung child would have appeared too late to be a human ancestor. Dart's interpretation of the Taung child as representing an extinct race of hominids that can be categorized between living apes and modern humans is important because it was the first major fossil human evidence from Africa. It confirmed Darwin's theory that human origins would be traced back to Africa and not Asia or Europe. As a result, more people began to search in Africa for human fossils. Today, hundreds of human fossils from Africa support Dart's original interpretation.

Dart's theory about human origins in Africa was meeting stiff opposition because some naturalists gave priority to the theory of Asian ancestry. This theory became even more dominant with the discovery known as Peking man. Since the discovery of *Pithecanthropus erectus* by Dubois in Java had become popular, the fossils of Peking man were more readily accepted. The first evidence was that of two fossil human teeth from Zhoukoudian near Beijing. In 1926, they were given to Davidson Black, an anatomy professor, who began excavating the same site the next year. Following the discovery of another tooth there, he created a new genus and species, *Sinanthropus pekinensis,* the "Chinese man of Peking." Many anthropologists did not accept his conclusion based solely on three teeth. It was not until 1929 that a braincase of *Sinanthropus* was found. Although it possessed a slightly larger brain and steeper forehead than the Java man, analysis showed that it was an early human very similar to that individual. From this, Black concluded that *Sinanthropus* was an intermediate form between *Pithecanthropus* and the Neanderthals. Today, it is classified as *Homo erectus*. While proving that *Pithecanthropus* was an early human form and not an ape form, it also gave some insight on the advancements made by *Sinanthropus*. Among the stone tools found at the site were animal bones that showed signs that they had been burned. Black interpreted this as evidence that *Sinanthropus* used fire; this contention is still debated. By 1937, 14 fragmented skulls, more than 100 teeth, and various other bone fragments had been found at the site. In 1941, unfortunately, the original fossils were lost, stolen, or destroyed while in transit to the United States for safekeeping during World War II, but not before casts of the fossils were made. The casts still exist today.

Later Interpretations: South Africa and Tanzania

Although the discovery of Peking man fostered the claim that Asia was the origin of human existence, Dart's discovery of the Taung child had already begun the shift in focus toward an African origin for human beings. One such supporter of Dart's interpretation of human evolution in Africa was Robert Broom. Convinced that Dart's theory of *Australopithecus* as an ape–human intermediate was correct, the Scottish physician stopped practicing medicine to take a position as an assistant in paleontology at the Transvaal Museum in Pretoria in 1934. During excavations at a limestone mine in Sterkfontein in 1936, Broom found an incomplete *Australopithecus* skull. He immediately presented the evidence as proof of the validity of Dart's interpretation. Broom's next discovery came at Kromdraai, across the valley from Sterkfontein, in 1938, when a young boy named Gert Terblanche found hominid fossils. The fossils were of a mandible and maxilla, with teeth. The thickness of the bones and the large molar teeth led Broom to classify the remains as *Paranthropus robustus*. At another nearby site, Swartkrans, additional fossils were found that further revealed the facial structure of these hominids. After observing the similarities between the fossils found at Kromdraai and Swartkrans and those of known

Australopithecus africanus (both are bipedal with brain capacities intermediate between modern humans and apes), Broom's *Paranthropus robustus* became referred to as *Australopithecus robustus*. It is now considered a facially robust species of australopithecine that went extinct about 1 million years ago. One of Brooms's most important discoveries was made in 1949 with the help of his assistant John Robinson at Swartkrans. The hominid fossils were much more human-like and eventually became classified in the genus *Homo*. The significance of this find at Swartkrans was that it demonstrated for the first time the apparent coexistence of two types of hominids. This coexistence of more than one lineage of hominid from the divergence of early australopithecines was later seen in East Africa as well.

The pioneering discoveries of the Leakey family in Olduvai Gorge, Tanzania, in East Africa, have become the cornerstone of our knowledge of the human lineage. Louis Leakey assumed that Olduvai Gorge held the secrets to human evolutionary history. Throughout the 1950s, he searched for hominid fossil remains with little success, finding only a few hominid teeth and the remains of large mammals. The fossil remains he believed had been killed and eaten by humans because of the various stone tools found in the same sites. As Louis Leakey maintained at the time that toolmaking was the distinguishing characteristic between humans and ape-like forms, he claimed that these sites were used by the earliest members of the genus *Homo*. But in 1959, Mary Leakey found, in a site known as FLK 1, the skull of a robust *Australopithecus*. Very similar to the skulls found by Broom in Swartkrans and Kromdraai, the skull, named Olduvai Hominid (OH) 5, had massive chewing molars, undersized canines and incisors, a small brain size (about 530 ml), and a large sagittal crest (the ridge of bone that runs along the midline of the skull as the attachment site for jaw muscles). This indicated great jaw strength. Although Louis Leakey had argued that modern humans did not have an australopithecine ancestry, the evidence contradicted his theory that toolmaking was a uniquely human (*Homo*) ability. To resolve this conflict, he classified the skull as an australopithecine but of a new genus and species, *Zinjanthropus boisei*. Nicknaming it the "Zinj skull," Leakey described it as a distinct form from the South African specimens found by Broom and Robinson. Not long afterward, Robinson challenged Leakey's evidence as insufficient for classifying his australopithecine in a new genus. Eventually renamed *Australopithecus boisei,* just as Robin-son's *Paranthropus robustus* was renamed *Australopithecus robustus,* both are now sometimes reclassified again as further evidence has been found to justify *Paranthropus* as a genus distinct from *Australopithecus*. There continues to be debate to this day whether this distinction should be made.

Another issue that existed was Louis Leakey's doubt that his *A. boisei* was the actual maker of the stone tools found in the similar strata. The size of its brain was quite small, and as a result of this evidence, he did not believe that it would have possessed the cognitive ability needed to create tools. The fashioning of stone tools required several complex levels of thought. It required knowledge of rocks to know which type is ideal. It required a capacity to understand physics, to know at what angle and with how much strength to strike the stones together. It also required an advanced ability to recall previous events, such as hunts, to know how to make the tools effective and efficient. These are all advanced, higher levels of cognitive thinking that Louis Leakey did not think an australopithecine brain was capable of accomplishing. His unwavering theory proved to be correct when in 1964 he, along with his own team members as well as Phillip Tobias and John Napier, described a specimen they thought was the creator of the stone tools. First discovered by Jonathan Leakey in 1960, the fossil remains consisted of an incomplete mandible with several teeth, various hand and wrist bones, and two parietal bones. From an examination of the mandible and teeth, the team determined that the hominid had possessed a less robust jaw, smaller and more rounded molars, and a facial structure much more similar to modern humans than any australopithecine. The parietal bones gave perhaps the most significant and most debated evidence. Tobias estimated that the bones from the juvenile skull would have given a brain capacity at maturity of 675 ml, much larger than any australopithecine. Between 1960 and 1964, additional similar hominid fossils were found, and by 1964 enough evidence existed, Leakey claimed, to classify the hominid remains as *Homo habilis* or "handy man."

Its increased brain capacity and reduced molar size convinced Leakey that *Homo habilis* was the toolmaker. The ability to use tools allowed for a more general diet. This is reflected in the reduced molar size, which had been specialized for plant consumption in the australopithecines. Many believe that *H. habilis* was a scavenger rather than strictly a plant eater. This may explain why *H. habilis,* which coexisted with *Australopithecus* for over a million years, was able to survive longer within the same environment. Its decreased specialization allowed this species to more easily adapt to global climate changes in the past.

Later Interpretations: Ethiopia and Tanzania
