The concept of eternal recurrence also has interesting implications for the concept of space. According to both Nietzsche and Heraclitus, there is only one substance, which changes on the basis of one determined law that represents one aspect of the substance. All things and qualities are aspects of the one existing substance; that is, space and time are such aspects, too. Because the amount of substance is finite, it is also limited at its end. Limitation can only come about by something other, so that substance would have to be limited by another something. If such a something limited the substance, then it would exist outside of the substance. However, there can be only one substance.

In addition, substance can interact only with itself; two absolutely different substances cannot interact. Hence, the one substance cannot be limited by another substance. It cannot be limited by a vacuum either, as this would imply that there is an empty space. However, space exists only as an aspect of the substance, so empty space cannot exist. As substance can be limited neither by another substance nor by empty space, it has to be limited by itself. If the substance is limited, and if it can be limited only by itself—the amount of substance being finite and space being one aspect of the substance, then space can only be regarded as curved. Even though the concept of curved space was developed only about 150 years ago by first Georg Friedrich Bernhard Riemann and then Einstein, it has to be implicitly included in the philosophy of all those thinkers like Heraclitus and Nietzsche who defended the great year or the eternal recurrence of everything.

Science

In addition, we can argue that even on the basis of contemporary physics, the premises necessary for the occurrence of the eternal recurrence to occur are such that corresponding premises can be found there:

1. Time and space have aspects of ones subtance: Since Einstein formed his general theory of relativity, this has been the dominant scientific paradigm.
2. Energy or substance is limited: Scientifically, this is a very probable premise. If the density of matter is sufficiently high, the Friedmann equations, which can be deduced from Einstein's equations of the general theory of relativity, demand a closed universe. If the mass of neutrinos were zero, then when they are not moving, the density of matter of the universe would be great enough for a closed universe.
3. Force is limited, which implies that it is being limited in amount and in its divisibility: Again, a comparable premise can be found in contemporary physics. Energy can turn up only as an integer multiple of the Planck constant.
4. There is a determined law responsible for change: Physicists attempt to find a grand unified theory (GUT) in which they hope to unite the four basic forces: the weak force, the strong force, the electromagnetic force, and gravitation. The GUT can be seen as the determined law demanded by eternal recurrence.
5. The reversibility of all states has to be given: The law of the conservation of energy alone might be sufficient to imply this premise. However, one can also argue against the validity of this premise by referring to the second law of thermodynamics, which implies the permanent striving for entropy. However, there are natural scientists, such as Benjamin Gal-Or, who hold that the second law of thermodynamics might just be connected to the expansion of the universe. We might have antientropy during the collapse of the universe.

Given the foregoing comparison between the premises of the eternal recurrence and of modern science, we can see that even from a scientific standpoint, eternal recurrence bears some plausibility. However, this does not mean that eternal recurrence can simply be identified with the physical theory of the big bang and the expansion and contraction of the universe, because here problems concerning the understanding of singularity come in. Stephen Hawking's and Roland Penrose's understanding of singularity is dominant today, and it causes problems for this kind of understanding of the eternal recurrence. This again does not mean that all cosmological interpretations of the eternal recurrence have to fail. With the eternal recurrence or the great year, Nietzsche and Heraclitus developed concepts of time that are very different from our everyday perception of time, but once grasped, these concepts inspire a lifelong fascination.

Nirvana

Nirvana is from a Sanskrit word that means "extinguishing." It is also spelled *nibbana.* The idea of nirvana is found most prominently in Buddhism, although Hinduism alludes to the idea. Buddhist doctrine includes the idea of *karma* (one's actions), *dukkha* (suffering), and *samsara* (reincarnation). Buddhists live a life filled with karma, acquired through positive and negative actions. When a Buddhist dies, the life is continued through rebirth; the condition of the rebirth is determined by the karma acquired in previous lives. In addition, Buddhism teaches that life is filled with dukkha. The acknowledgment of dukkha ties a Buddhist to the stream of samsara. By realizing that the essence of a Buddhist is not the accumulated lives lived but instead is separate from the experiences of the past and present lives, a Buddhist experiences enlightenment, which leads to nirvana. Through a reduction in karmic actions plus an awareness that a state of being exists beyond the physical one of samsara, the Buddhist can attain nirvana.

Nirvana is neither a physical nor a spiritual place; therefore it is beyond questions of where and when. No description of nirvana has been given, although descriptions of its attributes exist. In the *Dharmapada Sutra,* the Buddha described nirvana as the highest happiness (or bliss). Yet this happiness and bliss is not to be confused with that state experienced while in the process of transmigration, but with a state of calmness that transcends the earthly experience. A Buddhist who is "in" nirvana will not "leave" nirvana; death does not again occur. Siddhartha Gautama (or Gotama; 5th century BCE) realized how to reach enlightenment without aid and so became the Buddha. Upon the death of his last life (or his "cessation") Siddhartha entered into a state of nirvana. He is currently "in" nirvana and will no longer die or return to a physical form.

Entrances into nirvana, and the definition of nirvana itself, differ between the two larger groups within Buddhism: Theravada and Mahayana. Theravada ("doctrine of the elders") Buddhism teaches that each Buddhist must attain nirvana individually. The Buddha left teachings that can guide Buddhists toward reducing suffering and negating karma, but these must be attained alone. In addition, only a monk can attain enlightenment. Upon being enlightened, that is, upon realizing that illusion of rebirths and of suffering, the Theravada Buddhist becomes an *arhat,* or one who will not be reborn and enters into nirvana. Consequently, Theravada Buddhism necessitates a long period of rebirths in which to reach nirvana. For this reason, it is also known as Hinayana, or "lesser raft" Buddhism, because of the smaller number of Buddhists who reach the state of nirvana during a set time period.

Mahayana Buddhism teaches that each Buddhist has help from those who have been enlightened and decide to remain in the physical world of rebirths in order to aid other Buddhists. These previously enlightened individuals are called *bodhisattvas* (as opposed to arhats in Theravada Buddhism.) Tibetan Buddhism, a branch of Mahayana Buddhism, gives these bodhisattvas the name of lama, with the chief lama being known as the Dalai Lama. The highest goal in Mahayana Buddhism is to reach enlightenment yet decline to enter into nirvana, instead choosing to return in future rebirths. These bodhisattvas experience death and rebirth, but it is their choice to delay entrance into nirvana in order to aid others.

Within the Mahayana Buddhism tradition exists a writing known as the *Nirvana Sutra* (or *Mahaparinirvana Sutra* or *Maha-nirvana Sutra*). Mahayana Buddhists believe this is the last teaching of the Buddha. This writing teaches a different understanding of nirvana. The *Mahaparinirvana Sutra* also draws a distinction between nirvana and mahaparinirvana. Nirvana is the realization that suffering is an illusive aspect of one's physical lives. Mahaparinirvana is the realization of one's Buddha-nature. This idea of the Buddha-nature is unique to Mahayana Buddhism. The Buddha-nature exists in everyone and is the capacity of understanding reality. Therefore, the state of Mahaparinirvana consists of realizing the true nature of suffering plus an awareness of one's Buddha-nature.

The word *nirvana* is found in Hinduism. Hinduism also teaches the doctrines of karma and rebirths. The idea of a break in the cycle of rebirths differs from Buddhism, though, for in Hinduism one is connected with Brahman, the impersonal spirit. The word *nirvana* as a Hindu idea occurs primarily in the *Mahabharata,* an epic poem within Hinduism, and specifically a writing within the *Mahabharata* called the *Bhagavad Gita.* Within the *Bhagavad Gita,* the idea is linked with the Hindu idea of moksa or "release" from the rebirths: "Only that [one] whose joy is inward, inward his peace, and his vision inward shall come to Brahman and know nirvana. All-consumed are their imperfections, doubts are dispelled, their senses mastered, their every action is wed to the welfare of fellow-creatures: Such are the [ones] who enter Brahman and know nirvana." Thus, the Hindu ideal is for liberation from the passions and acknowledgments of a physical life; when this occurs, one experiences moksha or nirvana, and is united with Brahman. Consequently, the idea of nirvana as found in Hinduism differs from the nirvana as taught in Buddhism, although both are similar in that nirvana is the experience of and result from being released or enlightened.

Buddhist doctrine also includes the concept of parinirvana. *Parinirvana* is the term given to the death of one who has been enlightened yet chooses to remain in a physical state a while longer. In Mahayana Buddhism, the day that celebrates the Buddha's final death is known and celebrated as Parinirvana (or Nirvana) Day. The Buddha died in present-day Kushinigar, India, where today exists a parinirvana temple commemorating the site where the Buddha left his last physical life (died). Inside the temple lies a statue of the Buddha at his moment of parinirvana, or moment when he ceased his earthly lives and entered into nirvana.

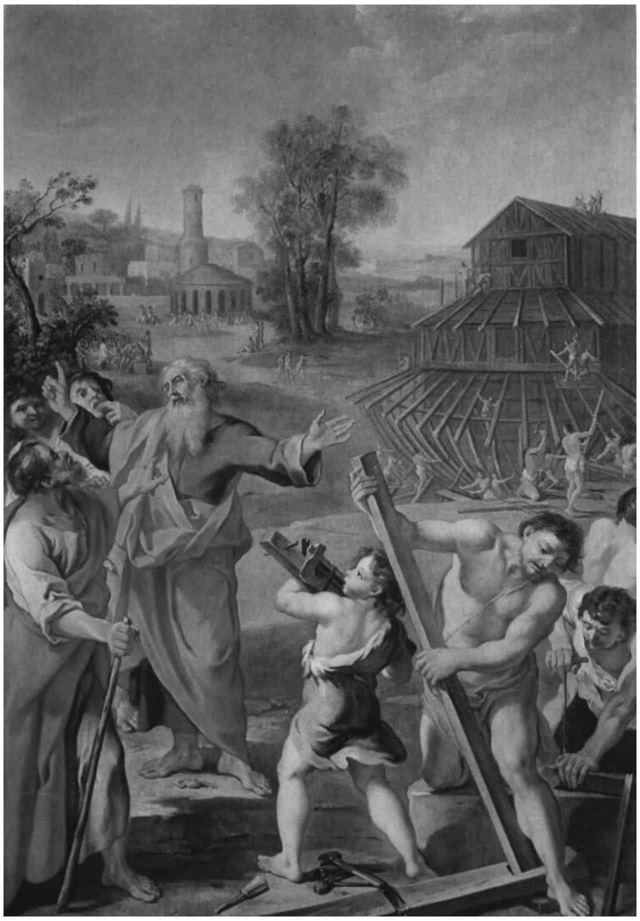
Noah

Noah is the main character of the cataclysmic flood story told in the biblical Book of Genesis (chapters 6–9). Noah represented the last generation of the era of the antediluvian Creation and became the father of the current world order, thus a link between the ancient past and the present.



Noah's Ark, *by the Französischer Meister ("The French Master"), Magyar Szépmű́vészeti Múzeum, Budapest. c. 1675. The ark story told in Genesis has parallels in the Sumerian myth of Ziusudra, which tells how Ziusudra was warned by the gods to build a vessel in which to escape a flood that would destroy humankind. The deluge story is one of the most common folk stories throughout the world.*

According to the Book of Genesis, Noah lived nine generations past the first created humans—Adam and Eve. Adam and Eve introduced sin into the world by disobeying God when they ate from the tree of knowledge of good and evil. This sin escalated throughout Creation to the point where all humanity was wicked by Noah's time. Then God regretted he had made humanity and decided to destroy the world with a flood. However, God chose to spare Noah, the only righteous man, and his family. God ordered him to build a massive ark upon which Noah, his family, and a pair of animals representative of each species would be spared from a watery annihilation. Noah obeyed, built the ark, and survived the deluge. After the flood, the ark landed on Mt. Ararat, a mountain located somewhere in the area that is now eastern Turkey, where Noah and his family disembarked.

Noah represents the best and worst of humans. He represents the best because before the flood God deemed him alone as righteous and blameless of all the people in the world (Gen 6:9). He is the only one who deserved to be spared from destruction. However, he also represents the worst of a corrupt world. After the flood, Noah became drunk and passed out. Ham, one of Noah's sons, sinned when he "saw the nakedness of his father" (Gen 9:22). Therefore, through Noah sin carried over from the initial Creation into the postdiluvial world.

Noah is one of many heroes of ancient Near Eastern flood stories. Ziusudra, hero of the Sumerian flood story, overheard the gods plotting to wipe out humanity. He was saved from a 7-day and 7-night flood by making a boat. Afterward, he offered a large sacrifice to the gods. Being pleased, the gods gave him eternal life. Atrahasis, hero of the Akkadian flood story, is warned by the god Enki that the gods intended to flood the earth and destroy humanity. Atrahasis built a boat and escaped the flood. Utnapishtim, hero of the flood story in the Gilgamesh epic, has an experience similar to that of Atrahasis, except after the flood Utnapishtim offered a sacrifice to the gods, who were so thankful that they gave Utnapishtim and his wife eternal life and placed them in a distant location separate from the rest of humanity.

The story of Noah has two timeless elements. First, the story has a theological connection, that is, the seriousness of sin and the grace of God. This theme is the basis of the flood story and is prominent throughout the Hebrew Bible. Second, the story of Noah has inspired some people to search for the remains of the ark, in a sense to find a modern physical connection with the ancient past. Some people believe that the ark landed on the Agri Dagh peak in the Ararat mountain range. However, to date no evidence of the ark has been found.

Nostradamus (1503–1566)

Michel de Nostredame, more commonly known as Nostradamus, is criticized by some and acclaimed by many as a seer whose 942 quatrains (poems with four lines each) transcend time and predict the future. Born on December 14, 1503, in Saint Remy de Provence in the south of France, Nostradamus was the first son and one of nine children born to Reyniere de St. Remy and grain dealer and notary Jaume de Nostredame. He is best known for his book *Les Prophecies* (1555) and *The Almanac,* a set of annual predictions published until his death on July 2, 1566.

Historically, the Nostredame and St. Remy families had strong academic ties. Several family members were doctors and scholars. Although originally of Jewish descent, the family converted to Christianity in 1502 as a consequence of the ascension of Louis XII. Starting at the age of 15, Nostradamus followed family tradition and attended the University of Avignon for more than a year. An outbreak of the black plague forced the university to close its doors, leading Nostradamus to pursue a career as an apothecary. In 1529 he entered the University of Montpelier to study for a doctorate in medicine, but upon the discovery of Nostradamus's occupation as an apothecary, he was expelled. Despite his lack of university credentials, many of his colleagues and publishers still addressed him as Doctor.

Following his expulsion, Nostradamus married and had two children, but his wife and children succumbed to the plague in 1534. Thirteen years later, in 1547, Nostradamus married a wealthy widow named Anne Ponsarde Gemelle, and the two had six children: three sons and three daughters.

In 1550, *The Almanac* was first published, and Michel de Nostredame became widely known under the name Nostradamus. *The Almanac* was so successful that he decided to publish his predictions annually.

Today, many admirers of Nostradamus believe that he accurately predicted such events as the great fire of London, the rise of Adolf Hitler, the crash of the American space shuttle *Challenger,* and the September 11, 2001, attack on the World Trade Center and the Pentagon. Overall, Nostradamus made 6,338 predictions, many of which, however, never came to fruition. In any event, skeptic and follower alike cannot contest that Nostradamus left his mark; his prophesies remain an ongoing source of speculation and debate. In the wake of the events of September 11, 2001, an Internet hoax cited a Nostradamus quatrain that, it was claimed, predicted the fiery attack. Later, to the delight of skeptics, the quatrain was proven false. As both skeptics and neutral observers have noted, Nostradamus's prophecies are ambiguous because they fail to provide specific dates; therefore these predictions are open to numerous and contradictory interpretations.

NOTHINGNESS

The term *nothingness* denotes the result of specific negation of a reality (metaphysical or ontological meaning) and/or of a value and validity of something (axiological meaning). Its content is close to the terms "nothing," "nonbeing," "emptiness," and "vanity."

As opposed to the common meaning of the word "nothing" ("nonbeing"), which relatively negates the attributes, state, or existence of a particular object (or a category of objects), *nothingness,* in its ontological meaning, is concerned with absolute negation of the whole of entities, thus of any particular object (or category of objects) at all. For example, in the sentence "Yesterday, there was a glass on the table, but today there is nothing there," by "nothing" we mean only the so-called relative nothing—the absence of the glass in the given place and not the fact that there is no other particular object in the place of the expected glass. In contrast, in the sentence "The world was created from nothing," by "nothing" we mean exactly the absence of any particular object (category of objects), absolute nothing, nothingness. In the first case, the absence (nothing) of something is the presence (existence, entity) of something else, other than the negated thing. In the second case, this does not apply: Absence (nothing) is the absolute opposite of any presence (existence, entity). Because of this negation of all that exists, the concept of nothingness is often considered the result of illegitimate abstraction and therefore unacceptable for rational thinking. To favor it during the explanation of reality is considered to be (ontological) nihilism. This applies even more so to its stronger alternative, which negates not only all reality but also possibility (so-called negative, or absolute nothingness).

Nothingness in its axiological meaning is in human experience and its reflections thematized in several ways. Depending on which aspect of a value it negates (positive, negative, or both), the basic positions of value nihilism vary from the extreme pessimistic, for example when we sigh along with the preacher, "Vanity of vanities! all is vanity"; through the more moderate one, which answers the question of what humanity is with "A Nothing in comparison with the Infinite, an All in comparison with Nothing" (Pascal); all the way to the mystic ideal of a mind emptied of values (neutral), for example in the state of nirvana. Depending on the kind of the negated value, we differentiate between ethical nihilism (negating the obligatory validity of moral values), religious nihilism (denying the existence of the sacred or gods), political nihilism (negating the obligatory validity of social order), logical nihilism (denying the existence of truth), and gnoseological nihilism (rejecting the possibility of knowledge).

The concept of nothing, or nothingness, as an ultimate explanation principle of reality and human life, played a more important role historically in Asian religious and philosophical thinking than it did in the thinking of Western civilization. It was also to a great extent particular to mystically inclined thinking rather than to rationalistic systems. For example, in the ancient Chinese doctrine of Laozi (5th century–4th century BCE), the basic principle of reality, *tao,* is empty—nameless and formless; later in the writings of Zuang-zhou (4th century BCE) it is the emptiness itself—*xu*. In ancient India, it was mainly the teaching about *nirvana* (Hinduism, Buddhism), the content of which is the emptying of the mind of an individual of partial contents and its transition into the state of "nonbeing." But most of all the doctrine of emptiness (*sunyata*), understood in an ontological as well as axiological way, developed in Mahayana Buddhism. The concept of nonbeing (*abhava*), also in absolute meaning, can be found as one of the categories even in the logically tuned system Vaisesika. Later it was Zen Buddhism that attempted a synthesis of the ways of Buddhism and Taoism, also in the area of the understanding of emptiness as a central concept. In Jewish mysticism, a similar function of holy nothingness was carried by the concept of *ein sof*.

Unlike oriental doctrines, ancient Greek philosophy was more hostile toward the concept of nothing and nonbeing (nothingness). According to Parmenides of Elea (540–450 BCE), being (*on*) is and nothing (nonbeing—*me on*) is not, because it is unthinkable, as thinking and being are the same thing. Nothing (nothingness) as the absolute opposite of being should have been excluded from the rational discourse. But already Democritus (450–370 BCE) was forced in his philosophy, in an effort to explain plurality and motion, to postulate alongside being (plenitude, atoms) also the existence of nonbeing—of empty space. Even Plato (428–348 BCE) admits in a certain way to the existence of nonbeing, in order to explain, for example, the possibility of an error in human knowledge, because an erroneous statement is a statement about the nonexistent. Nonentity (nothing), however, is not the opposite of being, as it was with Parmenides, but it's a part of it; it is not absolute nonbeing, but merely relative—it is other being, the being of other, because each determined entity, as identical with its own self (*tauton,* is also at the same time different from another determined entity (*heteron*). For example, motion *is* motion (itself), but it *is not* stability (something other). In another context, in an attempt to clarify the changeable nature of the perceptible world, Plato again admits to the existence of nonbeing (matter), in which this world participates, as being similar to being itself (ideas). Nonbeing not only *is not* any determined other, but also it is not itself; it is presented here as a generalized principle of an undetermined otherness. Later, for Aristotle, with his differentiation of matter (possibility) and form (reality) as the necessary aspects of the existence of every object, nonbeing is a not yet realized entity, *ens potentialis,* which lacks some or all attributes of a future thing; it is rid of its positive determination (lack of being, *privatio*).

Greek philosophy, despite its plurality in the understanding of nonbeing, in principle did not overstep its rationalist rule according to which "out of nothing, nothing comes" (*ex nihilo nihil fit*). On the contrary, medieval Christian thinking acknowledged the concept of the absolute nothing, nothingness as a legitimate element of discourse about reality and man, by the fact that on the basis of its credo, it explained the origin of the world as "creation from nothing" (*creatio ex nihilo*). It was mainly Saint Augustine of Hippo who, in an attempt to demonstrate the unlimited nature of God's power, theoretically justified this change, whereas he also endowed nothingness with a morally sacral dimension. Nothingness was worthless, connected to evil and sin. As a result of this, all creatures carried its dual seal—ontological as well as axiological.

A new aspect was added to meontological problematics by thinkers influenced by Neoplatonic mysticism, most of all Pseudo-Dionysios (5th century CE), Meister Eckhart (1260–1327), and Nicholas of Cusa (1401–1464), who on the grounds of negative theology applied the concept of nonbeing (nothing) through various ways even to God himself. However, in their case, it was not nothingness in the sense of absence or lack of being (or its determination), but the opposite, nothingness "resulting" from surplus of being, because the infinite and absolute God, according to them, cannot be identical with being that is specified as an entity by finite determinations. God is beyond it and above it; he is incomparably (even in terms of worth) more than being itself. If, despite all differences, this thinking was closer to

Plato's ancient message, Aristotle's reflections on lacking (*ens potentialis, ens rationis*) were developed mostly through scholastic tradition (Saint Thomas Aquinas, 1225–1274; Francisco Suarez, 1548–1617; and others). Later it was followed by the classics of modern philosophy—Baruch de Spinoza (1632–1677), G. W. Leibniz (1646–1716), and Immanuel Kant (1724–1804).

Significant for further development of these problematics were Georg Wilhelm Friedrich Hegel's reflections on nothing (and negativity as such). Hegel (1770–1831) in a quasi-rationalistic reception of mystical views, gets almost as far as negation of the logical law of contradiction through a provocative statement that "pure being and pure nothing are therefore the same," whereby their truth is becoming. Here, the negativity of nothingness becomes the driving force of dialectics. These reflections, together with his master-slave dialectic, significantly inspired existentialists (Martin Heidegger, 1889–1976; Jean-Paul Sartre, 1905–1980; Albert Camus, 1913–1960; and others), as the main successors of the meontological problematics in the 20th century. According to Heidegger, who in his ontological difference distinguishes between entity and being, nothing is the absolute negation of the whole of entities. However, one does not encounter it in thinking, but in anxiety. Nothing, nonbeing (which paradoxically is the veil of being) enables human being (*being-there, dasein*), because for one to be means to be held out into this nothing, to transcend one's self. Later, Sartre uses nothingness, as opposed to being in-itself, as being for-itself, that is, empty, contentless, and undetermined consciousness that allows human freedom, because paradoxically "it is what it is not and it is not what it is." This approach received great criticism from analytically oriented philosophy and particularly from logical empiricism. According to Rudolf Carnap (1891–1971), violation of logical rules of language lies behind Heideggerian reflections, when for example the word *nothing* is used as a name of an object, whereby it is a form of negation, used to create negative existential statements. All thoughts of a similar kind are therefore in their ultimate effects meaningless.

Novels, Historical

The historical novel is a genre of literature whose story is set during a period that predates the author's own time, often by a significant number of years. A historical novel generally involves substantial research by the author concerning details of the period. The genre became widely popular during the 19th century Romantic period, advanced by great novelists such as Sir Walter Scott.

The purpose of the historical novel extends beyond that of entertainment, though many excel at this in their own right. Authors have often intended to deliver a message, advance a cause or ideology, or popularize history and present a time period to the public; none of these intentions is necessarily exclusive of the others. Historical novels are commonly set during eventful periods in human history, depicting a conflict or a transitional moment in time. Some historical novels span a lengthy duration and may include many accurate details about the past.

A prominent example of a historical novel that deals with the notion of time is Mika Waltari's *The Egyptian,* published in 1945. First written in Finnish, *The Egyptian* is set during the reign of the pharaoh Akhenaton, more than 3,000 years ago. The novel is centered on a fictional character, Sinuhe, the personal physician to the pharaoh, who recounts the tale of the pharaoh's decline and fall. The tale also parts from Egypt and describes Sinuhe's extensive travels throughout the ancient world. Published immediately following World War II, Waltari's novel was intended to explore the violence and brutality of the human condition and to imply that this has changed little from ancient to modern times.

The legendary Greek conqueror Alexander the Great has been depicted in numerous works of literature. Nikos Kazantzakis's *Alexander the Great,* written in the 1940s, is one modern example intended primarily for a younger audience. Kazantzakis was already a prominent author and philosopher by the time he penned the novel. *Alexander the Great* is a flattering depiction of the hero from a Greek author with a sense of pride in Greek history. However, Kazantzakis does not entirely succumb to glorification of the hero, presenting his faults and human qualities as well. The modern reader can thus relate to an ancient heroic figure.

The intention of delivering a powerful message through a classic work is exemplified by Henryk Sienkiewicz's historical novel *Quo Vadis: A Narrative of the Time of Nero*. Published in 1895, *Quo Vadis* is the Polish author's most famous work. The story is centered on a romance between a Roman patrician (Marcus Vinicius) and a young Christian woman (Lygia) at a time when Christians faced violent persecution by the Roman authorities. The novel conveys a strongly Christian message, implicit in the title as well as in the vivid depictions of Christian martyrdom. Sienkiewicz received the Nobel Prize for Literature in 1905. *Quo Vadis* has withstood the test of time, having been adapted to several film interpretations.

Popular interest in the time of imperial Rome and the birth of Christianity is evident by the reception of *Ben-Hur: A Tale of the Christ* in 1880. The author, Lew Wallace, was an American Civil War general, politician, and novelist. The book has been acclaimed for its accurate descriptions of the Holy Land of 2,000 years ago, though Wallace had never set foot there. Set during the reign of Tiberius, *Ben-Hur* is a tale of a Jewish aristocratic named Judea Ben-Hur who is falsely accused of murder by a Roman officer, Messala. Like *Quo Vadis,* the story deals with a pivotal moment in time as Christianity emerges within the Roman Empire. *Ben-Hur's* exceptional popularity helped to make the historical novel a popular literary and cinematic genre in the United States.

The author of *Ivanhoe,* Sir Walter Scott, is often credited as the father of the historical novel. Scott's 27 historical novels established the standard structure of the genre and greatly influenced later writers. His interest in the European Middle Ages is reflected in *Ivanhoe,* published in 1819. The story is set in 12th-century England during the time of King John. *Ivanhoe* is not only a tale of chivalry, combining fictional characters and actual events, but also a critique of the persecution of Jews in England. *Ivanhoe* helped to rekindle popular interest in the Middle Ages during the 19th century.

Leo Tolstoy deviated from the conventional novel with *War and Peace,* published as a series between 1865 and 1869. This ambitious story is set during the Napoleonic period and specifically during the Russian campaign. The Russian author spurned the "great man" paradigm of history in favor of capturing the daily human struggles during warfare. As such a human, Napoleon does not fare well in Tolstoy's depiction, whereas the personal interactions within Russian society form the narrative. This notion of "history from below" is central to Tolstoy's understanding of time and the movement of events.

Perhaps the most significant antiwar novel written is Erich Maria Remarque's 1929 classic *All Quiet on the Western Front.* Remarque's novel was timely; it was published in German during the interwar period. The novel is set during the First World War and is narrated by a young German soldier, Paul Baumer, who is engaged in the infamous trench warfare emblematic of the conflict. Baumer experiences the horrors of war and comes to recognize the deception of blind nationalism. The novel breaks sharply from the traditional portrayal of warfare over time, in which it has generally been glamorized. So powerful is the message in *All Quiet on the Western Front* that the novel was banned as subversive by the Nazi party in 1933.

A host of other distinguished novels could be added to this list. All of the aforementioned historical novels have film adaptations, which have also contributed to the popularity of the genre. Historical novels continue to connect readers to the past and to the passage of time.

Novels, Time in

Time in novels is based on a fundamental duality. Günther Müller, a German literature theorist, was the first who reflected thoroughly on this duality. In 1948 he introduced the opposition between *erzählte Zeit* (story time) and *Erzählzeit* (narrative time), a literary terminology that has gained international acceptance. *Story time* designates the chronology of the events told—that is, the time of the story—whereas *narrative time* means the time of the narrative presentation of the story; in other words, the time of the plot. The temporal complexities that result from the relation between story time and narrative time were studied in detail by Gérard Genette, a French literary theorist who is primarily associated with the structuralist movement. In his canonical work, *Narrative Discourse: An Essay in Method* (1972), Genette proposes that time in novels may be classified in terms of order, duration, and frequency. We shall follow Genette's terminology, because it fills the need for a systematic theory of time in narrative texts.

The first main category discussed by Genette is the category of *order.* It designates the discrepancies between, on the one hand, the temporal order of a series of real or fictitious events connected by a certain chronology and, on the other hand, the temporal arrangement of these events in the narrative discourse. Genette pays attention to the fact that events occur in one order but are narrated in another. This discordance between the temporal succession of events in the story and their arrangement in the plot is called *anachrony.* Anachronical relations between story and plot are realized mostly by means of analepses and prolepses. *Analepses* are narrative episodes that take place earlier than the temporal point of departure of the narrative into which they are inserted. They are narrative retrospections or backflashes. The framing narrative is the first narrative, containing the analeptic sequence as the second narrative. *Prolepses* are temporal anticipations, narrative episodes that take place later than the temporal point of departure of the narrative, into which they are inserted. The framing narrative that contains the proleptic sequence is the first narrative, whereas the framed episode is the second narrative. Yet a careful analysis of the temporal order of narrative texts is not finished with the mere identification of analepses and prolepses, which must be further specified in respect to reach and extent. *Reach* designates the temporal distance of events told in the analeptic (proleptic) sequence from the moment in the story when the narrative was interrupted to make room for the anachrony. To determine the reach of analepses (prolepses) the reader must ask, "How long is the temporal distance between first and second narrative?" *Extent* is used to describe the duration of the story that is covered by the analeptic (proleptic) sequence. In this case the reader's question is, "How long is the period of time told in the second narrative?" In addition, analepses (prolepses) may contain further anachronies. These narrative sequences already framed by an anachronic episode are analepses (prolepses) of second degree.

Duration is the second main category discussed in Genette's *Narrative Discourse.* The duality of story time and narrative time allows novelists to control precisely the speed of their narratives. Duration is defined by the relation between the length of the story (measured in seconds, minutes, days, etc.) and the length of the text used to describe it (measured in lines, pages, chapters, etc.). The discrepancies between the length of the story and the length of the text are *anisochronies* (variations in speed). Genette determines four types of speed variations: summary, scene, pause, and ellipses.

- *Summary* means that the period of time told in a story is much longer than the narrative sequence used to describe it. Summaric episodes may cover 50 years in three or four sentences. Usually they are used for the transition between two scenes; they form the background against which scenic presentations stand out.
- *Scene* designates the correspondence between the period of time told in the story and the length of the narrative that describes it. Most often scenic episodes are characterized by dialogues, they present important conversations between the protagonists as well as dramatic events in their real length.
- *Pause* means that the speed of a narrative text is remarkably slowed down. Descriptive pauses are realized by epic ecphrasis or digression. The length of the narrative discourse of a pause may cover eight or nine pages, though it tells nothing about the further development of the story. Descriptive pauses stop the temporal progression of the story while the narrative discourse moves on constantly.
- *Ellipses* are gaps in the temporal continuity of the story. The period of time left out may cover hours, days, years, and more. For a precise knowledge of ellipses, readers have to consider the elided story time. Thus, their first question is to know whether the temporal elision is explicitly announced by quick summaries of the type "some time later" (explicit ellipses) or left out without any comment (implicit ellipses). Their second question is to know whether the duration of these time gaps is indicated (definite ellipses) or not (indefinite ellipses).

Frequency is the last main category discussed by Genette to describe the complex relations between story time and narrative time. It designates the relation of repetition between the events told in the story and their presentation in the narrative discourse. The frequency of a narrative text determines its temporal rhythm. Genette works out four types of frequency: narrating once what happened once, narrating *n* times what happened *n* times, narrating *n* times what happened once, and narrating once what happened *n* times. The first two types are singular narratives. In singular narratives the number of events in the story corresponds exactly to the number of statements about these events in the narrative text: If something happens once in the story, it is mentioned once in the narrative discourse; if something happens twice in the story, it is mentioned twice in the narrative discourse, and so on. The third type of frequency is the repeating narrative. Repeating narratives are characterized by a discrepancy between the number of events told in the story and the number of statements about these events in the narrative. For example, something happened only once, yet it is mentioned two times or more in the narrative discourse. The last type of frequency is the iterative narrative. In iterative narratives regular events are reduced to one single utterance of the type "Every Monday he caught the train at 11 p.m."

Genette's *Narrative Discourse* exclusively analyzes the literary presentation of time with regard to the form of narratives. Yet time can also be the thematic center of a novel. When we study time as the theme of a narrative, we no longer refer to its form but to its content. In this respect a fundamental distinction of time is the one between objective and subjective time. *Objective time* designates the regular succession of minutes, hours, and days that is measurable with a watch or a calendar. It is a consistent kind of time without deviations. *Subjective time* is based on the perception of characters in a novel. It depends on their individual experience, capricious imagination, or rambling memory. Subjective time changes constantly; hours are stretched into months, years compressed into days.

A careful textual analysis of the duality between story time and narrative time has to consider the specific characteristics of both kinds of time, especially in their relation to form and content. In the following section (Time as Form) we shall focus on some of the most famous novels of world literature in which the literary presentation of time decisively determines the narrative form. The final section, Time as Content, discusses renowned novels in which time is a thematic center. Although the presentation of time in novels has to be considered separately in respect to form and content, the two aspects are not to be isolated from each other. It is exactly their correspondence, or their significant contrast, that constitutes the temporal complexity of a narrative piece of writing.

Time as Form

Thomas Mann's *The Magic Mountain* (1924) is one of the most prominent novels in which the presentation of time in the story is mirrored in the form of the narrative. The protagonist's subjective experience of, and his reflection on, time is formally expressed by variations in speed. Hans Castorp, an ordinary young man, takes a short break between his final examinations in engineering and his first job. He plans a 3-week visit to his cousin Joachim, who stays at a sanatorium in the Swiss mountains because he suffers from pulmonary tuberculosis. Though Hans's visit begins as a holiday trip, it turns into a stay of 7 years that is abruptly ended by the outbreak of World War I.

The spatial distance between the mountains and the so-called flatland turns the sanatorium into a hermetic place. The rhythm of time on the mountain is completely different from the rhythm of time in the plain where the young protagonist comes from. At first, Hans views life on the mountain from the perspective of the flatland. He accuses Joachim of wasting his time in the sanatorium and does not understand why for him and the other patients the smallest temporal unit is a month. Yet life in the sanatorium rapidly benumbs Hans's sense of time. Soon he has experienced all the details of clinical routine and knows by heart its daily, weekly, and even monthly rhythms. The protagonist begins to live in a perpetual present, lacking even the temporal clues of nature, because in the mountains all kinds of weather appear in disorder throughout the year. Paradoxically, the extratemporal present on the mountain inspires Hans Castorp to reflect about the essence of time and to question temporal categories he has previously taken for granted. The new patient learns by experience that time in the flatland (objective time) is completely different from the psychological experience of time on the mountain (subjective time). The protagonist's complete absorption in atemporality ends with the outbreak of the First World War: He has to do military service and dies, presumably in a battle.

Hans's subjective experience of time and his isolation in an eternal present find their formal expression in a significant acceleration of speed. The length of the text that describes the first 3 weeks on the mountain is about seven times longer than the summary of the following 3 weeks. Apart from Hans's discussion with the Italian humanist Lodovico Settembrini and his opponent Leo Naphta, the remaining time of the protagonist's stay in the sanatorium (altogether 7 years) is summarized even more briefly. Another outstanding event in respect to time is Hans Castorp's dreamlike vision of life and death in a blizzard during a solitary skiing expedition. For the presentation of this event, the narrative speed slows down again, just to accelerate even faster afterward. These variations of speed illustrate clearly that Mann tried to find a formal equivalent for the temporal experience of the protagonist.

James Joyce pursued a similar idea when he wrote *Ulysses* (1922), whose composition of time depends primarily on the author's new approach to characterization. Instead of describing the characters from outside, Joyce puts himself in their place and depicts them from inside. This radical internalization is called "stream of consciousness." It tries to present the thoughts and feelings of literary figures exactly as they pass through the characters' minds. Joyce was the first writer to use a stream-of-consciousness presentation continuously in his narratives. This new approach to characterization significantly influences the presentation of time in *Ulysses*. In respect to the story, internal characterization leads to an emphasis on subjective time. Objective time provides merely an external framework for the temporal structure of Joyce's novel. The major action takes place in the temporal experience of the main characters (Leopold Bloom, his wife Molly, and Stephen Daedalus). The intertextual references to Homer's *Odyssey* enrich the presentation of time in *Ulysses* on a symbolic level. Each episode of Joyce's novel has its parallel in the *Odyssey.* Yet the Irish author summarizes Odysseus's wanderings, which lasted around 10 years, in just 1 day: The action of *Ulysses* takes place exclusively on June 16th, 1904.

Because the story of Homer's epic poem is implicitly integrated into *Ulysses,* time in Joyce's narrative assumes a mythological quality. In respect to the form of *Ulysses,* the consequent use of the stream-of-consciousness technique provokes a deceleration of speed in the narrative discourse: Whereas the story time covers just one day, the narrative time is significantly longer. It is impossible to read Joyce's novel in precisely 24 hours, even if readers want to. The literary presentation of the character's thoughts and feelings consumes much more time than their actual succession in reality. Thus it is precisely the technique of the stream of consciousness that shapes the conception of time in *Ulysses* in respect to both form and content.

In contrast to the 1-day summary of *Ulysses,* the events in Homer's *Odyssey* (c. 700 BCE) cover a temporal period of approximately 10 years. Yet the passage of time is not reported continuously. The *Odyssey* is full of anachronic sequences that switch back to the protagonist's past or implicitly hint at his future. The anachronic presentation of time allows Homer to portray the wanderings of Odysseus exclusively in their final and decisive phase, which lasts about 40 days. All events that precede this starting point of the first narrative (from the fall of Troy until the protagonist's shipwrecking on Ogygia) are told in analeptic sequences by Odysseus himself or in the songs of a minstrel. A similar temporal order applies also to Homer's earlier work, the *Iliad* (c. 750 BCE), that centers around a quarrel between Achilles and Agamemnon. Having evoked the conflict between the characters that the narrator proclaims to be the starting point of his story, he switches back about 10 days to reveal the cause of the quarrel. The first analeptic sequence is thus inserted in the very beginning of Homer's epic poem. It reveals the cause of the conflict in about 140 retrospective lines. A closer look at Homer's epics makes clear, therefore, that the temporal structures of the *Iliad* and the *Odyssey* are based fundamentally on anachronies.

Returning to 20th-century literature, the most complex literary presentation of time can be found in Marcel Proust's *In Search of Lost Time* (also known as *Remembrance of Things Past,* 1913–1927). The reflection on time in the *Search* is exceptional in respect to form and content. As in Mann's *Magic Mountain* and Joyce's *Ulysses,* subjective time determines the story of Proust's narrative. In the *Search,* time assumes the form of involuntary memory (*mémoire involontaire*). The narrator-protagonist, Marcel, tries to remember his life. He learns that only the involuntary memory is able to bring back the complete image of the past immediately. The voluntary memory (*mémoire volontaire*) is under rational control and thus remains superficial. A canonical example of the workings of the involuntary memory is the so-called madeleine passage in the opening of the *Search*. A discrete similarity between present and past (in this case the unexpected flavor of a piece of madeleine cake that Marcel dips into a cup of tea) transports Marcel immediately back to his childhood at Combray. The involuntary memory evokes an overpowering recollection and grants Marcel a glimpse into the essence of the past.

Proust's literary presentation of the involuntary memory was significantly inspired by the philosophy of Henri Bergson. His philosophical study *Matter and Memory* (1896) appeared when Proust was 25. In the second chapter of his work, Bergson distinguishes two kinds of memory: the memory of habit and the pure or spontaneous memory. He argues that the latter is independent of our will. Proust's poetics can be called "Bergsonian" insofar as he implicitly adopts the philosopher's distinction between an intentional and an unintentional form of remembrance.

The involuntary memory also determines the narrative form of the *Search*. Although remembrance is a temporal process, the basic structure of the novel seems to be static and lifts the action out of time. The impression of atemporality is primarily evoked by the iterative character of the narrative form of the *Search:* Marcel tells us once what happened every Sunday in Aunt Léonie's household; he tells us once about the daily walks with his family. Regular repetition has turned these ordinary actions into a ritual. It is the iterative narration of ritualized events that evokes the impression of immovability and makes Marcel's remembrance of the past eternal.

The last important literary technique for the presentation of time we shall discuss is digression. The complexity of time in Laurence Sterne's *Tristram Shandy* (1759–1767) results primarily from the exuberant use of rhetorical digression. Digressions are excurses from the primary line of a narrative. They slow down the narrative speed or even cause it to stagnate. Rhetorical digressions thus traditionally assume the function of pauses: In a digressive sequence, the time of the story is stopped while the narrative discourse moves on. In *Tristram Shandy,* however, the use of digression is driven to the extreme and undermines its classical function. Digression causes an inversion of the ordinary flow of time: Having set himself the task to omit nothing of his life that is relevant, the narrator-protagonist, Tristram, has to admit its impossibility. Up to the middle of the fourth volume of the novel, he has gotten no farther than the first day of his life. The more Tristram tells about his life, the more he will have to tell. He dwells upon long excurses while his own life is constantly proceeding but remains undocumented. Sterne's exuberant use of digression turns it into progression: His novel is digressive and progressive at the same time. Sentences are interrupted abruptly and not finished until 30 pages farther on. Yet the time in between is stuffed with oddities and strange encounters that enrich the characters by adding new details of their past lives. By driving digression to the extreme, the author creates temporal paradoxes that completely suspend the linear flow of time.

Rhetorical digression also shapes the presentation of time in Herman Melville's *Moby Dick* (1851). Although *Moby Dick* is a work of fiction, Melville included chapters that are largely concerned with an almost scientific discussion of whales. These chapters are known as episodes of cetology (from the Greek nouns *cetus* "whale" and *logos* "knowledge"). They significantly slow down the narrative speed of the story that focuses on Captain Ahab's furious obsession to kill Moby Dick, the white whale, who swallowed his leg. The cetology chapters form a story of second degree that parallels Captain Ahab's obsession on a more abstract level: They present the narrator's untiring effort to bring the mythic power of Moby Dick under rational control by scientific reflection. Yet, as Ahab drowns in a fight with Moby Dick, the intention of Ishmael, the narrator, remains unfulfilled, too. All the scientific approaches fail to give him an adequate account of the white whale's ineffable mystery and strength. The conception of time in *Moby Dick* is thus determined to a significant degree by rhetorical digression. In contrast to *Tristram Shandy,* however, digression keeps its traditional function in *Moby Dick:* It does not generate the whole novel but remains a deviation from the primary line of the narrative.

Time as Content

This section discusses in chronological order certain novels in which time is a central theme of the story and thus primarily relevant in respect to the narrative's content.

The content of Ovid's *Metamorphoses* (completed in 8 CE) unites three kinds of time: primeval time, mythological time, and historical time. Ovid starts his epic poem with the story of Creation. He proceeds with a literary description of the mythological history of the world and ends his narration in his own time under the rule of Augustus. The major theme of the *Metamorphoses* is, as the title already suggests, transformation or change. Divine and human beings are physically transformed into animals or plants. The story of each single transformation is intended to give a reason for the existence of things. Metamorphosis thematically unites the loosely connected episodes. It is a process in time that demonstrates that continuous change is the fundamental principle of the mythological as well as the terrestrial world. Containing versions of many of the most famous myths of Greece and Rome, Ovid's epic poem has become one of the cornerstones of Western culture.

Dante's *Divine Comedy* (c. 1300) opposes two time schemes: the historical time of the terrestrial world on the one hand, and the time of salvation history on the other. In the middle of his life, Dante (the author, narrator, and protagonist) has lost the straightforward pathway to God. To be purified again, he has to cross the three empires of the beyond: hell, purgatory, and paradise. Dante enters the eternal sphere as an individual person, though his figure has a representative meaning, too: Dante's voyage beyond the grave is also the voyage of humankind. By assuming both an individual and a representative meaning, the figure of the narrator–protagonist unites historical time and eternity. This double meaning applies also to the voyage that is not a mere movement through time and space but a spiritual journey. We can measure Dante's travel in historical time: It lasts about 7 days. Yet, what is more important than the measurement of time in days is the traveler's process of purification during his transition from hell to paradise. This process is spiritual and thus situated outside of time, in eternity. However, the narrative discourse shows no traces of reflecting this extratemporality. The narrative form of Dante's epic poem can be described as a regular alternation between scene and summary. The *Divine Comedy* thus illustrates a strict division between the representation of time in respect to its content and the temporal conception of the narrative discourse.

Temporal paradoxes are thematically discussed in Lewis Carroll's book *Alice's Adventures in Wonderland* (1865). Following a white rabbit down a rabbit hole, Alice finds herself in a dreamlike world where the logic of reality is completely abandoned. In Wonderland even time runs differently so that Alice joins, for instance, a never-ending tea party in which it is always six o'clock. The temporal absurdities the young girl is confronted with are discussed in the story. They find, however, no corresponding expression in the narrative discourse that shows the classical alternation between scene and summary.

Gustave Flaubert's *The Temptation of Saint Anthony* (1874) is about Anthony the Great, a recluse who lives isolated on a mountain top in the Egyptian desert. The novel describes one night in the life of Anthony during which he is besieged by carnal temptation and philosophical doubt. Asceticism and meditation completely suspend the protagonist's sense of time and space. In this hallucinatory mood Anthony is confronted with the vision of a primordial earth. He witnesses the first signs of inanimate and animate nature as well as the birth of humankind. In addition, the saint is haunted by several allegorical figures (among them Lust and Death) who want to change his belief that isolation is the truest form of worship. In *The Temptation of Saint Anthony* Flaubert tried to summarize the history of the world in the visions of one night.

The discussion of time as memory is an important theme in Fyodor M. Dostoevsky's *The Brothers Karamazov* (1880). Whereas the primary line of narrative centers around the story of a parricide, the topic of memory is discussed primarily in the most important side story of Dostoevsky's novel. It focuses on a group of schoolboys throwing rocks at one of their peers, Ilyusha. In the course of the novel, however, Ilyusha dies. His funeral is discussed at length in the epilogue of *The Brothers Karamazov.* Alyosha, the youngest of the Karamazov brothers, makes a speech near the stone where Ilyusha's parents wanted to bury their son. Alyosha asks the boys to keep Ilyusha as well as the day of his funeral in their memories forever. He proclaims that especially the memory of one's childhood is the best kind of education. Memory shall unite Ilyusha, his friends, and Alyosha forever. With Alyosha's memorial speech Dostoevsky emphasizes the importance of living memory, that is, an active kind of commemoration that constantly tries to evoke the dead as companions of the living.

Time as history is the thematic center of Henryk Sienkiewicz's *Quo Vadis. A Narrative of the Time of Nero* (1895) whose story takes place in antiquity. *Quo Vadis* is the most famous historical novel of the late 19th century. It tells of a love between Lygia, a young Christian woman, and Marcus Vicinius, a Roman patrician. The action is set around 64 CE in the city of Rome under the rule of Nero. Before writing *Quo Vadis,* Sienkiewicz thoroughly studied the history of the Roman empire. He filled his novel with historical conflicts and characters to evoke the time of Nero as authentically as possible. The tradition of the historical novel experienced a great revival with Umberto Eco's *The Name of the Rose* (1980), perhaps the most famous historical novel of the 20th century.

In contrast to historical novels that deal with a distant past, science fiction novels discuss imaginary technological or scientific advances that may determine our life in the future. With *The Time Machine* (1895), H. G. Wells set the cornerstone for this literary genre. His narrative is concerned with the concept of time travel using a vehicle that brings the traveler into the past or the future. The physical constitution of time is discussed at length in the framework story of *The Time Machine:* The time traveler, a nameless amateur inventor living in London, explains to his evening guests that time is nothing but the fourth dimension of space. He is convinced of the fact that there must exist a suitable apparatus that can move back and forth in time.

Eventually the inventor constructs such a machine that takes him to the year 802701 CE, where he is faced with a society that has diverged into two branches: There are the peaceful, childlike, but unintelligent Eloi on the one hand, and the intelligent but bestial Morlocks on the other. Both species are of subhuman intelligence. Another adventure brings the time traveler to a future that is 30 million years from his own time. He sees the last traces of life on a dying Earth, where the only sign of life is a black creature with tentacles. From a last voyage in time, the inventor never returns.

The Time Machine also set the ground for the literary tradition of dystopia in the 20th century. Dystopian narratives present the picture of an imaginary society that is worse than our own that the majority of us would fear to live in. Dystopian images are for the most part visions of a future society. Wells's narrative is both a science fiction novel and a dystopian novel that presents the author's vision of a troubled future.

The basic conception of time in Arthur Conan Doyle's *The Lost World* (1912) resembles to some degree the conception of time in Mann's *The Magic Mountain*. It tells the story of an expedition to a hidden plateau in South America where dinosaurs and other extinct animals are still alive. Again it seems to be spatial isolation that provokes a significant change of time and takes the explorers back into a prehistoric past. Conan Doyle's narrative is among the first science fiction novels of the 20th century.

James Hilton's utopian novel *Lost Horizon* (1933) is a further narrative that centers on the specific conception of time in a geographically isolated place. Hugh Conway, a member of the British diplomatic service, is among four kidnap victims who are brought to Shangri-La, a lamasery in the mountains of Tibet. They receive a very friendly welcome by the monks, who firmly believe in an ethics of moderation. Like the sanatorium in *The Magic Mountain,* the valley of Shangri-La is a peaceful but isolated place that ignores the actions of the outer world. Conway and the other victims soon realize that the temporal rhythm in Shangri-La differs to a large degree from the rhythm of time outside the valley. This dichotomy is a further aspect that resembles the conception of time in *The Magic Mountain,* though a closer look reveals that time in the Tibetan lamasery also differs significantly from time in the Swiss sanatorium: Whereas Hans Castorp experiences an extreme acceleration of time, the temporal rhythm of life in Shangri-La is remarkably slowed down. This deceleration of time affects primarily the physical processes of the human body. By a combination of drugs, meditation, and a special diet, the metabolism itself is slowed. Thus the inhabitants of Shangri-La may arrive at an age of several hundred years. In contrast to the artistic masterpiece of Mann that reflects the protagonist's subjective experience of time in the form of the novel, the deceleration of time finds no corresponding expression in the narrative form of the *Lost Horizon.*

Now, Eternal

The eternal now is a notion often linked with the nature of God, according to Western theology and according to various mystical, Asian, and so-called New Age traditions.

Anicius Boethius (480–c. 524 CE) and Saint Thomas Aquinas (c.1225–1274 CE) conceive of God as existing outside of time. They argue that the divine essence involves a perpetual present or now, without succession of moments. God exists in a kind of unchanging specious present. Such a divine essence could not thus be described as existing "before" any event in time. It could exist, instead, as intimately present at every moment of our time, while being itself outside of time. Even Jesus, the alleged physical embodiment of God, is said to have asserted that "Before Abraham was, I am" (instead of "I was"). Paul Tillich (1886–1965) in his book *The Eternal Now* claims that a timeless eternal now is what makes possible our sense of the temporal present now. For, looked at objectively, time as a succession of moments does not exhibit any present or any now. Yet we experience a now. The experience of a present now, Tillich claims, is made possible only by the breaking through of a timeless eternal present (of God, and of our essential divine self) in the time sequence.

A much-repeated metaphor meant to shed light on the paradoxical relation between a divine eternal now and our successive time is the image of God as an immovable point at the center of a circle, a center point equally distant from every point on the circumference. The circumference represents the moving, successive, spread-out nature of time. Such a circumference would have to be imagined as infinitely long and as not necessarily returning to close upon itself. Also, in this image the distance between God, as center point, and each point on the circumference would have to be imagined as nonexistent—to establish the immediacy of God's presence in every moment of time.

Philosophical Challenges

One of the challenges for this notion of a timeless divine specious present, or eternal now, is to preclude it from being static or frozen, thus lifeless and nonconscious. Can there be nondurational, nonsuccessive consciousness? Does consciousness not require some dynamism or activity? Those who answer in the positive, like the philosopher Josiah Royce, tend to insist that our durational present should remain the model for understanding the divine consciousness and its eternal now. These critics understand the divine state as still somehow temporal, although this temporal present would be much wider in scope, perhaps infinitely wider, than our human specious present. Would such a divine durational now be a temporal flow that is parallel to our time? Or would it involve some sort of temporality, some hypertime, unknown to us? Could this divine now be, instead, some sort of nontemporal, nonsequential, dynamism? Does the latter notion make logical sense? Are we to take refuge in paradox here?

It is worth noting that 20th-century physics has also addressed the notion of time and of the present now. The theory of relativity proposed a union of space with time. According to a widespread interpretation of this union, though it is still debated, time becomes assimilated to a fourth dimension of the static continuum "spacetime." Some philosophers and scientists have objected to this static-like interpretation of time. Even Albert Einstein argued that in relativistic spacetime, the time dimension is not equivalent to the spatial dimensions. He preferred viewing space as being dynamized by this union with time, instead of time being spatialized by it. For instance, simultaneity becomes relativized in Einstein's theory. This means that the notion of "instantaneous space," that is, the notion of all events occurring at the same time across all space, becomes problematic. Such a set of "simultaneous" events cannot be extracted unambiguously from the four-dimensional world process. This is because a point-event occurring before, at the same time, or after, another point-event depends in part on the standpoint from which the sequential observation is made. (The exceptions might be cases of causally related events.) Thus in relativistic physics, unlike Newtonian physics, past and future are not separated by a durationless three-dimensional "now" instantaneously spread across the universe. Past and future are instead better viewed as separated by a four-dimensional region of "elsewhere."

Recently there has been a resurgence of nonphilosophical and nontheological experience-based claims regarding some form of timeless eternity. These accounts derive partly from the New Age movement since the 1950s—a dispersed movement characterized by eclectic nontraditional mysticism-based spirituality. Similar claims derive also from the now widespread phenomena of near-death experiences.

The former movement includes a number of alleged spirit channelers reporting on pantheistic claims to the effect that God is in everything and that by turning inward we can access God's and our own (and more real) timeless nature. This viewpoint advises that beneath our ordinary temporal realm there is another and more basic one, often characterized as a divine eternal now. The metaphysics underlying this claim seems to be that the ultimately timeless divine reality opts to manifest itself as the temporal and spatial multitude of things we call the universe (and perhaps as many other universes as well). The "Seth" books by Jane

Roberts are among the most popular examples of this New Age account of reality.

There is, in addition, an extensive recent literature regarding the *experience* of some form of timelessness during alleged "near death experiences" (experiences one has during certain traumas, and sometimes in hospitals through moments while one is mistakenly declared clinically dead). During parts of such experiences—while reviewing one's whole life "instantaneously," or while engaging in some form of "instantaneous" thought-travel—many people claim that their sense of time slows down drastically, or stops altogether, while their awareness of countless events continues. Some claim that this represents the experience of an eternal now, and they often attribute this eternal now to a feature of the postlife divine environment.

Nuclear Winter

Nuclear winter is a term used to describe the potential environmental and climate effects resulting from a large-scale nuclear war. On December 23, 1983, five scientists, Richard P. Turco, Owen B. Toon, Thomas P. Ackerman, James B. Pollack, and Carl Sagan, published a paper in the journal *Science* that has come to be known as the TTAPS Study. The paper raised concern over the short-term and long-term consequences of dust, smoke, radioactivity, and toxic vapors that would be generated by a nuclear war. Although with the end of the Cold War in the 1980s, the threat of nuclear war has subsided, it should never be dismissed completely.

In the article, the five scientists concluded that exploding just one half of the combined nuclear weapons of the United States and the former Soviet Union would throw billions of metric tons of dust, soot, smoke, and ash into the atmosphere. In each explosion, most of this dust would be carried up by the nuclear fireball itself, and some of it would be sucked up the stem of the mushroom cloud. Even a more modest explosion on or above cities would produce massive fires like those in Hiroshima and Nagasaki at the end of World War II. These fires would consume wood, natural gas, and a wide variety of combustibles. The resulting smoke would be far more dangerous to the earth's climate than the dust; the smoke, the scientists argued, could produce a blanket of air pollution so thick that it would have the potential to block more than 80% of the sunlight that would otherwise reach the northern hemisphere.

As a result, they claimed, severe worldwide climate changes could occur, including prolonged periods of darkness and below-freezing temperatures, making the average land cool to 10°C to 20°C; continental interiors could cool by up to 20°C to 40°C, with subzero temperatures possible even in summer. There would also be the potential for violent windstorms. The combination of cold temperatures, dryness, and lack of sunlight would also cripple agricultural production and destroy ecosystems, putting most of the world's population at risk of starvation, according to the 1985 report by the International Council of Scientific Unions. Other studies suggest that even a small nuclear war would devastate the earth.

Severe climate change may have been a factor in the demise of the dinosaurs toward the end of the Mesozoic era. There is evidence that the end of the Mesozoic era saw changes in climate resulting in a pronounced drop in temperatures, similar to a nuclear winter. Major volcanic eruptions may have produced enormous quantities of smoke and ash that blocked the sunlight over major portions of the earth's land mass; alternatively, as some geological evidence suggests, an extraterrestrial object, most likely a meteor or asteroid, may have struck the earth, throwing up huge quantities of debris into the atmosphere and blocking out sunlight for a time. Such an event would have created a winter condition that killed plants and larger animals. This scenario is similar to that of a nuclear winter that could follow a major nuclear war.

The nuclear winter theory has been the subject of some controversy. Efforts were made by government and military scientists to play down the possible consequences. They argued that the effects would not be nearly so severe and began talking of a "nuclear autumn." In 1984, the U.S. National Research Council publicly stated that it agreed with the ideas advanced in the *Science* article; however, in 1985, the U.S. Department of Defense issued a report saying that while the nuclear winter theory might be valid, it would not change defense policies.

Today, although the threat of nuclear war has receded somewhat, the continued existence of nuclear weapons is a reminder that the possibility of a nuclear winter cannot be entirely dismissed.

O

Observatories

Throughout history, humans have watched the stars in the night sky. Observatories were built to aid in the study of celestial objects as a means of measuring time. Many calendars are based upon the information gathered through these observations, including the Julian and Gregorian calendars. Different cultures and countries built observatories of different kinds to study the skies and track their calendars.

Prehistoric and Early Observatories

Arguably the most well-known prehistoric observatory is Stonehenge in Wiltshire, England, a circle of massive stones arranged to align with certain celestial events. Stonehenge was used as a way of tracking the moon, stars, and eclipses. There are a number of other Neolithic structures throughout Europe similar to Stonehenge in design and serving a similar purpose.

Native Americans built rock pattern structures called medicine wheels, or spiritual healing sites, that are strongly connected to the night skies. The three most notable medicine wheels are located at Big Horn, Wyoming, in the United States and at Moose Mountain in central Saskatchewan and east of Calgary in Majorville, Alberta, Canada. Most medicine wheels are created of stones located on top of hills or mountains, and they consist of a central stone from which spokes radiate toward a rim.

The Mayans have written records of astronomical observations, and several of the Mayan buildings were architecturally designed around the heavens or for the purpose of observing the skies. One such building is the Caracol Tower in Chichen Itza, which has three windows used by Mayan astronomers for observations. The Mayan people used the information gathered through these observations as a source for creating the Mayan calendar.

Muslim Observatories

In medieval Islam, there existed a desire to retain and elaborate upon the knowledge created by the ancient Greeks. Constructed in Baghdad, in what is now Iraq, during the Abbasid era of Islam, the House of Wisdom, a research center with observatory, enabled astronomers to create updated charts of planetary motion based on Ptolemy's research.

Many observatories were destroyed or abandoned due to superstition or political conflict. One such research facility, also known as the House of Wisdom, was constructed in Cairo, Egypt early in the 11th century CE. The observatory was destroyed 100 years later due to the superstition held by the populace toward planetary observation and political strife. The Istanbul Observatory, built 500 years after the Egyptian House of Wisdom, met a similar fate for similar reasons.

Not all Islamic observatories met such ill-fated demise. The two most successful observatories in the Islamic world were located at Maragha, in modern-day Iran; and at Samarkand, in modern-day

El Caracól observatory at Chichen Itza, dedicated to the study of astronomy, consists of a tower erected on two rectangular platforms.

Uzbekistan. The Maragha observatory was originally constructed with astrological, rather than astronomical, intent. The major accomplishment associated with the Maragha observatory is the Ilkhanic tables charting the motion of the planets, the moon, and the sun. Fifteenth century astronomer Ulugh Beg used the ruins of the Maragha observatory as a model for the observatory at Samarkand built in the 15th century CE, where a sextant with a 120-foot radius was constructed. This instrument allowed for a resolution of arc seconds in its measurements, which was not to be surpassed until the invention of the telescope 200 years later. Astronomers at the Samarkand observatory recorded a list of nearly 1,000 stars visible from their location. Today, a crater on the moon is named after Ulugh Beg.

Asian Observatories

The Beijing observatory, built in the 15th century CE, was occupied by astronomers charged with watching the night skies. Over the course of 3,000 years, these astronomers had recorded data on hundreds of astronomical activities, including lunar and solar eclipses, meteor showers, and comets. The Chinese, in the 1st century CE, were the first to build automated instruments to measure celestial objects. The Chinese used a water clock as the timer for these devices, creating the first known clock drive. In the 1670s, Jesuits convinced Chinese astronomers to add Western instruments to the Beijing observatory. Observational activities were limited due to a conflict of interests. The Chinese astronomers' interests in observations were only in revising the current calendar. The church's stance against any activities associated with heliocentric ideas, and the Jesuits' strict adherence to this position, also prevented further contribution.

India's most notable observatories were constructed in the 18th century under the direction of the Hindu prince Jai Singh. He constructed the largest instruments he could to increase accuracy. One tool he commissioned to be built was an 88-foot-tall sundial. Updating Ulugh Beg's star data, Singh added 4 degrees, 8 arc minutes to the ecliptic longitudinal measurements to accommodate the earth's precession for the past 300 years.

European Observatories

Bernard Walther built the first notable European observatory in Nuremberg, Germany, in the mid-1470s CE. Observational data collected at this observatory noted a slight discrepancy in the Alfonso Tables, the most popular star tables in Europe from 1300–1500.

Galileo is often credited with inventing the telescope, which was in fact created in 1608 by the Danish spectacle maker Hans Lippershey. Galileo, however, was the first, in 1609, to turn the device to the skies, using the invention as an astronomical observational device and making a number of improvements to Lippershey's model. Galileo's observations through the telescope changed the study of astronomy. Galileo's most notable observations include the surface features of Earth's moon and four of the moons of Jupiter. Galileo noted the surface of Earth's moon was abundant with mountains and dark spots believed to be large bodies of water, which he named *maria,* or seas. Galileo also observed the phases of Earth's moon and those of Venus.

Tycho Brahe's 16th century observatory, built on the Danish island of Hven, was named Uraniborg and housed a number of instruments used in observations. Brahe is credited with recording the most accurate observational data of his time, prior to the invention of the telescope. Johannes Kepler assisted Brahe, and after Brahe's death, Kepler used the data gathered by Brahe to create his laws of planetary motion.

The Paris Observatory, built in 1667, became a model for national observatories. National observatories, such as the Paris and Greenwich observatories, were dedicated to gathering observational data for national interests, including improving navigation and calendars. By creating accurate tables of star positions, and with the invention of the chronometer, seafaring vessels were capable of determining their geographical location at sea.

Private observatories were also constructed, usually by wealthy individuals or organizations. In 1781, William Herschel's discovery of Uranus won favor with King George III, and Herschel was soon appointed as the king's astronomer. Herschel built his own telescopes, creating them with a high-enough resolution to open the field to galactic astronomy. Inspired by Herschel, Johann Schröter built the largest observatory of its time in Europe in the small town of Lilienthal, Germany. Schröter sketched the surfaces of the moon and of Mars, creating an interest in the studies of planetary astronomy.

Lowell Observatory, Clark Dome, in Flagstaff, Arizona. The observatory's stated mission is to pursue the study of our solar system and its evolution; to conduct pure research in astronomical phenomena; and to maintain public education and outreach programs to bring the results of astronomical research to the public.

American Observatories

Following in the footsteps of early national observatories, younger nations also built their own modern observatories, some shaped by the field of astrophysics. One such nation, the United States, erected the United States Naval Observatory in 1839.

While attending the Massachusetts Institute of Technology, George Hale invented a device known as a spectroheliograph, which is capable of photographing the sun. Hale built a solar observatory in his parents' backyard, located in a Chicago suburb. Hale accepted a position at the University of Chicago, and the construction of the university's Yerkes Observatory in Wisconsin was completed in 1897. The Yerkes Observatory was one of the first observatories constructed for the purpose of studying astrophysics rather than average celestial observations. Hale also planned the construction of the Mt. Wilson Observatory in California in 1904.

Conclusion

After the success of the Mt. Wilson Observatory and the Palomar Observatory in California, it was recognized that mountaintop locations near the ocean were ideal for observatories. Most observatories are now constructed upon higher elevations in an attempt to observe above, rather than through, the atmospheric interference. Today, observatories use not only optical telescopes but also radio telescopes and X-ray and gamma-ray telescopes. These telescopes allow us to "see" wavelegths outside of visible light. While radio telescopes can be used on Earth, most X-ray, gamma-ray, infrared, and ultraviolet *wavelengths* are blocked by the atmosphere and are best observed from space, through space-based observatories such as the Hubble Space

Telescope. Optical telescopes also capture their best images from space, due to the lack of interference from the atmosphere.

Old Faithful

Nathaniel P. Langford and Gustavus C. Doane, of the 1870 Washburn Expedition, coined the name Old Faithful to testify to this geyser's punctual regularity. Old Faithful is one of thousands of thermal features in Yellowstone National Park that result from a subterranean magma spike—where magma rises to within 40 miles of the earth's surface, compared to an average distance of 90 miles. This unique feature accounts for the park's Upper Geyser Basin, which contains nearly one quarter of Earth's geysers.

Predicting Eruption Time

Yellowstone boasts six grand geysers, each ejecting water spouts exceeding 100 feet. One of these giants, Old Faithful, ranges in height from 105 to 185 feet. It is a popular attraction; crowds flock to see it year round. For visitors to better understand the geyser, general rules have been devised to help predict eruption times.

Joseph Le Conte's claim that Old Faithful erupted hourly became replaced by a generalization saying eruptions lasting under 4 minutes are followed by another in 40 to 60 minutes, and eruptions over 4 minutes are followed in 75 to 100 minutes. Over time, more detailed studies yielded more specific rules. In general, an eruption of 1.5 minutes will be followed in 45 minutes. Approximately 65 minutes of rest follow a 3-minute eruption, and it takes 86 minutes to rebuild after a 5-minute eruption. Old Faithful's eruptions, on average, last 4 minutes.

Many factors upset the balance of geysers over time. People can cause immense damage. Even within two years, from the 1870 expedition to a formal survey in 1872, noticeable damage had been done to Old Faithful's cone by specimen collectors. More damage has ensued as the geyser sees 3 million visitors yearly. A 1980s cleanup project removed debris from the geyser itself, as visitors sometimes throw coins and other objects in. These activities all affect a geyser's stability.

Earthquakes serve as an additional factor that could contribute to lessening the reliability of Old Faithful. Seismographs record up to 215 tremors on the Yellowstone Plateau each year. Large earthquakes noticeably affect the balance of geysers. Before a 1959 quake, eruptions occurred at an average 65-minute interval. This quake and another in 1975 lengthened intervals, and a 1983 quake increased the average to 78 minutes.

Although geysers come and go, one should not prematurely conclude Old Faithful has yet become less predictable. Correlations and frequent observation continue to yield reliable estimates even as rest intervals increase. Though Old Faithful now erupts less often, it still maintains an uncannily consistent schedule.

Olduvai Gorge

Olduvai Gorge remains one of the most recognized archaeological sites in the world. It has provided, and continues to provide, vital information to researchers seeking answers about the origins of humanity and its evolution through time.

Wilhelm Kattwinkel, a German entomologist, stumbled across Olduvai Gorge in 1911 in northern Tanzania. The location is a canyon approximately 40 kilometers long with walls standing nearly 100 meters high that showcase nearly 2 million years of history. Extensive investigations at Olduvai Gorge began shortly afterward, yielding an array of lithic tools and fossilized animal remains amongst which were the remains of early hominids, including those of *Australopithecine* (*boisei*) and *Homo habilis* specimens. The variety of nonhominid remains discovered at Olduvai Gorge, found both separate from and amongst those of hominids, includes giraffe, antelope, and elephant. Collectively, the remains and associated tools continue to provide researchers with crucial data regarding the activities of early hominids and the overall development of humanity through time. For the latter issue, Olduvai Gorge helped put Africa in the forefront of human origins research, leading to other significant finds within the region. This includes Mary D. Leakey's 1979 discovery of *Australopithecus afarensis* footprints in Laetoli, Tanzania, which provided evidence of bipedalism approximately 3.6 million years before the present (BP).

A host of researchers investigated Olduvai Gorge's assemblages after Kattwinkel's discovery in 1911. However, it is the Leakey family of researchers in particular who are most noted for their excavation of and reporting on Olduvai Gorge. The Leakeys, particularly Louis, Mary, and Richard, are a multigenerational family of scholars who continue to spearhead human origin investigations as they did throughout the 20th century. Although their fieldwork has been curtailed in recent years, the Leakey family's collective impact on our understanding of the development of the human species through time is still strong. As for their collection and analysis of fossil and lithic material recovered from Olduvai Gorge, it was the parents, Louis and Mary, who initiated their activities throughout the early and middle portions of the 20th century. With the help of their children, the Leakeys uncovered evidence of early hominids evolving within Africa, including *Australopithecines* and *Homo habilis,* and of changes in lithic technology over time. Ultimately, the Leakey family's impact on the study of human origins and time itself is unparalleled. Through their examination of Olduvai Gorge and its various sites, the Leakeys helped determine multiple stages of hominid evolution and expand our contemplation of human evolution to accept the long duration of time through which humanity changed from early hominids to humankind's present form.

The finding of Olduvai Gorge was in and of itself an important discovery for archaeologists, paleontologists, and other researchers interested in the evolution of species and the changes of technologies developed by hominids. Specifically,

Olduvai Gorge is an archaeological site located in the eastern Serengeti Plains, northern Tanzania. Some of the oldest remains of early hominids have been found in this ancient gorge.

Source: Chris Crafter/iStockphoto.

however, there are a few discoveries in particular that set Olduvai Gorge apart from other archaeological sites pertaining to prehistoric populations. The first such find was uncovered in 1959.

After years of excavating in Olduvai Gorge, Mary Leakey uncovered the remains of an early hominid, which was later designated as *Zinjanthropus boisei.* These thick-boned and almost complete skeletal remains, discovered in 1959, were later dated to 1.8 millions years BP and ultimately classified as *Australopithecus boisei.* As stated earlier, this discovery not only provided a broader understanding of the development of the human species from earlier primate forms, it also provided an impetus for investigating Africa for evidence of human origins and evolution. That fact alone is grounds for securing Olduvai Gorge's place among the most important archaeological sites throughout the world, although it also provided other landmark discoveries.

Decades of excavation, analysis, and interpretation on the part of the Leakey family helped direct the attention of researchers toward Africa in the quest to unravel the mysteries of human evolution. The Leakeys' reputation, which was enhanced by the uncovering of *Zinjanthropus boisei,* was further cemented by the early 1970s discovery of human remains that were eventually classified *Homo habilis.* It was the first set of *Homo habilis* remains to be discovered and further hinted at Africa's being the location where humanity developed.

A final Olduvai Gorge discovery that requires mentioning is the Oldowan Tradition. With all the early hominid remains and ancient tools recovered from the gorge, it ultimately became possible for researchers to determine stages of technological development on the part of hominids along with the stages of biological development that humanity endured. The Oldowan Tradition, a term coined by the Leakey family, included lithic tool forms resembling rocks with flakes removed to create a cutting or puncturing edge; this tool kit included cores and flakes, both possibly used as tools and weaponry. While rudimentary in design, the Oldowan Tradition showed a propensity toward technology on the part of early hominids unmatched by other organisms. As for Olduvai Gorge's temporal significance as related to this technology, the gorge provided researchers with an idea of when the technology surfaced and for how long it survived.

Additional evidence of early hominids has been discovered elsewhere, including Laetoli (Tanzania), Ethiopia, and South Africa. Yet Olduvai Gorge, which continues to yield data regarding human evolution, retains lasting significance. By helping to guide researchers toward Africa in their efforts to ascertain how modern human beings evolved from earlier hominids, the discoveries at Olduvai Gorge were crucial in helping to provide a foundation for the study of humanity's development through time.

Omega Point

See Teilhard de Chardin, Pierre

Omens

An omen, also known as a portent, is a sign that is believed to foretell a future event, which may or may not be supernatural in nature. From earliest times, omens have been given credence in the world's cultures and folklore. Although usually classified according to the generic terms "good" and "bad," an omen is more likely referred to in the foreboding sense, to indicate something sinister that has yet to occur.

The first recorded omens are those of the ancient Babylonians and Assyrians. Both of these cultures believed that the future could be foretold and controlled. Because religion was integral in these ancients' lives, and the omens were thought to be directly from the gods, appeasements could be made in an attempt to stave off the impending calamity. Priests skilled in the arts of omen reading and divination, known as *baratu,* would interpret the portents. These portents could be found in the sky, in animal entrails (known as extispicy), and in the weather, among other sources. The omen could be as simple as a lightning bolt hitting a tree or as complex as a pregnant snake circling a statue, laying her eggs, and dying right after. Each of these meant something different and required the baratu to interpret them, though the meaning may have been explicitly clear.

Ancient Greece and Rome also were filled with omens. In ancient Rome, before official state business was conducted, omens or the auspices (special omens observed in birds, either involving their flight in the sky or observations of the bird in general) were taken. One such auspice involved the observation of a sacred chicken's choice of whether or not it would eat food placed in front of it by an augur (a priest specially trained in auspicy). The chicken would even accompany armies to battle in a cage and the auspices would be taken before battle. A famous omen from ancient Rome involves the consul Publius Claudius Pulcher before his attack against the Carthaginians. The chicken refused to eat the grain laid before it, which was interpreted as a bad omen, and consequently as it being an inopportune time to attack the Carthaginians. Knowing his crew would find this an unfavorable omen, Claudius threw the chicken overboard. Subsequently, the Romans suffered a terrible defeat, with almost all the ships under Pulcher's command sunk.

A more popular category of omens are those concerning the weather. One such modern omen of this type is observed every year in the United States and Canada on February 2nd. It is colloquially known as "Groundhog Day" and involves the observation of a groundhog's shadow. If the groundhog fails to see his shadow because it isn't a bright day, winter will end very soon. If in fact, he does see his shadow, due to the sun being out in that particular moment, then the groundhog will be frightened, run back into his hole, and winter will continue for at least 6 more weeks. Although more of a tradition now than an actual example of a prophecy, it remains classified as a bad omen if the groundhog sees his shadow and a good one if he does not.

Supernatural and paranormal omens exist as well. These may be in the form of dreams, visions, or apparitions. One particularly frightening omen, found in the folklore of Ireland, involves the spectral banshee, or "otherworld woman," that appears before certain Irish families, then weeps and wails to portend the impending death of one of the family members. Another popular omen in this category is visions seen in the sky. One such example of this is Constantine I's legendary vision, in which he observed the Christian cross along with the words "by this sign you will be the victor." Whether or not this truly happened is subject to debate, though it is interesting to note Constantine's devotion to the Christian religion after his victory.

Another interesting omen category involves the appearance of astronomical occurrences that include, but are not limited to, comets, eclipses, and shooting stars. These particular omens sometimes signify notable births, deaths, and other significant events. A shooting star after a funeral may be confirmation that the deceased will be warmly accepted into an afterlife. A famous example, often referred to by astrologers, is the astrological chart of Princess Diana. She was married to Prince Charles on a solar eclipse date, and the day before her death was another day when a solar eclipse occurred.

Among the most frightening types of omens are those that are believed to signify the apocalypse, or the end of the world. Every culture seems to have some notion of this, and it usually has religious connotations. For example, in Christian literature, one is expected to see the sun go dark and the moon to not give off light. Another popular omen considered to foretell the end of the world, successfully adapted into the aptly named film *The Omen,* is the appearance of the Antichrist. The Y2K bug was the source of some fear for a while also, some believing it would result in a technological catastrophe that would ultimately lead to the end of the world.

It is important to note that omens can be culture dependent and not universal. For example, in the United States, it is considered that one will have bad luck if a black cat crosses his path, but in the United Kingdom, the effect is good luck. Likewise, there are certain omens that do seem to be universal. Omens that fall into the supernatural and paranormal category are almost always considered bad omens. Appearances of spectral warnings seem to be viewed with much anxiety and are considered to be signs of impending disaster.

Omens continue to be read and misread by people all over the world, in accordance with local traditions. The continuing fascination with omens may lie in humankind's uneasiness with what is yet to come. Whereas skeptics will attribute to chance any bad events that may follow the appearance of an omen, others continue to view them with fear and dread.

Ontology

The term *ontology* (from Greek *to on, ontos*—being, entity; *logos*—concept, science) usually denotes: (a) a philosophical discipline that studies being (entity) as being (entity), that is, being in general; (b) the ontology of a theory: the kind of entities that should exist if the given theory is true. One of the fundamental problems of ontology (particularly in its first meaning) is the question about the relation between being and becoming and thus the question about the place and role of time in the explanation of reality.

As a philosophical discipline, ontology has existed at least since the time of Aristotle (384–322 BCE), who in his *Metaphysics* claims that one of its tasks is to investigate "being as being and the attributes that belong to this in virtue of its own nature." While the investigation itself is old, the name is relatively new. It was not created until the 17th century as a result of the efforts of ontology to emancipate itself as an element of metaphysics in relation to its other disciplines, most of all however in relation to (rational) theology. The first to have used it was the German scholastic Rudolf Goclenius (1547–1628) in his work *Lexicon Philosophicum* dated 1613, but it was Christian Wolff (1679–1754) who definitively introduced it into philosophical terminology and thus the period's intellectual awareness. In his work *Philosophia Prima Sive Ontologia* from 1730, he identified ontology as a fundamental philosophical discipline within general metaphysics. While the latter describes being (entity) in general, the disciplines of specific metaphysics are concerned with its partial domains, such as God, soul (humanity), and nature.

Historically, there are three basic and interconnected areas of problems that differentiate themselves within ontology, and these may be briefly delimited by these three questions: (1) *What is being?* (2) *What really exists?* (3) *What exists?*

What Is Being, or, What Does It Mean to Be, to Exist?

Although it may seem that this question would be central to ontology, most philosophers gave up on any serious research in this direction as something problematic, perhaps even impossible. Already Aristotle, in his polemics with Parmenides (540–450 BCE), considered it disputable to think of being as such—that is, as the most general concept in a single meaning, and he emphasized its polysemic nature. Blaise Pascal (1623–1662), for example, pointed out the danger of circular definition (*circulus in definiendo*) in such generally understood being (as it can only be determined with the help of the word "is"). Immanuel Kant (1724–1804) argued that being, or existence, is not an attribute (predicate). There is no empirical attribute within the concept of an existing object by which it would differ from the concept of a similar, but nonexisting, object. With similar intentions, modern logic solves the problem of statements about existence; for example, it transforms the statement *Man is* into a formally correct form of the statement with an existential quantifier, that is, *There exists a thing that is a man.*

Despite difficulties in thinking about being (existence), Martin Heidegger (1889–1976) attempted early in the 20th century to build a fundamental ontology, the main aim of which is exactly to seek the meaning of being. As opposed to the previous philosophy (ontotheology), which forgot about being, replaced it with entity, and would explain one entity with the help of another (even divine) entity, it is necessary to clearly distinguish an entity from the being of this entity (*ontological difference*). The key to the understanding of the meaning of being is the analytics of a particular type of entity—human being, being-there (*dasein*), through the medium of objectless forms of thinking—existentials. The project of fundamental ontology remained unfinished, but it inspired phenomenological, existentialist, and hermeneutical thinking in the given field (Jean-Paul Sartre, 1905–1980; Maurice Merleau-Ponty, 1980–1961; and others).

What Really Exists, or, Which Things Do Really Exist?

Although the question "What does really, therefore truly, ultimately, exist?" is logically a version of the question "What exists?" it is historically older and it has been perhaps the most typical of ontological questions in traditional metaphysics since its beginnings. It presumes a split of reality into two ontologically as well as axiologically unequal fields: (a) a privileged, true reality (*noumenon,* substance) which exists in-itself, as a autonomous, changeless, and independent of all else, and (b) a secondary, ontologically less valuable phenomenon (*fainomenon, akcidencia*), which, as nonautonomous and changeable, is derived from the first. It is mainly the ontology of middle-period Plato (428–348 BCE) that is paradigmatically known in this sense, with his differentiation of a perfect world of intelligible ideas and an imperfect world of empirical particulars, which have reality only to that extent to which they have a part in the former.

It is the same with time as a movable and imperfect picture of eternity. In his understanding of the *first philosophy* as a teaching about a divine substance, Aristotle supported such a model of an axiologically saturated ontology when he placed against each other the perfect entity of an unmoved first mover and the hierarchically lower, by their form dependent, and derived entities. Unlike the first one, their characteristic is time as a number of movement with regard to before and after.

The dispute between idealism and materialism also became classic in this sense. Idealism considered matter as merely a manifestation (other-being) of an absolute spirit, and time as intuitive becoming was the essential but imperfect and temporary manifestation of this spirit (G. W. F. Hegel 1770–1830), or a bundle of perceptions (ideas) of the human mind (G. Berkeley, 1685–1753). Materialism considered consciousness, mind, and spirit as merely a product, an attribute or a function of matter. This traditional, substantialist ontology model dominated until the times of René Descartes (1596–1650), or Kant, after which it became the subject of perennial criticism. In the 20th century, this criticism came mainly from analytical philosophy, but also from Heidegger, Alfred North Whitehead's (1861–1947) process philosophy, Nicolai Hartmann's (1882–1950) critical ontology, and others.

What Exists, or, Which Kinds of Things Do Exist?

At the beginning of this investigation, more neutral and unreductionist—compared with the previous one—was Aristotle, with his understanding of ontology as teaching about categories, that is, about the most general kinds (predicates) of things. Categorical analysis has been a component of philosophy until the present day, but historically, both the understanding of the nature of categories and their selection have changed within it. While Aristotle understands them first and foremost realistically (they are the attributes of things themselves), and he lists 10 of these—substance, quality, quantity, etc.,—Kant understands them transcendentally, as fundamental forms of our cognition of things, so far as is possible a priori, and there are 12 of these—unity, plurality, totality, etc. Time too is a priori transcendental and does not belong to things in themselves but is one of two principles of pure intuition (the second one being space) that allow humans' inner experience and vicariously an experience of external phenomena. Similar thoughts are those of Edmund Husserl (1859–1938) in his ontology, as an eidetic science about intentional objects in general with time as "world horizon" that allows a contact between humans and the whole of existence, whereas Bertrand Russell (1872–1970) as an analytic philosopher presumes that the structure of the world (atomistic facts) exposes itself to us through the structure and categories of language (atomistic propositions).

A stimulating conception of so-called critical ontology—realistically understood categorical analysis that investigates the forms of being gained by observation of reality and the relations between them—was created by Hartmann in the 20th century. Hartmann understands reality in its gradual unfolding from an inorganic level through organic and psychic levels to a spiritual level, whereby he presumes that these levels are categorically heterogeneous. Every one has specific categories that cannot be reduced to categories of other levels, neither downwards (criticism of materialism) nor upwards (criticism of idealism). All beings are understood to be dynamic as becoming; time is a more fundamental determination of reality than space.

The development of linguistically and mainly analytically orientated philosophy in the 20th century has led to specific reasonings about the ontological implications of language, which in the second half of the century resulted in discussions about so-called ontological commitments. According to the protagonist of this discussion and the author of the term, Willard van Orman Quine (1908–2000), the answer to the ancient ontological question "*What exists?*" does not come from philosophy but from science. Because acceptance of a scientific theory always presumes some ontology, it also therefore postulates some kind of entities that should exist if the theory is true. Quine also formulates a concrete criterion for specification of thus-formed ontological commitments of theories. If the theories are formulated in a standard language of first-order predicate logic, then for them "to be means to be the value of a bound variable." However, as he points out, this criterion is not absolute—the given theory can be satisfied by several different ontologies, and it is not possible to definitely decide which one of them is valid (the principle of ontological relativity). Quine holds a perdurantist understanding of persistence of things in time, according to which a concrete particular is an aggregation of its temporal parts. Such an understanding is anchored in an eternalist conception of time that (unlike the presentist one) supposes that all time dimensions, not only the present, are ontologically real.

Oparin, A. I. (1894–1980)

Aleksandr Ivanovich Oparin, a Russian biochemist, was noted for his contributions to the explanation for the origin of life. Profoundly influenced by Charles Darwin (1809–1882), Oparin presented a theoretical foundation that stressed both a materialistic and mechanistic explanation for both planetary formation and the evolution of life on this planet. His understanding of astronomy, chemistry, geology, biology, and philosophy had allowed for a comprehensive view of a temporally evolving world and humankind's place within it. Oparin's underlying principles encompassed not only the chemical processes that constituted the precursors to and the emergence of life but also the immense evolutionary time that was necessary for its formation. Oparin is best known for his major works *The Origin of Life* (1938) and *Genesis and Evolutionary Development of Life* (1968).

The biological history of this planet could be found within its remote geological history. Against prevailing philosophies and theologies, Oparin viewed the emergence of life as a result of chemical synthesis and external influences of our planet's developing environment. Acknowledging and encompassing the universe in its totality, this chemical synthesis and development of cellular organisms are unique to this planet within the cosmos. In terms of theoretical or cosmological origin paradigms, Oparin rejected the concepts of autogeneration, cosmozoa, spontaneous generation, panspermia, and vitalism as possible explanations. For Oparin, only inorganic matter existed in the beginning of Earth's development. This evolving matter would later emerge as organic. The implications are certain: life emerged from inorganic matter. The saga of symbiotic relationships between and among organic and environmental (inorganic) matter is as complex as life itself. Nevertheless, the origin of life evolved from simple beginnings.

According to Oparin, the evolution of carbon compounds, especially hydrocarbons, was necessary for a biogenic synthesis of organic substances. The formation of proteins and the development of amphoteric electrolytes allowed for multiple reactions with water. The subsequent complexity of protein and protein molecules allowed for greater organization and even greater complexity. This billon-year process resulted in the primordial "soup" by which greater complexity would slowly evolve. Although it would be over 2 billion years before the earth would attain single-celled life, the protobionts stage encompassed the emergence of coacervates, coenzymes, enzymes (including genetic information), and anaerobes. Additionally, changes in atmospheric conditions allowed for further evolution and emergence of aerobes. Over this span of nearly a billion years developed greater complexity and symbiotic relationships that resulted in multicellular life.

Oparin's speculations offered a unique perspective on the relationships within the inorganic matter from which life itself emerged. Stressing chemical action and reaction, the chance "environment" in which greater organization and complexity took place makes life unique within a highly improbable universe containing life. This point has two implications. First, the idea that life emerged from inorganic matter over billions of years implies a rejection of anthropocentric philosophies and theologies. Second, it answers the question, "Are we alone in the universe?" with a degree of implausibility. Today, design theories and the "God gene" are alternative explanations for the philosophical questions of human existence. There is very little doubt that Oparin would reject any version of these ideas and their manipulation of science. The principles set forth by Darwin, when applied in a comprehensive manner, would exclude these assertions. Oparin, a Darwinian evolutionist, understood both the temporal nature of organic and inorganic processes and their implication for humankind. From inorganic to organic, life, especially human life, is distinctive but not necessarily unique within this dynamic material universe.

Orwell, George (1903–1950)

George Orwell was the pen name of Eric Arthur Blair, an English novelist and journalist. He is best known for his political satires *Animal Farm* (1945) and *Nineteen Eighty-Four* (1949). The two novels criticize totalitarianism and social injustice.

Nineteen Eighty-Four was one of the most popular and widely quoted novels of the 20th century. It describes a bleak picture of a future world ruled by totalitarian regimes. Individual freedom and privacy are suppressed in the tightly controlled society described by Orwell. "Big brother is watching" is one of the many famous lines that have been frequently quoted from the book. The Stalinist regime of the Soviet Union was the real-life archetype for Orwell's idea.

George Orwell was born in Motihari, Bengal, India, on June 25, 1903, into a lower-middle-class family. He attended the prestigious Eton School in London. In 1922 he returned to India and joined the British imperial police. In India and in Burma Orwell developed a strong antipathy toward imperialism and class division. He resigned from the imperial police and returned to Europe, where he moved between England and France, living a life of poverty. This experience gave him the material to write the memoir *Down and Out in Paris and London* (1933). His other works of the period include *A Clergyman's Daughter* (1935), and *The Road to Wigan Pier* (1937), in which Orwell describes his strong socialist sympathies. In 1936 he traveled to Spain and fought alongside the Republicans in the Spanish Civil War. He also became highly critical of communism during this period, expressing these sentiments in *Homage to Catalonia* (1938).

Orwell returned to England in 1937 and became a productive journalist, writing numerous articles and essays before and during World War II. He denounced Nazism but opposed war with Germany. In 1944 he completed *Animal Farm,* a brilliant satire in which barnyard animals overthrow their oppressive human master, only to divide into a new social order thereafter. The pigs assume power over the other animals and establish privileges for themselves. Orwell wrote *Animal Farm* to parody the Russian Revolution and the dishonesty of leaders such as Joseph Stalin. Orwell's book was especially relevant during a time in human history marked by ideological struggles and totalitarian regimes. He believed that fascism and communism were not inevitable outcomes in time, but were dangerous ideas that should be resisted. Many lines from the book continue to be quoted in popular culture, including "All animals are equal, but some are more equal than others." Government's actions hostile to a free society are often referred to as "Orwellian."

Orwell was married twice and had one adopted son. He suffered from tuberculosis during the later years of his life. He died in a London hospital on January 21, 1950.

Ovid (43 BCE–17 CE)

The poet Ovid lived in Rome under the reign of the Emperor Augustus in the 1st century BCE. He is best known for the *Metamorphoses,* an epic poem chronicling the history of the cosmos from creation to his own era. He incorporated many ancient myths and legends into this work, many of which had never been recorded. In doing this he preserved centuries of oral history for future generations to enjoy.

Ovid was born in 43 BCE in central Italy near the Abruzzi Mountains. At age 16 he left for Rome to study rhetoric. By 18 he had become a judge but was unsatisfied with a career in law. While in Rome he developed a passion for poetry and decided to make his living as a writer. He also found happiness with Fabia, his third wife, with whom he had one daughter.

Ovid began his career by writing love poems, and his first public work was titled *Amore*. His works were very popular, because they referred to the daily activities of "modern" young people. This was very unusual for poets of his time. As his career progressed, Ovid began writing more erotic poems. He considered himself an instructor for young lovers. This sometimes explicit poetry got him into trouble with the law. To counteract the amoral trend of Roman society, Augustus created new morality laws to help reinstate family structures. On hearing of these laws, Ovid decided to write a poem based on mythological stories he had enjoyed as a child.

The *Metamorphoses* was completed in 8 CE and consists of 15 books, 12,000 verses, and 246 legends. The poem's title comes from the focus on transformation stories in which gods and spirits are changed into plants and animals. The first transformation story is the changing of Earth into Man, and the work ends with the story of Julius Caesar becoming a star. Ovid wrote it in dactylic hexameter, the meter closely associated with epics and the poets Virgil and Homer. However, the content is not that of a traditional epic. Instead of chronicling the story of a single protagonist, it spans all time, from Earth's creation from chaos right up to the reign of Augustus. The theme is the same as in all of Ovid's poems, love. Each story seems to glorify love—the emotion or the god Amor (Cupid).

Ovid's attempt to evade punishment for his early risqué poetry was in vain. He was exiled to Romania, where he is still considered a national hero. Because of his immense popularity with the Roman public, he was allowed to keep his fortune and continued to write and publish until he died in Tomis, now Constanța, in 17 CE.

Ovid's greatest work influenced many of the writers that would follow him. Dante mentions him twice in his great *Divine Comedy.* Many scholars believe that Shakespeare's famous *Romeo and Juliet* was based on *Pyramus and Thisbe,* which also features in *A Midsummer Night's Dream.*

Paleogene

The Paleogene is a geochronological and chronostratigraphic unit of the Cenozoic era/erathem. It is a period in the geochronological scale and a system in the chronostratigraphic scale, and it is placed between the Cretaceous and Neogene periods. It began 65 million years ago, at the Cretaceous-Paleogene (K-Pg or K-T) boundary, and ended 23 million years ago, at the Oligocene-Miocene (O-M) boundary; thus, the Paleogene lasted 42 million years. It consists of three epochs and/or series: Paleocene, Eocene, and Oligocene.

The Paleogene followed the Cretaceous period and began with the Cretaceous-Paleogene mass extinction event. There is paleontological evidence of abrupt changes in flora and fauna in this event (most often referred to as the K-T boundary mass extinction), including the total extinction of dinosaurs, ammonites, belemnites, cephalopods, and rudist molluscs; and the catastrophic mass extinction of planktic foraminifers, calcareous nannofossils, corals, bivalves, brachiopods, fishes, mammals, and other reptile groups. The Paleogene is most notable as being the period in which mammals and birds were diversified, exploiting ecological niches untouched by the previously extinct dinosaurs. Both groups evolved and came to dominate the land. Mammals evolved considerably into large forms in terrestrial and marine environments; birds evolved into roughly modern forms in an airborne environment.

During the Paleogene, global tectonic processes continued that had begun during the Mesozoic era, with the continents drifting toward their present positions. Although these were gradual processes, the drifting of the continents caused significant paleoclimatic and paleoceanographic turnovers during the Paleogene. The former components of the old supercontinent Gondwana continued to split apart, with South America, Africa, and Antarctica-Australia pulling away from each other. Africa moved north toward Europe, slowly closing the occidental Tethys Ocean until it disappeared during the Eocene, and uplifting the Alps during the Oligocene. Similarly, India initiated its rapid migration toward the north, until it collided with Asia, narrowing the oriental Tethys Ocean, folding the Himalayas, and forming the Indian Ocean. The Tethys Ocean vanished during the Paleogene, becoming today's Mediterranean Sea, the remnant of that old ocean. The northern supercontinent Laurasia began to break up during the Eocene, with Europe, Greenland, and North America drifting apart. The tectonic splitting of the Greenland and Norwegian seas increased the submarine volcanic and hydrothermal activity (North Atlantic flood basalts) during the Paleocene-Eocene transition. Antarctica and Australia began to split in the late Eocene, and South America and Antarctica in the Oligocene, which allowed the formation of the circumantarctic current.

The climate of the earliest Paleogene was slightly cooler than that of the preceding Cretaceous. Nevertheless, the temperature rose again in the late Paleocene, reaching its highest point at the Paleocene-Eocene (P-E) boundary. A sudden and extreme global warming event occurred in the P-E boundary, 55.8 million years ago, called the Paleocene-Eocene Thermal Maximum (PETM). It was an episode that lasted less than 100,000 years, very rapid in geologic terms, and it caused an intense warming of the high latitudes (up to 7° C) and a mass extinction in the benthonic fauna of the bathyal and abyssal oceanic environments (mainly benthic foraminifera). It is hypothesized that PETM was caused by runaway greenhouse effect due to a sudden release of methane from oceanic hydrates. This methane flux and its oxidation product carbon dioxide could be of a magnitude similar to that from present-day anthropogenic sources, creating the sudden increase of greenhouse warming. The main cause of this short-term change may be related to the reorganization of tectonic plates that produced an increase of volcanic activity (mainly in the North Atlantic) as well as significant paleogeographic and paleoceanographic turnovers. Among these last, the most important was the closing of the Tethys Ocean with the formation of vast areas of shallow epicontinental seas. This may have been responsible for the shift in the locus of ongoing deep-water formation from cold and nutrient-depleted deep waters produced in the polar (Artic and Antarctic) regions to warm, saline, and oxygen-deficient deep waters formed in Tethyan evaporative basins. The stability of these methane hydrates depends on temperature, and, therefore, it is possible that the abrupt deep sea warming induced a shift in sediment geotherms.

The climate continued to be warm and humid worldwide during the early and middle Eocene, with tropical-subtropical deciduous forest covering nearly the entire globe (even in Greenland and Patagonia) and ice-free polar regions covered with coniferous and deciduous trees in a temperate environment. The equatorial areas, including the Tethys Ocean region, were characterized by a tropical, hot, and arid climate. The Eocene global climate was the warmest and most homogeneous of the Cenozoic, but the climatic conditions began to change in the late Eocene. A global cooling, initiated toward the end of the Eocene, occurred during the Oligocene. This cooling caused gradual extinctions along the Eocene-Oligocene (E-O) transition, between 39 and 33 million years ago, that drastically affected land mammals and vegetation. Tropical areas, such as jungles and rainforests, were replaced by more temperate savannahs and grasslands. The E-O cooling episode was the most recent transition from a greenhouse (Cretaceous to Eocene) to an icehouse (Oligocene to present-day) climate mode. The cause of this climatic cooling was the establishment of the circumantarctic current that isolated the Antarctic. Feedback mechanisms, such as the formation of the Antarctic icecap, a substantial drop in sea level, and an increase in the earth's albedo, drove rapid climate change, which eventually led to the Pleistocene glaciations.

During the first epoch of the Paleogene, the Paleocene, the flora are marked by the development of modern plant species, including the appearance of cacti and palms. The flowering plants or angiosperms, which first appeared in the beginning of the Cretaceous, continued their development and proliferation. Along with them evolved the insects that fed on these plants and pollinated them. During the PETM and Eocene, the high temperatures and warm oceans created a tropical, humid environment, with forests spreading throughout the globe from pole to pole. By the time of the climatic cooling of the late Eocene and Oligocene, deciduous forests covered large parts of the northern continents (North America and Eurasia, including the Arctic areas), and tropical rainforests held on only in equatorial South America, Africa, India, and Australia. The tundra stretched out over vast areas of Antarctica, and open plains and deserts became more common.

Because of the dinosaur extinction at the K-T boundary, the reptiles were reduced to palaeophid snakes, soft-shelled turtles, varanid lizards, and crocodilia. With the extinction of marine plesiosaurs and ichthyosaurs, sharks became the chief ocean predators. Birds began to diversify during the Paleocene, but the most modern bird groups appeared during the Eocene and Oligocene, including hawks, owls, pelicans, loons, and pigeons, among others. The fossil mammal evidence from the Paleocene is scarce, but it is characterized by an evolutionary radiation of small mammals, mainly insectivorous species, including monotremes, marsupials, multituberculates, and primitive placentals, such as the mesonychid. The most important radiation of mammals occurred during the climatic optimum of the Eocene, when there appeared new and modern groups such as artidactyls and perissodactyls. Early forms of many other mammalian orders also appeared, including primates, bats, proboscidians, rodents, and cetaceans. Several mammal groups were extinguished during the cooling episode of the E-O transition, including mesonychids and creodonts.

PALEONTOLOGY

Paleontology (from Greek: *palaeo,* "old, ancient"; *on,* "being"; and *logos,* "speech, thought") is the study of ancient life. Life appeared on Earth about 3,550 million years ago in the oceans, subsequently evolved from simple bacteria-like cells to complex multicellular forms, and colonized the land. Countless adaptations resulted in a great diversity of biological forms and in addition changed the planet itself. We have learned about extinct organisms through the examination of fossils, the visible evidences left behind by them and preserved in rocks and sediments. Fossils include mineralized, carbonized, mummified, and frozen remains of bodies after death, or of cast-off parts, normally of the skeleton or portions, such as teeth, that became partially mineralized during life; the preservation of soft tissues, however, is extremely rare. Many other fossils consist of casts or impressions, tracks, burrows, fossilized feces (coprolites), as well as chemical residues.

People have collected fossils ever since recorded history began, and probably before that, but the nature of fossils and their relationship to life in the past became better understood during the modern era as a part of the changes in natural philosophy that occurred during the 17th and 18th centuries. The emergence of paleontology, in association with comparative anatomy, as a scientific discipline occurred at the end of the 18th century, when Georges Cuvier clearly demonstrated that fossils were left behind by species that had become extinct. Paleontology therefore is the study of fossils throughout geological time. The totality of fossils, both discovered and undiscovered, and their placement in sedimentary layers or strata is known as the *fossil record.* The fossil record ranges in age from the Holocene, the most recent geological epoch that began 12,000 years ago and continues until present, to the Archean eon, which extends from about 3.8 to 2.5 billion years ago.

Fossils vary in size from the microscopic (microfossils), such as fossilized shells of unicellular organisms, to those of gigantic proportions, such as the fossil bones of dinosaurs. Micropaleontology studies microscopic fossils, including organic-walled microfossils, the study of which is called *palynology.* The study of microfossils requires a variety of physical and chemical laboratory techniques to extract them from rocks and the use of light or electron microscopy to observe them. Macrofossils are usually studied with the naked eye or under low-power magnification, but the observation of fine skeletal details often needs high-powered magnification.

The study of macrofossils is undertaken by several specialties. Invertebrate paleontology deals with fossils of animals with no vertebral column, while vertebrate paleontology deals with those of animals with a vertebral column, including fossil hominids (paleoanthropology). Paleobotany undertakes the study of macrofossils of plants. There are many developing specialties, such as paleoichnology (the study of trace fossils), molecular paleontology (the study of chemical fossils or biomarkers), and isotope paleontology (the study of the isotopic composition of fossils).

Two of the most important portions of knowledge that paleontologists obtain from fossils include first how they were formed (taphonomy), that is, the process of fossilization through which some material or information was incorporated from the biosphere to the lithosphere; and second, what the organisms were that produced them (paleobiology), as well as how and where they lived and what their evolutionary history was. The source information for this purpose is the biology and ecology of present-day organisms, applying the uniformitarian principle. Fossils usually contain morphological information that allows us to recognize most of them as living organisms and then to identify and classify them according to the Linnaean taxonomy, as well as to study their relationships to other taxa.

Fossils are generally found in sedimentary rock with differentiated strata representing a succession of deposited material. To place the fossils in context in terms of the time, setting, and surroundings in which the organisms lived, paleontologists require knowledge of the precise geological location where the fossils were found and details of their source rock strata. Paleontology has provided important tools for both geologists and biologists.

In geology, fossils are important in the analysis of the order and relative position of strata and their relationship to the geologic timescale, and also in correlating successions of rock strata from the same time interval across the globe. The deep time of Earth's past has been organized into a timescale composed of various units that are usually delimited by major geological or paleontological events, such as mass extinctions. In a pioneering application of stratigraphy, at the end of the 18th century, William Smith in England and Georges Cuvier and Alexandre Brongniart in France made extensive use of fossils to help correlate rock strata in different locations. They observed that sedimentary rock strata contain particular assemblages of fossilized flora and fauna and that these assemblages succeed each other vertically in a specific, reliable order that can be recognized even in widely separated geologic formations (principle of faunal succession). Later, Darwin's theory of evolution closely described the causal mechanism of the observed faunal and floral succession preserved in rocks.

This principle is of great importance in determining the relative age of rocks and strata by using the fossils contained within them (biostratigraphy). As the distribution and diversity of living organisms are limited by environmental factors, and as vestiges of biochemistry of the original organism and isotopic signatures of ancient environments are preserved on fossilized skeletal remains, fossils provide an insight into the environment once inhabited by living organisms (paleoecology) and help in the interpretation of the nature of ancient sedimentary environments and the diagenetic processes undergone by the rocks that contained them. The primary economic importance of paleontology lies in both applications to geology. The study of the fossils, especially microfossils, contained in a rock remains one of the fastest, cheapest, and most accurate means to determine the age and nature of the rocks that contain them or the layers above or below. This information is vital to the mining industry and especially the petroleum industry.

In biology, fossils are the most direct evidence of the evolution of life on Earth; they have helped to establish evolutionary relationships and to date the divergences between taxa (phylogeny). An expanding knowledge of the fossil record encouraged the formulation of early evolutionary theories. In fact, Darwin himself collected and studied South American fossils during his trip on the H.M.S. *Beagle*. After Darwin's evolutionary theory was published in 1859, much of the focus of paleontology shifted to understanding lineage evolution, including human evolution. George Gaylord Simpson and, later, Stephen J. Gould played a crucial role in incorporating ideas from paleontology to evolutionary theory.

Fossils indicate long-term patterns of biodiversity in the geological past. The story of the development of life on Earth, of the biosphere, forms the subject of paleontology. Modern paleontology sets ancient life in its context by studying how, over this vast time span, life has adapted to a changing world; this change is barely discernible during a single human lifetime. Long-term physical changes of global geography (continents and oceans pushed by plate tectonics, mountains formed and eroded) and long-term fluctuations between hot and cold climates (ice ages driven by orbital factors, warm periods in response to rapid increases in atmospheric carbon dioxide) triggered changes in living things: Populations, species, and whole lineages disappeared, and new ones emerged. Ecosystems have responded to these changes and have adapted to the planetary environment in turn. These processes continue, and today's biodiversity is affected by these mutual responses.

Very few species, known as living fossils, survive virtually unchanged for tens or hundreds of millions of years. Most species today appeared very recently in geological terms. It has been estimated that more than 95% of species that ever lived have become extinct. Paleontology has shown that extinction is a natural process that generally happens at a continuously low rate. Throughout geologic history, very few mass-extinction events have occurred in which many species have disappeared in a relatively short period of geological time. Thus, paleontology evidences the fragility of the world. Humans appeared only about 2.5 million years ago, and several human species have become extinct. Modern man appeared very recently in geological terms, no more than 200,000 years ago. At the end of the last glacial period, around 12,000 years ago, many mammals weighing more than 40 kilograms (megafauna) disappeared. There is a debate as to the extent to which this extinction event can be attributed to environmental and ecological factors, to the onset of warmer climates, or to human activities, directly by overkilling megafauna or indirectly. Megafaunal extinctions continue to the present day, and this deteriorating situation is being referred to as "the sixth mass-extinction."

The present biodiversity of an area is the consequence of the natural evolution of the species in its dating back to more than 3 million years ago. This evolution has been conditioned, in many ways, by geological history and certain other natural phenomena. But for the first time, a single species—ours—appears to be almost wholly responsible for an extinction crisis. Natural environments are now so degraded that we must go back in time to true known natural environments to understand natural processes. Paleontology furnishes an extensive database that, when integrated with neontological data, allows us to define models that explain better the past and present biodiversity and that would be useful in prospective studies.

As a consequence, the strategies aimed at the protection of biodiversity should also take into account the preservation of paleobiodiversity (paleontological heritage) and of geological materials (geological heritage and geodiversity), which constitute proof of past natural processes. Although fossils are also preserved in museums and private collections, the paleontological heritage exists in the natural environment as fossil sites. These sites compose an irreplaceable and finite resource for science, education, and recreation. Paleotourism, as part of adventure tourism, is poised for dramatic growth in the decades ahead, a fact directly related to the demography of wealthy nations. As this industry grows in years to come, it will be important for scientists and government officials to work together with the local inhabitants of the fossiliferous regions to create effective partnerships to educate the public and to protect and develop our paleontological heritage. This element of natural and cultural heritage is vulnerable to abuse and damage and therefore needs safeguarding and management to ensure its survival for future generations.

Paley, William (1743–1805)

William Paley, English churchman, theologian, moral philosopher, and apologist, is best known for his "watchmaker analogy," a classic argument for the existence of God, the Creator. From its publication in 1802, Archdeacon Paley's famous book, *Natural Theology,* influenced the Creation/evolution debate, which became especially lively from Darwin's era until the present. Few issues related to the study of time hold more significance.

Paley was born in Peterborough in 1743, the son of a vicar and schoolmaster. To prepare himself for the ministry, Paley enrolled in Christ's

College, Cambridge, in 1758, from which he graduated and where he later became a fellow and tutor. (Nearly 70 years later, Charles Darwin also enrolled in Christ's College, lived in rooms formerly occupied by Paley, and studied—and admired—the latter's writings.) Ordained in 1767 and married in 1776, William Paley advanced through clerical ranks and held various appointments. In 1782, he became archdeacon in Carlisle. There he began the process of expanding his Cambridge lectures on apologetics and ethics for publication.

Though he published several other books, Paley's fame rests on four works, all of which exerted considerable influence in his lifetime—and beyond. His first study, *The Principles of Moral and Political Philosophy* (1785) became a standard textbook at Cambridge. He taught a form of ethical utilitarianism and opposed the slave trade. In 1790, Paley published his second book, *Horae Paulinae, or the Truth of the Scripture History of St. Paul,* a defense of the Bible's historical nature. The third book, *A View of the Evidences of Christianity* (1794), another study on Christian apologetics, sorted and updated important material from earlier authors and achieved wide acclaim. In contrast to Hume, he supported the historicity of biblical miracles.

He published a fourth volume in 1802 under the title *Natural Theology, or Evidences of the Existence and Attributes of the Deity Collected from the Appearances of Nature.* Paley regarded this last book as the most important, a logical predecessor to the rest. Through an orderly arrangement and readable style, Paley—like his predecessors who advanced the cause of natural theology (e.g., John Ray, William Derham)—compiled a series of case studies to support the teleological argument for the existence of God, also known as the argument from design. In his *Natural Theology,* still in print after more than two centuries, Paley pointed primarily to complex parts and systems of human anatomy as arguments in favor of "intelligent design." As a watch's functioning components imply the existence of a watchmaker, he suggested, the biological realm reflects the work of a purposeful designer.

Critics point to various flaws in this famous analogy (e.g., it begs the question by assuming that the watchmaker must be the God of the Bible) and claim that Darwin's conclusions have obviated the need for an external, divine artificer. Others still find Paley's simple premise compelling. As the church reacted to intellectual challenges of that era (e.g., deism; Enlightenment writers such as Hume and Kant), Paley offered hope to readers who believed in a Creator with a personal interest in the universe.

Panbiogeography

In 1964 the biogeographer and evolutionist Leon Croizat published a book titled *Space, Time, Form: The Evolutionary Synthesis.* The title of the book presented a renewed emphasis on the role and significance of space and time in the evolutionary process and in understanding evolutionary history. Many representations of the theory of evolution from the time of Darwin's *On the Origin of Species* (1859) assumed that space and time together constituted a separate environmental container through which organisms moved and evolved. Croizat pointed out that this perspective resulted in an erroneous understanding of the evolutionary process.

For most people, time is perhaps the most compelling element of evolution that directly links the present with the past, principally through the geological fossil record. Fossilized organisms are identifiably related to those of the living world, either at a general level of organization or at more specialized levels such as those of genera and species. These fossils have contributed to the idea that living species have a history of ancestral species, some of which are preserved in the fossil record. However, this record alone was not necessarily enough to convince everyone of evolution by descent with modification—including Darwin himself. But it was during his world voyage on H.M.S. *Beagle* that Darwin found that some fossils in Argentina were more closely related to organisms currently living in that region than to those of other areas. This geographic juxtaposition of temporal records and biological relationships provided Darwin with a critical insight that helped lead him from a creationist to an evolutionary perspective. So it is no surprise that the very first sentence in Darwin's 1859 book began with the observation that the distribution of organisms and the geological relationships of the present to the past inhabitants of South America "seemed to throw some light on the origin of species."

Darwin's discovery pointed to a key aspect of evolution, that time and space are causally interrelated. But this interrelationship was taken largely for granted in much of evolutionary theory until nearly a century later, when Leon Croizat developed his unique approach to evolution called panbiogeography. In this approach Croizat did what no one else had ever done before. He tested Darwin's theory of evolution through the comparative study of animal and plant distributions, whether living or fossil. Animal and plant distributions provide a direct representation of time and space in evolution. The spatial component is represented by their location, while the temporal component is represented by their differentiation or divergence as well as the spatial correlation of distributions with tectonic features associated with earth history.

In recognizing the integral relationship of time with geographic location and the evolution of biological form, Croizat proposed the representation of evolution as the summation of their individual and combined effects by the following equation: Evolution = space + time + form. This formulation showed that the study of evolution was effectively the study of how all three elements are interrelated and affect each other, rather than just the study of a purely physical (biological) process. Time now becomes part of the evolutionary process rather than just a temporal record of evolutionary events. Because of this integral relationship, Croizat regarded the process of biological evolution (which he referred to as "form-making") in space over time as fundamental for the whole of biology in both its theoretical and practical aspects.

Croizat's approach to time as an aspect of space has its historical background in new ways of thinking about time and space that were developing at the transition between the 19th and 20th centuries, particular in Italy where Croizat was born and spent his formative years concurrently with the emergence of the Italian futurist movement. Futurists challenged the conventional assumptions of space and time as absolute categories by developing space and time as relational concepts with physical form. This was further developed in challenging presence and absence as independent and localized concepts. Croizat's panbiogeography showed that the full meaning of an organism at any one place and time is always permeated by a phylogenetic, morphological, ecological, or biogeographic counterpart or complement that is located somewhere else in space and time. The trace of this vicariant counterpart is represented graphically as a line or track that shows the connection of organisms in space and time. In this context, organism and environments are not absolute entities, but biogeographic and ecological relationships where spacing and temporalization are the ways in which replication of the past in the present influences the future.

By comparing the geographic distributions of animal and plant species, Croizat concluded that evolutionary differentiation of biological form (e.g., speciation) results in related taxa (species, genera, families, etc.) occupying different geographic sectors without any of these taxa having individually moved to those locations. This process was made possible by their common ancestor already having a distribution range that encompassed all the descendant locations. Each descendant came to occupy different areas through their biological divergence over different parts of the ancestral range. Croizat called this process *vicariant form-making*. These various taxa may be assigned any one of a number of different taxonomic ranks (species, genus, family, etc.), but Croizat was adamant that time in evolution is not tantamount to age as expressed in any particular taxonomic group. He argued, for example, that even though one might assume that a genus comes before a species because the genus is made up of species, in reality a genus could hardly exist independently from at least some of its species, so that the two ranks are effectively contemporary in origin. In this way Croizat attempted to distinguish between absolute time as an overall process inherent to the spatial evolution and differentiation of taxa, and relative time as the relationship between a specific taxonomic rank and its place in evolutionary rather than absolute time, so a species in one group may be as old as a genus or family in another group.

Key questions of time in evolution include the estimation of evolutionary rates of differentiation and the provision of a temporal scale for divergence between lineages. To address these questions, evolutionists often refer to the fossil record. The fossil record provides a general geological timescale for the first appearance of various lineages in the fossil record. Fossils can represent only the minimal age of fossilization for a recognized group of organisms. Fossils contain no information on whether or how long a group existed before the appearance of their earliest fossil. For example, the earliest known bird fossil, dated at about 150 million years old, may show that birds had evolved by this time, but the fossil contains no information as to how much earlier birds originated or the age of the common ancestor of birds and their nearest dinosaurian relatives. The fossil record is replete with examples of organisms for which the fossil record extends the organism's history tens of millions of years further than previously existing records did.

Method

Panbiogeography provides a spatial method for estimating temporal divergence and understanding evolutionary rates by correlating animal and plant distributions with tectonic features involved with geological history. Tectonic formations such as spreading ridges, plate boundaries, transform faults, and zones of uplift or subsidence are all indicators of geological process that underlie the geological topography now occupied by plant and animal distributions. These features can be geologically dated through radioactive decay rates to provide a geological timescale for their formation. A temporal correlation is often made for fossils that are imbedded in dated geological strata, but this approach may also be used for living taxa. This geological correlation technique may have significant implications for dating the origin of taxa where the fossil record is sparse or lacking altogether, and it may even lead to controversial challenges to accepted ages of origin based on the fossil record.

The possible temporal implications for evolutionary rates and age of origin may be illustrated by the spatial correlation between the 200-million-year-old Triassic fossil mollusk *Monotis* and the modern flowering plant genus *Coriaria*. The fossil distribution of *Monotis* overlaps with extensive circum-Pacific geological terranes (geological strata that have a different origin than other strata immediately adjacent) as well as a series of terranes extending through central Asia to Europe. This fossil range is spatially comparable with the modern distribution of *Coriaria* with the exception of western North America, where the plant is absent and no fossil representatives are known. The overall spatial correlation with circum-Pacific terranes may suggest that the modern distribution of Coriaria is as old as the Triassic, or it may have a more recent origin that was still affected by the subsequent geological history of those terrains that previously influenced the Triassic distribution of *Monotis*. The controversial aspect of this spatial correlation between geology and biology is that it suggests the genus *Coriaria* may be older than the earliest known fossil flowering plants recorded from the early Cretaceous (125–130 million years ago). Although some interpretations of the fossil record allow for an earlier origin for the evolution of flowering plants, the idea that some modern genera may also be this old would be widely viewed as problematic if not impossible.

Croizat's Mesozoic Theory

Spatial correlations between modern distributions and the earth's tectonic features (including spreading ridges, faults, and ocean basins) led Croizat to conclude in the 1950s that the origin of most groups of plants and animals distributed between continents originated in the Mesozoic. He proposed that their ancestors were already widely distributed before the Mesozoic, and so they are now isolated between continents, because these land areas have since become isolated. Croizat argued that some modern plant groups may have originated within the Jurassic, while others originated later in the Cretaceous. Even within continents he suggested that many groups originated in the Tertiary and survived the Pleistocene glaciations, an evolutionary model that was later to gain greater support from researchers but at the time was rarely considered.

The Mesozoic theory was strongly opposed by the influential theorists of Croizat's time, such as George Gaylord Simpson and Ernst Mayr, who looked to a much more recent origin of modern life and therefore had to appeal to theoretical migrations, whereby a vast range of animals and plants had to embark on a globetrotting series of migrations in different directions all over the globe to establish themselves on the different continents. Over the last 3 decades, Croizat's model has become widely accepted, although it remains controversial for many groups where other biogeographers believe that the plants or animals in question are of recent origin. A Mesozoic origin for modern life also has critical implications for understanding the mass extinction of dinosaurs and other groups at the end of the Cretaceous that has been attributed to a comet impact. The correlation of modern plant and animal distributions with Mesozoic tectonic structures may suggest that the ancestors of these groups survived the extinction event.

The expanded biogeographic timescale for plant and animal evolution was even proposed for the origin of animals and plants on oceanic islands such as Hawai'i and the Galapagos. Even though these islands were only a few million years old, Croizat argued that they inherited life that occupied earlier islands or island groups that no longer existed in the immediate vicinity. This model was later corroborated by the discovery that the Galapagos and Hawai'i, for example, are the latest formations in a series of volcanoes generated at a stable hotspot, and that both hot spots have a history of volcanic eruption extending back at least 90 to 100 million years. If these hot spots came into contact with mobile island arcs or microcontinents, some of their inhabitants may have colonized the volcanoes and continued to persist at the hot spots by sequentially migrating onto new volcanoes as they appeared, while the older islands were moved away by plate transport and as they eroded finally submerged beneath the sea. Because life is able to colonize new landscapes, it is possible for a young geological surface to support a very ancient biota, whether in reference to recent volcanic islands, volcanoes within a continent, or newly emergent land covered by recent oceanic sediments (e.g., mudstone, limestone).

The Mesozoic model and extended timescale for evolution has recently come into conflict with the popular application of molecular clocks. Molecular clock methods rely on the establishment of a temporal rate of molecular difference between related organisms as a function of time. In order to link a divergence rate to a particular temporal difference, it is necessary for the molecular divergence to be calibrated against a known geological age. This is most often accomplished by using a fossil representative and then extrapolating the relative age for those species for which there is no fossil representative. This method has resulted in the divergence of many groups being calculated as later than a particular geological event (such as the separation of continents occupied by the group), with the conclusion that the origin of the divergence postdated the earlier geological connection, so the current disjunction (such as between different continents) must be the result of recent dispersal or migration. This line of reasoning has been shown to be erroneous, because the molecular divergence date is calibrated by a fossil that can only provide a minimal divergence date. Any molecular dates applied by extrapolation to other taxa must, therefore, also represent minimal, not maximal, divergence estimates. Molecular divergence estimates that postdate a geological event do not, therefore, falsify the possibility that the geological event was actually involved with a divergence that was underestimated by the molecular clock. Molecular clock divergence dates may, however, provide potential falsification of a later geological event. The widespread reference to molecular clock divergence estimates as a falsification of Croizat's biogeographic model is, therefore, unfounded.

Panbiogeography and Theories of Divergence

As a final example of the panbiogeographic perspective on time and molecular approaches to evolution, one may contrast the chimpanzee and orangutan theories of divergence between humans and their nearest living great ape relatives. According to molecular similarity, chimpanzees are our nearest living relatives. Based on the molecular clock theory calibrated by the fossil orangutan relative *Sivapithecus* at about 13 million years, or by other primate fossils, the divergence between humans and chimpanzees has been estimated from as little as 4 million years to as much as 10, with 6 to 8 million years being often favored. In the absence of a fossil record for chimpanzees or gorillas, there is no other corroboration of this divergence estimate. The orangutan theory of relationship would establish an entirely different timescale, with divergence between orangutans and humans occurring at least 13 million years ago. This temporal alternative is also supported spatially with fossil orangutan relatives being distributed around parts of the Mediterranean, central Asia, and eastern Asia. These distributions, along with that of the fossil hominids of East Africa, are largely vicariant, and this would suggest that the temporal differentiation of hominids, the fossil apes, and the orangutans all occurred in their respective areas from a common ancestor that was already widely distributed over all localities. Subsequent extinction of many of these lineages by about 9 million years ago (some apparently the result of climate change and loss of forested environments) resulted in the apparent discrepancy between the origin of hominids in Africa and the origin of modern orangutans in southeastern Asia. It is only through the triple consideration of biological affinity (the evolutionary relationships), the temporal history (in the fossil record), and the spatial distribution of living and fossil taxa that the modern geographic disconnection can be understood as a spatial artifact resulting from the extinction of geographically intermediate forms.

Pangea

Pangea (Greek for "all earth") was a supercontinent that gradually formed during the early Paleozoic era (beginning approximately 450 million years ago) and broke apart beginning in the Middle Jurassic era (approximately 180 million years ago). At its most complete state in the Early Jurassic, Pangea consisted of nearly all of the world's continental crust sutured together into a single giant landmass. This landmass was C-shaped, centered on the equator, and surrounded by a single giant ocean, termed Panthalassa. Pangea enclosed an eastward-facing body of water called the Tethys Sea, of which the modern Mediterranean is a much-reduced remnant, and was home to vast subtropical deserts. The existence of a single giant continent had profound effects on life, and many important evolutionary events occurred on Pangea, including the radiation of the dinosaurs and the early evolution of birds and mammals.

During the early history of geology it was thought that Earth was a static, stable planet whose surface remained largely unchanged through time. However, beginning in the early 1900s, German meteorologist Alfred Wegener accumulated substantial evidence showing that the continents had not always occupied their present positions. Wegener discovered that South America, Africa, India, Australia, and Antarctica shared a suite of unique Mesozoic fossils, including a tropical plant flora characterized by the fern *Glossopteris* and a reptile fauna that included the tusked, pig-like *Lystrosaurus*. Because modern animals do not range across all continents, owing to the existence of oceans, mountain ranges, and other barriers, Wegener hypothesized that these landmasses must have been linked during the Mesozoic era (225–65 million years ago), and have since moved to their present, widely divergent positions. Additionally, Wegener chronicled closely matching rock units shared by Africa and South America, as well as evidence of former equatorial climate belts and glaciations shared between now divergent continents. Taken together, these facts suggested to Wegener that all of the continents had once been joined together into a supercontinent, which he named Pangea. Initially Wegener's ideas were controversial, as he could provide no plausible mechanism for continental motion. However, further research in the years after World War II roundly supported Wegener's observations and firmly established the existence of a Paleozoic-Mesozoic supercontinent. Today, many geologists believe that Earth is characterized by a supercontinent cycle, in which these giant landmasses form and disintegrate roughly every 500 million years.

The formation of Pangea was gradual and can be traced to the breakup of a previous supercontinent, Pannotia, approximately 750 million years ago. Pannotia split into three large landmasses, including a large southern platform called Gondwana and the more northern Proto-Laurasia, which subsequently split into several smaller landmasses. Two of these smaller landmasses, termed Laurentia and Baltica, collided in the Late Ordovician (about 450 million years ago) and were joined several million years later by Avalonia, a slice of crust comprising present-day New England, Nova Scotia, and Great Britain. Meanwhile, Gondwana was fragmenting into many small landmasses that periodically collided with the Laurentia-Baltica-Avalonia landmass, known as Euramerica. These smaller collisions occurred throughout the Devonian, Mississippian, Pennsylvanian, Permian, and Triassic periods (about 420–200 million years ago), until nearly all of the world's continental crust was completely sutured together during the Early Jurassic.

The breakup of Pangea began during the Middle Jurassic, approximately 180 million years ago. During this time North America moved to the northwest away from Africa and South America, opening the central Atlantic Ocean. North America remained connected to Europe and Asia, and together the land that is now these continents composed the landmass of Laurasia. Laurasia rotated clockwise and completely split from the southern expanse of Pangea, now termed Gondwana and composed of present-day South America, Africa, India, Australia, Antarctica, and Madagascar. Further disintegration of these two large landmasses occurred during the Cretaceous period (about 145–65 million years ago). South America split from Africa to form the south Atlantic Ocean, with the two continents gradually separating from south to north. There is some controversy about the timing of this separation, as most geophysical models place the breakup at about 100 million years ago, but recently published reconstructions suggest it may have occurred much earlier, perhaps up to 140 million years ago. Around the same time as the South America–Africa split, India and Madagascar rifted away from Antarctica and Australia, forming the eastern Indian Ocean. India separated from Madagascar about 95 million years ago and moved rapidly northeastward before colliding with Asia near the end of the Cretaceous. In the Late Cretaceous, North America and Europe rifted apart, forming the North Atlantic Ocean, and Australia and Antarctica separated. Further motion during the Cenozoic brought the continents to their modern positions.

The existence of a single large landmass had profound effects on geography, climate, and life. The numerous continental collisions that built Pangea produced many mountain ranges, including the Appalachians, which were formed by the Silurian collision between Laurentia and Avalonia and subsequently raised by the Mississippian collision between northwest Africa and Euramerica. Alteration in wind and precipitation patterns led to vast inland subtropical deserts. These deserts, along with an extensive central Pangean mountain range, formed substantial barriers for floral and faunal migration. On the whole, however, the presence of a single landmass allowed for easy dispersal of organisms, and many plant and animal species (including Wegener's *Glossopteris* and *Lystrosaurus*) had a cosmopolitan distribution during the Mesozoic.

Many important evolutionary events also happened on Pangea. Dinosaurs first evolved as small, swift predators during the Late Triassic (about 225 million years ago), and the key to their subsequent rise to dominance may have been their ability to thrive in the dry interior of Pangea. The first mammals and birds also arose during the Late Triassic and Early Jurassic, and the early evolutionary history of both groups played out on Pangea. Furthermore, two major extinctions occurred during the existence of Pangea: the Permo-Triassic mass extinction, history's largest mass die-off in which perhaps 95% of all marine species were killed; and the end of Triassic extinction, which decimated both marine and terrestrial communities. Although several different hypotheses have attempted to explain these events (including extraterrestrial impact for the Permo-Triassic), it is possible that the altered climate regimes and ease of migration on Pangea were contributing factors, at least for terrestrial extinctions.

PARACELSUS (1493–1541)

Philippus Theophrastus Aureolus Bombastus von Hohenheim, otherwise less exhaustively known as Paracelsus, was a medieval alchemist, astrologer, occultist, and physician who was well ahead of his time. The title Paracelsus, literally meaning "greater than or equal to Celsus," pays homage to the Roman encyclopedist Aulus Cornelis Celsus (25 BCE–50 CE), whose only extant work, *De Medicina,* deals largely with archaic medical practices. Stories of Paracelsus's ego and arrogance would lead one to believe that Paracelsus accepted this title readily. His interest in time is evident in his numerous prophecies.

Born in Switzerland some time in late 1493 (conflicting accounts exist as to whether the month was November or December), Paracelsus was the son of a German physician and chemist and a Swiss mother. In fact, his earliest medical training was likely with his father, until more formal arrangements were made later on at the University of Vienna, where he graduated with a bachelor's degree in 1510. A doctorate was later procured, but the university he received it from is unknown, although some believe it to be the University of Ferrara.

After completing his research, Paracelsus adopted a wanderer's life for some 10-odd years. His journeys took him across Europe and landed him in Russia, where he was taken prisoner by the Tartars. Gaining the favor of the ruler of the Tartars, Paracelsus eventually was enlisted to escort the ruler's son to Constantinople.

It was in Constantinople that Paracelsus's latent quest for hermetic knowledge was nourished by Arabian adepts, although Paracelsus was a devout Catholic. Perhaps this was his first encounter with the mentioning of *alkahest,* the universal element and solvent that Paracelsus believed to be the philosopher's stone, the pursuit of all alchemists. It was the belief of many alchemists that the philosopher's stone, in addition to being able to transmute other metals into gold, was also the key to immortality.

After returning to Europe, Paracelsus began his practice of medicine as an army surgeon. His contempt for contemporary medical tradition would become apparent after his witnessing of many amputations. Paracelsus's approach to medicine was all natural, similar to some homeopathic practices that exist today. His knowledge of alchemy allowed him to clean wounds with chemicals rather than allowing them to become gangrenous and require amputation. In fact, he would become the first to name the element zinc in 1526, after the German word for pointed: *zinke*. This combination of alchemical knowledge with medicinal practice would become the precursor to the modern discipline of pharmacy.

Also, like many other physicians and alchemists of the time, Paracelsus consulted astrology to help treat various ailments that he encountered in his practice. He believed in the idea that humankind was governed by the movement of celestial bodies. A medical astrologist, Paracelsus would base diagnoses on natal charts and Zodiac signs, with the understanding that each of the 12 signs of the Zodiac corresponded to various regions of the body.

Paracelsus's background in alchemy and astrology would allow him to become acquainted with much mystical knowledge. This is confirmed by an account of Paracelsus mentioning that he had created a homunculus, the so-called little man. This artificially created human was purportedly one foot tall and carried out menial tasks for its creator. As unbelievable as this may sound, humankind's current preoccupations with creating robots and other artificial intelligence show similar pursuits.

Perhaps the most striking of all of Paracelsus's mystical cornerstones are his prophecies. Like the more popular prophecies of Nostradamus, Paracelsus's prophecies seem to be heavily abstracted. A majority of them seem to hint at the course of the Reformation and other ecclesiastical affairs. One particular prophecy seems to predict Napoleon Bonaparte's imprisonment on Saint Helena.

Scholarly dispute exists as to whether Paracelsus's prophecies are prognostications of future historical events or whether they are merely a collection of allegories pertaining to the evolution and development of the human soul. The human soul and its relation to the cosmos was certainly an essential part of Paracelsus's teachings. Most likely both of these arguments have some foundation, as many seers of the time cloaked their messages in layers of symbolism to escape religious persecution.

Paracelsus, however, was one who was constantly plagued with persecution, and even his vast mystical and medical knowledge could not cure this malady. After being threatened with imprisonment for fining a clergyman with a medical fee, Paracelsus abandoned his post at the University of Basel and returned to his former nomadic lifestyle. His dedication to his medical practices and pursuit of hermetic knowledge continued. Years later, in 1536, his *Die Grosse Wundartzney* ("The Great Surgery Book") would be published, thereby enhancing his reputation.

On September 24, 1541, Paracelsus died in Salzburg. His wish to be buried at St. Sebastian Church in Salzburg was honored. After his death, his work continued to be studied for its remarkable value in medicine and other areas. Almost 4 centuries later, the psychiatrist Carl Jung praised Paracelsus for his bombastic nature. Without Paracelsus's stubbornness, he said, it is unlikely that the practice of medicine would have progressed as fast as it did.

Paradigm Shifts

See Darwin and Aristotle

Parmenides of Elea (c. 500 BCE)

Parmenides of Elea was one of the most influential of the Presocratic philosophers. He was born before 500 BCE in Elea, a Hellenic city on the southern coast of Italy where he founded the School of Elea. Unfortunately, his only known work, the didactic poem later titled "On Nature," written in hexameter verse, is extant only in fragments totaling approximately 150 of what were originally around 3,000 lines. It deals with the topic of time indirectly by separating real being from the influences of time.

The poem was divided into an introduction and two main sections about "the way of truth" (*aletheia*) and "the way of opinion" (*doxa*). In the proem the narrator describes his ascent to the home of an unnamed goddess from night to day, unusual for human beings. With the help of the sun maidens, he passes the gates of night and day and meets the goddess, who reveals to him the natures of truth and opinion, that is that which "is" and that which "is not." According to her instruction, real inquiry via pure reason (*logos*) is only possible concerning that which "is," because it is a true, real, unchanging, ungenerated, imperishable, indestructible, continuous whole that keeps remaining in being. But one cannot know or name that which "is not," because it is the opposite of that which "is." Ordinary human beings believe that which "is not," namely, the physical cosmos including sun, moon, earth, and the stars, to be real. But they are mistaken, due to their using deceptive sense perception. They trust the illusion that perceived or imagined things actually "are," and even give them names.

Although Parmenides does not explicitly lay down a philosophy of time, the characterization of that which "is" and which "is not" indicates his point of view. Scholars have different opinions on this subject, but they agree that according to Parmenides, unchanging being is never affected by time, because it has neither a "before" nor an "after," both of which are indissolubly linked with change and process. Because the "is" has no duration, but is "now," the question arises if being should be adequately described as atemporal or even atemporal eternity. Surely one is not allowed to identify the "now" of being with the "now" in the realm of opinion that is embedded in the process of coming-to-be and passing away. Whereas the latter "now" is changing all the time, the "now" of being remains always the same without lasting in time. Because being is free from doxical time, it seems correct to understand it as atemporal. It can also be addressed as eternal, insofar as being eternal is usually characteristic of the revered realm that has neither beginning nor end, and insofar as eternity is not meant as everlastingness here but as a continuous present beyond ordinary time.

The Parmenidean duality of appearance and reality as well as the connotations for a philosophy of time considerably influenced Plato and Neoplatonic thinkers, as is apparent in Plato's *Sophist* and *Parmenides,* as well as in Proclus's commentary on the latter dialogue. Both philosophers treated Parmenides' work with extreme respect and saw themselves as adherents of his ontology, but they introduced further differentiations, such as the ontological comparative and the explicit distinction between real eternity, everlastingness, and time.

Parousia

The word *parousia* is borrowed from the Greek; it means "presence" or "arrival." It is used in Christianity to refer to the coming of Jesus; the word is also commonly used in the Christian Bible.

In I Corinthians 16:17, Paul writes of the parousia of several Christians to Corinth. In II Corinthians 7:6, Paul writes of the parousia of Titus to Corinth. These two passages refer to people who are coming to Corinth. But the word is also used to denote a time in the future when Jesus will come back to earth, as in Matthew 24:27, 37, and 39 and I Thessalonians 2:19, for example.

The timing of Jesus's parousia has caused debate. Christians who lived soon after Jesus believed that his parousia was imminent. I John, which many scholars believe was written in the 90s CE, states, "Dear children, this is the last hour." Revelation 1:3, also written in the 90s, states: "Blessed are those who hear it and take to heart what is written in it, because the time is near." As time passed and Jesus did not return, Christians nevertheless continued to anticipate his arrival. Among the most famous of the predictors was William Miller, who predicted that Jesus would return in 1844. Many Christians in the 19th century believed him. After Jesus failed to return, some formed the Christian denomination the Seventh-Day Adventists. Currently, some Christians believe that the parousia of Jesus will occur in their lifetimes.

Over time, Christians have debated the nature of Jesus's coming: Some link it with the "rapture," or Second Coming of Jesus. These events are not synonymous. The rapture is best described in I Thessalonians 4:16, 17: "For the Lord himself will come down from heaven . . . and the dead in Christ will rise first. After that, we who are still alive and are left will be caught up together with them in the clouds to meet the Lord in the air. And so we will be with the Lord forever." At this parousia, Jesus will not come to earth but will call Christians to him while suspended in the air.

The Second Coming of Jesus is recorded in Matthew 24 and Revelation 19:11ff. This event forecasts Jesus's coming to earth with a resultant battle against the forces of evil. The result of this battle will be a victory for Jesus, and Christians will rule in peace with Jesus. The amount of time that Christians will spend in peace with Jesus is debated, with some believing that this will last forever and others believing it will last for 1,000 years (Revelation 20:4).

Not all Christians believe that the parousia of Jesus will be a physical one, or even one in some future time. Some Christians believe that the events spoken of in Matthew 24 and the Book of Revelation have already occurred, that they were referring to persecutions meted out by the Romans. Others believe that these events are not meant to be taken literally but refer instead to spiritual phenomena and situations.

Peloponnesian War

The Peloponnesian War (431–404 BCE) was more than a classic conflict between two Greek city-states and their allies; it was also a clash of ideologies—a democracy (Athens) and an oligarchy (Sparta)—and of opposing views on the nature of the world. This war is an example of conflict between two militaries with very different and incompatible styles of fighting; thus, it serves as an example of adaptation (or the lack of it). A large volume of information, including contemporary accounts of the war, has survived, providing greater detail than is known about any other ancient war. Because of the opponents' political and military differences and the amount of information available, modern war colleges study the Peloponnesian War in terms of strategies, consequences of actions, and politics.

History of the War

The cause of the Peloponnesian War dates back to the time of the Greek wars with the Persians in the early 5th century BCE. Sparta, with its totally land-based military, had taken command of the Hellenic League. The seafaring powers resented

Sparta's leadership, especially over naval forces. Athens, a sea power, accepted leadership of a new league of sea-power states called the Delian League in 479–478 BCE. Sparta remained the leader of the land-power states called the Peloponnesian League. Tension mounted between Athens and Sparta until war broke out in 460 BCE. The causes of the conflict, sometimes called the First Peloponnesian War, include Spartan suspicion of the growing Athenian empire, the defection of the city of Megara to Athens, and the Athenian construction of a long wall to the sea. The war continued until the both sides ratified the Thirty Years' Peace in 445 BCE.

The conflict restarted in 431 BCE, beginning the Peloponnesian War. Historians divide the war into three phases: the Archidamian war (431–421), the Sicilian campaigns (420–413), and the Decelean war (413–404). In the Archidamian war, Sparta launched brief land invasions into Attica in hopes of scaring Athens into capitulation. This strategy did not work, for two reasons. First, Sparta was far from home, which made sustaining operations difficult. Second, Sparta's slave class, the Helots, was always at risk of revolting when the army was away. Therefore, the Spartan army tended to keep excursions brief in order to prevent a Helot uprising. Athens, following the advice of their army general, Pericles, chose to fight a passive war, to remain behind her strong city walls, and to avoid a direct land battle. Athens did raid the Peloponnesian coast using her superior navy. Their aim was to harass Sparta and her allies in the hope that the Spartans would withdraw to Peloponnesus and sue for peace. Neither strategy worked nor could one side exploit the other side's weakness in order to win a decisive battle. This period concluded with the Peace of Nicias in 421 BCE.

The peace reflected poorly on Sparta in that its allies thought Sparta had sold them out; however, it gave the Athenians time to rest, rearm, and reevaluate their strategy. Athens, with a new general named Alcibiades, a new fleet, a replenished treasury, and a pacified empire, decided to take the offensive. Athens convinced Argos, Sparta's greatest rival, to join the alliance. Athens sent troops to Argos for a battle with Sparta, but they were too few in number. Sparta won the battle and regained the momentum; Athens had lost an opportunity to win the war.

Next, Athens chose to attack Sparta's supply lines from the west. This move began the Sicilian campaigns. Syracuse, an ally of Sparta, posed a threat to Athenian allies on Sicily. Athens sent a fleet to destroy Syracuse; however, poor decisions on strategy and slow movement to action gave Syracuse time to prepare its defenses and cost the Athenians their opportunity to achieve their goal. This campaign, far from home, ended disastrously for Athens. Athens tried to fight a land battle instead of relying on her strength—the fleet. This led to the destruction of the Athenian fleet, the capture of almost the entire army, and the defection of her enthusiastic general, Alcibiades, to the Spartans.

The Decelean phase of the war was a time of desperate strategy for both sides. Sparta made an unlikely alliance with the Persians, while the Athenians reverted to a defensive strategy. Furthermore, Sparta took to the seas, an unusual strategy for a land-based army, to cut off the Athens supply lines at the Hellespont. The Athenian fleet, once again under the command of Alcibiades, was able to put together a string of victories, but none of them was decisive. Finally, in 405 BCE, the Spartan general Lysander caught the Athenian fleet on shore. He knew not to face the Athenian fleet head on but chose to fight Athens on Spartan terms, that is, to battle a moored Athenian fleet. Lysander won a decisive victory, destroyed 168 ships of the Athenian fleet, and captured over 3,000 sailors. This, the Battle of Aegospotami, probably is the best example in the war of perfectly using one's strength against another's strength. This battle effectively ended the war.

The Peloponnesian War devastated Greece, from which she would never recover. Not only did the war bring an end to her Golden Age, a time when she was the cultural and intellectual center of the world, but it also left the countryside ravaged and the general populace struggling for survival. The Greeks lost their place as a regional power and, in 371 BCE, lost their independence to the Macedon king Philip II.

The War's Lessons

The Peloponnesian War has timeless elements that are relevant to the modern world. First, the war represents a battle between vastly differing political ideologies—a democracy versus an oligarchy. This political difference bred distrust, which led to alliance building and then to war and destruction. Because these same political differences exist in modern times, the Peloponnesian War serves as a paradigm and an example of what can go wrong.

Second, the mismatch between the two sides' military capabilities—with Sparta strong on land and Athens strong at sea—resulted in two phenomena that still have relevance in the 21st century. First, because neither alliance could effectively attack the other's center of gravity, each initially opted for a war of attrition that sapped resources without essentially harming the opponent in any serious way. Second, the opponents clearly saw the need for joint or coordinated operations, that is, operations on land and sea simultaneously. The Spartans ultimately succeeded in joint operations, while the Athenians failed. This concept of joint operations has become fully ingrained in the Western military system, especially since the rise of the European navies in the 16th century. In addition to the areas of land and sea, modern warfare adds air, space, and the cybernetic world to the arena of joint operations.

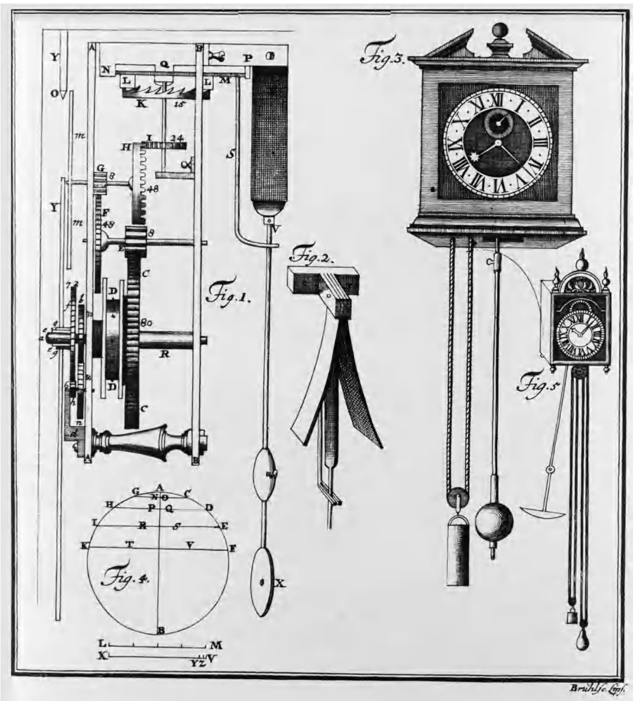
Pendulums

A pendulum is a suspended body that swings back and forth or oscillates about a fixed point. The simple pendulum consists of a heavy object called a bob suspended from a string, rope, wire, or light cord that, when given an initial push, will swing back and forth under the influence of gravity over its central or lowest point. Its swing or oscillation is regular and periodic. It is believed that the famous scientist Galileo Galilei (1564–1642) observed the regularity and periodicity of the pendulum's motion as early as 1583 by comparing the movement of a swinging lamp in a cathedral in Pisa, Italy, with his pulse rate.

Pendulums have made a valuable contribution to our understanding and appreciation of the concept of time since Galileo's observations and subsequent analysis of their motion led to the utilization of pendulums in clockwork, providing the world's first accurate measure of time. Prior to the advent of the pendulum, time was measured by the use of natural periodic phenomena, which appeared to be steadily rhythmic but varied widely from system to system and place to place. For example, use was made of the sun (sundials), flowing water (water clocks or clepsydra), flowing sand (sand clock or hourglass), burning candles and incense, and then early mechanical clocks in which weights would slowly drop, turning a gear



The mechanical system of a clock driven by weights and pendulum (1725). The Dutch mathematician and astronomer Christiaan Huygens was the first to successfully produce the first pendulum clock in 1656.

Source: Library of Congress, Prints & Photographs Division.

to move the clock's hand and display the time. Before the pendulum, these early mechanical clocks were probably the most accurate, and yet it was not unusual for these clocks to be off by as much as 2 hours per day! It is easy to imagine the colossal negative effects of this on society as a whole, particularly on work practices and on scientific investigations.

Within 30 years of the first use of pendulums in clocks, the average error of measuring time went from about 15 minutes a day to less than 10 seconds. By the early 1900s, time could be measured to within a hundredth of a second a day because of the pendulum. The implications of this ability to accurately measure time for the first time in history were significant, resulting in considerable technical, social, cultural, and scientific advances. Indeed, some believe that it is this (which was facilitated by the pendulum) which ushered in the scientific revolution, so creating the foundations of modern science and society. Rapid advances in our knowledge about ourselves, nature, the earth, and the entire universe would have been impossible without accurate time measurement (and therefore the pendulum).

The time required for a pendulum to swing back and forth (one complete oscillation) is called the *period* of the pendulum. This time is constant at a fixed location on earth. It does not depend on the weight of the bob or on the size of the swing (for small swings). It is dependent only on the length of the pendulum. It is this invariant time for one oscillation that makes pendulums useful for regulating the action of several devices, especially clocks. For example, one well-known use of the pendulum is as a metronome to aid musical students to keep time.

The motion of the idealized so-called simple pendulum with a light string and frictionless system is referred to as simple harmonic motion, because it is continuous and repetitive, oscillating in such a way that it swings out an equal distance on either side of a central point, with its acceleration toward the central point proportional to the distance of the pendulum from it.

The term *pendulum* is often used outside of timekeeping and science to describe systems or situations where anything undergoes regular shifts or reversals in value, direction, attitude, opinion, or state. For example, one may hear about the "pendulum of public opinion" spinning from one extreme to the next. It is also used to describe systems that use any kind of "to and fro" process. For example, *pendulum arbitration* is a method of arbitration where one side makes a proposal, and then the other suggests their proposal, with the arbitrator finally choosing one of the proposals, which then becomes binding on both sides. A technique for delivering supplies or for rescue using a helicopter, where a rope or hoist cable is set swinging by rocking the helicopter or pushing and pulling the rope, is called a *pendulum maneuver.*

The Period of a Simple Pendulum

The simple pendulum is an idealized or mathematical model of a practical pendulum for which it is assumed that the

- ring, cord, rope, wire, or rod from which the bob is suspended is so light that it is considered massless.
- string, cord, rope, wire, or rod from which the bob is suspended is inextensible; that is, of unvarying length; in simple terms, it must not stretch.
- bob is a point mass (i.e., its mass must be concentrated at a point).
- amplitude of the swing, that is, the angular displacement, is small (less than about 10 degrees) and thus the motion is simple harmonic (see θ in Figure 1).
- pendulum swings only in the vertical plane.
- effects of the air in which it moves are negligible.
- effects of the pivot or point of suspension are negligible.

In the simple idealized pendulum, when it is displaced from its rest position, only two forces act on the pendulum as shown in Figure 1. The first force is the tension in the cord acting upward along the cord, and the second force is the weight of the bob acting directly downward. The weight is given by mg, where m is the mass of the bob and g is the acceleration due to gravity. The weight consists of the two components, F_1 which balances the tension in the cord and F_2 which acts along the path of the pendulum. The force F_2, acting to restore the pendulum to its original position is equal to $-mgx/L$, where x is the displacement and

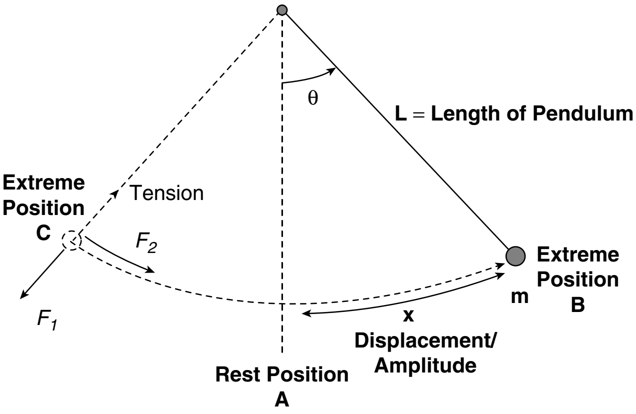


Figure 1 Principle of the simple pendulum

L is the length of the cord. The value of F_2 is always negative since it acts in the opposite direction to the displacement.

The law governing the motion of the idealized simple pendulum was discovered in the late 1500s by Galileo and states mathematically that the period of oscillation of a pendulum varies directly with the square root of the length of the pendulum and inversely with the force of gravity (acceleration due to gravity). The time, T, required for a complete swing (the period) is described as follows:

$$T = 2\pi\sqrt{\frac{L}{g}}$$

where L is the length of the pendulum and g is the acceleration due to gravity. Because π is a constant and g is a constant at a fixed location, the period of the pendulum varies only with its length. In other words for a pendulum of constant length, at a fixed location, the period is constant. Much more sophisticated mathematics is required to describe the motion of an actual physical or complex compound pendulum.

History of Pendulums

By some reports, the pendulum was used as early as 132 CE in a seismoscope or earthquake recording instrument invented by a Chinese philosopher named Chang Heng. Thus, almost certainly, people have been using pendulums for thousands of years in devices and possibly looking at swinging pendulums. Indeed, the notebooks of Leonardo da Vinci (1452–1519) include a theoretical design of a silent pendulum mechanism that could be used to regulate the motion of a clock.

Yet, the first detailed studies of the motion of the pendulum were reported only in the 17th century, by some leading scientists of the time. These included Galileo Galilei, Christiaan Huygens (1629–1695), Isaac Newton (1643–1727), and Robert Hooke (1635–1703). Although the extent of the contributions to pendulum theory and clock making of the various scientists, particularly Galileo and Huygens, is sometimes the subject of debate, it is generally accepted that it was Galileo who, at different times, made four entirely new claims about pendulum motion, as follows:

1. The period varies with the length of the pendulum (and later with the square root of length—the *law of length*).
2. The period is independent of the size of the swing or amplitude (the *law of amplitude independence*). (Huygens and Mersenne later showed this to be true only for pendulums with small amplitudes.)
3. The period is independent of the weight of the bob (the *law of weight independence*).
4. For a given pendulum length, all periods are the same (*Law of Isochrony*).

Christiaan Huygens's Contribution

It is thought that the ideas of Galileo inspired the Dutch scientist Christiaan Huygens to patent a mechanical clock in 1656 that employed a pendulum to regulate its movement. Others believe that it was the theologian and mathematician Marin Mersenne (1588–1648) who gave Huygens the idea to use the pendulum as a timing device. Whatever his inspiration, Huygens is credited with making the first pendulum clock, and after this invention, he continued to work on increasing the precision and stability of these clocks. He also devoted much time to the construction of pendulum clocks for use on ships in the open sea. The construction and use of pendulum clocks quickly spread. Indeed, in 1658, only 2 years after Huygens obtained the patent for the first pendulum clock, a clock maker from Utrecht named Samuel Coster built a church pendulum clock with a guaranteed accuracy. Indeed, by then most major towns in Holland had pendulum tower clocks.

In Huygens's memoirs, published in 1673 and entitled *Horologium Oscillatorium,* he gave a detailed description of pendulum clocks and their theory. There, he confirmed the earlier observation by Marin Mersenne that the period of a pendulum does vary with the size of the swing, and that Galileo's observation of amplitude independence was accurate only for small swings or amplitudes.

Much later, around 1675, Christiaan Huygens (with Robert Hooke) invented the coiled balance spring to make clocks more mobile. The modern version is now sometimes called the hairspring, and it is still found in some of today's wristwatches. Although this mechanism depends on the elastic properties of a spring and not a pendulum, the underlying physics of the device is the same as that of the pendulum.

Huygens has also been credited with being the first scientist who observed and described the "synchronization phenomenon." In 1665, he noticed, while lying in bed sick observing two clocks hanging on a wall in his room, that the pair of pendulum clocks that hung from a common support had synchronized: Their oscillations coincided perfectly, and they moved always in opposite directions. He described this synchronization as the "sympathy of two clocks."

This discovery was probably just as important as his invention of the first pendulum clock, because synchronization phenomena are frequently found in engineering, nature, science, and everyday life. Systems as varied as recurrent viral epidemics (e.g., childhood infections), orbits of celestial bodies, singing crickets, flashing fireflies, and applauding audiences display synchronization. Synchronization has today become a popular research topic.

Other Scientists' Contributions

Apart from Huygens and Galileo, several other scientists of the time used pendulums to increase our knowledge of the earth and to construct useful devices. The English scientist Robert Hooke was responsible for suggesting (as early as 1666) that the pendulum could be used to measure the force of gravity. He was also the inventor of the conical pendulum, consisting of a weight attached to a light rod, which was made to execute circular motion. He applied his observations of this pendulum to his study of orbital planetary motion. His observations of the conical pendulum and its application to planetary motion were also thought to have influenced the development of Newton's laws of motion.

In 1671, during an expedition to Cayenne, French Guyana, Jean Richer demonstrated the variation in the force of gravity with location on the earth by observing that the period of a pendulum was slower at Cayenne than it was at Paris.

For pendulums that used metal wire or rods to suspend the bob, it was observed that the length of the pendulum changed with temperature due to expansion of the metal with increased temperature. This, of course, caused the period to vary and was to be avoided in making an accurate clock. George Graham in 1726 designed a type of "compensated" pendulum having a glass hollow bob filled with mercury suspended by a steel pendulum rod. In his design, the thermal expansion of the mercury balanced or compensated for the thermal expansion of the pendulum rod. This came to be known as Graham's pendulum.

John Harrison, a British clockmaker, expanded on this idea of compensation for changes in the length of pendulums due to temperature changes by inventing a pendulum with up to nine alternating steel and brass rods that was known as the gridiron pendulum.

An experiment with an unusual pendulum has been credited with contributing to the popularization of pendulums and science in the early 19th and 20th centuries. This experiment was also used to demonstrate, for the first time in a simple way, that the earth indeed rotated on its axis. In 1851, Jean Bernard Léon Foucault suspended a pendulum (later named the Foucault pendulum) from the dome of the Panthéon in Paris. The bob of the pendulum was a 62-pound iron ball suspended from an iron wire 220 feet long. Foucault set it in motion, causing it to rock slowly back and forth. To record the swing of the pendulum, he attached a pointer to the ball and placed a ring of damp sand on the floor. From the patterns in the sand, the pendulum appeared to rotate, leaving a slightly different trace with each swing, thus illustrating that the earth rotated on its axis.

There were many more developments in pendulum clocks over the next century, and these led in 1889 to Siegmund Riefler's invention of a clock made with a nearly free pendulum, which attained an accuracy of a hundredth of a second a day, becoming the standard in many astronomical observatories. A more accurate free pendulum clock was later invented by W. H. Shortt in 1921. Interestingly, the Shortt clock contained two pendulums, one called the master and the other the slave. The National Institute of Standards and Technology (NIST) based in the United States had used the Riefler clock from 1904 until 1929 as the national time standard. It was briefly replaced by the Shortt double pendulum clock before the NIST finally switched to an electronic timekeeping system.

Types of Pendulums

Following Galileo's analysis and Huygens's work, several different types of pendulums were designed and constructed for use in timekeeping and in other applications. Indeed, Newton's pendulum (sometimes called Newton's cradle) survives today as a very popular desk and table ornament. It consists of five metal spheres as bobs suspended, so they all touch one another along the same line. One or more of the metal bobs are drawn back and released, causing the released spheres to swing and collide with the remaining spheres. Other types of pendulums include these:

- *Astatic pendulum:* a pendulum that is not restricted to swinging in a plane.
- *Ballistic pendulum:* a device consisting of a heavy block suspended by rods that measures the velocity of a projectile, such as a bullet, by calculating the angle of the pendulum's swing.
- *Barton's pendulum:* in its simplest construction, a device that uses approximately 10 different pendulums hung from one common string.
- *Compensated pendulum:* a clock pendulum that has mechanisms that are designed to maintain constant pendulum length in spite of temperature changes. One example of this type of pendulum using zinc and steel was used in the Big Ben clock of London, England.
- *Cycloidal pendulum:* a device that consists of a heavy weight suspended by a cord that hangs between two cycloid-shaped metal constraints.
- *Double pendulum:* a pendulum that has been attached to the end of another pendulum to make what is often called a chaotic pendulum.
- *Galitzin pendulum:* a very large horizontal pendulum that is used to measure changes in the direction of the force of gravity with time, serving as the basis of a seismograph.
- *Horizontal pendulum:* a pendulum that moves in a horizontal plane, such as a compass needle turning on its pivot.
- *Kater's (reversible) pendulum:* a pendulum that can be supported from either of two movable knife edges that is used to accurately measure the acceleration of gravity.
- *Long period pendulum:* a pendulum used for measurements of gravity, in seismometers, and for vibration isolation. In 1901, one such pendulum, 4,440 feet long and with a period of 70 seconds, was made by the faculty of the Michigan Technological University.
- *Magnetic pendulum:* consists of a permanent magnet that is suspended and free to turn in a horizontal plane in a magnetic field with a horizontal component.
- *Torsional/torsion pendulum:* This consists of a horizontal disk suspended by a wire attached to its center. When the disk is twisted and released, it returns to its original position. The disk continues to spin first one way and then the other.

Other Uses of Pendulums

Child Development/Cognitive Development

The pendulum was used by the Swiss psychologist Jean Piaget in investigations of the cognitive development of children. This involved testing the children's knowledge of the physical world by observing their understanding of the laws governing the motion of a simple pendulum. The pendulum test has been used in several investigations to identify the onset of formal operational thinking in children.

Divination

Pendulums are often used as a so-called divination device or tool in unscientific methods of searching for subsurface water, minerals, or other hidden materials. In a process sometimes known as dowsing, a forked twig or pendulum is often used as the "dowser" or "divining rod." Reportedly, this was first practiced in Europe during the Middle Ages. Although it is not widely recognized by science, dowsing has been used commercially and in archaeology. In particular, dowsing with a pendulum is sometimes called *radiesthesia* and is used in many fields, including alternative medical diagnosis, and in the location of missing persons or objects.

Hypnosis

Pendulums are sometimes used as tools to induce the so-called altered state of consciousness characteristic of the hypnotized subject. The use of a swinging pendulum to bring about a trancelike state is well known in popular culture.

Impact of Pendulums

The pendulum has played an important role in the development of science, culture, and society. Indeed, the developments in timekeeping and watchmaking that were made possible by the pendulum were so significant that the century from 1660 to 1760 is referred to as the British horological revolution. The pendulum provided the world with the first accurate measure of time. The accuracy of mechanical clocks went from within half an hour a day to a few seconds per day in just a few years. This dramatic increase in the accuracy of measuring time enabled new types of accurate measurements in fields as diverse as astronomy, navigation, and mechanics. Certainly, accurate measurement of time led to the determination of longitude. Because latitude was already known, the accurate mapping of the earth was made possible. Some believe that the British horological revolution, which began with Huygens's invention of the pendulum clock, played a major role in Britain's supremacy at sea and may have led to the industrial revolution in Britain.

The pendulum also played a key role in establishing many laws of motion in physics, including the collision laws. It was used to determine the value of the acceleration due to gravity *(g)*. By using the pendulum to determine the variation in g at different parts of the earth (specifically at the poles and equator), it was possible to deduce the earth's shape. This led to the creation of the science of geodesy.

Foucault's pendulum provided evidence for the rotation of the earth on its axis and also played a role in the popularization of science in the 19th and early 20th centuries. The many significant scientific and social developments that occurred because of the accurate measurement of time that became possible with the advent of pendulum clocks are the subject of several published works.

Jennifer Papin-Ramcharan

Perception

When considering the concept of time perception, we must first ask the following question: Is it right to talk about perception when dealing with time? We must, in this context, remember James J. Gibson's remark to the effect that time, as such, is not a distinct stimulus and note that no one has so far discovered a sense or sensory organs that function directly to process time-related stimuli, nor do we know much about the information we use in the process that eventually generates a sense of duration. We know that there is a relationship between certain hormones, such as melatonin and dopamine, and the activities of some biological pacemakers, but this does not by a long stretch amount to a definition of *time perception.* Strange as this hiatus in our knowledge may seem given the crucial role of time in the adaptation of any living organism, we cannot as a result talk about time as we do about visual, auditory, or tactile stimuli, for instance.

Let us remember that the term *perception* refers to the process whereby a stimulus in some form of physical energy reaches dedicated sensory organs, in which, then, a process takes place that translates the energy into neural signals. These signals, in turn, reach a certain brain area via the nervous system in which they are decoded in order to create a sensory experience. Even though brain research has been making progress in the identification of brain areas associated with time-related processes, it is still wholly impossible to describe a perceptual track for the creation of time-related experience. So far, the research for a clear, stable, and meaningful connection between the pace of activity of any type of biological pacemakers or of any cyclical biological activity such as, for example, daily temperature fluctuations, on the one hand, and the properties of duration estimations of events, on the other, has been in vain. Thus for instance, research conducted in "time-free" environments, where individuals are located in deep caves or isolated bunkers without any connection to the world and with no way of obtaining external information so that, in estimating duration, they have to rely exclusively on their internal senses, did not succeed to find a significant relationship between, say, the circadian rhythm and duration estimations. Given this situation, many researchers tend to assume that the sense of time is a product of information processing or a cognitive process that utilizes information from various sources, at least while speaking of humans. If this, indeed, is the case, then it would be more adequate to talk in terms of a process of time estimation or judgment rather than of "time perception." We will, nevertheless, continue using the latter notion, but taking account of its above explained meaning.

We should also remember that the experience of time has a number of dimensions, the most prominent of which is that of duration, but which also include the order of events in time, simultaneity of events as opposed to successiveness, perception of rhythm, and more. Most of the research is concerned with duration, and hence we shall focus on it below and more particularly on prospective time judgment of short—seconds or minutes long—durations in humans. The reason for this focus is that prospective duration judgments of short intervals resemble the "perception" notion much more than duration judgments of long intervals or perception of other temporal dimensions. Temporal order perception, for example, is not determined solely by the discriminability of two events' duration but, to a large extent, by the meaning of the stimuli. Long durations, unlike short ones, are related to long series of events that are not simply an integral property of a single event, and the processes involved in experiencing and remembering the duration of a series of events are probably consciously controlled. This is not the case regarding brief durations, where duration information may be assumed to be an integral part of the experience of a single event

Psychophysical Properties and Sensitivity of Time Perception

Due to the high dependency of time perception on contextual factors and on stimuli's parameters, it is not easy to portray a clear-cut and simple picture of the psychophysical properties or of the sensitivity of time perception. Hence, only a general description is outlined in this section.

If an event lasts for less than a few milliseconds, it is perceived as instantaneous and without duration, but if, for example, two auditory stimuli are presented dichotically with an interval greater than several milliseconds between onset times, successiveness will be experienced. This is the case regarding the auditory modality, which is the most sensitive of all modalities to time. The sensitivity to time is lower in the visual modality. For example, if two binocularly presented stimuli occur with an interval of about 44 milliseconds or less between the onset times of the two, they are perceived as a single stimulus. However, if two 100-millisecond visual stimuli strike spatially adjacent receptors on the retina, an apparent movement from one position to the other will be experienced when the interval between the onsets of the two stimuli is as short as 3 to 10 milliseconds. A different experience of a flicker will be reported if the two stimuli strike the same retinal receptor. Successiveness will be experienced, in dependence on stimuli's parameters, only when the interval between the onsets of two 100-millisecond stimuli is longer than 120 milliseconds. This indicates that two successive stimuli can be discriminated reliably as separate events only if they are at least 20 to 25 milliseconds apart. Stroud (1995) suggested that psychological time is not a continuous dimension but rather consists of discrete chunks, called "perceptual moments," that are the psychological units of time. He estimated that the duration of a psychological moment is about 100 milliseconds. Other researchers estimate this duration to be 30, or 60 to 70, milliseconds in length. In any case, the psychological moment notion suggests that its duration should be the shortest possible perceived duration, an idea supported by the visual masking phenomenon. Most studies report that only beyond the range of 100 to 150 milliseconds will people be able to discriminate time intervals as being of different durations.

Judgments of time periods in the range from about 500 milliseconds to a few minutes tend to be monotonously and linearly related to objective durations with a slope of about 1.0, or in other words, duration estimates are a power function of actual duration with an exponent slightly less than 1.0.

Judgments of duration usually vary approximately up to 10 percent around the mean. However, it was found that accuracy can be significantly improved by extended practice.

The Impact of Sensory Modality

Psychophysical studies demonstrate modality differences in time perception. In both absolute judgments and discrimination tasks, people typically estimate auditory stimuli as longer than visual ones. Evidence from electrophysiological studies revealed greater sensitivity to duration in the auditory than in the visual modality.

The Impact of Contextual Factors

Duration estimations involve processes that are highly sensitive to contextual factors. A major contextual factor is the duration estimation paradigm. Estimating short durations is called *prospective* if a person knows before the beginning of a target interval that its duration should be estimated, and *retrospective* if a person is not aware of the need to estimate duration until the target interval has ended. Block differentiated between *experienced* and *remembered* time in relation to the two paradigms, respectively.

It was J. J. James who asserted that duration in passing lengthens when one pays attention to the passage of time itself, but duration in retrospect lengthens as a function of the complexity of the memories that the time affords.

Indeed, the ability to pay attention to the passage of time under prospective conditions is a major distinction between the processes that underlie timing in the two paradigms. A 1997 meta-analytic study revealed that there are some fundamental differences between duration estimations under prospective and retrospective conditions. For example, prospective judgments are longer than respective retrospective judgments in about 16% of all cases and tend to be more accurate. In both cases the judgments tend to be underestimates of objective durations. A major difference between the two paradigms is revealed when the nontemporal information processing load is manipulated during a target interval. Whereas retrospective estimates lengthen as the amount of nontemporal information increases, prospective estimates shorten as the nontemporal information processing load increases. Such fundamental differences imply that somewhat different mechanisms subserve duration judgments under prospective and retrospective conditions.

Models of Time Perception

Models of time perception vary according to the type of timing mechanism suggested.

Whereas time perception of very brief durations is grounded primarily in models of biopsychological and sensory-perceptual processes, the experience of time regarding periods in the range of seconds and minutes seems to be a manifestation of temporal information processing. This realization occurred only after it was recognized that the experience of time cannot be explained solely in terms of biological pacemakers.

Types of Duration Judgment Models

Models of duration judgment can be classified as models with and without an internal clock mechanism. Models that do not incorporate the notion of an internal clock are based on some sort of a neural or cognitive mechanism that is able to represent the passage of time. Neural-network models are one example. These models do not assume any dedicated circuit or area for encoding duration. Rather they rely on de facto neural activation responding to stimuli in order to represent its temporal features.

Some of these models assume that the activity of some neural nets in the brain can represent a certain time interval by the state of the neural net itself. This time interval can later on be reproduced by reactivating the net until it reaches the former state. Other models propose that timing is based on the detection of simultaneous activity across multiple neural inputs or the detection of patterns of neural activity associated with a specific time interval.

Despite the appealing nature of neural-net and brain models, many researchers believe that models that do not include a timer of any sort are unable, at the present time, to account for many of the characteristics of temporal behavior, like its scalar properties.

Clock models assume the existence of a biological clock, a pacemaker, or a cognitive mechanism with the characteristics of a physical clock such as the regular and constant emittance of a pulse of signals in a constant pace.

Scalar Timing Theory (SET)

Scalar timing or scalar expectancy theory (SET) is usually considered to be the most completely developed model of timing. It was originally developed by behavioral psychologists like Gibbon and Church in order to account for animals' timing behavior, which is characterized by the ability to exhibit temporal judgments of a wide range of durations, as in the case of time-based schedules of reinforcement.

SET postulates an internal clock, a memory store, and a decision mechanism. The clock itself consists of a pacemaker, a switch, and an accumulator. The pacemaker produces pulses at regular intervals. The switch acts as a gate to the pulses and either passes them or blocks them from arriving at the accumulator, in which the pulses are counted. The operation of the switch can start and stop the timing of an event. Because the pacemaker produces pulses at a regular pace, the animal's internal clock measures time along a scale that is linear with objective time, and perceived duration is a monotonic function of the total number of pulses that were counted in the accumulator.

The two major properties of scalar timing are

1. mean accuracy, which implies that mean measures of time behavior vary linearly with respective objective time intervals, and
2. scalar property of variance, which implies that timing sensitivity remains constant as duration timed vary. This property can be considered to be a form of Weber's law.

Indeed, it was found that animal timing behavior reflects these properties.

Recently, some researchers, like Wearden, found evidence for both scalar properties in human adults and in children. The internal clock notion can also provide an explanation for the auditory modality dominance over the visual modality in temporal processing. It was assumed that the internal clock is running faster for auditory than for visual stimuli, and as a result more pulses are accumulated for similar objective durations in the auditory accumulator, and for this reason subjective time is perceived as longer in the auditory modality.

Cognitive Models of Retrospective Time Judgments

Most models of retrospective duration judgments are cognitive ones and do not incorporate a notion of an internal clock. These models are confined to memory processes. The basic idea behind such models is that retrospective duration judgment relies on retrieval of information, believed to represent the target interval, from memory. The models differ in the definition of the nature of that information, but all of them assume that retrospective duration judgments are a function of the amount of relevant information that was successfully retrieved. While Ornstein's storage size model does not specify the type of information, the contextual change model (Block) claims that estimates of durations are based on the number of changes observed during an interval, or in Fraisse's words, "Psychological duration is composed of psychological changes." The model assumes that alternating cognitive operations increases the sense of subjectively experienced change and in consequence increases the subjective experience of duration. An elaboration of the contextual change model is the segmentation model introduced by Poynter. The assumption here is that contextual changes are coded as significant markers that segment experience and provide subjective referents for the estimation of the passage of time. As a result, the more an interval is segmented by meaningful stimuli, the more its retrospective duration estimates increase.

The weakness of cognitive models of retrospective duration judgment without an internal clock is rooted in its inability to provide an explanation for empirical findings, which show that under constant conditions, retrospective duration estimates are linearly correlated with objective durations. Note that even a completely "empty" interval will not be retrospectively estimated as a "duration-less" interval. In order to account for this property of retrospective duration estimates, Zakay suggested that retrospective duration experiences reflect some sort of an integration between the output of the memory retrieval process with the output of some internal clock mechanism.

Cognitive Models of Prospective Duration Judgment

Under prospective conditions, a person may intentionally encode temporal information as an integral part of the experience of the time period. Due to this characteristic, most models are relying on some sort of an attentional process in order to account for prospective duration judgments.

Models that do not assume the existence of an internal clock posit the existence of a cognitive counter that may be viewed as a processor of temporal information. The counter is incremented as a function of the amount of temporal information being processed, which depends on the amount of attentional resources allocated to it. The more attentional resources allocated for timing, the more units of temporal information are being processed and the higher the experience of prospective duration will be. Because timing competes constantly with current nontemporal tasks for attentional resources, the end result is that when one has to prospectively judge the duration of an interval during which an easy nontemporal task has to be performed, the prospective duration estimate will be higher as compared with a similar interval during which the performance of a difficult nontemporal task is required (see Time, Illusion of). The weakness of attentional models without an internal clock is that the definition of temporal information and the meaning of allocating attentional resources for temporal information processing are vague and unclear. These models are also unable to provide strong support for scalar properties of prospective duration judgments. In order to cure this situation, Zakay and Block introduced the attentional gate model (AGM), which is an elaboration of SET.

What is added to the components of SET is an attentional gate, which is a unit that enables more pulses from the pacemaker to pass through to the counter when more attentional resources are allocated for timing and that reduces the number of passing pulses when the amount of attentional resources is reduced. Thus, according to the AGM, allocating attention for temporal information processing means opening the attentional gate wider, and temporal information processing consists of accumulating and counting the number of pulses emitted by the pacemaker.

Thus, the AGM provides an explanation for scalar properties of prospective duration judgments while enabling us to take an evolutionary perspective on the development of timing mechanisms in humans.

Conclusions

It can be concluded that time perception in humans is a complex cognitive activity rather than a real perceptual process, except for very brief durations of less than 1 second. Subjective time in the context of intervals longer than 1 second can be understood only by taking into account complex interactions among all the relevant contextual factors in both the internal and in the external environments within which duration is being judged.

At the moment it seems that models that incorporate the notion of an internal clock poses better explanatory power regarding the variety of timing phenomena, in both animals and humans, as compared with models without an internal clock.

It is plausible, however, that models based on brain mechanisms that do not operate in a clock-like manner will be able, in the future, to surpass the former type of models and will have higher explanatory power.

Permian Extinction

After more than 100 million years of relative stability during the Carboniferous and the Permian eras, this last period ended 251 million years ago with the largest extinction event in the Earth's history. This biotic crisis is known in paleontology as the Permian-Triassic (P-T) boundary extinction event, sometimes popularly called the Great Dying. It was more devastating than the much more famous K-T boundary extinction event, when the dinosaurs were extinguished. It has been estimated that as many as 52% of families and 90% to 95% of species were lost, far more than were lost in the K-T extinction, in which 11% of families and 75% to 80% of species were extinguished. Some authors have considered that perhaps 99.5% of individuals died as a result of the event. The primary marine and terrestrial victims included the fusulinid foraminifera, trilobites, rugose and tabulate corals, blastoid echinoderms, acanthodians, placoderms, and pelycosaurs, which did not survive beyond the P-T boundary. Other groups that were substantially reduced include the bryozoans, brachiopods, nautiloids, ammonites, sharks, bony fish, crinoids, eurypterid arthropods, ostracodes, and echinoderms. Terrestrial fauna affected included insects, amphibians, reptiles, as well as the dominant terrestrial group, the therapsids (mammal-like reptiles).

During the Carboniferous and Permian, life flourished with crinoids, nautiloids, and ammonites. Corals and fishes dominated the oceans, and amphibians and reptiles progressively invaded the terrestrial environment. This scenario changed in the end of the Permian due to causes that still are under debate. Many causes have been proposed, including meteorite impacts, volcanic activity, glaciations, and fluctuations in sea level. It is known that the formation of the supercontinent Pangea occurred in the Permian, collecting all the earth's major landmasses; that it extended from the North to South poles, and that it caused an effect on ocean currents. These large continental landmasses created climates with extreme variations of heat and cold (continental climates), and the deserts were widespread on Pangea. One of the first scenarios proposed for explaining the Late Permian extinctions was the reduction of shallow continental shelves as a result of the formation of this supercontinent. Such reduction would cause an ecological competition for space, acting as an agent for extinction. In fact, it is suggested that the marine environment was more affected than the terrestrial one, estimating that more than 95% of marine species and only 70% of land species became extinguished. Although this is a viable hypothesis, it is known as the formation of Pangea and the putative destruction of the continental shelves occurred in the Early and Middle Permian—that is, unrelated to the Late Permian mass extinction.

A second possible mechanism for the Permian extinction was severe climatic fluctuations produced by concurrent glaciation events on the North and South poles, and subsequent sea level changes. There is sedimentological evidence of significant cooling and drying in temperate latitudes, such as thick sequences of dune sands and evaporites, and prominent glaciation in the polar latitudes, such as glacial tillites.

The hypothesis for the Permian extinction most broadly accepted by paleontologists posits an increase in volcanic activity. There is abundant evidence that massive flood basalts from magma output contributed to rapid climatic turnovers and environmental stress. A massive eruptive event spanning the Permian-Triassic transition, about 252 to 250 million years ago, formed the famous Siberian Traps, a large igneous province in Siberia that covered over 200,000 square kilometers. Extensive pyroclastic deposits suggest that numerous large explosive eruptions occurred during or before the eruptions of basaltic lavas. The combination of a worldwide ash cloud and sulphates in the atmosphere might have initiated sudden climatic changes. Dust clouds and acid rain might have disrupted photosynthesis and caused the collapse of the food chains, triggering the P-T mass extinction. Later, the carbon dioxide emitted by the Siberian Traps eruptions caused the possibly cyclical climatic warming (greenhouse effect).

The main challenge to this hypothesis is the need to prove that the emissions of dust and aerosols were enough to explain the extinction event. Estimations suggest that the Siberian Traps eruptions occurred within a period of no less than 200,000 years, doubling the atmosphere's carbon dioxide content and raising global temperatures by 1.5° C to 4.5° C. This seems to be insufficient to explain the P-T extinction, but the greenhouse effect might have exponentially increased due to the release of methane from oceanic methane hydrates trapped in deep-sea sediments. Carbon isotopic analyses suggest giant methane hydrate gasification across the P-T boundary, and oxygen isotopic analyses indicate that global temperatures increased by about 6 °C near the equator and therefore by more at higher latitudes. Methane is a greenhouse gas about 62 times as powerful as carbon dioxide. Because the stability of the methane hydrates depends on temperature, it is possible that a light deep-sea warming caused a giant transfer of methane from oceanic hydrates to the atmosphere, increasing the greenhouse effect and triggering the P-T extinction event.

There are questions as to the velocity of the extinctions during the Late Permian event, because some specialists consider that those extinctions were compatible with a more gradual mass extinction model and with the gradual volcanic theories. However, other studies indicate that the extinctions occurred very abruptly, consistent with a catastrophic, possibly extraterrestrial, cause. These data suggest that an impact event (asteroidal or cometary) accompanied the P-T extinction event, as was the case for the K-T boundary event. P-T boundary impact evidence has been reported, including chondritic fragments in Antarctica, shocked quartz, fullerenes trapping extraterrestrial noble gases, and several potential impact craters: the 120-kilometer-diameter Woodleigh crater (western Australia), the 250-kilometer-diameter Bedout crater (northeastern coast of Australia), and even the giant 500-kilometer-diameter Wilkes Land crater (Wilkes Land, Antarctica). It has been suggested that the large-scale volcanism in the Siberian Traps was triggered by some of these impacts. Nevertheless, for all proposed craters, the size, impact origin, and precise age of the impacting object have not been yet completely demonstrated.

Therefore, the real initial cause for the Permian mass extinction event is under debate. At present, the most broadly accepted hypothesis considers a multicausal scenario including climatic cycles between glacial and greenhouse conditions, volcanic eruptions, dissociations of methane hydrate, and probable meteoritic impacts.

Petrarch, Francesco (1304–1374)

Francesco Petrarch (Petracco) was an Italian poet and scholar widely recognized as the "father of humanism." He revived European interest in the knowledge of antiquity through his writings and collection of ancient texts.

Petrarch marks a transition in time from the Middle Ages to the Renaissance. Deeply critical of the neglect that ancient texts received in Europe during the Middle Ages, he sought to personally collect and translate ancient writings, visiting monasteries and churches around Europe. Were it not for his work, the Latin writing of ancient historians such as Cicero might be largely unknown today. Petrarch thus preserved the historical record for future generations. He referred to the centuries after the fall of Rome as the Dark Ages and personally laid the foundation for the rebirth of learning now known as the Renaissance.

Petrarch was born in Arezzo, Italy, on July 20, 1304. His family moved to Avignon in 1309 in support of Pope Clement V and the Avignon papacy. Petrarch studied at Montpellier and Bologna where he developed an interest in Latin literature. Following his studies he held various clerical posts and devoted much time to writing. His first major work, *Africa,* is a Latin epic about the Roman general Scipio Africanus. Petrarch considered this his greatest work, revising it throughout his life. His other Latin works include *De Contemptu Mundi,* an imaginary dialogue between the author and Saint Augustine, and *Itinerarium* (1358), a guide to the Holy Land. Petrarch saw no contradiction between humanism and faith, expressing his own religious faith in *De Vita Solitaria,* in praise of monastic life.

Petrarch wrote hundreds of poems in Italian. Most of these are compiled in his famous *Canzioniere,* a book of songs. In these poems, which consist primarily of sonnets and odes, Petrarch expresses his devotion to a beloved woman named Laura. He pursued Laura until her death and afterward wrote of her as a guide to God. Petrarch achieved great fame with his *Canzioniere.* In 1341 he was crowned as poet laureate in Rome. This tribute is often cited as marking the transition to the beginning of the Renaissance period, as Petrarch was the first poet in centuries to have received the honor. He traveled widely throughout Europe on diplomatic missions, befriending both Dante Alighieri, author of the *Divine Comedy,* and Giovanni Boccaccio, author of the *Decameron.* Together with the writings of these two prominent authors, Petrarch's writing helped to render the Tuscan dialect as the standard Italian language. He also maintained a wide correspondence, exchanging numerous letters with scholars around Europe. By his role in initiating the Italian Renaissance, Petrarch set in motion a series of revolutions over time that changed the course of world history. He has often been referred to as the first modern man.

Petrarch died on July 19, 1374, a day short of his 70th birthday. He is buried in Padua.

Philo Judeaus (c. 20 BCE–c. 50 CE)

Philo Judeaus, also known as Philo of Alexandria, was a Jewish philosopher born in Hellenic Alexandria, Egypt. His writings are a unique blend of Greek philosophy and Jewish teachings and are the only surviving manuscripts from the culture of Hellenistic Judaism. Philo's work reflects a deep concern with time and the meaning of life.

Philo's writing gives much insight into the experience of the Jews within the Roman world. He was a contemporary of Jesus of Nazareth but makes no mention of Jesus in his work. Philo does discuss Pontius Pilate, the Roman governor of Judea, as well as the Roman emperors Augustus, Tiberius, Gaius Caligula, and Claudius. Around 40 CE Philo was chosen by the Jews of Alexandria to lead a delegation to Rome to protest injustices committed against them. Philo was highly regarded within his community because of the wisdom and knowledge, as expressed in his extensive philosophical writings.

Little is known about the private life of Philo. Scholars believe he was born around 20 BCE to a wealthy and influential family in Alexandria. He later wrote negatively about affluence. Philo most likely received a traditional Jewish education as well as schooling in the writings of the Greeks. His writing shows the influences of Plato, Aristotle, and the philosophies of stoicism and cynicism. Philo's work can be divided into three general categories: (1) discussions of Jewish law, (2) popular works, and (3) philosophical essays. The discussions of Jewish law include Philo's *Allegorical Commentary on Genesis,* an interpretation of the Ten Commandments and the lives of the prophets. Popular works include the *Life of Moses,* intended for a wider audience. Philosophical essays consist of treatises on a variety of issues, such as *On Providence* and *On Animals.* Philo believed that the Torah contains both literal and allegorical meaning.

The Temple of Jerusalem still stood during Philo's lifetime and had great meaning to him. He made at least one pilgrimage there. He believed that Gentiles could not be excluded from Judaism and that Jewish teachings had universal application. Philo never departed from his strongly held Jewish beliefs, and he often serves as a bridge between the ideas of the Jews and the Greeks. Clearly the teachings of both the Jews and the Greeks have had a profound impact on the development of knowledge over time. Both schools of thought deal with the nature of humankind and its place in the universe. Philo's work stands as the most important link between the two.

The Jewish historian Josephus wrote an account of the delegation to Rome led by Philo. The emperor Caligula had ordered statues of himself as a god erected in the Jewish temples of Alexandria. The Jews naturally viewed this as a deliberate provocation. Philo met with Caligula directly, but the two did not find common ground. Scholars place the date of Philo's death around 50 CE.

Philoponus and Simplicius

The beginning or the eternity of the world and infinity or finitude of time is a central topic in the philosophy of late antiquity, especially in the debate between Christians and pagans. This quarrel started for the first time in the Neoplatonic school of Alexandria in the 6th century CE between John Philoponus and Simplicius, who were the philosophically most talented pupils of Ammonius Hermeiou. Simplicius preserved the orthodox Neoplatonic doctrine (Ammonius and his master Proclus always held to the eternity of the world), whereas the Christian Philoponus opposed this view. It is astonishing that the grammarian Philoponus (he called himself John the Grammarian and edited most of Ammonius's lectures on Aristotle's writings) argued without Christian presuppositions and personal disparagement; Simplicius, however, usually a very modest and well-educated philosopher, very rudely called Philoponus's arguments "rubbish" and accused him of "bragging and contentiousness." Obviously, they had never met personally (most probably, Simplicius had been working in Athens long before 529 CE, when the academy was closed by Justinian; Philoponus apparently never left Alexandria). Philoponus argued against the eternity of the world in his commentaries on Aristotle's *Physics* (probably written in 517 CE) and *Meteorology,* then in *On the Eternity of the World, Against Proclus* (*De aeternitate mundi contra Proclum,* written in 529 CE; this treatise refutes 18 arguments from a lost treatise written by Proclus about the eternity of the world). The writing *Against Aristotle* (*Contra Aristotelem*), which can be dated between approximately 530 CE and 534 CE, is preserved only in fragments. The first five books contained Philoponus's criticism of Aristotle's theory of the fifth element, the sixth book his criticism of Aristotle's theory of eternal movement, and at least two further books contained reflections about a Christian theory of divine creation. Simplicius's answer to Philoponus can be found mainly in his commentary on Aristotle's *De caelo I* and *Physics VIII.*

Philoponus attacks the eternity of the world by demonstrating inner contradictions in Aristotle's theory of time and eternity and by refuting Aristotle through Aristotle himself. One argument goes as follows: The eternity of the world is incompatible with Aristotle's definition of movement, because movement is the act of what is movable in potency, that is, the movable in potency exists prior to the movement. This implies that the eternal movements (e.g., the heavens' circular movements) have some movable in potency prior to them (e.g., the heavens), if the movable in potency is always anterior to the movement. Philoponus concludes that the Aristotelian definition of movement is not universal. Simplicius defends the universality of Aristotle's definition of movement by making a difference between infinite and finite movement: In the case of finite movement, the movable is still there, if the movement has finished; in the case of infinite, eternal movement, only one state of movement is prior to another state. For instance, if the sun is in Aries, then it is the movable, which is potentially in Taurus.

Further, if any first movement is excluded, Philoponus argues that all present movements become unintelligible, because every movement presupposes an infinite number of previous movements; we could not avoid a *regressus in infinitum*. Moreover, all present movements are added to those of the past; that leads to the evidently absurd notion of an infinite constantly increasing. The same problem arises concerning the future: If time and movement infinitely continue in the future, there would be an infinite body with infinite power. But that is not possible, so the world could not exist indefinitely in the future. The core of this argument is Philoponus's attack on Aristotle's notion of infinity: Aristotle contends that infinity is merely potential and never actual. For if you divide a line or a duration, you can actually mark off only a finite number of divisions, either physically or mentally. There is only a potential infinity of divisions, inasmuch as infinity exists through a process of dividing one point (or one now) after another; it is the same with the infinity of numbers.

Philoponus attacks this notion of infinity by several arguments. First, the universe must have had a beginning, or it would by now have traversed an actual infinity of years. The second argument is this: If you suppose an actual infinite number of years up to this year, next year will be an infinity plus one year. So the infinity is increasing. Simplicius says Aristotle had already anticipated Philoponus's objections, for he had pointed out that the past years have finished, so you do not get an actual infinity of them existing. That implies that time and movement are not an actually infinite quantity, but their infinity means there is a possibility of transcending every given limitation. The most fundamental difference between Philoponus and Simplicius is this: Whereas, Simplicius's infinite time is a circular indefinite repetition of finite times, Philoponus's notion of time is linear. However, the rejection of Philoponus's argument appears difficult in the context of Aristotle's philosophy of nature if you want to preserve the singularity of the individual parts of time, for instance, days or hours.

Philoponus's arguments against the eternity of the world were repeated by Bonaventure in the 13th century, after the arguments had been elaborated by Islamic philosophers. Finally, the dispute between Philoponus and Simplicius has an equivalent in Kant's doctrine of the "antinomy of pure reason" in his *Critique of Pure Reason,* especially the "first conflict of transcendental ideas." One branch of the antinomy is equivalent to Philoponus's argument (in Kant's words, "The world has a beginning in time"); this and the opposite argument ("the world has no beginning in time") is equivalent to Simplicius. Probably, there is not any "immediate effective historical connection" between the Alexandrian school quarrel and Kant's cosmological antinomy, but it shows that in this quarrel, "Greek thinking comes to the limits of its own presuppositions."

Philosopher's Stone

The philosopher's stone is a substance, tincture, or item created through alchemy that is supposed to change base metals into more precious ones and has the ability to extend one's life, cure sickness, and even grant immortality. Western traditions of alchemy are more closely associated with the concept of the philosopher's stone; the Eastern traditions of alchemy were more closely associated with the concept of the elixir of life.

Europeans probably discovered Islamic alchemy following the influence brought about by the Crusades. Islamic alchemy has its roots in Alexandria, which combined various traditions of both Greece and Egypt. The Western traditions were much more involved with the idea of changing base metals into higher or noble metals (gold or silver from lead) with longevity as a secondary effect. That is not to say that there was no interest in longevity, but that wealth was the primary motivator for many alchemists in Western Europe.

There were some European alchemists, however, who pursued the aspects of longevity as well as those of healing. Paracelsus (1493–1541) was both a physician and alchemist, using alchemy to cure the sick and pursuing the art in a different manner than others before him. He was one of the first to separate the pursuit of transmuting metals (*alchemia transmutatoria*) from that of healing (*alchemia medica*). Paracelsus is also considered the founder of toxicology. He died at the age of 48, possibly of cancer, somewhat young for one devoted to pursuing longevity and healing.

Another well-known alchemist associated with the philosopher's stone is Nicolas Flamel (1330–1418). He began a career as a scrivener but found a small book on alchemy that he wanted to understand and began his career as an alchemist. Several books are attributed to him and describe his pursuit of the philosopher's stone, but many scholars now believe that some of these works were written later by others to lend legitimacy to the field of alchemy and the pursuit of longevity. There are myths surrounding the death of Flamel and his wife; notably, the legend that he did not die but faked his death and is still living today on his discovery of the philosopher's stone. Again, these legends are attributed to those who want to add to the legitimacy of the field of alchemy.

As with the Eastern tradition of alchemy, the Western tradition became more and more philosophical or transcendental. The idea that the transmutation of a human was less a physical process and more of a spiritual exercise, and not achievable through any physical process, became important as the role of science became more prevalent. Scientists continued to make discoveries regarding the immutability of metals and, by extension, humans also could not physically transmute. Therefore, they had to do so internally, through mysticism, philosophy, or some other transcendental means.

In one respect, Nicolas Flamel and others have achieved a kind of immortality. As seen in some of today's popular media (e.g., the *Harry Potter* movies, and the *Da Vinci Code* novel by Dan Brown), Flamel has lived on, although not in the way he intended.

PHI PHENOMENON

The phi phenomenon is a type of apparent movement or an illusion of movement. It is also known as *stroboscopic movement.* In fact the phi phenomenon consists of three types of apparent movement: beta, gamma, and delta movements. For reasons of space, we shall elaborate only on the first, the beta movement. As in the case of the tau and kappa illusions, the phi phenomenon illustrates the complex nature of the interrelations between the perceptions of movement, distance, and time.

The apparent movement occurs when two physically distinct stimuli—say, two light points—are alternately displayed at a frequency that exceeds a certain threshold value. Under such conditions, a continuous movement from one stimulus to the other is perceived. The apparent movement's characteristics depend on a number of factors: the physical spatial distance between the two stimuli; the physical intensity of the stimuli, which determines the amount of energy reaching the relevant sensory apparatus in the perceiver; and the duration or time span between appearance of one stimulus and the next. If the distance and intensity factors are kept constant, then when the time span between the first stimulus and the second is approximately 20 milliseconds, this will result in a perceptual experience of simultaneity. When the time span is increased to approximately 60 milliseconds, this will result in a perception of continuous movement between the two stimuli. At approximately 200 milliseconds, the resulting perception will be of one stimulus followed by the next, without any movement between them.

By 1915, the psychologist A. Korte had defined the conditions for apparent movement as follows:

- If the intensity of stimuli is kept constant, then the time span needed for optimal apparent movement changes in direct proportion to the changes in distance between the stimuli.
- If the time span between stimuli is kept constant, then the required distance between them in order to generate optimal apparent movement changes in direct proportion to stimuli intensity.
- If the distance between stimuli is kept constant, then the stimulus intensity required for optimal apparent movement is inversely proportionate to the time span between the first stimulus and the second one.

Some researchers, however, have questioned the relevance of light intensity—in the visual case—for apparent movement.

Beta movement is a continuous apparent movement between two, closely adjacent static light points that alternate lighting up. Continuous movement is perceived when the frequency at which the lights go on and off exceeds a certain threshold value, which depends on the distance between the two light points. Some researchers believe that light intensity is a significant factor here as well.

Beta movement is used, for instance, on billboards that are actually made up out of tiny static light points: Each couple of adjacent light points switches on and off at an appropriate frequency and thus the flowing effect we are all familiar with is created.

Cinema is the ultimate application of the beta phenomenon. The audience is presented with projections of static images at a frequency that ranges between 12 and 24 images per second, and this is what creates the experience of continuous movement.

Another manifestation of beta movement is its tactile variant: This occurs when an apparent sense of movement is experienced between two adjacent locations on the skin when they receive alternating stimulations. Here, too, the felt quality of the resulting apparent movement will depend on factors of distance between the two locations, the time span between one stimulus and the next, and—according to some researchers—on stimulus intensity. The existence of the tactile phenomenon indicates that the phi phenomenon is a fundamental physical principle that is not specific to one sensory modality.

The first to describe the phi phenomenon was Max Wertheimer (1912), a Gestalt psychologist. The phenomenon served as early empirical evidence for Gestaltist psychologists' claim that perceptual experience cannot be explained by means of a one-to-one relation between proximal stimulus and sensory process. There is no fit, in the case of the phi phenomenon, between the perceived movement and the external physical stimuli, which are actually static. In the visual case, even though there is no motion of a retinal image, there is a perceptual experience of movement. And so, the basic argument of the Gestaltists is that a perceptual experience does not constitute a simple mapping of the external stimulus. Perceptual processes, in fact, reflect rules of perceptual organization that the perceptual system imposes on the external stimulus.

The phi phenomenon has not been fully and exactly explained to date. Explanations relating to the visual variant refer to the persistence of vision and to the existence of a degree of temporal overlap in the activity of adjacent receptors on the retina.

Persistence of vision occurs as a retinal image continues to exist for one sixteenth of a second after the disappearance of an external stimulus. Hence, if a second stimulus occurs, creating a retinal image on an adjacent receptor within that time span (i.e., within less than one sixteenth of a second), what emerges is a temporal overlap between the activities of the two receptors. This then leads to the emergence of the perception of apparent movement.

Photography, Time-Lapse

The purpose of using time-lapse photography is to speed up events that normally take considerable time. A simple example is the opening of a flower. In a sense, it is just the opposite of the process used in creating slow-motion pictures. Both processes involve a technique for intentionally altering a normal duration of time in order to learn more about the subject by closer examination. But, whereas slow-motion focuses only on the specific subject being filmed at the time, time-lapse photography can record processes that in real time take or months or years to be completed. With both techniques, humans are able to effectively manipulate time for their own practical or artistic purposes.

In time-lapse photography, the photographer takes a sequence of pictures at a slower rate than the standard 24 frames per second used by the movie industry. The special skills needed to perform time-lapse photography include being able to discern how much time should be allowed to lapse between each photograph being taken, so as to record discernable changes that are occurring. Time intervals may need to be adjusted depending on the particular changes the subject is undergoing, but the process will usually involve taking individual pictures over 24-hour periods for as long as is needed to record the entire process. The effects of both temperature and light must also always be considered.

John Ott is generally considered a pioneer in time-lapse photography. What began as a hobby in his high school days in the late 1920s developed into a career in which his skills became influential. Because this type of photography was relatively unexplored, he had to use whatever equipment was available and to devise improved equipment himself until he was satisfied that he was photographing subjects in their most realistic setting. Starting with a Brownie camera and a timer made from kitchen clock works, he eventually built an automatic plastic greenhouse. He developed the ability to take microscopic pictures, as well as a process known as "total spectrum lighting."

Ott witnessed growing interest in uses of time-lapse photography beyond entertainment and advertising, such as applications in horticulture and medicine. He received numerous honors, including an honorary degree from Loyola University, and eventually became a faculty member in the Department of Horticulture at Michigan State University. He worked as a researcher for various companies, including Quaker Oats and General Electric.

In working with Walt Disney on the film *Secrets of Life,* which was to include a segment on the growth of an apple, Ott discovered that ordinary glass would not transmit all the ultraviolet and shorter wavelengths needed to accurately record the normal process. He was finally able to complete the assignment by substituting special plastic materials.

In his film *Our Changing World,* he wanted to depict the orderly progressions of earth and the creation of life and its development. The power of the single cell had always impressed him. He noted that humankind has been on earth a much shorter time than plants and that plants and animals tend to respond similarly to light.

Though Ott had said that his work was often slow and discouraging, his pioneering efforts were very impressive. His advances encouraged others to devise and use more sophisticated techniques and equipment. Those working with the process continued to emphasize the importance of correct lighting and determining the most appropriate time intervals between pictures.

Time-lapse photography has been used in many scientific studies, such as research on glacier motion in Glacier National Park, studies of sleep patterns, studies of slow-acting geologic processes in natural settings, studies of movement in plants, and studies of weather phenomena. In addition to exploring the natural world, there are also many other potential applications of time-lapse photography with respect to human activities, such as monitoring business projects and procedures, and studying the urban environment and urban renewal. An example of a successful project related to the urban landscape can be found in the work of Camilio Jose Vergara, a photographer, sociologist, and ethnographer. For 30 years he recorded the changes in inner-city neighborhoods in New York, Newark, Chicago, Detroit, and Los Angeles.

Perhaps one of the most dramatic uses has occurred at Ground Zero, the site of the World Trade Center disaster. Documentary filmmaker Jim Whitaker initiated Project Rebirth in the spring of 2002, with the goal of recording what was happening in this area. As the project continued, cameras were installed at all four corners and at ground level. Some results of the ongoing process are available on the Project Rebirth Web site. The process involves taking one frame every 5 minutes for 7 days a week; the final result will be viewable within a span of 20 minutes.

PHOTOSYNTHESIS

Photosynthesis is the process by which organisms convert light energy into chemical energy in the form of carbohydrates. The inputs of the chemical reaction are light energy, carbon dioxide, and water; the outputs are carbohydrates and oxygen.

The overall reaction, which has many intermediate steps, is written as follows:

$$\text{Light energy} + CO_2 + H_2O => (CH_2O) + O_2$$

The sun is the main source of light for the process. Photosynthetic organisms break down the bonds in the resulting carbohydrates to obtain the necessary energy for life-sustaining functions. Plants, algae, and some bacteria are the known organisms capable of photosynthetic activity. They all produce pigments, specialized proteins that capture energy when exposed to light. Numerous photosynthetic organisms have developed adaptations to regulate the timing of photosynthesis. By lengthening the time spent in photosynthesis per day or changing the time of day when photosynthesis occurs, organisms improve the efficiency of photosynthesis and their ability to survive.

Locations and Functions of Pigments

The location of pigments in photosynthetic organisms depends on whether the organism is prokaryotic (does not have a cell nucleus or organelles) or eukaryotic (has cell nucleus and organelles). The prokaryote *Halobacterium halobium* and other photosynthetic bacteria have pigments embedded in their cell membranes. Prokaryotic blue-green alga has pigment proteins inserted in a more complicated system of stacked membranes interior to the cell wall. Higher plants, such as needle-leaved plants and flowering plants, have a specialized organelle for photosynthesis within the plant cell, the chloroplast. The double-membraned organelle contains photosynthetic membranes that are embedded most commonly with the pigments, chlorophyll-a and chlorophyll-b.

Pigments are essential to photosynthesis, because they can absorb energy from photons, the units of light energy. Each pigment absorbs a characteristic wavelength, which is a stream of photons. For example, chlorophyll-a absorbs wavelengths in the range between 550 and 700 nanometers (nm, 1×10^{-9} meter), and bacteriochlorophyll-a in bacteria absorbs wavelengths between 470 and 750 nanometers.

Pigments efficiently absorb energy because they contain chemical bonds that accommodate fluctuating levels of energy. The characteristic carbon rings in pigments include many double bonds. Carbon atoms joined by double bonds share their electrons; thus the electrons are not strongly attracted to a particular carbon nucleus and move in a loose cloud around the entire molecule. When photons strike a pigment, their energy is accepted by the pigment's electrons, which can easily move from a lower energy level to a higher one in the cloud of electrons. Chlorophyll-a has five carbon rings with a total of 10 double bonds, making it an excellent acceptor of energy from light. The pigment can either donate the energized electrons to other molecules or release the energy from the electrons as longer wavelengths than those the pigment absorbed.

Structures in Photosynthesis

Organisms have structures in their photosynthetic membranes called *reaction centers* and *antennae,* respectively, both of which are necessary for photosynthesis to occur. The reaction center is composed of the unique pigments capable of initiating the chemical reactions of photosynthesis by donating electrons to molecules within cells; the pigments are bacteriochlorophyll-*a* in bacteria and chlorophyll-*a* in algae and plants. Scientists have identified special forms of these chlorophylls that are responsible for the actual work of changing light energy into chemical energy in the reaction centers. The chlorophylls are P870 in bacteria and P700 and P680 in algae and plants, where P stands for pigment and the number refers to an absorption wavelength. However, the specialized chlorophylls cannot absorb enough light energy on their own to drive photosynthesis; they are fed energy by the antennae.

The antenna structure in membranes is the locus of light energy absorption and concentration. It is composed of accessory pigments that generally can absorb shorter wavelengths than P680, P700, and P870 can. Examples of accessory pigments are bacteriochlorophyll-*b* (absorbs 400 nm–1020 nm wavelengths) in purple bacteria and chlorophyll-*b* (absorbs 454 nm–670 nm wavelengths) in higher plants. Accessory pigments capture light energy and then release it to other accessory pigments or chlorophylls in the antennae as longer wavelengths, but these accessory pigments are not capable of donating electrons to other molecules. The accessory pigments pass along longer wavelengths to each other until the waves reach a length that can be absorbed by the specialized chlorophylls in the reaction center.

A substantial number of accessory pigment proteins are needed to feed a reaction center with enough light energy to drive photosynthesis. Over 300 molecules of chlorophyll-*b* are needed to funnel enough light energy to activate one molecule of chlorophyll-*a* in the reaction center of a typical higher plant.

Adaptations in Photosynthesis

Photosynthetic organisms are capable of making photosynthesis more efficient by regulating the time spent in photosynthesis per day or changing the time of day when photosynthesis occurs. Some higher plants can change their leaf position over the course of a day to track the sun's movement. This adaptation allows the plants to increase the number of hours per day spent in direct sunlight and maximum light absorption. Experiments have confirmed that this behavior, called *diaheliotropism,* increases the efficiency of photosynthesis.

Plants that live in hot, dry climates, such as cacti, have developed an adaptation of photosynthesis that allows parts of the process to occur at a different time of day than in the majority of plants. Generally, all steps of photosynthesis occur during daylight, including the intake of carbon dioxide through stomata, which are openings in the leaves of plants. The majority of plants take in carbon dioxide and initially fix the carbon into a compound called 3-phosphoglycerate. However, plants in hot, arid regions lose water at a high rate when the stomata are open, so many have developed crassulacean acid metabolism (CAM) to avoid dehydration. CAM plants open their stomata only at night, initially fix carbon dioxide into malic acid, and then store the acid. During the day, CAM plants close their stomata, break down the malic acid to release the carbon dioxide, and then proceed with photosynthesis. The CAM adaptation makes it possible for plants to withstand long periods of drought.

Phylogeny

A phylogeny is an evolutionary history of an organism or group of organisms; it may be interpreted as a genealogical tree, an ancestor and descendant lineage, or as systematic relationships of form within a classification scheme. Phylogenies are studied principally in the fields of phylogenetics and systematics.

History of Phylogenetics

Phylogeny was discussed in detail by the 19th-century German morphologist Ernst Haeckel, who proposed a biogenetic law (or the law of recapitulation). The biogenetic law states that phylogeny, or the evolutionary history of an organism, is recapitulated through its ontogeny, or the development of an individual organism in embryo. The subsequent rejection of Haeckel's law was a significant move away from using mechanical explanations or causes, such as embryonic development, to explain the relationship between organisms. Haeckel's most significant contribution was that of the phylogenetic tree (*Phylogenetisches Stambaum*), the now universally accepted way to depict genealogical relationships.

A phylogenetic tree may depict hypothetical ancestor-descendant relationships, sometimes called a *transformation series,* between groups of organisms (species, genera, and families) or their characteristics, through time. Such phylogenetic trees have been popular tools of paleontologists who use them to establish so-called ghost lineages between similar-looking fossils throughout the stratigraphic record. Phylogenetic trees were challenged in the early 20th century by the German-speaking systematic morphologists, led by Adolf Naef. The evolutionary relationships that phylogenetic trees were claimed to depict were based on linking similar-looking organisms that overlapped through time, rather than considering relationships of form.

The systematic morphologists considered *homologues* (different manifestations of the same morphological structure) to be a sounder basis for the discovery of relationship than the assembly of ghost lineages. If organisms are related, their characters are homologous, that is, the same; as opposed to analogous, that is, similar but not the same. Naef's trees related organisms only at the terminal branches, rather than depicting hypothetical lineages, with organisms (hypothetical or real) at both the nodes and tips. Homologous organisms belonged to "natural groups or classifications" that share a greater relationship among themselves than they do to any other group.

The rejection of phylogenetic trees and the concomitant support for natural groups was criticized by Anglo American phylogeneticists such as George Gaylord Simpson and Ernst Mayr, who defended the depiction of lineages in phylogenetic trees rather than the discovery of natural groups, which challenged some traditional taxonomic groups. Anglo American phylogenetics, however, changed considerably in the latter half of the 20th century when the work of Willi Hennig, a German entomologist, was translated into English.

Phylogenetic Systematics

Hennig's *Phylogenetic Systematics* attempted to resurrect Haeckel's systematic phylogenetics by reintroducing the causal mechanisms that had been rejected by Adolf Naef. Hennig's phylogenetic systematics combined Haeckel's transformational viewpoint—but at the level of character rather than taxon—with Naef's trees of relationships to form ancestor-descendant schemes of relationship with organisms only at the tips, and character transformations leading from the nodes to the tips. The resulting trees attempted to group homologous organisms into "natural" or monophyletic classifications based on a causal mechanism, thus combining Haeckel's phylogenetic tree with Naef's systematic morphology.

Phylogenetic systematics developed into a numerical method by incorporating the principal notion of *phenetics,* that is, similarity concepts, with a causal mechanism to find optimal trees.

Phylogenetic systematics, later referred to as *cladistics,* underwent a revolution in the work of Gareth Nelson by returning to systematic morphology. Pattern cladistics rejected causal homologies and ancestor-descendant relationships as uninformative and misleading, because they introduced bias into phylogenetics. The pattern cladists, led by Ronald Brady and Gareth Nelson, considered monophyly to indicate "natural groups," which can be used to test existing taxonomies rather than to identify causal relationships (a common ancestor). The resulting diagrams, called cladograms, could represent numerous lineages but only a single classification. Hennig's elimination of paraphyly and its connection made with ancestry by cladists such as Colin Patterson helped to define phylogenetics as a science of classification based on the relationships of form.

Molecular Phylogenetics

Molecular phylogenetics is the study of amino acid or DNA sequences and how they may be related among different organisms. The field has grown exponentially and amassed a significant volume of data. Unlike phylogenetic systematics, molecular phylogenies tend to consist of individual character trees (relationships between organisms based on a single character) and are used to hypothesize recent genealogies in populations as well as ancestor-descendant relationships in species. Despite its popularity, very little theoretical work has been done on the relevance of homology of DNA sequences. Molecular phylogenetics, however, has progressed methodologically and technologically in such issues as alignment of sequences and in mapping the similarity distances in phenetic methods.

Phylogenetic Classification

Phylogenies may be interpreted as explicit evolutionary pathways, natural groups (classifications), or a combination of both. The latter has caused the most controversy in its claim for phylogenetic classifications. Recent debate has focused on defending lineages rather than classifications in taxonomy. A *nonmonophyletic* group (also known as a *paraphyletic* or *polyphyletic* group) is an artificial or incongruous set that shares greater relationship to other groups than to its own. A proposed lineage may be paraphyletic and therefore contradict any given natural classification. Reptiles are an example of a paraphyletic group that exists in name only, not within a natural classification. The defense of paraphyletic groups in classification reflects the battle between the Anglo American paleontologists and systematic morphologists in the early 20th century, during which classification and hypothetical lineages were confused.

Phylogenetic Biogeography

Phylogenies have been used in biogeography (the study of biotic distributions) during three periods: in the late 19th century, with the advent of natural selection as a viable mechanism for species evolution (e.g., Haeckel); in the 1960s, with the onset of Hennig's phylogenetic systematics; and in the late 20th century, with the use of molecular phylogenies. The same method has been used in each of these periods, namely that of proposing a center of origin and drawing the direction of dispersal and/or vicariance events (allopatry) on a phylogenetic tree.

Since the late 19th century, fossils were used to date such events within any given phylogenetic tree. The method is still widely practiced today (i.e., using a molecular clock). The only difference between these periods is the data used. Nineteenth-century phylogeneticists relied on fossils, mid-20th-century phylogeneticists on the morphology of extant taxa, and 21st-century molecular systematists on molecular data.

Piaget, Jean (1896–1980)

Jean Piaget was a Swiss philosopher and psychologist whose principal research interests were in epistemology and developmental psychology. He believed that to understand knowledge, one must look at its psychological origins and how it evolves as children become adults. His research led him to the epistemological stance he deemed *constructivism*—the position that knowledge is constructed from experience over time.

During work in Alfred Binet's lab at the Sorbonne, Piaget noticed that children of the same age consistently made the same mistakes on intelligence tests. Later, after very careful observations of children during which he would ask questions or assign tasks to elicit behaviors that would give him insight, Piaget noted that children were organizing and reorganizing the world as they gained more experience. He concluded that children were not simply imitating or regurgitating what they were told or observed; they were creatively interpreting the world based on their past experiences at a fairly constant rate, which could be organized into stages.

According to Piaget, children proceed with this process of interpretation by constructing and revising gestalt-type schema, which allow for future recognition of patterns that have been experienced. With this view in mind, Piaget conducted experiments to determine specifically how the knowledge of time is constructed in children. His results are outlined primarily in *The Construction of Reality in the Child* (1937) and *The Child's Conception of Time* (1946).

These experiments led Piaget to conclude that children begin with an egocentric conception of time where duration (number of minutes, years, etc.) depends on speed of action—the faster one goes the less time one spends on an action.

Eventually children develop a distinction between duration and succession (past, present, future; before and after), which allows them to see that the flow of time is constant. For Piaget, the fact that children seem to move from special relations constituting the concept of time to the more complex notion of independent time flow showed that space was a more basic concept from which the concept of time is constructed.

Many have criticized Piaget's epistemology and conception of time. J. T. Fraser, a prominent author on time who debated Piaget, held that there must be some intuition of time in children. Later, other prominent authors critiqued Piaget for unwarranted generalizations and other experimental problems. However, his importance to the progression toward understanding time in psychology and philosophy is evident in his influence on such thinkers as Jürgen Habermas, Thomas S. Kuhn, and contemporary constructivist epistemologists, as well as reactions from such prominent thinkers as Noam Chomsky and Hilary Putnam.

Piltdown Man Hoax

In 1912, fragments of a skull and jawbone were found in a gravel pit at Piltdown, a village in East Sussex, England. When assembled, scientists believed the specimen to be the "missing link" between ape and human, providing solid proof of the theory of evolution. Forty years after its discovery, Piltdown man became exposed as the Piltdown hoax, one of the most notorious frauds in the history of science.

The Find

A laborer working in the Piltdown gravel pit in the early 1900s claimed to have found a piece of a skull. He passed it on to Charles Dawson, a local solicitor and well-known amateur archaeologist. Dawson found additional fragments at the site in 1911, and presented them to Sir Arthur Smith Woodward, keeper of geology at the British Museum. Interested in the finds, Woodward returned to the site with Dawson, where they recovered additional skull fragments and half of a lower jawbone. The same pit also produced a few fossil animal bones and a tooth. In December 1912, they presented their reconstructed skull to the Geological Society of London as a new type of early human, *Eoanthropus dawsoni,* or "Dawson's Dawn Man." The bone of the skull was unusually thick and stained with age, implying primitiveness, while having the shape and larger size of a modern braincase. However, the mandible associated with it was far more simian than human. This apparent ape-man found with the bones of extinct mammals in a Pleistocene gravel bed was exciting news for English paleontologists. Until that point, all fossil human remains had been found in various locations on the Continent, especially Germany and France. England could now claim a place on the evolutionary tree even earlier than these other hominids.

Additional finds were made at Piltdown through 1915, including additional animal bones, stone tools, and a second skull (also found by Dawson) 2 miles away from the original site. Interestingly, no more finds were made after Dawson's death in 1916.

The reconstruction of Piltdown man was challenged from its introduction. The hinge joining the jaw to the skull was conveniently missing, causing some experts to doubt that the skull and jaw were from the same individual. Others developed a completely different model from the pieces. In the 1920s, Franz Weidenreich, an anatomist, examined the specimen and reported that it was a modern human cranium and an orangutan jaw with filed teeth. He was correct, but it took 30 years for paleontologists to admit it. As more and more hominid finds were made around the world in the following years, including *Homo erectus* and *Australopithecus, Eoanthropus* was pushed aside.

Not only did it not fit into the increasingly clear evolutionary tree, but also no other specimen was ever found resembling it.

Exposure of the Hoax

Joseph Weiner, an anthropology professor at Oxford University, has been given credit for exposing the hoax. In the early 1950s, he attended a paleontology congress in London. Piltdown man was hardly mentioned once again, for not "fitting in." The possibility of fraud dawned on him. After meticulously gathering evidence, conducting interviews, and using recently developed tests on the bones themselves, he exposed the forgery in 1953. A new dating technique, the fluorine absorption test, was developed to determine age and had been applied to the Piltdown fossils in 1949. The results established that the remains were, in fact, relatively modern, but they were still assumed to be genuine. In 1953, with the fluorine test more advanced, the Piltdown remains were retested. It was determined that the cranium was from the Upper Pleistocene and approximately 50,000 years old, while the mandible and tooth were modern. Another new test devised by American scientists analyzed nitrogen content to determine age and corroborated these results. In 1959, however, the recently discovered carbon-14 dating technique was applied to the bones. The skull was shown to be between 520 and 720 years old, and the jawbone a bit younger.

Eventually it was proven that the Piltdown site had been salted with bones and artifacts from a variety of sources. The hoax had succeeded for 40 years due to a variety of circumstances. The find gave experts evidence supporting a theory they believed to be true at the time. The scientists closest to Piltdown were experts, but not in hominid evolution. In the early 20th century, there were no chemical tests or dating techniques. Analytical tools were primitive by today's standards. At the time of the find, there were no hominid fossils other than the earliest Neanderthal remains for comparison. Finally, the Piltdown bones were kept locked away in the British Museum as valuables, so most scientists wishing to study them had to rely on pictures, sketches, or poor-quality X-rays.

Identity of the Forger

The identity of the perpetrator has never been proven. The reason for the entire hoax is also debated. This hoax was deliberately and systematically carried out over a number of years with no obvious motive. About two dozen suspects have been suggested over the intervening years, and there is plenty of circumstantial evidence implicating several of them.

The most obvious suspect is Dawson himself. He had no formal training but a lot of luck at finding unique artifacts. He was present at Piltdown when all the major finds were made. Once Piltdown was exposed, scientists reexamined his other finds, and 46 objects credited to him turned out to have questionable backgrounds or were outright forgeries. He appears to have appropriated the finds of others as his own, and many of his writings were plagiarized. Most people agree he was involved, but question the presence of an accomplice. Woodward is also suspect. He was Piltdown's strongest supporter and refused to allow some of the simplest scientific tests to be given to the specimens, which would have exposed the forgery immediately. Sir Arthur Conan Doyle, author of the Sherlock Holmes stories, is often presented as a suspect. He was a neighbor of Dawson, an amateur fossil hunter, and a participant in the digs at Piltdown. It has been argued that his novel, *The Lost World,* has clues referring to the hoax. Pierre Teilhard de Chardin has also been accused. He was a Jesuit, a theologian, and an anthropologist. As Dawson's friend, he participated in the work and was present for many of the key discoveries. He had traveled to locations in Africa where some of the frauds originated, and his later recollections of the events at Piltdown were very vague.

The most recent accusations, however, have been against Martin Hinton, zoology curator at the Natural History Museum in London. He worked under Woodward at the time of the hoax and had a public conflict with him over salary. There was also professional rivalry between the two, and Hinton may have perpetrated the hoax to embarrass his colleague. He was known for creating elaborate practical jokes. In the mid-1970s a trunk was found in a loft of the museum with Hinton's initials on the lid. Among other things, there were a variety of bones and teeth stained with chemicals identical to those used on the Piltdown finds. The chemical recipe was apparently created by Hinton and presented in an 1899 scientific paper.

The identity of the culprit and the reasons for creating such an elaborate scheme may never be proven, but there is an important lesson to be learned. The hoax was successful for decades, owing to inconsistent examination and analysis. Once an expert had established the importance of the find, it was accepted uncritically. Scientists embraced the Piltdown find because it supported the prevailing beliefs of the time. Scientists are still human, and ambition, pride, and rivalry can all come into play.

PLANCK TIME

The *Planck time* has a value of 5.39121×10^{-44} second (current uncertainty 40×10^{-44}). It is the smallest time that can be operationally defined, that is, measured even in principle. The *Planck length* has a value of 1.61624×10^{-35} (current uncertainty 12×10^{-35}) meter and represents the smallest length that can be operationally defined.

By international agreement, the distance or length, L, between two points in space is defined as the time, t, it takes for light to travel between the points in a vacuum, multiplied by a constant, c

$$L = ct, \tag{1}$$

where c = 299,792,458 meters per second is the speed of light in a vacuum. (This number is exact by definition.) In order to measure t, and thus L, we need a clock with an uncertainty Δt no larger than t. The time-energy uncertainty principle says that the product of Δt and the uncertainty in a measurement of energy in that time interval, ΔE, can be no less than $\hbar/2$, where $\hbar = h/2\pi$ and $h = 6.6260693 \times 10^{-34}$ joule-second (current uncertainty 11×10^{-34}) is Planck's constant. That is,

$$\Delta E t \geq \Delta E \Delta t \geq \frac{\hbar}{2}\ . \tag{2}$$

Thus,

$$\Delta E \geq \frac{\hbar}{2t} \geq \frac{\hbar c}{2L}\ . \tag{3}$$

This energy is equivalent to the rest energy of a body of mass m,

$$\Delta E = mc^2. \tag{4}$$

Equation 5 implies that within a spherical region of space of radius L, we cannot determine, by any measurement, that it contains a mass less than

$$m = \frac{\hbar}{2cL}\ . \tag{5}$$

Now, a spherical body of mass M will be a black hole if its radius R is less than or equal to

$$R = \frac{2GM}{c^2}, \tag{6}$$

where $G = 6.6742 \times 10^{-11}$ cubic meters per kilogram per square second (current uncertainty 10×10^{-11}) is Newton's gravitational constant. This is called the *Schwarzschild radius.*

Consider a body of mass m given in Equation 5. Its Schwarzschild radius will be

$$L_{PL} = \left(\frac{\hbar G}{c^3}\right)^{\frac{1}{2}}, \tag{7}$$

which is called the Planck length. Notice it is simply the length formed from the three basic constants in physics, $\hbar$, c, and G. It represents the smallest length that can be operationally defined, that is, defined in terms of measurements that can be made by any instrument. If we tried to measure a smaller distance, the time interval would be smaller, the uncertainty in rest energy larger, the uncertainty in mass larger, and the region of space would be experimentally indistinguishable from a black hole. Because nothing inside a black hole can climb outside its gravitational field, we cannot see inside and thus cannot make a smaller measurement of distance.

Similarly, we can make no smaller measurement of time than the Planck time,

$$t_{PL} = \frac{L_{PL}}{c} = \left(\frac{hG}{c^5}\right)^{\frac{1}{2}}. \quad (8)$$

The Planck time and Planck length are the most basic units of time and space. Although distance and time are assumed continuous variables, they are fundamentally discrete. However, because physics experiments have not yet even come close to probing space and time on the Planck scale, treating them as continuous remains a good approximation.

General relativity, the theory of gravity introduced by Albert Einstein in 1915, has so far passed every empirical test to high precision. However, not being a quantum theory, it can be expected to break down at the Planck scale, where it will have to be replaced by a quantum theory of gravity, still not developed.

The Planck time represents the earliest time that can be operationally defined for our universe on the positive side of the time axis. However, this does not mean that "time began" at that moment. Nothing forbids, and time symmetry implies, another universe at earlier times, on the negative side of our time axis.

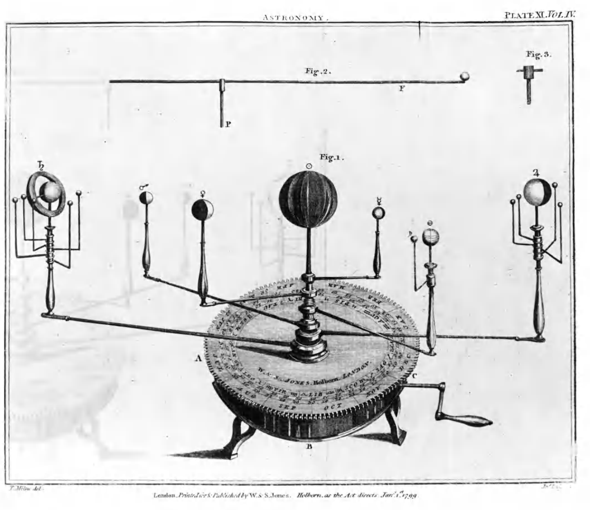
Planetariums

A planetarium is a device for artificially depicting the night sky, showing the relative positions and motions of the sun, moon, and planets. Modern planetariums are theaters, usually dome shaped, that employ elaborate equipment, including projector systems and lasers, for educating and entertaining the public about astronomy and for training nautical and military personnel in celestial navigation.

The lineage of the planetarium can be traced back to ancient Greece. An ancient mechanical calculator used to accurately determine astronomical positions was found in 1900 by sponge divers in what is now referred to as the "Antikythera wreck," off the Greek island of the same name (located between Kythera and Crete) and has been dated to about 150–100 BCE. This technology was extraordinarily complex for the time, and it has no known precursor and no successor or equivalent until the 18th century CE. This movement, or one similar, with its high level of sophistication for that and most other eras, is widely believed to have been used in Archimedes' construction of a primitive equivalent to the modern planetarium. Rather than providing public entertainment or instruction to navigators in training, the creation of Archimedes was used to predict the movements of the sun, moon, and planets as known at that time and also to approximate their relation to each other at various phases and points in time.

Giovanni Campano, more readily identified as Johannes Campanus, was an Italian astrologer, mathematician, and astronomer of the 13th century. In his *Theorica Planetarum,* Campano describes, and, more importantly, provides direction on how to assemble, a planetarium incorporating the astronomical knowledge at that time. Given the instructions left on how to build this piece, it can be stated that there is a very high correlation between the "planetarium" of Campano and the orrery of today. (The orrery is so named for the Earl of Orrery; Orrery is a location within Ireland, and an 18th-century Earl of Orrery had one constructed.) An orrery is a three-dimensional mechanical device that depicts the relative positions and motions of the planets and moons in the solar system, as well as their relation to each other,



An orrery or planetarium designed by George Adams showing the relative positions of the planets in relation to the sun (1799).

Source: Library of Congress, Prints & Photographs Division.

as based upon the presumption of Copernican heliocentrism. These pieces usually owe their movement to a large clockwork mechanism with a sphere (representing the sun) at its core and with a distinct and specific representation of a particular planet at the end of each of its arms. Given the small size of orreries as constructed by Campano and his predecessors, it appears that these devices were mostly used for personal curiosity, knowledge, and recreation, as they were not large enough to be of any true service to a crowd. One obvious limitation of this form of representation is its complete inability to replicate or depict the backdrop of stars and constellations.

Early 19th-century England provided the backdrop for Adam Walker and his Eidouranion, the name given his very large orrery, approximately 20 to 25 feet in height, with a proportionate width. Walker's Eidouranion provides the first documented usage of an orrery for either educational or entertainment purposes, with his lecture incorporating both facets into a simulated presentation on the heavens. While not extremely precise in its representation, this show provided the audience an opportunity to encounter elements of time beyond an immediate number, day, and date. In relaying the parallels of heavenly occurrences such as a lunar phase, or planetary alignment, with definite cycles and events (e.g., seasonal change resulting from the earth's positioning and alignment in relation to the sun), Walker can be seen as one of many to have helped establish the depth and permanence of events of this world by incorporating the heavens as support. As Walker's popularity, and presumably wealth, began to grow, others such as William Kitchener and his Ouranologia began to take their rather inaccurate orreries on the road, forgoing scientific display for sensationalism and the awe of large crowds.

The preeminent German optics firm of Carl Zeiss found itself in a unique situation at the turn of the 20th century. Working within the firm's compound in Jena, Germany, were astronomer Max Wolf, former director of Heidelberg's Baden Observatory, and Franz Meyer, chief engineer of optical works for Zeiss. Both men, in conjunction with Oskar von Miller of Munich's Deutsches Museum, looked to create a representation of the night sky free of movement created by overt force (e.g., the mechanically driven arms of an orrery). The result of their ingenuity and labor was a projector that produced the movements of planets and stars, without aid from bulky and visually obtrusive rails, supports, and the like. Instead, once centrally mounted, their optical projector was capable of projecting images upon the surface of a hemispherical ceiling, and in 1923 the first modern-day planetarium projected its representation of the heavens upon the inside of a dome erected on the roof of the Zeiss building. Given the complexities associated with production of a planetarium (named for the device used to project images, and not necessarily the hemispherical room or building in which the projector is housed; commonly the entire unit—projector[s]— and dome, are referred to as a planetarium) and the sterling reputation of Carl Zeiss, most every planetarium produced or in use upon the globe prior to World War II could be directly traced to the Zeiss factory of Jena.

Projectors such as those introduced by Zeiss use a hollow sphere with a light contained within as their primary means of projecting the appearance of the heavens. This "ball of stars" contains a tiny hole for each star being represented, with the location and relation of "star holes" being computed to near perfection when compared with their authentic form in the true night sky. To simulate the planets and their movements, another projector is commonly used to superimpose these images upon the starry backdrop.

Currently, digital projectors are beginning to appear in more and more planetarium settings. The cost of upkeep is considerably less than that of the traditional "star ball" models, and synchronization of various projectors (e.g., a star projector and a separate planet projector) is not required, as all solar/celestial data are stored and represented by one computer and its corresponding digital projector. Much like digital projectors in a lecture hall or elsewhere, images of the night sky are displayed as pixels, with higher pixilation resulting in a better viewing accuracy.

Planets

Astronomy, one of the oldest sciences of humankind, always provided orientation in space and time: Cardinal directions (east, north, west, south) are defined and obtained by basic astronomical measurements. Time and calendar issues are also definable and measurable by astronomical observations: One "year" is the period the earth needs for one full revolution around the sun (originally, before the Copernican revolution, it was seen the other way around), and one "month" is roughly the time our moon needs to orbit the earth. The currently most widely used calendar system, the Christian calendar in use in Europe, North and South America, and many other parts of the earth, is based mainly on the motion of the earth with respect to the sun. Other cultures have developed slightly different calendars based either on the moon (e.g., the Moslem calendar) or a combination of sun and moon (e.g., the Jewish calendar).

We count seven days per week because, a long time ago, people considered "seven" objects as "planets" or "planet-like objects," namely the real planets, which could be observed by the naked eye before the invention of the astronomical telescopes: Mercury, Venus, Mars, Jupiter, and Saturn, as well as the other two large visible bodies in the solar system, the sun and our moon, together seven objects, hence also the names of the seven days of the week:

Sunday, as the original first day of the week, is the day of the sun, the brightest object in the sky, often even worshipped as a god in several ancient cultures.

The word *Monday* obviously refers to the moon.

Tuesday is named after Mars, the god of War (notice in French, Italian, and Spanish, the words for Tuesday are still close to that for the Roman God Martius (for Mars), namely *Mardi, Martedi,* and *Martes,* respectively) and it originally comes from *Tiwes dag* or *Tyr dag,* from the old Teutonic word *Tyr* for Mars.

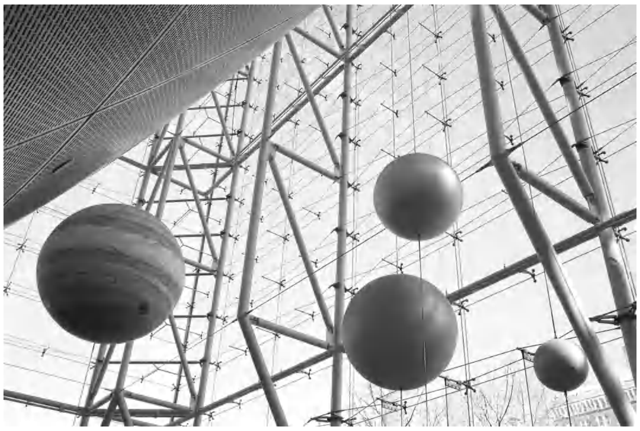
Wednesday is named after the Roman God Mercury (in Romanian, the day is still known as *Miercuri),* and the word Wednesday itself comes from *Wodan dag* for the Teutonic god Wodan.

In Roman times, the fifth day of the week (*Thursday*) was known as *dies Jovis,* after their god of thunder and chief of the gods, Jupiter, where Thursday itself comes from *Thunor dag,* the day of the Teutonic God Thor.

The Romans named another day after their goddess of beauty, Venus, and called it *dies Veneris* (still similar in French). When Germanic tribes invaded England more than 500 years ago, they imposed their goddess upon that day and called it *Frigedaeg,* now Friday.

And finally, *Saturday* is obviously called after Saturn.

Nowadays, both time and the unit *second* are defined by the speed of light. Previously, a second was defined by the atomic clocks, and also earlier as one certain small part of a day, that is, one small part of a revolution of the earth. Still, astronomical observations are important for fixing "time": Due to tidal interaction among the sun, earth, and



An upright shot of the planets at Hayden Planetarium in New York City. Since February 2000, the planetarium has been one of the two main attractions within the Rose Center for Earth and Space.

moon, the rotation period of the earth is very gradually slowing down.

Historical Background

The definition of a planet has changed over the centuries, always following new astronomical observations and new understanding. The word *planet* comes from the Greek word for wanderer, meaning a wandering or fast-moving starlike object (e.g., the old Arabic name for the Egyptian capital Cairo is "Al Qahira" for "the backwards wandering," meaning Mars). As mentioned above, a few hundred to 3,000 years ago, people could see, by the naked eye, seven objects apparently moving fast in the sky (compared to the "fixed stars"), incorrectly thought to orbit around the earth in the center, namely the sun, Mercury, Venus, the moon, Mars, Jupiter, and Saturn. The next planet known today behind Saturn, called Uranus, is also visible to the naked eye during clear and dark nights, and may be visible when Uranus is close to the sun and the earth is roughly in between the sun and Uranus. This is called *opposition:* when an outer planet like Uranus is brightest as seen from the inner planet like Earth, but no such reports are known so far, possibly because Uranus moves only slowly and is quite faint.

During the Renaissance period in general and the so-called Copernican revolution in particular, it became clear, through a number of new observations, that the old theory placing the earth in the center of the universe was not perfect. Those observations became possible with the invention of the astronomical telescope. In 1609, Galileo Galilei observed the phases of Venus and craters on our moon and discovered moons around Jupiter (first called "Medici planets" or "Medici stars" after his supporters of the Italian Medici family, and now known as "Galileian moons"). All this together favored an alternative explanation, putting the sun in the center of our solar system and having the planets orbiting around the sun. At this moment, it also became clear that the earth is orbiting the sun and, hence, was now seen as a planet. Later, two more planets were discovered beyond Saturn, namely Uranus and Neptune.

While it was always possible to estimate the orbital periods of planets around the sun by their periodic appearance and disappearance in the sky, it was originally difficult to measure distances between the planets, or from Earth to either its moon or the sun. The distance between Earth and the sun is now called the *astronomical unit,* which is about 150 million kilometers. The first good estimates of such distances were obtained a few centuries ago by observing eclipses of the sun by the inner planets Venus and Mercury, which happen only very rarely (usually only once or a few times per century): One has to measure exactly either the angular distance between the apparent path of the planet across the solar disk, as seen from two different locations on Earth, or the exact times of ingress and egress of the planet moving in front of the sun. These four so-called contacts must be observed and measured from different locations on Earth with as large as possible a distance in between them, for example from South Africa and Europe. A few centuries ago, it was still difficult to coordinate such efforts and also to run precise clocks. A first observation was done in 1639, a Venus transit. After several attempts, the first good values for the distance between Earth and the sun were obtained in 1761 and 1769—these values also giving evidence about the size of the sun. Together with the laws of gravity just determined by Isaac Newton and their application to the solar system by Johannes Kepler, these values immediately yielded all distances between each of the planets and the sun.

Toward the end of the 18th century, the so-called Titius-Bode law was found and discussed: According to this law, the distance from planet to planet roughly doubles with each planet reached as one moves further away from the sun; for example, Saturn is roughly twice as distant from the sun as Jupiter, Uranus is roughly twice as distant as Saturn, and so on.

However, from Mars to Jupiter, the distance increases roughly by a factor of four, so that there would be space for one more planet. Even the famous philosopher G. W. F. Hegel wrote his dissertation about this problem at the University of Jena in Germany. Many astronomers were already hunting for this new planet. Then, in January 1801, an object was found at the expected distance from the sun, called Ceres, and celebrated as a new planet. However, soon afterward, more similar objects were found, all at a similar distance; a few decades later, the solar system had more than 20 "planets." It was also found that these new objects were smaller than all other previous planets, so it was decided to call them "minor planets" (a new class of objects). Hence, objects celebrated and counted as planets were removed from the list of planets by a new definition.

Early in the 20th century, another new object was discovered and celebrated as a new, ninth planet, called Pluto, located most of the time beyond Neptune, but sometimes crossing its orbit.

Planet Redefined

In August 2006, the general assembly of the International Astronomical Union (recognized by the UN as the international body to define and name celestial objects) discussed, among many other issues, the definition of "planet" again. The definition was prompted by two new discoveries in the 1990s: (1) Minor bodies like Pluto were discovered near and beyond Pluto; and (2) planets around other stars, so-called extrasolar planets or exoplanets, were discovered, and they were apparently different in many respects from the solar system planets, so that a new definition seemed necessary.

After lengthy and heated debates, a new definition was confirmed by a majority vote. This definition reads as follows:

> The IAU resolves that planets and other bodies (except moons) in our solar system be defined into three distinct categories. A "planet" (see note 1, below) is a celestial body that (a) is in orbit around the Sun, (b) has sufficient mass for its self-gravity to overcome rigid body forces, so that it assumes a hydrostatic equilibrium (nearly round) shape (see note 2, below), and (c) has cleared the neighborhood around its orbit.
>
> A "dwarf planet" is a celestial body that (a) is in orbit around the Sun, (b) has sufficient mass for its self-gravity to overcome rigid body forces, so that it assumes a hydrostatic equilibrium (nearly round) shape (see note 2, below), (c) has not cleared the neighborhood around its orbit, and (d) is not a moon. All other objects (see note 3, below)—except moons—orbiting the Sun shall be referred to collectively as "Small Solar System Bodies."
>
> Note 1: The eight planets are Mercury, Venus, Earth, Mars, Jupiter, Saturn, Uranus, and Neptune.
>
> Note 2: An IAU process will be established to assign borderline objects into either dwarf planets or other categories.
>
> Note 3: These objects include asteroids, trans-Neptunian objects, comets, and other small bodies.

This says mainly that objects that (a) are in orbit around the sun (i.e., not being moons of planets), (b) have at least a certain mass (to be round by gravitational effects), and (c) have maintained their orbits by their own gravitational forces are the "planets" of our solar system. According to this definition, Pluto is not a planet (anymore). However, this was not the first time that an object was deleted from the list of planets (see above regarding Ceres and the other "minor planets"). This effect, however, is highly controversial, and it is very well possible that the definition will be changed again soon.

The Solar System

There are now eight planets in the solar system.

Mercury, the innermost known planet, is also the smallest known planet in our solar system with a diameter of less than 5,000 kilometers. (Pluto is smaller, but it is not a planet anymore according to the new definition.) It has a rotation period of 59 days, which is about two thirds of its orbital period around the sun (88 days); hence one "Mercury-day" is equal to two "Mercury-years." Mercury does not have an atmosphere that is comparable to that of Earth, and its surface is similar to that of the moon. Two thirds of its material and mass is made of iron. According to Einstein's general theory of relativity, the orbit of Mercury should change slowly: The location of the perihelion (the point in the planet's orbit at which it is the smallest distance from the sun) moves by a small angle of 43 seconds or arc per century, which has been confirmed observationally.

Venus needs 225 days for orbiting the sun (compared to 365 days for one Earth orbit around the sun). The rotation of Venus around its own axis is retrograde, that is, in the rotational direction opposite to the direction in which it revolves around the sun, and one such "Venus-day" lasts 243 days; that is, it is longer than one "Venus-year." Venus has a dense atmosphere consisting mostly of carbon dioxide and nitrogen, and it has strong pressure on the surface, from where one would never be able to see the stars in the night sky through the dense clouds.

Mercury and Venus, as planets inside the earth's orbit, orbit the sun faster than the earth does and are often close to the sun, as seen from Earth. Hence, they are observable either in the evening sky just after sunset or in the morning sky just before sunrise; that is, Venus is also called the "morning star" or the "evening star." The Greeks called Mercury "Hermes" when it appeared as the evening star and "Apollo" when it appeared as the morning star; Venus was similarly called either "Hesperus" or "Phosphorus," respectively.

Earth is the third planet from the sun; it needs 365 days for a complete orbit around the central star and 24 hours for one rotation. Its atmosphere consists mainly of oxygen and nitrogen. This planet is the only one known so far to harbor living beings like plants, animals, and intelligent life.

The fourth planet is called Mars. It has an orbital period of 687 days and a rotation period of 24.6 hours, so that a "Mars-day" is only slightly longer than a day on Earth. Its thin atmosphere consists mostly of carbon dioxide and nitrogen, but this atmosphere is not identical to that of Earth. There is frozen carbon dioxide and water ice at the poles, but no fluid water has yet been detected. However, some surface structures look like dry river beds and may indicate that fluid water was present some billions of years ago. It is not impossible that life has formed on Mars, too, but no clear evidence for life on Mars has been found yet. Mars is orbited by two small moons, called Phobos and Deimos, with 8-hour and 30-hour orbital periods, respectively. Like the moon of Earth, their rotation is bound: Their orbital period equals their rotational period; they are rotating around themselves only by orbiting their planet and always show the same side to their planet.

The innermost four planets are also called terrestrial planets, as they are all made mostly of solid material like Earth (*terra*). Between Mars, the fourth planet, and Jupiter, the fifth planet, there is a large gap where many small bodies are orbiting the sun. These are called minor planets or sometimes *planetoids,* because they are physically like terrestrial planets; that is, they are rocky objects. They are also called *asteroids,* because in the sky they look like the stars looked when they were discovered, namely pointlike (as opposed to the planets of our solar system, which appeared to be extended on the sky even in naked-eye observations, because of their larger size and smaller distance from observers).

The four outermost known planets (Jupiter, Saturn, Uranus, and Neptune) all are larger in size than the terrestrial planets, mostly because of their large atmospheres and only small solid or fluid cores. (In the case of Jupiter, there may not even be a core at all.) Hence, they are called the "gaseous giant planets."

Jupiter is the largest planet in our solar system; it has a diameter of 143,000 kilometers and a mass of 318 times the mass of Earth. It needs almost 12 years for one orbit around the sun, but only 10 hours for a rotation around itself, as can be observed with even a small telescope because of the moving large red spot in its outer atmosphere. Given its diameter, mass, and composition (mostly molecular hydrogen), it is not absolutely clear whether it has a solid or fluid core or possibly even no core, that is, no solid surface. If it has a core, the core could have a mass of a few or maybe 10 Earth masses. Due to contraction, Jupiter is still radiating more energy to outer space than it is receiving from the sun. This giant planet also has a small ring system and a large number of moons, probably a few dozen; new small moons are still being discovered. The four largest moons were originally discovered by Galileo, when he observed Jupiter for the first time with a telescope. These four moons (Io, Europa, Ganymede, and Callisto) are called the Galileian satellites.

Saturn is twice as far from the sun as Jupiter is. Saturn is known mostly for its large ring system. It also has a large number of moons. Saturn needs 29.5 years to orbit the sun and has a rotation period of 10 hours and 40 minutes. It has a solid core of a few Earth masses and a large atmosphere made mostly of molecular hydrogen gas. Saturn is the second largest planet (120,000 kilometers in diameter) and the second most massive (95 times the mass of Earth) in our solar system.

All planets from Mercury to Saturn (including Earth) have been known for several thousand years to most cultures on Earth, because they can be observed by the naked eye. The outermost planets, Uranus and Neptune (as well as Pluto), were discovered after the invention of the telescope. While Jupiter and Saturn are called "gas giants," Uranus and Neptune are also gaseous planets that can be seen as "ice giants."

Uranus was discovered (and recognized as a planet) in 1781 by William Herschel. Others had observed it before but did not recognize that it as a planet. Uranus is also a gaseous planet with a central solid core, but in total it is only 15 times as massive as Earth. Uranus needs 84 years to circle around the sun, and one "day" on Uranus lasts around 17 hours. Uranus's atmosphere consists of 83% hydrogen, 15% helium, and 2% methane. So far, 21 moons have been discovered (and astronomers are still counting). Uranus also has a small ring system as discovered by the Voyager satellites.

Neptune is the outermost known (and accepted) planet. It was observed by Galileo in 1612, but he did not recognize it as a planet. Because of apparent deviations in the orbit of Uranus, both John Couch Adams and Urbain Le Verrier predicted the existence of another planet theoretically and tried to forecast its rough location in the sky. Later, in 1846, the observer Johann Gottfried Galle in Berlin, Germany, searched that area of the sky for a small moving object and discovered Neptune within a few hours. Neptune needs 165 years for one full circle around the sun. One "day" on Neptune lasts 16 hours. Neptune has a small solid core, a large gaseous atmosphere composed mostly of molecular hydrogen, and a total mass of 17 times the mass of Earth. Neptune, like all gaseous planets in our solar system, has moons and rings.

The object Pluto was discovered in 1930 and celebrated as a new planet, but it was deleted from the list of planets in the 2006 definition of *planet* by the International Astronomical Union.

The new definition of *planet* is formulated for the solar system, but it can and should be applied analogously to other planetary systems around other stars. However, there is as yet no consensus or definition for the upper mass limit of planets. Such an upper mass limit, however, would be very important for extrasolar planets, to be able to decide whether they are planets or so-called brown dwarfs.

In history, the two definitions for a planet worked for about 200 years: The first definition worked from the Copernican revolution to the discovery of Ceres and other minor planets (which now form the asteroid belt between Mars and Jupiter); the second definition, excluding the minor planets, was in effect again for about 200 years until 2006.

Both the problem regarding Pluto and the missing upper mass limit for planets may very well lead to a new definition at one of the next meetings of the International Astronomical Society, which holds a general assembly every three years.

PLANETS, EXTRASOLAR

The term *extrasolar planets* or *exoplanets* stands for planets outside our solar system—that is, planets that orbit other stars, not our sun. Planets in our solar system are defined as objects with enough mass to be spherical and round by their own gravity and to be alone on their orbit around the sun; in other words, to be the dominant object in a particular orbit and not to be a moon or asteroid

Most exoplanets are discovered by observing the stellar motion around the common center of mass of the combined star-and-planet system, that is, by observing somehow the motion of the objects in orbit around each other. This is typically done by measuring precisely the periodic variation of certain values, such as radial velocity or brightness, with time. For example, the first extrasolar planets were found with this timing technique around a pulsating neutron star.

The recent definition of "planets of our solar system" by the International Astronomical Union deals mainly with the question of the minimum mass for an object to qualify as planet and excludes Pluto. This matter was raised by the fact that more and more objects similar to Pluto were discovered by larger and larger telescopes. The questions of maximum mass and formation of planets were left out in this new definition, possibly partly because there is not yet a consensus in the international community. For a discussion of extrasolar planets, however, the maximum mass is very important in order to classify an object as planet or nonplanet and to distinguish between planets and brown dwarfs.

Both planets and brown dwarfs are substellar objects in the sense that they are less massive than stars so that they cannot fuse normal hydrogen (as stars do to produce energy and to shine for a long time). Brown dwarfs, while they cannot fuse normal hydrogen (which has an atomic nucleus of just one proton), can burn deuterium (heavy hydrogen, which has an atomic nucleus of a proton plus a neutron) so that they are self-luminous for a few millions of years until the original deuterium content is depleted.

The upper mass limit of planets can be defined either through the lower mass limit for deuterium fusion, which is around 13 times the mass of Jupiter (depending slightly on the chemical composition) or by the mass range of the so-called brown dwarf desert (as discussed in the following paragraphs).

We will next discuss the different exoplanet discovery techniques by chronological order of success and thereby also discuss the properties of objects found so far.

Radial Velocity

For a few thousand years, speculations have existed as to whether other stars can have their own planets. Both Giordano Bruno and Nicholas of Cusa answered this question positively a few hundred years ago. However, not until 1989 was the first object discovered that could really be an extrasolar planet and that is today still regarded as planet candidate. This first extrasolar planet candidate was discovered serendipitously by the so-called radial velocity technique: The velocity of the motion of an object directly toward us or away from us (in one dimension) is called *radial velocity* and can be measured by the so-called Doppler shift of spectral lines. Atoms in the atmosphere of stars can absorb light coming from the interior of the star at a certain energy, frequency, or wavelength for each kind of atom or ion, producing absorption lines in the spectrum of the star. If the star moves away from us, such lines are said to be *red-shifted;* if the star is approaching us, they are called *blue-shifted;* in either case, their wavelength is different from the normal wavelength (larger for red-shifted).

When a second object, like a planet, orbits around a star, actually both objects orbit around their common center of mass. Hence, also, the star wobbles: It sometimes approaches us, sometimes flies away from us. This can be observed as periodically changing radial velocity. The period of the variation gives the orbital period, and the amplitude of the change in radial velocity yields the mass of the companion. However, because the inclination between the orbital plane and our line of sight is normally not known, only a lower mass limit is known. Therefore, such low-mass companions detected by the radial velocity technique are to be seen as planet candidates; they could have a mass above the maximum mass for planets, making them perhaps brown dwarfs or even low-mass stars. The first such case was published in 1989 by Latham, Stefanik, Mazeh, Mayor, and Burki, namely a companion with minimum mass of 11 Jupiter masses around the star HD 114762. This planet is called HD 114762 b, following the convention that the first planet found around a star is called by the name of the star plus a lowercase *b* behind the star name (thus, a lowercase *c* for the next planet, etc.). This planet may very well have a true mass above 13 Jupiter masses, in which case it could be regarded as brown dwarf.

The first object discovered around a sunlike normal star, which is almost certainly a planet, is called 51 Peg b and is a planet with about half the mass of Jupiter as minimum mass found by Mayor and Queloz around the star 51 Peg in 1995.

The radial velocity can nowadays be measured with an accuracy of about 1 meter per second, so that planets with minimum mass of a few Earth masses can be detected by the wobble they produce on a low-mass star. In the time of one Jupiter orbit, that is, 12 years, since the important discovery of 51 Peg b, about 250 planet candidates have been discovered. In some cases, several planet candidates are orbiting a single star, in some other cases, individual planet candidates are found in binary stars. Because the high precision of the radial velocity technique has been available only since about the early 1990s, planets with more than 20 years of orbital period have not yet been discovered; one needs to observe at least one orbital period. Many planet candidates found so far orbit their stars within only a few days, which is quite different from our solar system, where the innermost planet Mercury needs several months to orbit the sun. The high number of planet candidates with short orbital period, however, can be seen as observational bias, because such planets also introduce a larger wobble on their stars due to Johannes Kepler's and Isaac Newton's laws of gravity.

The mass range of all these planet candidates shows a strong peak at about one Jupiter mass and a strong dip at around 20 to 30 Jupiter masses, even though this method would be biased toward more massive companions, because they have a stronger effect on their central star. Across the range of planet candidates, there are about 250 planet candidates all with masses below about 20 Jupiter masses, then almost no objects with minimum mass between about 20 and 70 Jupiter masses (that is, there are only a few brown dwarfs), and then again a large number of stellar companions with minimum mass above 70 Jupiter masses. This paucity of brown dwarfs identified with the radial velocity technique is called the *brown dwarf desert,* and the dip in the mass spectrum is deepest at around 20 to 30 Jupiter masses. Either the lower mass range of the brown dwarf desert or the minimum mass for deuterium burning can be used as an upper mass limit for planets, if one would define the upper mass limit for planets.

Pulsar Timing

At the end of the lifetime of a massive star, after most of the material is burned by fusion, the star collapses due to its own gravity, then forms a very dense and compact object made up mostly by neutrons, called a *neutron star,* while the rest explodes due to a rebound as supernova. A neutron star typically has about 1.4 times the mass of our sun but a diameter of only 20 to 30 kilometers. Such neutron stars rotate very fast, sometimes even about 100 times per second, sometimes once in few seconds. Most known neutron stars emit strong radio emission along their rotation axes (beams), which appear pulsed due to the fast rotation. Such objects are called *pulsars.* We should keep in mind that so-called pulsars are not pulsating, but rotating fast. One can measure the rotation period with both high precision and high accuracy. In the case of the pulsar called PSR1257, Wolszczan and Frail discovered sinusoidal variations of the millisecond pulses in 1992 and interpreted these variations to be caused by low-mass objects in orbit around the neutron star, each with a mass equivalent only to about that of Earth. This discovery of pulsar planets (by pulsar timing) came as a big surprise, because planets were not expected around neutron stars; it is still dubious as to whether planets can survive the supernova explosion, and it is unknown whether the objects found around PSR1257 are remnants of the explosion or were formed afterwards.

In the case of planets or planet candidates discovered by the radial velocity technique, the inclination of the orbit of the planet around the star in not known. One way to determine this inclination would be to use a transit. A transit occurs when the planet orbits around the star into our line of sight; the planet moves in front of the star once per orbit (and behind the star also once per orbit). When the planet is in front of the star (that is, in front of the spatially unresolved stellar disk), a small part of the stellar light is blocked by the planet. This event is called *transit* or *eclipse.* Such events also happen in our solar system; for example, as seen from Earth, the inner planets Mercury and Venus can follow a path directly in front of the sun, which can even be observed as spatially resolved. The transit light curve enables observers on Earth to measure the inclination of the orbit and also the radii of stars and planets. Then, one can determine not only the true mass of the companion (planet or brown dwarf), but also, from mass and radius, its density.

The first case for which this was successfully observed was HD 209458 in the year 2000, the first radial-velocity planet candidate confirmed to be a true planet (and found to be a gas giant planet with low density like Jupiter). About one Jupiter orbit after the discovery of 51 Peg b, about 33 transiting planets are known (as of November 2007), most of which have also been discovered first by the transit, then confirmed as planets by radial velocity. In a few cases, also the secondary transit is detected; this is a small decrease in the total combined brightness of star plus planet (one should keep in mind that in all such cases, the planet is not seen directly) when the planet is behind the star. From the difference in brightness between the time of secondary transit and the time immediately before and/or after the transit, one can indirectly determine the brightness of the planet.

Astrometry

Whereas the radial velocity technique measures the wobble of the star due to the orbiting planet in just one dimension (radial), one can measure the wobble in the two other dimensions by *astrometry,* very accurate and/or precise determination of the position of a star on the sky. Our sun as seen from about 30 light years' distance also moves slightly in the sky due to Jupiter orbiting it, but this is a very small effect, less than .001 of an arc second (the moon has a diameter of 1,800 arc seconds). The star GJ 876 was the first for which this wobble was detected, using the fine guidance sensor of the Hubble Space Telescope, confirming the radial velocity planet candidate GJ 876 b to be a real planet with just about two Jupiter masses. In the meantime, a few more planet candidates were confirmed by astrometry, and also one radial velocity planet candidate was found to be a low-mass star. Other observing programs have started, using both ground-based and space-borne telescopes, wherein one tries to discover such a wobble in stars where no planets or candidates have been found by other techniques.

Direct Detection

All previous techniques—radial velocity, astrometry, and transits—cannot determine which photons are coming from the stars and which photons from the planet; that is, they cannot directly detect (or see) the planet. While stars are bright and self-luminous due to fusion, planets are very faint, mostly shining only due to reflected light, and they are also very close to their respective stars so that they cannot be detected or seen next to the much brighter star. Young planets, which are still contracting and/or accreting matter, are self-luminous and, hence, not that faint, so that it could be less difficult to directly detect a young planet next to a young star. Several observational campaigns were started around the turn of the millennium in 2000 with the Hubble Space Telescope and ground-based 8- to 10-meter telescopes.

In the case of the ground-based observations, the earth's atmosphere is another problem, leading to the twinkling of stars, so that we obtain images lacking the best possible image quality. With the new technique of so-called adaptive optics, one can de-twinkle the stars: flatten the disturbed wave front with a deformable mirror in the telescope. With such a technique used at the 8-meter Very Large Telescope of the European Southern Observatory in Chile, a few companions to young stars have been found since 2004 that could really be young planets detected directly. The first such case was the star GQ Lupi with its companion GQ Lupi b detected by Neuhäuser, Guenther, Wuchterl, Mugrauer, Bedalov, and Hauschildt. In such cases, it is more difficult to be sure about the exact mass of the companion, because the orbital period is several hundreds of years, so that these few objects could also be low-mass brown dwarfs.

Microlensing

According to Albert Einstein's theory of general relativity, mass or matter deforms space, so that a light ray moving close to matter would be diverted. One would see a ring of light (Einstein ring) around the object. If such an Einstein ring is not resolved spatially due to small mass and/or small angular resolution, one would still see the background object being brightened by the foreground object, the gravitational lens. Such an event is called *microlensing*. If a binary lens (a star plus a planet) were to move—as seen from Earth—directly in front of a background single star, one would observe a double-peaked light curve, one brightening due to the star and one brightening due to the planet. This way, one also can detect planets at great distances—thousands of light years away. There are a few cases where such a double-peaked light curve has been observed that could possibly be due to a planet. However, in all such cases, due to the large distance and hence small brightness, the nature, mass, and distance of neither the lens (or the primary object in the double lens, the star) nor of the lensed background object are known, so that the mass of the secondary object in the lens (possibly a planet) cannot be determined without great uncertainty. The mass of the companion is determined from the mass of the primary (unknown) and the brightness ratio of the two peaks. Practically, such events can never be observed again nor confirmed.

Timing of Pulsating Stars

Some stars toward the end of their normal lifespan (i.e., after most of the light material is burned) are pulsating: They periodically increase and decrease their volume and, hence, brightness. Such a pulsation is observable as periodic brightness change. With precise observations, one can detect a small periodic variation in the pulsations, which can be explained by a wobble of the star due to an orbiting low-mass object. This is very similar to the pulsar timing and radial velocity technique. In the case of the pulsating star V391 Peg, such a variation was detected recently that can best be explained by a planet candidate with three Jupiter masses as minimum mass. This star has burned all its hydrogen already, has expanded to the red giant phase, has lost large amounts of its material, and is now again contracted to become a so-called white dwarf. This is the first time that a planet candidate has been detected in a star after the red giant phase (except for the pulsar planets). This case shows that planets can survive the red giant phase. Our sun will undergo this red giant phase in a few billion years, when it will then expand enough to swallow Mercury and Venus. It is not yet clear what effects this will have on the earth, but it is likely that all life will be extinguished.

All these different techniques to discover planets have resulted in several hundred planets and planet candidates, including some planetary systems, where several planets orbit the same star. (Updates on planet discoveries can be found on www.exoplanets.org.) Planetary systems consist not only of the planets and their host star but also of minor bodies like asteroids, comets, and moons, and often if not always also of a circumstellar disk with dust remaining from the formation phase. This is also the case in our solar system, where dust in the so-called zodiacal disk can be observed on dark moonless nights due to reflection of sunlight on dust particles; such dust debris disks can also observed around other stars, with or without planets.

All the planets discovered so far have masses of at least several Earth masses and are much different from Earth. It is not yet possible to detect earthlike planets. Such discoveries may be possible in the future, either by the use of larger telescopes or by ground- or space-based interferometry, using a combination of several telesopes.

Another eminent question is the habitability of exoplanets. So far, no signs of life have been found on other planets, neither in our solar system nor elsewhere. It is difficult not only to define life, but also to detect earthlike planets—to say nothing of earthlike or even nonearthlike life on distant planets. However, it may well be that life could form either on some already detected planets or on their moons, if these exist.

Planets, Motion of

As viewed from Earth, the other planets in our solar system exhibit some apparent motional changes as each revolves around the sun. These oddities long puzzled a succession of civilizations as observers contemplated the structure of the universe. For thousands of years, it was common belief that the earth was the center of the universe, around which all other objects revolved. Many times, planets were seen as omens, not necessarily benevolent ones; they could also represent destructive prophecies. Most times, this led to self-fulfilling prophecies, but through time humankind has finally come to better understand the position of celestial objects.

The inferior planets (Mercury and Venus) obey a different set of observational parameters than do superior planets (those outside the earth's orbit). Inferior planets pass from inferior conjunction counterclockwise to greatest western elongation (GWE), superior conjunction and greatest eastern elongation (GEE). Superior planets, on the other hand, have no inferior conjunction, but rather a point of opposition. Additionally, they have observational points called eastern and western quadratures. In the sky of the observer, planets move regularly from west to east against the background of stars; this is called *prograde motion.* As part of orbital mechanics, this direct motion reverses as an inner body catches up to, and surpasses, the outer one. This is called *retrograde motion* (see Figure 1).

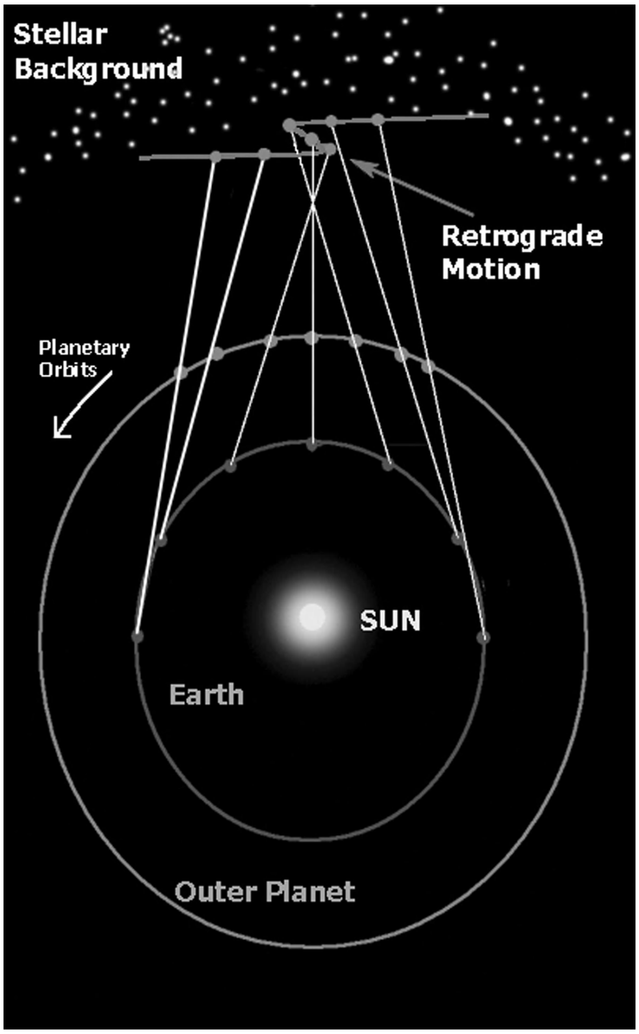

Figure 1 Retrograde motion of a superior planet

Note: Prograde motion stops midcycle, reverses, then resumes.

Inferior Planets

Every planet exhibits a consistent orbital behavior. A planetary conjunction occurs when two or more planets are in the same or opposite orbital location with respect to each other and the sun (see Figures 2a and 2b). Assuming a level plane of orbit, the sun and conjunctive planets would be in a straight line.

Inferior conjunction occurs when the inferior planet passes between Earth and the sun. In Figure 2a, the inferior planet enters into inferior conjunction with Earth. As it surpasses Earth, it will be lost in the glare of the sun. On rare occasions, the inferior planet will appear from Earth to transit the sun. At GEE, the motion of the inner planet will appear to slow, and then it will begin retrograde motion and pass behind the sun to superior conjunction. Once beyond GWE, the inferior planet will return to prograde motion. If this trajectory were seen from a location in space near Earth (which would remove the effects of Earth's daily motion), the observer would view the entire motion of the inferior planet around the sun. Note that a conjunction can occur when the two planets are at any point in their orbits; it is not necessary for them to be at perihelion or aphelion.

The inferior planets are visible between their conjunctions, but at the conjunctions they are lost in the solar glare of daylight. Each of the elongation points is related to the terrestrial cardinal direction that the planet is located in relative to the sun. As a result, observing an inner planet as a morning star prior to sunrise means that the inferior planet is in proximity to GEE. As it emerges from behind the sun, it becomes an evening star after sunset, moving toward greatest western elongation (GWE).

It is noteworthy to remember that none of these objects is fixed, including Earth. Another terrestrial observational feature is that inferior planets go through phasing similar to that of the moon. The full phase is superior conjunction, and the new phase is inferior conjunction, at which neither point can the planet be seen unaided.

Superior Planets

The outer planets, however, have a slightly different set of observational characteristics (see Figure 2b). At conjunction, the outer planet appears to pass behind the sun, while at opposition it will rise at sunset, similar to a full moon. These points are called quadratures, and they are the points where the superior planet forms a right angle with the earth and sun. At eastern quadrature, prograde motion continues but in decreasing angular measurements. Terrestrially, the superior planet sets 6 hours after the sun. As Earth approaches eastern

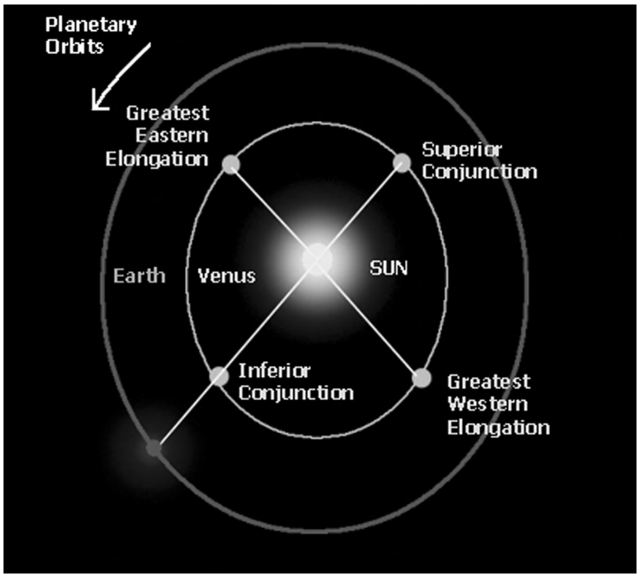

Figure 2a Inferior planetary motion

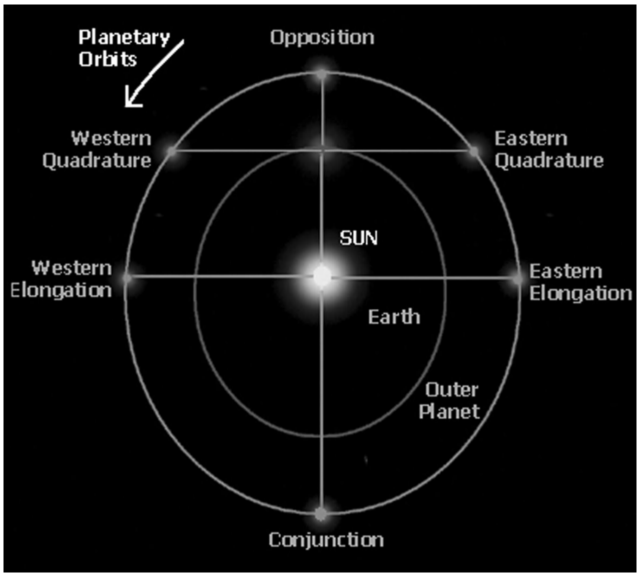

Figure 2b Superior planetary motion

quadrature, the magnitudes of prograde measurements decrease until the daily progression of the outer planet motion apparently stops and reverses into an east-to-west direction (see Figure 1). Retrograde motion continues through opposition but returns to prograde motion shortly after Earth has passed the superior planet, and the prograde distances appear to increase. Earth then continues to western quadrature, where the planet appears due south in the dawn sky. Finally, Earth returns to conjunction with the superior planet and the sun.

Predictability

A planetary alignment occurs when planets visibly cluster in the terrestrial sky. Although it is common for people to call these planetary groupings conjunctions, this is a slight misnomer. There are many planetary motions that occur, and are all part of nominal orbital mechanics. Because all planetary orbits are consistent, it is possible to predict alignments accurately. Computer-driven applet models present a three-dimensional look at when a conjunction or opposition will occur, as well as various alignments, and make it possible to predict similar occurrences in our solar system. These models are located on several Web sites on the Internet and located by utilizing a search engine.

Throughout history, planetary alignments have been blamed for the start of many wars and have been the cause for mass hysteria. In May 2000, Mercury, Venus, Mars, Earth, the moon, Jupiter, and Saturn aligned together in the western sky. News agencies reported several concerns regarding the coming tectonic, magnetic, radioactivity, and tidal catastrophes that were going to occur as a result. Over time, this has always been the case when such alignments occur. In the modern technological era, panic and hysteria is even more apt to spread with the usage of the Internet, rather than word of mouth, to carry the message. Furthermore, the enhanced ability of predicting such events gives hoaxers time to prepare their allegations. Since 2003, the Mars hoax occurs every August as Earth nears opposition with Mars; spreading mostly by e-mail to millions of people, the message claims that Mars will appear in the sky as large as the moon.

In 1974, John Gribbin misused the term *planetary alignment,* in the book *The Jupiter Effect.* The book was about the rare grouping of all nine planets being on the same side of the sun. (This actually occurs once about every 200 years.) The result would be that their combined gravitational effect would cause chaos with the sun and create massive earthquakes and floods on Earth. After reading the book, many people believed the hypothesis, and a great panic ensued. Gribbin tried to publicly quell the panic and reinforce the fictional nature of the book.

Despite the attempt to attribute terrestrial destructive forces to predictable solar system events, they simply occur as a result of the physics of motion around the sun. As each planet orbits the sun, the optical illusions of prograde and retrograde motion will be seen relative to the planetary location of the observer. Future alignments of planets will occur because they are mathematically connected, not as a precursor to chaos. Each planet takes a specific period of time to complete a solar revolution that will remain relatively constant throughout the life cycle of the solar system.

Plate Tectonics

From the beginnings of science, it was thought that Earth was a static, stable planet whose surface remained largely unchanged through time. This view radically changed during the 1960s, as an array of improved analytical techniques and an influx of new observations revealed that Earth's surface is in a state of constant change. This new approach to understanding the earth is known as plate tectonics, and it holds that the outer skin of our planet is divided into several plates whose motion results in mountain building, earthquakes, volcanism, and other geological events. Understanding the processes of plate tectonics has allowed scientists to systematically explain the history and structure of the earth and to study both past and modern geological events in a unified and rigorous fashion. The philosophical shift from viewing Earth as static to viewing it as a dynamic planet governed by plate tectonics is also regarded as a prime example of a paradigm shift in science.

Early Speculation

The first recorded suggestions of a dynamic and changing Earth were offered by 16th-century philosophers and geographers, who noted the congruence between the Atlantic coastlines of Africa and South America. In 1596 the geographer Abraham Ortelius argued that the Americas were once conjoined with Europe and Asia, but later "torn away" by earthquakes and other catastrophes. In recent years, historians of science have discovered nascent hints of plate tectonics in the writings of Francis Bacon, Scottish philosopher Thomas Dick, noted French scientist Comte de Buffon, German explorer Alexander von Humboldt, and Benjamin Franklin. However, it wasn't until the early 20th century that scientists began to assemble strong evidence that the surface of the earth has changed over time, as well as a coherent hypothesis to explain how. Much of this data set was articulated by Alfred Lothar Wegener, a German meteorologist who assembled widely divergent lines of evidence into an understandable theory of continental motion.

Wegener and Continental Drift

Like the early geographers before him, Wegener was intrigued by the closely matching Atlantic coasts of South America and Africa. After reading a paper describing similar Paleozoic fossils from these two continents, Wegener launched a massive literature search in the hopes of finding additional data to support the concept of continental drift. The data he uncovered were varied and wide ranging. Not only did the coastlines of South America and Africa match, but so too did the coasts of Newfoundland, England, parts of Greenland, and Scandinavia, especially when the outlines of the continental shelf were taken into account. Additionally, Wegener discovered that South America, Africa, India, Australia, and Antarctica shared a suite of unique Mesozoic fossils, including a tropical plant flora characterized by the fern *Glossopteris* and a reptile fauna that included the tusked, piglike *Lystrosaurus*. Modern animals do not range across all continents, because it is often impossible to disperse across oceans and other barriers. This suggested to Wegener that these continents were linked during the Mesozoic era (225–65 million years ago), and have since moved to their present, widely divergent positions. Furthermore, the presence of tropical fern fossils in Antarctica makes no sense if the continent has always occupied a polar position.

Wegener supported these observations with several additional lines of evidence. This included closely matching rock units shared by Africa and South America, the distributions of former equatorial climate belts (as shown by coals and fossil reefs shared by the five aforementioned lands), and the locations of past Paleozoic glaciations. Taken together, these facts suggested to Wegener that all of the continents had once been joined into a supercontinent (which he named Pangea) that later split into two larger fragments. The first fragment, termed Laurasia, included North America, Europe, and Asia, while the second landmass, called Gondwana, consisted of Africa, South America, India, Madagascar, Australia, and Antarctica. Over time these two fragments further split into the individual continents recognized today.

Wegener presented his hypothesis of continental motion in a series of lectures and journal articles in 1912. Three years later he outlined his ideas in a short, 94-page book, *Die Entstehung der Kontinente und Ozeane,* which was subsequently revised three times and translated into English as *The Origin of Continents and Oceans*. The notion of continental drift, which overturned much of the conventional geological wisdom of the day, was initially dismissed by critics as untenable, largely because Wegener could provide no plausible mechanism for continental motion. In his book, Wegener suggested that the centrifugal force resulting from the Earth's rotation, or possibly the pull of gravity from the moon, drove the lighter, granite-rich continents through the denser, basalt-rich oceanic crust like a ship plowing through water. However, eminent Cambridge geologist Harold Jeffreys, one of the most respected scientists of his time, did the calculations and found these forces insufficient to move something as large as a continent. In response to Wegener's evidence, many in the scientific establishment suggested that now-sunken land bridges allowed for floral and faunal interchange between separate continents, and shifts in climate regimes explained the locations of past glaciations and similar rock units between South America and Africa.

At the time of Wegener's death during a 1930 expedition to Greenland, his hypothesis was openly ridiculed and his scientific credibility scorned. However, although Wegener would never know it, his hypothesis was later verified as a new age of science dawned in the shadow of World War II. Over the course of the 1960s a handful of earth scientists from across the globe instituted a scientific "revolution" that molded Wegener's observations into the theory of plate tectonics. Today, plate tectonics is regarded as the grand unifying theory of geology, and it helps to explain everything from animal dispersal and mountain building to volcanism and earthquakes.

Supporting Data

Important data supporting Wegener's evidence for continental motion came from studies of paleomagnetism. As lava cools into solid rock, tiny crystals of the magnetic mineral magnetite are "locked" into position, thereby recording the direction of Earth's magnetic field at the time of the rock's formation. Using trigonometric equations, geologists can take these data and determine the latitude at which a certain rock formed. This procedure was applied to igneous rocks across the globe, and it was discovered that the latitudes at which the rocks formed were usually different from the latitudes they occupy today. At first it was thought that the earth's magnetic pole simply wandered over time, thus causing the discrepancy in paleolatitude measurements. To test this hypothesis, scientists began compiling "polar wandering curves," charts of a continent's latitudinal position over time (enabled by recent advances in radioactive dating of rocks).

If the continents were fixed and the magnetic pole was actually wandering, the curves of different continents should match throughout geological history. However, extensive data sets showed the opposite to be the case: Each continent had its own unique polar wandering curve, which indicated that the magnetic pole is essentially fixed and the continents have drifted relative to each other. Interestingly, the polar wandering curves of North America and Europe were found to align during the early Mesozoic, indicating that these continents were moving together. Similar matches for other continents during this time support the existence of a supercontinent, as originally suggested by Wegener.

Paleomagnetic data strongly supported the reality of continental motion, but several questions about the form and cause of such motion still remained. Many of these questions were capriciously answered during the era of undersea exploration immediately after World War II. Leading this research was Princeton geologist Harry Hess, who discreetly took measurements with a fathometer while captaining a Navy transport ship in the Pacific during the war. Hess's surveys detailed the topography of the seafloor, and revealed that a series of long mountain ranges, deep trenches, and extinct volcanoes littered the deep abyss. Later evidence suggested that a large percentage of the world's earthquakes were occurring in these submerged mountains, hinting that the ocean bottom was a dynamic place.

Over time Hess became convinced that new seafloor was currently being formed in the mid-ocean mountain ridges that occurred in the centers of the Atlantic and Pacific, as well as other oceans and seas. In a landmark 1962 paper, Hess suggested that new basaltic seafloor was produced at the ridges and spread away symmetrically in both directions, a process called "seafloor spreading" by geologist Robert Dietz. This process was soon supported by a slew of additional observations. Magnetometers deployed by the Allies during the war had revealed strange magnetic patterns on the ocean floor, namely, the strength and direction of the magnetic field followed zebra-striped patterns that not only paralleled the midocean ridges, but also were symmetrically the same on both sides of the ridges. This pattern puzzled scientists until Cambridge geologists Drummond Matthews and Fred Vine directly dated much of the seafloor, and found that the absolute dates were also symmetrical about the ridges, with rocks becoming older with increased distance. Additionally, the amount of sedimentary cover and degree of erosion of extinct volcanoes increased systematically and symmetrically away from the ridge, as would be expected if the seafloor gradually increased in age. These and other observations only confirmed what Hess, Matthews, and Vine suspected: that new seafloor was created in midocean ridges and gradually spread outward in both directions.

The Theory Outlined

The coherent theory of plate tectonics, a unification of Wegener's continental drift and Hess's seafloor spreading, was largely pieced together during an 8-year period in the 1960s. Today, geologists view the earth as composed of two principal layers: the brittle, outer lithosphere (composed of the crust and upper mantle) and the denser, warmer asthenosphere (composed of the lower mantle and core). The lithosphere, akin to the fragile shell of an egg, is broken into some 20 distinct plates, which are rigid but deformable at their edges. These plates can contain both dense oceanic crust, which is rich in magnesium and iron, and lighter continental crust, which is enriched in silicon and aluminum. The interaction of plates produces many characteristic geological phenomena and is the subject of intense study by geologists and geophysicists.

When two plates meet, one of three general interactions occurs: They can move away from each other (divergent), move toward each other (convergent), or slide past each other (transform). When plates move away from each other at divergent boundaries, seafloor spreading takes place, and new oceanic crust is formed. Midocean ridges are an example of a divergent boundary, as are the rift zones of continental interiors (such as the present East African Rift). If a rift is successful and a piece of continuous continental crust is split in two, seafloor spreading commences and further pushes apart the continents. This process explains the mechanism of continental breakup, such as the splitting of the Mesozoic supercontinent Pangea into the seven main continents of today.

When plates come together at a convergent boundary, the result is more complicated. If denser oceanic crust meets lighter continental crust, the oceanic crust is subducted beneath the continent, often giving rise to volcanism. This process explains the so-called Ring of Fire, which follows many prominent subduction zones along the Pacific Rim. The subduction of oceanic crust is often associated with mountain building, most prominently the formation of the Andes of South America, which have resulted from the subduction of the Nazca Plate under the South American Plate. Additionally, subduction zones are frequently regions of deep and powerful earthquakes and are the source of the recurrent large tremors that rock Alaska and the northern Pacific. On the other hand, since continental crust is too buoyant to be subducted, the collision of two continents results in intense crustal wrinkling and thickening, producing mountains. Continental collision formed the Appalachians during the Paleozoic and today is responsible for the continuing uplift of the Tibetan Plateau, which formed via the collision of India and Asia during the Late Cretaceous and Early Tertiary.

Finally, when two plates slide past each other, earthquakes frequently occur, as manifested by the San Andreas Fault of California and the Anatolian Fault of Turkey. Such boundaries are among the most seismically active regions on Earth.

Despite this understanding of plate interactions, the exact driving force of plate tectonics is still poorly understood. Wegener originally proposed several possible mechanisms for continental motion, most of which were dismissed by critics as untenable. Years after Wegener's death, noted British geologist and physicist Arthur Holmes resurrected Wegener's suggestion that convective currents in the waxlike asthenosphere drive the motion of the overriding lithosphere, a hypothesis widely supported today. More recent research has added further details, and suggests that gravitational and frictional forces on subducting plates, as well as "push" from new extruded material at midocean ridges, also contribute to plate motion.

The ultimate driver of many of these forces is radioactive decay in the earth's core.

The "revolution" of plate tectonics, occurring between the first publication of Wegener's heretic views in 1912 and the accumulation of convincing paleomagnetic and oceanic data in the 1960s, is a prime example of a paradigm shift in science. When Wegener first proposed his theory of continental drift, nearly the entire geological community regarded Earth as static and unchanging, with current landmasses occupying the same position throughout the entirety of geological history. As would be expected, Wegener's views caused quite a stir in scientific circles, inspiring several symposia and publications that roundly criticized and dismissed continental drift. Respected geologist R. T. Chamberlin ridiculed the theory as being "of the foot-loose type," while Edward Berry bluntly labeled Wegener's method as "unscientific." Some of this criticism was pure obstinacy, but the majority of geologists chastised Wegener's failure to provide a plausible mechanism for continental motion. It was only several decades later, after new instruments and techniques revealed irrefutable evidence from paleomagnetism and oceanic surveys, that the scientific community accepted the reality of mobile continents. By this time, an increased understanding of radioactivity allowed for a plausible driving force: mantle convection. With the acceptance of plate tectonics came a new and open opportunity for understanding the processes and history of the earth, and it finally allowed for reasonable explanations of mountain building, volcanism, and earthquakes—geological phenomena that had puzzled geologists of the "static Earth" camp.

Conclusion

The theory of plate tectonics is the grand unifying theory of geology, a complete, understandable, working theory of the earth. Unlike most traditional sciences, geology deals with large-scale patterns and processes that operate over unthinkable lengths of time. Early geologists found it necessary to describe the geological history and processes of Earth based on events that occur in the present. Although intuitively rational, this "uniformitarianist" method of thinking prevented many geologists from recognizing complex processes that are difficult to observe, such as mountain building and earthquakes. An understanding of plate tectonics allows modern geologists to place volcanism, earthquakes, rifting, and other phenomena into a rigorous theoretical framework. The surface of the earth is divided into several plates that constantly move as new crust is generated at midocean ridges, driven by convective currents in the mantle. This basic set of processes has defined Earth for millions of years, differentiates our planet from other bodies in the solar system, and has governed both the physical and biological evolution of our world throughout geological history.

Plato (c. 427–c. 347 BCE)

Along with his teacher Socrates and his pupil Aristotle, Plato is recognized as one of the most influential thinkers in ancient philosophy. Plato deals with the notion of time in different contexts. He describes time as "a moving image of eternity" in his philosophy of nature (in his *Timaeus*, 37c–47c): the temporal structure of the cosmic universe aims at imitating the unchangeable eternal realm of the ideas, of which the real world is a reflection. Plato also develops (in the dialogue the

Statesman / the *Politikos,* 268d–274d) the idea of a cyclic dimension of the historical time, which consists of two "world ages" that alternate for eternity. The two ages have different characteristics and are seen as a result of a change of the overall inner motion of the cosmos. Finally, Plato aims at a deeper understanding of the paradoxes of movement that are linked to temporal becoming (in the dialogue *Parmenides,* 151e–157b). The main background for Plato's understanding of time is his doctrine of ideas, according to which the temporal world is in constant change; but "behind" this change lies the realm of unchangeable ideas, which exists outside of space and time.

Born in Athens, Greece, into an old aristocratic family, Plato was hindered in his pursuit of a political career by the turbulent politics of his times. In his youth he was a pupil of Socrates for 8 years, until Socrates' trial and execution in 399 BCE. After the death of Socrates, Plato's extended travels led him to Cyrene and Egypt and thus to Euclid of Megara, then to lower Italy, and to the Pythagoreans. In 385 Plato founded his famous school, the academy in Athens (which was only to be closed in 529 CE). He traveled several times to Sicily, where he attempted to put his political ideas into practice. He discarded this, however, after he fell into disgrace, became enslaved, and had to be redeemed by his pupils.

The platonic works that are preserved—besides the letters and the *Apology*—are all written in the form of dialogues, most of which depict Socrates debating with his interlocutors to seek the truth. Socrates' quest for a deeper understanding of the virtues and the nature of the good is presented as an antidote to the relativism and the empty rhetoric of the Sophists. In *Epistemology,* Plato aims thus at a distinction between true knowledge (*episteme*) and mere belief (*doxa*). In his political works he depicts a perfect state that is described as a corporate state, in which the people with the highest wisdom—the philosophers—should rule. Most influential for western metaphysics was Plato's doctrine of ideas, which also serves as a background for his cosmological notion of time.

Plato's Notion of Time

Plato develops his cosmological ideas in the dialogue *Timaeus* in the form of a mythical explanation of the creation of the universe. To understand this myth, one needs to look at Plato's doctrine of ideas. The core of this doctrine is the distinction between the realm of individual entities, which can be perceived by the senses and are in a constant state of change, and the eternal realm of unchanging ideas, which can only be perceived by reason. The constant change and motion of the elements of the empirical world make it impossible to secure general knowledge about them. In contrast, the eternal ideas form the realm of proper being, about which knowledge of mathematical certainty is possible. Ideas and individual entities are connected through a relation of "participation": An individual thing is only cognizable and has "being" to the degree in which it participates in a timeless idea. Something can for example be considered beautiful only if it participates at the idea of the beauty, if it is an instantiation of the general concept of beauty.

This distinction between ideas and the realm of real objects signifies on the one hand a relation of hierarchy: The archetype is more real and perfect than the image. On the other hand: the image resembles the archetype: Individual things can thus be regarded to be concrete instantiations of abstract ideas in space and time. It becomes clear that the distinction between unchanging ideas and the realm of the empirical world by Plato is also often regarded as a distinction between the timeless realm of eternal truth (like mathematical truth), in which no movement or change in time occurs, and the empirical world, in which no individual object remains the same, and a change over a period of time affects each of them.

The creation of time itself as a part of the visible universe is depicted in a myth told by Timaeus about the creation of the world. According to this myth, the godlike "demiurge" (craftsman) formed the cosmos out of preexisting matter guided by the unchangeable eternal ideas. He attempts thus to create an image of these ideas that is as nearly perfect as possible. The cosmos as a whole is seen as one perfect living being containing an invisible spirit and the visible parts of the universe (its body). The cosmos is created in the image of the perfect living creature (*zoon*) out of previously unstructured elements in a way that nothing is left outside of it. Because there is thus no exchange of matter or forces between an "outside" and an "inside," modes of spatial or temporal change cannot be attributed to the cosmos as a whole. The universe is thus eternal and does not grow in shape or size, and in this sense it also does not grow older (*Parmenides,* 33b). In the same line of argument also, the soul of the cosmos is declared to have an endless intelligent life for all times (ibid., 36e).

In order to make this image as perfect as possible, the demiurge creates "time" as a moving picture of eternity. The main idea here is that the cosmos cannot (as being created) be "eternal" in the same sense that the realm of the ideas is eternal (i.e., not affected by time), but it can mirror the idea of eternity through a cyclical periodical movement according to mathematical proportions. This movement is what we call time. One can illustrate this idea by comparing it to a thought we find in the *Symposium:* Individual living creatures are mortal and cannot be eternal, but they imitate the eternal idea through reproduction as a periodic act of the recreation of their species. Even though the individual is mortal and affected by time, the species—as the more general concept—is eternal and unchangeable.

Time is furthermore for Plato linked very closely to the realm of astronomy. It is created together with the heavens, and it finds its perfect expression in the periodic movements of the planets. The parts of time are therefore defined through astronomical relations: Days, months, and years are the natural elements of time, which are themselves determined by the movement of the earth, the moon, and the sun. In addition to this, Plato points out that there are numerous other parts of time, related to the movements of the other planets, that are—though often unknown to men—of equal importance and beauty. The most perfect cosmological "year" is completed when all planets have the same position again and the movement starts anew.

We can thus see that time aims at depicting eternity in the form of a periodic and cyclic movement, in the same sense as the circle is considered to be the perfect shape and circular movement as the most perfect type of movement. This cyclical understanding of time is characteristic of ancient Greek thought. Only in later periods (e.g., in early Christianity) did the idea of an overall direction of history culminating in salvation become important, eventually replacing the idea of an eternal return of everything by the notion of a clearly defined "progress."

Besides the parts of time (the days, months, years, etc.), Plato also discusses the modes of time, the past (the "it was"), the present (the "it is") and the future (the "it will be"). He insists that the "it was" and the "it will be" can only be applied to things within the world and not to the eternal realm of the idea, of which only the "it is" is an appropriate formulation. Linked to this idea is Plato's struggle to understand the processes of "becoming" and "changing" in general that all lead to logical paradoxes, discussed already in the Presocratic philosophy. In this context the Eleatic philosophy is very relevant, ascribing real being only to the things that "are" and remain always the same and thus denying the possibility of change. Change is thus seen as an illusion. We can see how Plato on the one hand replicates elements of this idea in his dualistic doctrine of ideas, but how he tries, on the other hand, to reconcile abstract dualism by depicting time itself as a "moving image of eternity" that itself tries to some extent to bridge the gap between the atemporal world of ideas and the temporal world of finite objects.

Cyclical Nature of History

In the *Politikos,* the question of the ideal statesman is discussed. In this context a myth of two world ages is reported by the "stranger," who takes the lead in this dialogue. Because the cosmos has a visible bodily part, it is submitted to forms of movement. Because there cannot be a movement to another place—as there is no "place" outside the cosmos—this movement takes the form of an inner rotation of the whole cosmos. This rotation is set by the gods in one direction at the beginning of the universe. In this age, determined by the overall direction of the rotation, men were born from earth and lived under the guidance of gods a pleasurable life dedicated to philosophy. This period is called the age of *Kronos* (time). (Kronos is in the Greek mythology the father of Zeus.)

After a long period of time, this age comes to its natural end when the cosmos has finished its movement in one direction. Now the gods release the cosmos to start spinning in the opposite direction: The planets and the sun move "backwards." In this second world age, the age of Zeus, nature is left to its own guidance. Men are born from men and will be buried in earth when they die. The further away this period moves from the first age, the more knowledge about the Good gets lost. Eventually this period will again come to its end, and the direction of rotation will change once more. This cyclic alteration keeps continuing for eternity. According to this myth, it is important to know in which of the two periods one is living, as the definition of the good statesman differs for both ages.

Again it can be seen that a cyclical understanding of time is prominent in Greek tradition, although Plato combines this thought with a specific direction for each age. The age we humans currently live in—the age of Zeus—is depicted as an age of decay that on the one hand moves further and further away from the golden age of the past. On the other hand—due to the eternal alternation—this age, like others, will come to an end and will be replaced by a new period "under the guidance of gods."

Logical Paradoxes of Motion and Time

In the *Parmenides,* Plato discusses central aspects of his doctrine of ideas. The main character is the aged Eleatic philosopher Parmenides, who explains to the very young Socrates his doctrine of the one being. In the first part of the dialogue, the doctrine of ideas is discussed; in the second part, several dialectical exercises are carried out by Parmenides that contain logical analyses and problems of the "one."

In this dialectical exercise, opposing theses are discussed and developed out of each other. Different interpretations have been suggested for these difficult passages; the main purpose is very likely to reject the radical dualism of the Eleatic opposition of the "unchangeable, atemporal one" and the moving unstable empirical world of changes of the other side: Zeno (the second Eleatic philosopher in this dialog, who represents this strict opposition) is becoming more and more a side-figure of the dialogue, as the main attempt seems to be to try to bridge those two realms and come to a more concrete understanding of the ontological principles of being (the ideas) and the changes happening in reality.

While the "one of being" is shown to be atemporal, every individual thing is said to have some relation to time. In this context, "existence" is identified as "being present" at a certain time: Everything that exists in time is, however, also capable of "becoming" or—more generally—of changing, especially, of course, of growing older. "Being" is thus deeply linked to time, as "is" means that something exists in the now, while "has been" means something existed in the past; "will be" finally refers to some existence in the future. Plato discusses the apparent paradox that things can thus grow older than they were while at the same time being younger than what they will be in the future.

Plato's notion of time was very influential in ancient philosophy. Its cosmological explanation (in the *Timaeus*) was adopted by Plotinus in later Neoplatonism, though in his explanation of time the relation to astronomy and mathematics gets more and more lost. Christian thought reinterpreted the myth of the *Timaeus* as a myth of creation, understanding the "timeless ideas" as a part of God's eternal mind. Aristotle's theory of "dynamis," and his distinction between the "actual" and the "potential," respectively, between the "substance" and his "attributes," can be seen as an attempt to solve some of the paradoxes linked to the question of how things can change in time and still remain the same (so that Socrates can grow older and still be "Socrates").

Plotinus (c. 205–270 ce)

Plotinus was born in the Nile Delta region of Egypt; he studied philosophy in Alexandria and later, Rome. He did not see himself as an original philosopher in the modern sense, but rather as interpreter of the truth that was first elucidated by Plato. Thus he became the founder of Greek Neoplatonism. Central issues of Plotinus's thinking are these: The first principle is the one; that is identical with the good; from the one, the intellect proceeds, which can be identified with being, and from the intellect proceeds the soul. These are the three principles or hypostases of reality.

In his treatise on eternity and time (*Enneade* III 7), Plato's theory of time developed in the *Timaeus* is the framework for Plotinus's own inquiry, but Aristotle's views intensively stimulate his notion of time in this world. Plato's definition of time as the "moving image of eternity" indicates that time can be described only in the context of eternity. Aristotle's definition of time as the "number of motion" shows that time is something closely linked to movement and to the counting soul. Plotinus's main thesis is this: Eternity is the life of the intellect, and time is the life of the soul.

His treatise on eternity and time starts with the presupposition that eternity (*aion*) is linked to the intelligible world of eternal being and time (*chronos*) to our sensible world of becoming. Eternity and intellect both include the same, because both are "most venerable" (*semnotaton*). While the intelligible includes everything just as a whole includes its parts, eternity includes the whole all at once (*homou*), that is, simultaneously and not as parts. Although rest corresponds to eternity as motion does to time, eternity is not identical with rest; otherwise the intelligible world would be limited to only one of the five concepts in Plato's *Sophist;* the other four (substance, motion, the other, the same) would be excluded. The first definition of eternity is this: "Eternity is the life, which belongs to that which exists and is in being, all together and full, completely without extension or interval" (all translations by Armstrong). This definition is founded on Plato's "living being" in the *Timaeus,* which is contemplated by the demiurge. This is described as "eternal" and as "always existing in the same state."

For Plotinus, eternity is not to be identified with the intellect or the intelligible world but it is related to the totality of the intelligible life. This life that is eternity is not identical with the intelligible, but is a manifestation of it: "Eternity is not the substrate but something which, as it were, shines out from the substrate itself." Eternity does not come to the intelligible from outside but it is from it and with it; that is, "The nature of eternity is contemplated in the intelligible nature existing in it as originated from it." So eternity is an aspect of the intelligible as much as beauty or truth and is very close to being like a Plotinian intelligible form. It is a true whole in such a way that it is deficient in nothing, with neither past nor future.

Whereas the universe has a future and hastens by its everlasting circular movement to everlasting existence by means of what is going to be, the complete and whole substance of reality is something that is always existing—from "always existing" (*aeion*) is derived eternity (*aion*). Eternity is described as "state [*diathesis*] and nature [*physis*]" of complete reality, so Plotinus held the thin line between giving eternity a precise ontological status and seeing it as a quality. The difference between "everlastingness" and "eternity" is as follows: Eternity is the substrate from which everlastingness manifests itself, but eternity is the substrate with the corresponding condition manifested. So the final definition of eternity is this: "And if someone were in this way to speak of eternity as a life which is here and now endless because it is total and expends nothing of itself, since it has no past or future . . . he would be near to defining it."

Plotinus's examination of time is based on other philosophers' theories of time, namely these: (a) Time is *movement* (e.g., Plato interpreted by Eudemus, Theophrastus, and Alexander as identifying time with the movement of the heavens); (b) time is *what is moved* (the heavens themselves); and (c) time is *something belonging to movement* (e.g., the Stoic view of time as extension of motion, the Epicurean definition of time as accompaniment of motion, or the Aristotelian definition of time as number of motion). For Plotinus, time proceeds from the transcendence of the intellect. As eternity is the life of the intellect (*nous*), time is the life of the soul, which is to be identified with discursive reason (*dianoia*) and which descends from the hypostasis of the intellect. "Before" the descent of the soul, time was "at rest with eternity." By "a restless active nature which wanted to control itself and be on its own," the soul "transferred what it saw to something else" and "moved on to the 'next' and the 'after.'"

Just as soul constitutes itself as an image of the intellect and then produces the physical world as an image of itself, therefore also soul constitutes time, which is its own life as an image of eternity, and then creates as an image of itself the sensible world in time. Time then exists on two levels: First, "time is the life of soul in a movement of passage from one way of life to another." Second, it is the measured time in the physical world. The life of soul is discursive reason; that is, the movement from one idea to another. Therefore, the notions of "before" and "after" are present even in the intellect, so that "before" and "after" signify the order of causality, not the temporal sequence. Therefore, Plotinus's theory of time connects Plato's definition of time as "moving image of eternity" with Aristotle's definition of time as "number or measure of motion."

According to Plotinus, Aristotle failed to explain the nature and origin of the preexistent measuring number. Plotinus was far from suggesting an exhaustive rejection of Aristotle; instead he only complained that Aristotle's writings lacked sufficient clarity, because they were addressed to an internal school audience. With regard to Plato, Plotinus only wanted to correct misinterpretations: Instead of equating the heavens with time, Plato means that the sphere and the planets "manifest" time. Thus, time as a distinct interval measured by the movement of the heavens could be used as a measure, but time itself is not a measure; it should rather be called what is measured. By integrating Plato's and Aristotle's theories of time in his own system of hypostases, Plotinus succeeded in explaining the substantial nature of time and in differentiating between the metaphysical notion of time itself and the physical measurement of time.

Plutarch (c. 46–c. 120)

Plutarch, a classical Greek writer, lived during the period when the Roman Empire ruled the Mediterranean region, including Greece. Born into an aristocratic and influential family, Plutarch spent much of his life in Chaeronea, his birthplace in Boeotia. In his travels he visited Athens, Egypt, and Italy, often teaching and lecturing in Rome. Later in life, he would found an academy before joining the priesthood of the Oracle at Delphi, as he was a devout believer in the ancient pieties as well as an astute student of antiquity. Plutarch received his education in Athens, where he composed many essays and dialogues and became a writer and thinker versed not only in philosophy but also in science and literature. His works have greatly influenced Western understanding of classical culture, especially in comparing and contrasting exceptional individuals who lived in ancient Greece and ancient Rome.

Plutarch is most renowned for his historical works, which focus on the heroic lives of those who shaped both the classical and Hellenistic ages in Greece. His *The Rise and Fall of Athens: Nine Greek Lives,* and *The Age of Alexander* and *Makers of Rome: Nine Lives* remain widely read as staples of a classical education, although they are sometimes viewed as flawed in their historical methodology. Plutarch often includes what some historians regard as an excess of critical commentary in his accounts; moreover, Plutarch was not a contemporary of many of his subjects and thus relied on secondary sources who did not necessarily witness the events they recorded, so his historical accuracy is sometimes questionable. His style of weaving into his stories a great deal of legend or myth can confound the modern reader seeking detailed historical explanations. Consequently, Plutarch's chief value may lie not in his fidelity to historical detail but in his embodiment of the spirit of the classical Greek and Roman ages.

A philosopher by trade, Plutarch habitually made moral judgments about the character of his subjects on the basis of their deeds; thus, his historical accounts were perhaps secondary to the moral example they provide the reader. Of special interest to Plutarch was the comparison between the great lives of classical Greece and those of his contemporary Romans. His *Parallel Lives* illustrates similarities in excellence of character, or lack thereof, for the purposes of providing social commentary and in a way acting as a moral compass to the leaders of his time.

For his efforts as both biographer and philosopher, Plutarch was honored by Emperor Hadrian with a government appointment in Greece. Until his death, Plutarch continued to travel between Greece, Rome, and Egypt.

Poetry

The inexorable passage of time and corollary facets of change, mortality, memory, and nostalgia are rich themes in literature and, particularly, in poetry. Poetry, in the Aristotelian sense, seeks to recreate human experience and capture both its sensory and abstract essence. Unlike prose, poetry relies on a separate set of conventions emphasizing rhythm and sound patterns as well as figurative language and symbolism to achieve a multilayered effect. Common symbols evoking associations with time include references to the phases of the moon and tides, the rising and setting of the sun, the cycle of seasons, and shifting sand in its natural state or as a calculation of time through an hourglass. Such concrete references intensify awareness of the inevitable passage of time, which, although an abstract concept, is measured concretely through human constructs.

A common theme in Western poetry is *carpe diem,* or "seize the day." This metaphor is derived from the Latin *carpere,* "to pluck or grab," and *die,* meaning "day." The phrase is generally attributed to the Roman lyric poet Horace (65 BCE–8 BCE) also known as Quintus Horatius Flaccus. Horace used metaphors from nature to advise against procrastination and urged his readers to enjoy the present, "Be wise, strain the wine; and since life is brief, prune back far-reaching hopes! Even while we speak, envious time has passed: Pluck the day, putting as little trust as possible in tomorrow" ("*carpe diem, quam minimum credula postero*"). This view focuses on the present and encourages making the most of each day and stage of life. The adage has often been extended to embody a hedonistic sense of enjoying pleasure without concern for the future, because time, and ultimately death, are destroyers of life's joys.

The *carpe diem* theme was popularized during the European Renaissance (14th to 17th centuries), which saw a rebirth in learning and emphasis on humanism. This intellectual revolution was marked with great achievement in art, music, and literature. It also followed the devastating Black Plague of the 14th century, which wiped out at least one third of the population of Europe from Italy to Norway. The suffering and fragility of human life, as well as its potential for great accomplishment, made *carpe diem* an anthem to life and living it fully.

English poet and playwright William Shakespeare (1564–1616), long considered one of the greatest writers in the English language, often reflected on mortality and the overarching power of time in his sonnets and plays. His 38 plays were written predominantly in iambic pentameter, or blank verse, as were his 154 sonnets. In Sonnet 18, Shakespeare uses his pen to defy time and bring immortality to his love: "So long as men can breathe or eyes can see,/So long lives this, and this gives life to thee." In Sonnet 30, Shakespeare expresses remorse over wasted time: "When to the sessions of sweet silent thought/I summon up remembrance of things past,/I sigh the lack of many a thing I sought,/And with old woes new wail my dear time's waste." But knowledge of mortality can even intensify love, as in Sonnet 73: "This thou perceivest, which makes thy love more strong,/To love that well which thou must leave ere long." And Sonnet 45 expresses human resistance, as well as powerlessness, against the ravages of time: "And nothing 'gainst Time's scythe can make defence/Save breed, to brave him when he takes thee hence."

Shakespeare also made numerous references to time in his plays, both comic and tragic, as illustrated by the clown's refrain in *Twelfth Night:* "What is love? 'Tis not hereafter;/Present mirth has present laughter, What's to come is still unsure:/ In delay there lies no plenty" (act 3, scene 2). A darker reference is made in *The Tragedy of King Richard II* when Richard laments: "I wasted time, and now doth time waste me:/For now hath time made me his numbering clock" (act 5, scene 5). Whether expressing hope, defiance, regret, or stoicism, Shakespeare grappled frequently with the relentless nature of time and its effect on the human condition.

Other 16th- and 17th-century English poets also addressed the *carpe diem* theme, particularly the Cavalier poet Robert Herrick (1591–1674) and the metaphysical poet Andrew Marvell (1621–1678). In "To the Virgins, Make Much of Time" Herrick urges, "Gather ye rosebuds while ye may,/Old time is still a-flying,/And this same flower that smiles today,/To-morrow will be dying." In "To His Coy Mistress," Marvell pleads, "Now let us sport us while we may,/And now like amorous birds of prey, Rather at once our time devour/Than languish in his slow-chapped power." These works impart a sense of immediacy and become an argument for satisfying desire in the moment. This sentiment was frequently expressed by 20th-century poet Edna St. Vincent Millay (1892–1950) who recognized the short lifespan of passionate love, as in sonnet "XI": "I shall forget you presently, my dear,/So make the most of this, your little day,/Your little month, your little half a year."

Regret over wasted time recurs frequently in the works of modern and contemporary poets looking back on misspent youth or oblivious to the passage of time until it is too late. British writer Christina Rossetti (1830–1894) in "A Daughter of Eve" laments: "A fool I was to sleep at noon,/And wake when night is chilly . . . /Oh it was summer when I slept,/It's winter now I waken." A profound sense of loss is conveyed by 20th-century Welsh writer Dylan Thomas (1914–1953) when he writes powerfully of his youth and disregard for the power of time. In "Fern Hill," Thomas recreates the idealized rural paradise of his early life, which he describes as "green and golden" while "Time let me play and be/Golden in the mercy of his means." But as an adult he realizes, "Time held me green and dying/Though I sang in my chains like the sea." Another of Thomas's poems, "Do Not Go Gentle Into That Good Night," pleads to his dying father, "Do not go gentle into that good night./ Rage, rage against the dying of the light." Thomas's tone conveys not an acceptance of the inevitability of time and death but, rather, resistance even against an insurmountable power.

American writers Archibald MacLeish (1892–1982) and Emily Dickinson (1830–1886), although separated by almost a century, both pondered the unfathomable concept of eternity. Dickinson, who led a most private and solitary life, often grappled with time as an abstract and her own place in the continuum, as in "Behind Me Dips Eternity": "Behind Me—dips Eternity—/ Before Me—immortality—/Myself—the Term between." Her use of punctuation to create pauses reminds the reader of the subtle transition by which past, present, and future flow into one. Archibald MacLeish, a more public figure who was artistically and politically active, echoed a similar voice in "An Eternity": "There is no dusk to be,/There is no dawn that was,/Only there's now, and now,/ And the wind in the grass." Both poems reinforce the significance of being fully alive in the moment and the realization that humans can comprehend the universe only through sensory experience in the present.

Walt Whitman (1819–1892), influential and iconoclastic American writer, applied his theory of an "Oversoul" to create a vision of the interconnectedness of human life and the natural world, which flow as one through time. In his masterwork, "Crossing Brooklyn Ferry," Whitman uses the movement of the river, clouds, and sunlight descriptively and metaphorically, as the ferry and its passengers flow together, not only through physical space, but also through time: "Others will enter the gates of the ferry, and cross from shore to shore . . . /A hundred years hence, or ever so many hundred years hence, others will see them,/Will enjoy the sunset the pouring in of the flood-tide, the rolling back to the sea of the ebb-tide." In Whitman's interpretation, the oneness of humanity is manifest through shared experience over time; therefore, time and the cycles of nature become unifying, rather than separating, elements.

The 19th-century American transcendental movement protested reliance on the empirical world and promoted intuition and spiritualiy over doctrine and pure reason. A leading writer and thinker in this movement, Ralph Waldo Emerson (1803–1882) personifies time in his poem "Days": "Daughters of Time, the hypocritic Days, . . . /Bring diadems and fagots in their hands/To each they offer gifts, after his will,—" This verse ponders how time brings new days that can be wasted or fulfilled, either through chance or the exercise of free will. Emerson juxtaposed the lasting quality and value of a jeweled crown with the ephemeral bundle of sticks that offer a brief light before turning to ashes. Transcendentalists encouraged close observation of nature, as expressed in Emerson's essay: "To the attentive eye, each moment of the year has its own beauty, and in the same field, it beholds, every hour, a picture which was never seen before, and which shall never be seen again." Time, then, creates an ever-changing, but impermanent, beauty.

American transcendentalism is strikingly similar to Eastern views of nature as expressed in traditional Japanese haiku, a 300-year-old classical form that embodies the awareness of time by capturing the moment, particularly the transition of seasons. This traditional form, whose structure is based on elements of sound in Japanese, has been adapted in English to 17 syllables arranged in three lines of 5, 7, and 5 syllables each, respectively. It is one of the shortest but most effective forms of verse and focuses on a fleeting moment or, otherwise, unnoticed event. One of the revered writers of haiku was Basho, born Matsu Kinsaku (1644–1694), a poet, teacher, and Zen philosopher. His poetry compresses time, observing the human life span as reflected in microcosms of nature and the significance of events that mark the transition from one season to another: "The first soft snow!/Enough to bend the leaves/Of the jonquil low." The reader may extend the metaphor, complete the chain of events, and transfer the meaning to human experience.

The concise, but powerful, form of haiku has been adapted to other languages and cultures as a means of escaping time-bound expression and characterizing time as a continuum, or what theologian Paul Tillich (1886–1965) has referred to as "The Eternal Now." Poetry serves as a bridge, transcending time and space and reaching back to the past and forward to the future. As renowned Japanese writer Natsume Soseki (1867–1916) expresses in his haiku: "On New Year's Day/I long to meet my parents/as they were before my birth." Imaginative time travel is also suggested by British poet T. E. Hulme (1883–1917) in "Image": "Old houses were scaffolding once/and workmen whistling." And British poet James Elroy Flecker (1884–1915) projects his greeting forward in his six-stanza quatrain "To a Poet a Thousand Years Hence": "Since I can never see your face,/And never shake you by the hand,/I send my soul through time and space/To greet you. You will understand."

As a literary form, poetry exposes the human mind and heart grappling with the concept of time by recreating the past, capturing the present, and imagining the future. American-born writer T. S. Eliot (1888–1965) considers the nature of time in *Four Quartets,* which poses the possibility of alternate realities, or "What might have been and what has been/Point to one end, which is always present." Each section of the Quartets is related to one of the four basic elements of air, earth, water, and fire, and in "Burnt Norton" (No. 1 of *Four Quartets*), Eliot frames the conundrum powerfully: "Time present and time past/Are both perhaps present in time future,/And time future contained in time past. If all is eternally present/All time is unredeemable."

Poincaré, Henri (1854–1912)

Henri Poincaré belongs to a small group of brilliant scientists who, living at the turn of the 20th century, made fundamental contributions to mathematics, physics, and philosophy. It has been said that Poincaré's mathematical knowledge comprised the whole mathematics of his time, and his lectures on theoretical physics show that he also had an encyclopedic overview of this field. Poincaré began his career as an engineer, but he quickly became famous for his great discoveries in mathematics, particularly in geometry and topology. Poincaré's results had a great impact on the history of mathematics and theoretical physics. For example, his consideration of the mechanical stability of systems composed of three bodies that attract each other by gravity led to the development of chaos theory. Poincaré's views of philosophical aspects of science, which he never presented in a systematic fashion, cannot be easily categorized as belonging to one of the main philosophical schools. This is also true of his idea of the relativity of time, which must be reconstructed from some of his papers collected in *Science and Hypothesis* (1902), *The Value of Science* (1906), *Science and Method* (1908), and the posthumous *Last Essays* (1913).

Jules Henri Poincaré was born on April 29, 1854, in Nancy, France. He was an outstanding pupil and made a very successful career in the French system of elite universities. His first academic degree was in mining engineering, and he worked for a short time as a coal-mining inspector. Yet after receiving his doctorate in mathematical sciences from the University of Paris in 1879, Poincaré began swiftly to publish important mathematical results, which brought him renowned chairs, particularly in mathematical physics, at different universities in Paris beginning in the mid-1880s. Besides being admitted to countless French and international scientific academies and societies, Poincaré was also an important member of the Bureau des Longitudes in Paris that organized the global coordination of clocks necessary for the production of precise maps. When he died prematurely in Paris on July 17, 1912, Poincaré was hailed as one of the most renowned researchers of his time. His fame as one of the last scientists who could make most important discoveries in different fields of research and reflect on his research philosophically continues to the present day.

Poincaré's consideration of time starts, like that of Einstein, with a seemingly innocent question: How can we judge objectively that two events are happening simultaneously? Any answer presupposes that it is possible to objectify the flow of time that our consciousness experiences qualitatively. Poincaré denies that human beings, scientists included, have access to some kind of absolute time beyond the scientific means of quantifying time by measurement instruments. If every process in nature were to be equally slowed down, we could not detect this deceleration, because the processes in the instruments for measuring time would also be slowed down.

Poincaré's criticism of the idea of absolute time exemplifies his philosophical stance on fundamental problems of science. He is convinced that the conceptual system by which we describe, analyze, and explain natural phenomena is a convention in the following sense: It is always possible to use, instead of the given conceptual system, other ones that can fulfill the same task. What convention we choose depends on pragmatic criteria, particularly on how simple it is to apply a conceptual system to the phenomena we want to understand. So conventions are neither true nor false; they are disguised definitions that prove to be more or less convenient for certain purposes.

To measure time, a periodic process in nature, such as the rotation of the earth on its axis, is needed whose cycles we suppose to be of the same duration. Yet this is only approximately true: The rotation of the earth, for example, is very gradually slowing down due to the friction caused by the tides. To explain this slowing down, and to detect it empirically, science presupposes the validity of well-known physical theories, namely thermodynamics and Newtonian mechanics. Their validity must not be affected however we define our measure of time, because we rely on these theories in the very act of defining. When we conventionally select one among the possible measures of time, we do this in such a way that the fundamental laws of nature can be mathematically formulated as simply as possible. As scientists, we ought not to say that one clock is right and the other one wrong; instead, we should say that it is more convenient to use this clock and not that one.

What events we suppose to be synchronous is also a matter of convenience. We choose such criteria of synchronicity as will allow the simplest formulation of the laws of nature we are using when we explain the physical processes by which we make local time measurements and by which we communicate the results of these measurements. Exploring the physics of time means, according to Poincaré, to investigate measurement processes in order to establish conventions that we can use both for an understanding of time and for an explanation of how our clocks would behave if they were perfect measuring instruments.

So far we have discussed only the philosophical sense of the relativity of time in Poincaré's thought. The question of whether Poincaré should be regarded, together with Einstein, as the discoverer of the special theory of the relativity of time and space has been intensely debated. The historical evidence seems to weigh against Poincaré: He relied too much on physical concepts (like the ether) that stood in the way of understanding Einstein's new conception of time and space. For Poincaré, the physical principle of the relativity of time is also a matter of convention, because it makes, for the sake of convenience, the following assumption that turns out to be only approximatively true: Two bodies that are very far away from each other can be described in different frames of reference, because they do not influence each other.

Polo, Marco (1254–1324)

Marco Polo was a Venetian traveler and merchant who traveled to China at a time when Europeans knew little about Asia. Polo served the Mongol Emperor Kublai Khan for 24 years before returning to Venice. He attained great fame with the publication of his account of the journey, *Il Milione*. This book helped to inspire Europe's Age of Exploration.

Marco Polo was born in Venice, Italy, into a family of merchants. Venice was an important center of trade in the medieval world. Venetian merchants maintained trading posts as far away as the Black Sea, where goods arrived along the ancient trade route known as the Silk Road. Marco's father, Nicolo Polo, and uncle, Maffeo Polo, had traveled across Asia on a trade expedition around the time of Marco's birth. They traveled deep into China, which Europeans called *Cathay,* and they met the Mongol ruler Kublai Khan. The Khan received them very courteously and invited them to return again with Western scholars who could teach Christianity to his people. Nicolo and Maffeo Polo returned to Venice in 1269 and prepared for a second expedition that would include Marco.

In 1271, the Polos began the long journey to the Far East along with two Christian missionaries. The two missionaries became frightened while passing through Armenia and abandoned the mission. Seventeen-year-old Marco Polo, along with his father and uncle, continued the trip alone. It took more than 3 years of travel before the Polos again met Kublai Khan, after traveling much of the way on camels. Marco Polo, with his knowledge of four languages, became a valuable diplomat in the service of the Khan. He traveled on missions throughout Asia, and for 3 years served as a government official in the Chinese city of Yanh-Chow (Janguy). After 24 years away from Venice, the Polos finally decided to return home. The Khan was very reluctant to let them go.

The Polos arrived in Venice in 1295 and were scarcely recognized. They returned to a Venice that was at war with the rival city of Genoa. Marco Polo commanded a Venetian galley during the conflict but was taken prisoner by Genoa following a naval defeat. In prison, Polo wrote an account of his travels across Asia and his relationship with the great Khan. With the help of Rustichello of Pisa, Polo's story was translated into French and completed in 1298. Polo called his book *The Description of the World,* but the name *Il Milione* was more commonly applied. The book became very popular and widely distributed in a time before the advent of the printing press. The Polos were not the first Europeans to travel across Asia, but they became the most well known. By the time the Polos returned to Venice, the advance of the Turks had already cut off trade routes to China. Europeans would in time sail west to reach China and India. Following Marco Polo's release from prison in Genoa, he returned to Venice and became a wealthy and respected merchant. He never left Venice again and died at nearly 70.

Marco Polo's experience had a lasting impact on the contact between Europe and the Far East over time. Historians believe that his book influenced later explorers such as Christopher Columbus.

Pompeii

Pompeii was an ancient city of the Roman Empire, located near the Bay of Naples in the Campania region of Italy, a few miles southeast of Mt. Vesuvius. Situated at the mouth of the Sarnus (modern Sarno) River, Pompeii was a popular resort town for wealthy Romans and a busy trade center. In the year 79 CE, Mt. Vesuvius erupted, destroying Pompeii, Herculaneum, Stabiae, and many smaller communities. Today Pompeii is one of the most important archaeological sites in the world. Most cities have many layers of occupation and stages of development, but the burial of this entire city under 30 feet of ash and debris has perfectly preserved for all time an ordinary day in the lives of ordinary people of the Roman Empire.

History of the City

The site of Pompeii was likely first settled by Oscan-speaking descendants of Neolithic people in the 8th century BCE. The strategic river location eventually came under the influence of Greeks who had settled across the bay. Pompeii and Herculaneum remained the center of Greek occupation until the 5th century BCE, when Samnites descended from the north and seized control. Rome drove the Samnites from the region in the 4th century BCE and claimed Pompeii. The city was permitted to keep its own language and culture, but its inhabitants were not granted citizenship or given any privileges. This situation was maintained for centuries, until the citizens of Pompeii had a chance to join with other rebels in an attempt to win freedom from Roman oppression. Sulla, a brilliant Roman general, eventually defeated the Campanians and took Pompeii and Herculaneum in 89 BCE. The rebels were granted Roman citizenship despite their defeat, but many liberties were taken away. Rome strategically housed army veterans in the area to maintain order.

The rich natural resources available in the area and easy access to the sea enabled Pompeii to flourish. As Rome became increasingly prosperous, the standard of living in Pompeii increased proportionally. The entire region along the coast of the Bay of Naples became a popular vacation destination for wealthy Roman citizens.

Mt. Vesuvius remained dormant throughout these many centuries of occupation. There was no way for Pompeians to know that they were living at the base of a volcano that had buried a Bronze Age settlement under 20 feet of debris directly beneath them in 1780 BCE. In the year 62 CE, a severe earthquake resulted in catastrophic damage to both Pompeii and Herculaneum. Repairs were still being made 17 years later when the city was destroyed.

The Eruption of Vesuvius

Roman science in the 1st century was based more on mythology than geology. Mild earth tremors were common and were not alarming to the population. Fumaroles—vents of volcanic gas escaping through the crust to relieve pressure—were seen from a distance and reported to be giants roaming the land. The gods would defeat the giants and trap them under the mountain, which would cause the earth to shake. There was no correlation made between seismic activity and volcanic activity.

Major seismic activity began on August 20, 79 CE. A series of quakes increased in frequency over the following 4 days. Animals were restless, and springs near the mountain ran dry. In the middle of the day on August 24, Vesuvius suddenly erupted. A huge column of superheated gas, rock, and ash blasted straight up from the top of the mountain. As the cloud cooled, it spread and drifted with the wind. A vivid eyewitness description of the initial explosion exists in letters written by Pliny the Younger, who witnessed the phenomenon with his uncle from 15 miles away. As the cloud began to collapse, the sky darkened and pieces of pumice rained down on Pompeii. This "Plinean" phase of the eruption lasted about 18 hours. The initial fall of ash, rock, and pumice deposited more than 9 feet of debris on the town. A few unfortunate individuals were struck down by falling stones or collapsing roofs, but there were few deaths on the first day. It has been estimated that perhaps 80% of the population escaped the region by leaving immediately. The 2,000 or so people who decided to take shelter and wait for the event to pass were the unlucky ones.

The true lethality of the eruption occurred in the final few hours of the second day. Surges of pyroclastic material and superheated gas roared down the mountain, reaching the city of Pompeii in minutes. There was no escape. All remaining residents were asphyxiated in seconds. A series of surges deposited an additional nine or more feet of ash and rock, effectively entombing the town. The complete and instantaneous burial of the town protected it from looting and natural weathering. When dawn broke on August 26, all was quiet and still. The entire region of Campania was buried under a thick layer of ash. The eruption changed the course of the river and raised the sea beach, masking the original location of the city. Over ensuing years, the memory of Pompeii and its neighboring cities faded into obscurity.

The Rediscovery of Pompeii

By the 4th century CE, Pompeii no longer appeared on maps. The area was called Civitas. The ash that had buried the region over 200 years earlier had become fertile soil. Farmers moved back into the area and planted their grapevines and olive trees. In 1709, some well diggers unearthed marble. The prince in charge of the region was building a new villa nearby, so the workers continued to strip the marble until the villa was completed. The marble was from the façade of the theater in Herculaneum. In 1738, King Charles III took control of the region and sent workers to the same location in search of additional treasure. Systematic studies and surveys of the area were carried out. Work began in the vicinity of Pompeii in 1748. An inscription identifying the site as Pompeii was uncovered in 1763. The methodical, deliberate work at these sites in the mid-18th century can be considered the origin of the field of archaeology.

Much of the earliest digging at both cities was often haphazard and careless. Workers were unskilled or were treasure hunters. Unauthorized digging was halted in 1860 when Giuseppe Fiorelli, an Italian archaeologist, became director of the excavations at Pompeii and Herculaneum. Pompeii was divided into regions, which were carefully cleared and documented. Fiorelli realized that there were cavities in the ash with bones in them. He took a revolutionary step in analyzing human remains at Pompeii. Rather than removing the skeletons, he had workers carefully fill the cavities with plaster. After the plaster dried, the volcanic debris was chipped away, leaving a cast of the person's dying moments. By studying the individuals, their dress, and the possessions they carried, researchers could reconstruct their last few minutes of life.

A museum was eventually established at Pompeii to house artifacts and dozens of the casts that were created. Pompeii became a mandatory stop on the grand tour of Italy that was so common among the European aristocracy. The richly colored murals that were exposed triggered a revival of neoclassical art. Well-appointed British homes often included an Etruscan salon, with décor copied from Pompeii.

While the public buildings of Pompeii are impressive, it is the private homes that set this site apart. The fine ash that smothered everything proved to be a remarkable preservative. Archaeologists have uncovered jars that still have food inside. Eighty-one loaves of bread were still in the oven of a bakery. Graffiti is intact on the walls of buildings. Shops and restaurants still have everyday tools in context. City planning and actual land use can be evaluated. Pompeii provides a unique and important source of information on many aspects of daily life during the Roman Empire. Much is written about the wealthy senators and citizens of Rome, but the vast majority of the Empire actually consisted of smaller towns and villages. Pompeii provides a snapshot of social, economic, religious, and political life of ordinary citizens of the ancient world frozen at a single moment in time.

Popper, Karl R. (1902–1994)

Karl R. Popper was a British-Austrian philosopher and theorist of science. He had significant influence upon 20th-century philosophy with his contributions to epistemology, philosophy of science, and social theories. His central works include *The Logic of Science* (1934), *The Open Society and Its Enemies* (1945), and *The Poverty of Historicism* (1957). This last work contains an explication and criticism of historical scholarship as it was being practiced. Popper argued that such scholarship possessed a metaphysical determinism that assumed that time had a definable shape, such as "progress." He rejected sociology's historical determinism that portrayed time itself as a vector of a teleological conception of history.

As the founder of critical rationalism, Popper challenged the methods of empirical science and the inductive approach of logical positivists such as the "Vienna Circle" philosophers devoted to Moritz Schlick. Because observation in itself is insufficient for establishing scientific validity, the critical rationalists proposed the "principle of falsification." In contrast to the classical empiricism that strove for perfect validity, critical rationalists argued that science is doing its best work when it puts forward theses as statements that are capable of being proven wrong. Despite any number of arguments, assertions can never be entirely verified. The conclusion is that scientific knowledge does not improve by positive evidence. Instead, according to the principle of falsification, the point is to prove all the false hypotheses wrong by finding compelling counterexamples. "Verification" is a mistaken notion. Theories that withstand scientific scrutiny are "more valid," according to Popper, and falsifiability is a much better criterion of demarcation between scientific and nonscientific theories. In the area of social philosophy, he likewise demonstrated the invalidity of "truth claims" for ideologies, be they sociohistorical or political theories. Preferring a motif of indeterminism, his political ideas merged into a liberalistic pleading for a pluralistic, liberal, and democratic "open society."

Popper's scholarly work focused mainly upon what scientists are doing when they are doing "science," and his reflections on methodology mark the central starting point of his thinking. Critical rationalists argue that any scientific theory is abstract and conjectural by nature, making it difficult to identify secure knowledge. Therefore, genuine scientific theories require a specific logical structure:

openness to testability and revisability. By being structurally open to a trial-and-error process, that is, by being falsifiable, new conceptual theories are far more effective than dogmatic assertions of truth by an establishment. Falsifiability provides both a new approach to the challenge of ultimate justification and a method of distinguishing metaphysical statements from theories of scientific validity and reliability. In this way, we see how Popper's critique of historicists is a methodological one.

In *The Poverty of Historicism,* Popper's critique goes against approaches that make historical predictions their main objective and thereby attempt to grasp universally valid patterns of history. Because historicism argues that historical events underlie inexorable laws of development and advance toward an ultimate and discernable end, historicists strive to empirically establish an authoritative chronology of events. Given this position, sociology becomes a mere science of theoretical history in which time assumes an orientating function. At the same time, historicists hold that the method of universalization is not transferable to the social sciences. As a result, social laws must be structured differently from common generalizations. Thus, to be valid for all human history, such laws have to transcend the succession of time. These epoch-spanning laws of historical development now provide the basis for large-scale forecasts that can be identified as prophecies and distinguished from technological predictions. While the former refer to unchangeable events and characteristically serve forewarning purposes, technological predictions, which Popper prefers, are of constructive value, entailing useful instructions or guidelines for dealing with situations most likely to come.

According to Popper, a holistic conception of society that follows unique evolutionistic laws of succession is scientifically unsupportable. Holists mistake tendencies and singular theorems for universal laws. But, because each scientific law must be verifiable empirically, and because the laws-of-development hypothesis and evolutionism are both confined to observing unique events, these theorems cannot get universalized in terms of laws and scientific predictions.

In order to specify his objections to historicist methods, Popper criticized the interpretation of time as a criterion for the elevation of "static laws" to "connective laws" akin to Auguste Comte's and John Stuart Mill's distinction between laws of coexistence (time-independent) and laws of succession (time as a constitutive coefficient). Indeed, laws can contain statements about dynamic processes, but they can never point beyond individual cases or subsume singular, basically distinct causal connections under one rule. Assertions about periodicity, such as the circle of the year, are bound to incorporate/consider a number of single laws that cannot be abstracted, such as those of the earth's rotation, thermal inertia, etc. For this reason, the perception of dynamic succession or development can be due only to metaphorical illustrations of certain tendencies, not to scientific laws.

Over and above this, Popper points out that historicist doctrines provide a theoretical breeding ground for authoritarianism and totalitarianism. First, he refers to Plato's ideal state as resulting in socially immanent and decadent tendencies by maintaining a strictly hierarchical form of government, stifling all change for the sake of political stability. Second, Popper refers to Hegel's dialectic progression of history as being directed toward a perfection that, in practice, results in the glorification of the Prussian monarchy. Third, he argues against the Marxist economic oversimplification of social spheres.

Rejecting such forms of collectivism, Popper proposes the autonomy of the social sciences and a method of analyzing historical events by reference to the behaviors of individuals. Unlike holistic approaches, a "technological" social science recognizes the incalculability of human characteristics. It allows both for the logic of particular circumstances and the unintended side effects. Learning from this methodological individualism, political institutions can be designed in a way to prevent incompetent leaders from wreaking havoc. Similarly, Popper advocates what he calls "piecemeal social engineering." Instead of large-scale utopianism, social and political planning has to proceed stepwise in consideration of human fallibility and the irreversibility of time. By emphasizing the value of democracy as the nonviolent generation and deposition of political leadership, Popper was a contributor to democratic theory from a functionalistic angle. Because of these ideas, Popper strongly defends an open society that is capable of monitoring social phenomena and minimizing misery to enable its members to take part in a broad landscape of critical discourse.

POSTHUMANISM

See TRANSHUMANISM

POSTMODERNISM

In few areas is it more problematic to arrive at a clean definition than it is for postmodernism. Not the least of the problems is the resistance of postmodernists to being defined, or, in many cases, to admit the authority or even the possibility of definition as an activity. Before attempting a definition, a series of useful distinctions can be drawn. However, postmodernists are very critical of scientific theories and empirical evidences. Consequently, they do not take seriously conceptions of time in terms of evolution and relativity (among other temporal frameworks).

Postmodernity and Postmodernism

The first important distinction to be made is that between postmodernity and postmodernism. Postmodernity is a name given to a period of history, and postmodernism is the body of theory that has developed to explain that period. Opinions differ about when postmodernity is supposed to have begun, with dates ranging between 1968 and 1973. All agree that conditions in the world have changed since then. In international politics, the sites of authority have fractured from the relatively straightforward conflict of the Cold War to the multipolar, less predictable, and more confusing international situation of today. Other fundamental changes have been made to our styles of work, with entirely new industries, work hours, and arrangements than were the case before. The assumption underlying the notion of postmodernity is that the world has seen not simply changes in style but a fundamental shift in the way the world operates, a shift that has been to the disadvantage of predictability, order, and rationality.

Those who argue for 1968 as a convenient date for the onset of postmodernity point to the student riots of that year, when the post–World War II baby boomer generation, the best-fed, best-educated generation in world history, spurned the cultural conventions they grew up with and demanded change. These revolts did not demand a specific set of political, social, and economic changes; they demanded *change,* as a general rejection of the old. The impact of the baby boomer generation is very significant, but even it was swept along by the broader transformation taking place after the events of 1973. This was the year when the international economy changed forever as a result of the oil shocks brought on by a newly radicalized Organization of Petroleum Exporting Countries (OPEC). The oil shocks were provoked by the oil-producing countries, most of which were from the Muslim world, wanting to express anger at the continued support by the West of Israel, which had been decisive in the recent Yom Kippur war. This marked a fundamental change in the balance of economic and political power and a dramatic shifting in priorities in global politics and economics. The widespread social changes that have occurred in the West are largely a product of these developments. Postmodernity can perhaps best be dated, therefore, from 1973.

It is important to note that "postmodernity" as discussed here is nothing more than a title given to a period by historians, like "Renaissance" or "Dark Ages." Others have called this period Late Capitalism. Still others have rejected the idea that the events of 1973 mean we can no longer speak of "modernity." This debate becomes a question about the periodizing of history and the usefulness of such a procedure.

Postmodernism as Reactions to Postmodernity

We have seen, then, that postmodernity and postmodernism are not related. Postmodernism is, as the suffix implies, an "ism," a series of reactions that have arisen to explain the times known to some as postmodernity. It is quite consistent to see value in postmodernity as a historical term while also rejecting the postmodernism that has arisen as a series of reactions to explain postmodernity. Most introductory essays to postmodernism begin with the insistence that any attempt at a comprehensive delineation and understanding of postmodernism is inherently contradictory and bound to fail. To overcome this problem, most characterizations of postmodernism portray it not as a coherent body of doctrine but as a general mood, or, as described in the previous paragraph, a series of reactions. What is more, the series of reactions are often expressed in negative terms.

Postmodernism is almost entirely confined to universities and literary circles. And within universities, some faculties are more likely to be favorable to postmodernism than others. Most branches of the sciences are hostile, whereas departments of English or French literature, architecture, visual arts, and sometimes anthropology and sociology are more likely to react favorably; opposition to postmodernism in philosophy departments, particularly in English-speaking countries, has grown since the mid-1990s.

In addition to these divisions between faculties, there is also a division based on geography. We have already noted this division among philosophy departments at universities. There are two general strands to the postmodernist reactions to postmodernity. One strand of postmodernism is content to *acknowledge* the changes that have taken place since 1973 and to try to understand them. The other, more radical strand is more willing to *celebrate* those changes. Broadly speaking, this fissure divides postmodernists in the Anglo American academic community from those from the Continental (mainly French) academic community. This is made more complicated when we note that this division is by no means exclusively a geographical one. The two styles of postmodernism, while having a geographical dimension, are principally divided by a series of contrasting emphases with respect to some important questions. The first of these dividing points centers around their attitudes toward philosophical analysis. Anglo American postmodernists may be cautious about analysis as a tool but still acknowledge its value. Postmodernists of the Continental variety, by contrast, are more inclined to view analysis as part of the problem they are looking to overcome than as a useful tool to gather new and better understandings.

A second major area of divergence can be seen in the attitudes toward metanarratives. Most postmodernists, whether Anglo American or Continental, see postmodernity as a time when traditional metanarratives broke down. A metanarrative is a general intellectual framework through which we view history. For example, the communist metanarrative is of a progressive, and inevitable, succession from feudalism, through capitalism to socialism, and, in the future, on to communism. A Christian metanarrative, by contrast, proceeds from a primitive innocence in Eden, followed by the Fall and the condition of sin and death among humans, relieved by the redemption of Jesus Christ, and which will be brought to an end when Christ returns to reward the faithful and judge the damned. The most oft-quoted definition of postmodernism comes from the French thinker Jean-François Lyotard, who defined it in terms of incredulity toward metanarratives. The differences lie in their contrasting attitudes to the end of metanarratives. As noted above, most postmodernists from the Continental tradition are likely to celebrate the end of metanarratives. They claim that not only are metanarratives no longer needed, they are no longer welcome. For with the end of metanarratives comes the end of the tyranny of history, and, more particularly, the end of the presumption of scholars to be chroniclers of historical fact. Instead, postmodernists argue, we have a mass of assertions and claims that can all compete for our attention as best they may, with little difference in the outcome of one being chosen over another.

Underlying this hostility to metanarratives is the postmodernist hostility to what they see as the dominating and bullying nature of science and reason. The central claim of postmodernists of the Anglo American strand is that rationality is a historically conditioned faculty, which means that different historical epochs will produce different notions of rationality. This is not a point many opponents of rationality would dispute. Indeed, many of the people derided by postmodernists, such as the philosopher Bertrand Russell, made these points long before postmodernism was an intellectual force. Others, usually of the Continental strand of postmodernism, are more extreme and seek to condemn what some call "legislative reason" as being inherently domineering and oppressive. In contrast to this, they say, postmodernism is a liberation from rationality, because it is a liberation from all socially constructed bounds and norms. As one prominent postmodernist put it in 1992, postmodernism is about splitting the truth, the standards, and the ideal into what has been deconstructed and what is about to be deconstructed and denying in advance the right of any new doctrine, theory, or revelation to take the place of the discarded rules of the past. David Harvey, in an influential postmodernist work published in 1991, enthused that postmodernism wallows in the fragmentary and chaotic currents of change, as if that is all there is. In a similar vein, Gregory Bruce Smith identified postmodernism as fundamentally a sign of disintegration, transition, and waning faith in what he called the Enlightenment project.

In defining postmodernism, then, we need to take account of these two strands of interpretation. The more moderate version of postmodernism is the assertion that we cannot *know* anything; we can only interpret, and any interpretation we make can only express our partial and narrow perspectives. The more radical version of postmodernism is the assertion that not only can we not know anything, but also our claims to knowledge are bound to be hegemonic and impatient of dissent, which means that our ability only to interpret from our partial and narrow perspectives constitutes a liberation from that tendency toward hegemony, which is particularly evident in science and rationality.

Behind the differences of emphasis and geography, there is a common political heritage for much of postmodernism. This is because postmodernism is a phenomenon of the political left. The reason postmodernists are anxious to write the obituary of metanarratives is that many of them were, earlier in their lives, proponents of variations of socialism and communism, which, as we have seen, have strong metanarrative components. This can be traced back to the disillusionment of German socialists after the failure of the Spartacist revolt in Berlin in 1919. Not only did socialist revolution fail, but also the parties of the left were then seen to fail as well, as they showed themselves incapable of resisting the rise of Nazism. By their slavish following of the dictates of Moscow, the parties of the left had betrayed their purpose. The school of Marxist-inspired criticism, known as the Frankfurt School, traced this progressive failure of each institution that had once been a source of hope.

After the Second World War, the Soviet Union joined the ranks of gods that failed. Between the Soviet invasions of Hungary in 1956 and Czechoslovakia in 1968, the promise of communism as a metanarrative of progressive liberation from alienation became ever more difficult to sustain. The choices of the left after 1968 were stark: acknowledge that capitalism and the metanarratives that sustain it had triumphed, or create a system of criticism that denied the legitimacy of any metanarratives at all. Postmodernism adopted the latter approach. The differences of emphasis between the Continental and Anglo American styles of postmodernism were most pronounced on the question of the degree to which Western culture could be salvaged. Critics like Theodor Adorno (1903–1969) and Max Horkheimer (1895–1973) were among the more pronounced cultural pessimists. In *Dialectics of Enlightenment* (1947), Adorno and Horkheimer saw modernity as inherently self-destructive, carrying the germs of its own dissolution and decay. There was a straight line, they argued, from the Enlightenment to Nazism and Stalinism. Later heirs of this high level of pessimism included the Polish-born sociologist Zygmunt Bauman (b. 1925), who argued that modernity is a long road to prison, and Michel Foucault (1926–1984), who saw all society as engaged in a war against people to impose on them a sterile understanding of what it is to be human.

The more moderate postmodernists in the Anglo American schools, however, were not prepared to go this far. Their general argument was to see value in the humanist tradition of the Enlightenment, merely wanting to excise from it the faults and excesses they perceived it brought with it. Advocates of this approach include the English philosopher Michael Luntley and the New Zealand sociologist Barry Smart.

Postmodernists agree on their suspicion of metanarratives, diverging only on the degree of opposition they are prepared to express. Another area of general agreement is in their attitudes toward science. Anglo American and Continental postmodernists agree that science involves a metanarrative, which they question. The metanarrative of science speaks of cumulative knowledge over time, leading to ever clearer understandings of the universe. And, just as important, postmodernists question the claim of science to being grounded in objective truth. But the attitudes toward science reveal the greatest splits between the Anglo American and the Continental styles of postmodernism. The Anglo American attitudes are best articulated in the works of Richard Rorty (1931–2007), whose critique has been directed against foundationalism, the practice of claiming that one's theories rest on objective foundations of truth. The Continental branch of postmodernism, once again, has wandered much further afield in its attitudes toward science. Indeed, it is this area that has provoked the strongest opposition. Working from an epistemic relativism, many Continental postmodernists have pressed the claims that science is a metanarrative like any other, with no special claims to authority, and indeed, meriting extra levels of criticism precisely because of those claims of authority they perceive scientists making.

The Decline of Postmodernism

Postmodernism began to attract some significant critical attention after about 1994. Much of the criticism was led by scientists and by philosophers who take science seriously. Leading the way was a devastating critique by Norman Levitt and Paul Gross, *Higher Superstition: The Academic Left and Its Quarrels With Science* (1994). Other significant milestones included *Derrida and Wittgenstein* (1994) by Newton Garver and Seung-Chong Lee, *The Poverty of Postmodernism* (1995) by John O'Neill, and *The Flight From Science and Reason* (1996) edited by Paul Gross, Norman Levitt, and Martin W. Lewis. But what publicized the decline of postmodernism was what has become known as the Sokal hoax. In 1996 Alan Sokal, a professor of physics at New York University, submitted a paper to the postmodernist journal *Social Text*. The paper, titled "Transgressing the Boundaries: Toward a Transformative Hermeneutics of Quantum Gravity" supposedly demonstrated that the laws of science are nothing more than social constructs—one of the central points of Continental postmodernism. The *Social Text* editors made the mistake of not submitting the article to the usual process of peer review, and on the day the article appeared, Sokal announced in the journal *Lingua Franca* that the article was a hoax.

The hoax and the controversy that followed was a major embarrassment for the editors of *Social Text* and for the wider claims of postmodernism to academic credibility. Sokal followed up his hoax with a scorching attack, coauthored with the Belgian physicist Jean Bricmont, on French postmodernism. The work was published in the United States under the title *Fashionable Nonsense: Postmodern Intellectuals' Abuse of Science* (1998).

Alongside this counterattack, some of the more moderate Anglo American thinkers who at one time had expressed support for elements of postmodernism have since stepped back. In Britain, Christopher Norris, a prominent defender of the works of Jacques Derrida, has more recently launched important critiques against the relativism inherent in postmodernist thinking. And in the United States, the late Richard Rorty, without having changed his position, expressed his regret over having used the term "postmodernist." Most recently, a newer movement called critical realism has arisen as the successor to postmodernism. The intellectual initiative has clearly now passed to the critics of postmodernism.

Predestination

Predestination is the idea, found within Islam, Hinduism, and Christianity, that human actions are predetermined by a divine being or superhuman force. This is not to be confused with foreknowledge, the idea that God knows outcomes before they occur. Foreknowledge leaves the decision to the individual, God merely knows the result beforehand. In predestination, God makes the decision as to the outcome of a situation; the individual has no choice.

Islamic thought contains the doctrine of *qadar.* In this doctrine, God (Allah) is understood to be all-powerful and to have control over all that happens. Allah must allow or even cause events to happen; no action occurs apart from the will of Allah. In this sense, predestination occurs when Allah decides to act, with resultant effects on individuals. Hinduism, with the idea of one's *karma* (actions) resulting in the determination of future lives, places responsibility on the individual; nevertheless, gods can act with resultant effects on humans, which is understood as an effect being predetermined for an individual. Thus predestination occurs when a god acts preemptively upon an individual.

In Christian theology, the most prominent example of predestination is found within Calvinism. This doctrine is named after John Calvin, a Protestant Reformation leader of the city of Geneva in the mid-1500s. Calvin was not the first Christian, however, to promote the idea of predestination. In the 300s the Christian theologian Augustine promoted the doctrine that God must make the initial step toward a relationship with a person. This was attributed to original sin (introduced when Adam and Eve disobeyed God in the Garden of Eden) having removed the option of individuals making a move toward God. After the fall of Adam, God's initiating grace was necessary for an individual to move toward God. In addition, God does not choose to give this grace to all, but only to the "elect," those individuals he has chosen to receive his grace. Pelagius, a contemporary of Augustine, developed the counterdoctrine that each person has free will to accept or decline Christ. These two thinkers wrote against each other's doctrines, and Augustine's view eventually prevailed. Pelagius was subsequently denounced by councils and popes. Yet Augustine's idea did not gain a strong following in Augustine's lifetime nor in the Middle Ages. It did not receive much attention until the Protestant Reformation in the 16th century.

Calvinism became closely associated with predestination in part through Calvin's writing about it in his most famous work, *The Institutes,* and partly through the Academy of Geneva, which drew Christians from throughout Europe who were interested in learning about Calvin's ideas.

Although Calvin originated a variety of Christian doctrines, his name is most closely associated with predestination. In addition, Christian predestination is associated with the acronym TULIP, which reduces the doctrine of predestination and Calvinism to five points: Total depravity of humanity, Unconditional election, Limited atonement, Irresistible grace, and Perseverance of the saints. Total depravity of humanity holds that all people are unable to please God through their own volition. Unconditional election states that God chose who would become a Christian and who would reject Christianity; the individuals had no role in the decision. Limited atonement is the idea that Christ's atonement (sacrifice to bring people to God) only included those chosen to become Christians; Christ's death on the cross did not include those God did not choose to become

Christians. Irresistible grace carries the idea that God's decision is irrefutable; those God choose cannot choose not to become a Christian. Perseverance of the saints is the idea that those God will ensure the perseverance of those chosen to be Christians.

While the idea of TULIP is associated with John Calvin, the acronym was not developed until decades after Calvin's death. The situation that spurred the development of TULIP was a debate in Holland over the predestination ideas of Calvin and the free will (the idea that each person chooses to accept or not accept Christ) idea of Jacobus Arminius. After Arminius's death, his followers reduced his free will ideas to five points. Later, at the Synod of Dort in 1618, the adherents of Calvin's idea of predestination countered by reducing Calvin's predestination ideas to five points: The acronym TULIP was the result.

Among Christian denominations today, the Presbyterians, reformed churches, and some Baptist groups accept the idea of predestination. Those who hold to predestination have differing ideas of when God made the choice of individuals. The idea that God made the choice before the fall of Adam and Eve is known as *supralapsarianism*. The idea that God made the choice after the fall of Adam and Eve is known as *sublapsarianism*. The Synod of Dort upheld the sublapsarianism doctrine. In comparing the doctrines of predestination and free will, they are known more specifically as double predestination and single predestination. Double predestination denotes the idea that God chose each person to either be a Christian or a non-Christian (double); single predestination denotes the idea that God predestined the way of Christ, and each person can either choose or reject Christ.

PREDETERMINISM

Predeterminism is, literally, the idea that events are determined in advance. All future actions and events are already decided or known (by God, fate, or some other force). This concept is closely related to determinism, and sometimes the terms are used interchangeably. More often, however, predeterminism is categorized as a specific type of determinism. In this case, determinism is defined more generally, as the idea that every event is caused by a chain of past events, without a specific being or force behind it.

Ancient Views

The idea of future events being already decided can be found in many cultures and religions throughout history. One early representation of this view is demonstrated by the Fates (also called the Moirae)—three goddesses in Greek mythology who controlled everyone's life span. As written by the early Greek poet Hesiod, each goddess's name indicated her purpose. Clotho was the spinner, who spun the thread of a person's life. Lachesis was the apportioner, who decided the length of the thread (thus determining the length of the life). Atropos was the inevitable (literally, the "unturning"), who cut the thread at the point where the person was to die. The Moirae acted independently of the other gods, and in some stories even Zeus was powerless against them.

A predeterministic view of the world was espoused by the Essenes (a separatist sect of Judaism) who settled in the Qumran region (near the shore of the Dead Sea) between 110 BCE and 70 CE. According to their beliefs, God determined everything that would happen in the universe before he created it. In accordance with God's plan, there were two ways: that of light (good) and that of darkness (evil). These two ways, which exist throughout the universe, are in constant conflict, which is held in control by God.

Christian Theology

The idea of God being all-knowing has created some questions in Christian thinking, for God's foreknowledge would seem to deny humans their free will. Although humans have knowledge of the world, their knowledge is limited and fallible. According to most monotheistic religions, God is infallible and knows everything (even the future) with certainty. This would seem to create a paradox if one were to believe in both God's foreknowledge and the idea of human free will.

Fifth-century philosopher and theologian St. Augustine of Hippo wrote that because God is omniscient, he therefore knows every future action that is going to happen. We cannot behave in any way other than the way God knows we will. However, Augustine felt that these ideas were not a threat to free will. In essence, God knows about future events because they are going to occur; they do not occur because God knows about them. Our future actions do not become involuntary because of God's foreknowledge, just as our remembering a past event does not make it involuntary. God is eternal, so he sees all of time in a way similar to the way we view the present. The terms *before* and *after* cannot be applied to him.

Other theologians concurred with St. Augustine's view that God's knowledge of future events does not take away from man's free will. Seventeenth-century American theologian Jonathan Edwards wrote that God's foreknowledge does not cause events, but it does make them inevitable. Saint Thomas Aquinas stated that God's knowledge is not in itself a cause of anything in the same way that a sign points to an object without actually causing the object to appear. Regarding the idea of God causing specific events to happen, he wrote that God does not intervene in the world in the sense that he enters into an occurrence of which he was not originally part. God is not absent from anything in the world to begin with, and therefore everything that happens does so because God made it that way.

Despite his agreement with Saint Augustine, Aquinas also wrote "On Evil IV," which includes 24 arguments against the view that human beings have free will. Yet he says that God working in all things is not incompatible with freedom. The human will can act, but the action is initiated by God. Although the action does originate outside of the person, the action is not forced upon him or her.

Martin Luther, who began the Protestant Reformation, felt that God didn't merely know about future events, he controlled them. He wrote that for humans to have the freedom to performing their own actions would be incompatible with God's omnipotence, and to believe such a thing was blasphemy. As human beings, all of our actions are evil unless we have the help of God's grace. It is not within our power to do good, and we are controlled by either God or Satan, who determine our actions.

One way to reconcile the seemingly opposing viewpoints of God's omniscience and human free will is to view future events simply as possibilities. God knows all the possibilities, and humans, by their choices, determine which possibility will occur.

Another possibility is that God can change his mind with regard to future events. At certain points in the Bible (such as Jonah 3:1–10 and Jeremiah 26:17–19), God first stated that he would destroy a city or a group of people but later relented due to human actions.

Presocratic Age

The conventional term *Presocratic* refers to philosophical and natural scientific thought in ancient Greece prior to the philosophical career of Socrates; hence the Presocratic period denotes the earliest stages of Greek philosophy. Years of this period began with the oldest recorded fragment of philosophical speculation in Greece; Thales reached his acme, or prime of life, in 585 BCE. This is the most natural beginning point for this period of early philosophy, which was still inseparable from myth. Nevertheless, one major focus of Presocratic thought was the concept of time. Socrates began his philosophical mission in around 434 BCE, in his 35th year when his friend Chaerephon returned from Delphi, which would be one sensible endpoint of the Presocratic age. While Socrates philosophized, there were still around him followers of Parmenides, Heraclitus, Pythagoras, and Democritus, among others.

Time in Presocratic Greece

In the Presocratic world of the Greeks, as across ancient civilizations, the sky was the universal timepiece. The time length from sunrise to sunrise was the natural basic unit of recording time. Each day was divided into 12 parts, as was the night, which would change in length by the season. Time within the daylight hours would have been told by sun dial; time across day and night would have been measured by a terra cotta water clock (*clepsydra*).

The ancient Greeks used a lunar/solar calendar, using both sun and moon, of 12 months. Each month was a lunar cycle. In addition, there were alternate months with 29 or 30 days and alternate years of 354 or 384 days. Extras days or even months were inserted in the calendar to prevent accumulated error. Nautical Greeks navigated and estimated time during the night by the movement of the constellations, planets, moon, and stars. Each city-state kept its own calendar, maintained by magistrates, which began at the new moon. Athenians began the year in summer, and it ran from July to June. Years were marked off into 4-year cycles, called *olympiads*. The first year of Olympiad 1 was 776 BCE. The cycles of the Milky Way would have been the final, limiting hand on the cosmic clock (by repeating its four-fold pattern in its own time). There were also planetary conjunctions and eclipses recorded. Astronomers used such cycles to correct accumulated error in the calendar.

Early Greeks had a circular notion of time; at the beginning of time was a primordial event that began the subsequent cycles of time. Human beings celebrated the passing and coming-to-be of cycles with festivals that harkened back to the first days (*in illo tempore, ab origine,* as Mircea Eliade put it). And indeed many months on the Greek calendar were named after festivals. Time was thought of as a cycle of festivals rather than as an abstraction. The early Greeks adopted much from Egypt, including calendar making. Greek civilization had gone through the Bronze Age during the Homeric period, but their folk religions bore witness to a distant Neolithic past, as well. Olympian sky gods had displaced mother earth goddesses and agricultural gods along with the Titans.

Greek Myth of Time (Kronos)

First-born in the long genesis of the world was Chaos, according to Hesiod, then "wide-bosomed Earth" as a dwelling for the gods. Tartarus, lower hemisphere of the future cosmos, was born next, and after it, Love, "most beautiful by far." From Chaos was born "dark-robed Night," which gave birth to Upper Air and Day. Born first to Earth was Heaven, "eternal dwelling place" for the blessed gods. Earth and Heaven were of one form initially, but separated later in the act of birthing. Heaven and Earth created children, who were sequestered away by Heaven, who had grown to become a wicked father. Earth conceived a plan and made a scythe of flint for one child, Kronos, to use in ambushing and castrating Heaven. Kronos threw his father's male member into space, but its scattered blood created on Earth the first generation of gods. Thus the child Kronos took his father's place in the cosmos. Acting on a prophecy of his own doom, Kronos ate each of his children born of Rhea, lest they overthrow him. But Zeus was hidden from Kronos by a stratagem, and he grew to overthrow his father. Kronos was forced to disgorge his children, who then battled the Titans, defeating them and ostracizing them to Tartarus. This introduced the age of the Olympians.

Herodotus and History

No survey of the Presocratic period, especially with regard to conceptions of time, would be complete without mention of Herodotus. With the *Histories* by Herodotus, the Greeks attained a historical sense of time. Events in the story of mankind gave a linear shape to time; in his *Histories,* there is a succession of more or less remarkable events, which makes up a more or less cogent narrative, and which undid the circularity of time so prevalent in the mythological mind. Herodotus was born in 484 BCE and died between 430 and 420 BCE.

Presocratic Philosophy

Eminent scholar Kathleen Freeman has listed nearly 100 Presocratic thinkers, of whom mostly mere names survive. The best-known and best-documented philosophers of this period include Thales, Anaximander, Anaximines, Pythagoras and members of the Pythagorean school, Heraclitus, Parmenides, Xenophanes, Zeno, Empedocles, Democritus and Leucippus.

Thales

Thales was an obscure figure about whom almost nothing is known. His acme was around 585 BCE, and that marks the beginnings of the Presocratic period of philosophy. He apparently wrote a text on nautical astronomy, but only the title survives. Attributed to him, as well, were "On the Solstice" and "On the Equinox." If he indeed wrote a work on nautical astronomy, he would have been able to read the night's sky as a navigational and timekeeping device perhaps expertly. And since Thales is said to have predicted an eclipse, he was observing patterns in time that few then understood.

Concerning the famous saying attributed to Thales—all is water—we might speculate that this was an early natural scientific reduction of all phenomena to water, either figurative or literal. This accords with the notion of a Milesian school of natural explanation. But Thales is also supposed to have said all things are filled with gods, which, in either a figurative or literal sense, is not at all natural scientific.

If applied to the topic of time, the alleged sayings of Thales would imply, first, that time is water; second, that time is filled with gods. If Thales believed in Kronos, he could say that time is one of the gods, but we have no evidence for this conjecture, either way. More likely is Aristotle's reading that soul is intermingled with all things, because it is the principle of motion. This would entail that soul is the principle of time as well.

Thales might have suggested that time is water, because time was measured by a terra cotta water clock, at least for some ancient Greeks, or by the tides. But this is a speculative reading, as well. Hesiod reported that Thales held Earth to float upon water. Now if Thales suggested that all things begin in water, that the universe *came from* water, as a first principle, which is the likely meaning according to Aristotle, time would be measured by water in a truly cosmic sense. Whatever foundational ideas Thales might have had about time are lost to us forever, however.

Anaximander

Anaximander came from Miletus 25 years after Thales, but not even mere titles of his works, if he wrote any at all, survive. Only a few fragments of his ideas remain. Fragments 1, 2, and 3 deal explicitly with the nature of time. The indefinite is the "original material" of existing things, according to Fragment 1.

In addition, "the source from which existing things derive their existence is also that to which they return at their destruction, according to necessity." The reason for this is that "they give justice and make reparation to one another for their injustice, according to the arrangement of time." Fragment 2 tells us that the indefinite is ageless and everlasting, while Fragment 3 calls the indefinite immortal and indestructible.

And so the image of the cosmos that we infer here is that at the origin of all things was an indefinite out of which came all the existents of the cosmos. While in existence, these existents right a wrong, the nature of which is hotly contested and is determined by the exact rendition of the passage one uses (some saying that Anaximander means existents repay a debt to each other, some saying he means that existents repay a debt to the indefinite). We are told by the fragment that time and necessity arrange this retribution. Then presumably measured time ceases, all things return to the source, and eternity continues on unabated.

Now if this interpretation is correct, then Anaximander has drawn the distinction between *eternity* and *measured time*. It would further seem to indicate that time is both endless (indestructible) and measured. Time and necessity sort out the eternal from the original. The rest is measured time. Further, measured time seems finite (as an accidental feature) and *for the sake of justice* (as its essence). If this is correct, then the entire drama of existence seems to be a morality play; we, as existents, have chosen to affirm the I and negate the Thou. Measured time begins only with our self-separation from the indefinite, and it exists only for the sake of restoring order and establishing justice, at which point all measured time ceases and eternity reigns supreme again. Perhaps the earth remains for eternity, because it is like a stone column, for Anaximander, but he may have been referring only to its structure or its appearance to the gods. In the absence of authoritative works, one may only speculate about possible interpretations; this is the risk run by saying anything substantial about the Presocratic thinkers.

From Fragment 1 we may legitimately infer that Anaximander subscribed to what we might now call a temporal realism, meaning that he treated time as a real thing and as eternal and indestructible. What is far less clear is how he further conceived of time: Is time merely reified, or did Anaximander also deify and worship it? If so, did he anthropomorphize it? Is Kronos meant here, in the naive mythical sense, along with Dike and Ananke? It seems incorrect, however, to read Anaximander in terms of alien religions; we may only say that he believed in necessity, time, and justice, as well as the indefinite.

Anaximines

Anaximines is known to have been from Miletus, hence he was presumably another Milesian natural observer, yet next to nothing, a single sentence, survives of his one writing. He was in his prime of life around 546 BCE. His observations that the soul is air, and that air surrounds the whole universe, give us no solid insight into his notion of time. If we may attribute the ideas of compression and dilation to Anaximines, however, then time would be measured most objectively by those physical natural processes.

The problems of change and motion were the major forum by which the Presocratics dealt with time. Change and motion were problems to the Greek mind. They sought a mechanism of change whether it be water, air, fire, or other. How do generation and degeneration come about? Coming-to-be and passing-away? Some thinkers (Anaxagoras, Parmenides, Zeno, the Pythagoreans) believed that mind, not a process of nature, accounted for change and motion. But they all seemed to strive to explain the phenomenon of change.

For the Presocratics, the question of time came down to developing a concept of *origins*. They still believed in the first times of mythical consciousness (*in illo tempore, ab origine*), as recorded in Hesiod and Homer, but reworked into an early natural scientific idiom. Later scientific notions, therefore, should not be anachronistically attributed to the Presocratics.

Pythagoreans

The figure of Pythagoras is largely apocryphal, but he was a religious reformer and cult leader. He was born on Samos but moved to Croton, perhaps in Olympiad 62. His place in the sequence of Presocratic thinkers is especially difficult, and the later Pythagoreans may have come considerably after the earliest members of the community. A conservative range for the acme of Pythagoras would be between Olympiads 62 and 69 (between 528 BCE and 500 BCE). Thus his prime of life was very close to being directly after the acme of Parmenides and Heraclitus.

Pythagoras refused the friendship of a local tyrant, Cylon of Croton, and the religious leader and his followers were cast out from Croton. They resettled in Metapontum, but the Cylonians followed and apparently massacred the majority of Pythagoreans. The survivors further resettled in Rhegium and Greece. The last Pythagoreans were active around 366 BCE. The ancients seemed confused about the relation between Zeno and Empedocles, on one hand, and the Pythagoreans, on the other. Some sources claimed that Empedocles was a follower of Pythagoras; others said he followed Parmenides. These sources also maintained that Zeno followed first Parmenides, then Pythagoras.

Pythagoras was apparently the first Greek to deify number, that is, he held number to be sacred and worthy of study as a universal ethical force. Number is self-moving and thus the principle of the psyche. Pythagoras said that happiness comes from knowledge of the "perfection of the numbers of the soul," and his followers took the study of number as their single concern. Their study encompassed arithmetic, geometry, music (harmonics), and astronomy. As Pythagorean scholar David Fideler has analyzed their curriculum, arithmetic was the study of number in itself; geometry was number in space; music was number in time; and astronomy was number in space and time. As a consequence, time was seen as number in harmonic motion, or rhythm. Number was considered immanent, not transcendent, to time.

The Pythagorean account of time would probably have involved a number of separate and perhaps conflicting elements. Time was number in harmony, of course. But Diogenes Laertius reported that Pythagoras divided the human life span into segments of 24 (childhood, youth, middle age, and old age), which corresponded to the proportions of the four seasons. And all accounts of the life of Pythagoras include a notion of reincarnation, that is, a sequence of lifetimes, which may have formed a circle (the *monad*) in its full development.

In the Pythagorean table of opposites, "one" and "plurality" are opposites, as are "at rest" and "moving." The one is time at rest, or eternity; its opposite is time as it moves, or fluid time.

Among Pythagoreans, the Tetraktys, a triangular figure made from arranging dots as the first four integers, was considered to be holy ("heaven") and to be the universal order (Kosmos and Pan). Pythagoras held number to be the source and first principle of all things. The monad (unity) was seen as the basis of all number and not a number itself. The dyad contains movement, growth, birth, and other aspects suggesting time in motion. Indeed, the dyad is also Rhea, wife of Kronos. If the monad is the producer of time (just as it is called the "space-provider"), then the dyad is time in motion. Both types of time, monad and dyad, together produce the triad, which is "the all" and "everything."

"Time, and wind, and the void" define where each thing exists, said Pythagoras. But time was also said by Pythagoras to be the sphere surrounding the world. Perhaps we may think of local and global time as an analogy; there is macrocosmic and microcosmic time. The tetrad, the square circumscribed by a circle, contains the nature of change. The integer 10 was called the *decad*. One of its aspects is "eternity (*aeon*)." The decad returns to the monad and shares its qualities. "All things accord in number," said Pythagoras, and his followers elaborated arithmetic and geometric evidence for his insight.

As time is an elemental part of the universe, and as time is number, it follows that time is divine. "Turn round when you worship," was a Pythagorean maxim meaning that we should "adore the immensity of God, who fills the universe." Hence, God transcends time but is also immanent to it.

Since the Pythagoreans ascribed all discoveries to Pythagoras himself, we cannot, in principle, discern the founder from his followers in terms of teachings. Some later Pythagoreans may have believed in circular time. According to Stobaeus, Philolaus, one of the last Pythagoreans, said that "the single world is continuous, and endowed with a natural respiration, moving eternally in a circle, having the principle of motion and change; one of its parts is immovable, the other is changing. . . . The one is entirely the domain of mind and soul, the other of generation and change." This echoes the fragment of Anaximander, of course. Much later, though, Friedrich Nietzsche ascribed a version of eternal recurrence of the same to the Pythagoreans.

Timaeus

One supposed Pythagorean astronomer was Timaeus of Locri, though the figure may well be legendary. Looking back into time immemorial, Plato's Timaeus said, "The sight of day and night and the months and the revolutions of the years have created number and have given us a conception of time, and the power of inquiring about the nature of the universe. And from this source we have derived philosophy, than which no greater good ever was or will be given by the gods to mortal man." Timaeus further said, "The night and the day were created, being the period of the one most intelligent revolution. And the month is accomplished when the moon has completed her orbit and overtaken the sun, and the year when the sun has completed his own orbit." Timaeus told his audience that God created the sun and moon, as well as five planets, "in order to distinguish and preserve the numbers of time." As for the stars, "Their wanderings, being of vast number and admirable for their variety, make up time." But this cosmology is more likely Platonic than Pythagorean.

Religious and Ethical Implications

We should never forget the religious and ethical consciousness of the Pythagoreans; they were united as a community by a set of rules of behavior, however esoteric. Every idea from Pythagoras had an ethical implication. There is an ethical meaning to time. Because mind becomes more aware of number, there is a gradual enlightenment of the individual soul and the society. The universe is the setting for a spiritual transformation, which must be seen as immanent to time, not a mere set of accidents. There is a Logos immanent to time, and a sort of wisdom.

Time is also a beautiful harmony; it is the tempo of the universe. Twenty-three hundred years later, Karl Ernst Ritter von Baer (see entry) suggested that if the rate of human perception were greatly increased, we would hear the orbits of the planets as music. There is a beautiful, higher, nobler understanding of time for the Pythagoreans, because time itself is number, and hence divine. To study number is the same as to study time and divinity.

Heraclitus

Life

With the figure of Heraclitus, we have the earliest Greek thinker with a rather developed philosophy of time. He reached his acme around 500 BCE. Heraclitus almost certainly wrote a book, but his fragments come down to us only through testimonies and traditions. Those fragments are themselves curious puzzles of a hermit's outlook on the ancient world. Though only 126 fragmented passages remain, most of them confront the problems of time, change, motion, and coming-to-be. Fragments from Heraclitus evidence his astronomical knowledge, which entailed an ability to tell time from the stars.

Heraclitus believed in necessity, justice, and time, as did Anaximander. The process of nature contained within itself a deeper Logos, for Heraclitus, and there was a distinctive flavor of morality in his view of the world. Character is destiny, for man. To the extent that we systematize and rationalize Heraclitus, we lose him. His worldview was deeply personal and emotional. His darkest sayings are probably impenetrable by the modern mind. But his metaphysical and religious beliefs do make some sense within the larger Greek cultural milieu.

Heraclitus taught a metaphysic of absolute nonpersistence in change, which he took, figuratively and/or literally, as Fire. Heraclitus may have meant that all things are fire (a "first principle," like Thales's water), or that a ring of fire encircles the remainder of the universe (a most inclusive thing, like Anaximines's air). Or Heraclitus may have seen fire not as the genesis but as the final goal of the universe. Everything must dry up and burn to ash due to the cosmic fire.

As a theory of time, then, Heraclitus's thought denied the ultimate reality of being. The universe burns away like a great bonfire over the long night. What exists solely is becoming; the energetic spark of the instant in time when the power of the universe actualizes itself, and just as soon is gone. There is no smallest uncutable particle in space and likewise no ultimate atom of time. So far down, or up, as one may go in looking, there is only change, not being. There is no ultimate individual or collective. This is as true of cosmic time as it is true of the moment. Heraclitus grasped, for himself, the great truth that all things must pass, and thus discovered the conflagration that is time.

Perhaps the deepest, darkest truth that we get from Heraclitus is that "passing away" comes to all, great and small, and the universe, ultimately, becomes a pile of dust. "This ordered universe, which is the same for all, was not created by any one of the gods or of mankind, but it was ever and is and shall be ever-living Fire, kindled in measure and quenched in measure." And "the fairest universe is but a dust heap piled up at random." Hence Fire is the beginning and final fate of the universe, a great Fire that slowly burns itself out. There is, for Heraclitus, a light that guides the universe and makes meaningful the events of the past, his Logos. It is lightning-like in its enlightening power. It illuminates truth and makes knowledge possible. The deeper question must be, what is the meaning of this cosmic Fire, if its end is only to burn out?

There is a bolt of meaning blazing in the universe, a deeper Logos evident for all to see, but incredibly, no one is willing to see it, according to Heraclitus. Souls are best preserved in a dried body, but man finds pleasure in fluids. Some souls even become soggy and moldy. They cannot see the truth, because they do not look for it. To find meaning, one must look for it. Yet, paradoxically, when we look for meaning, we find something else. "If one does not hope, one will not find the unhoped-for, because there will be no trail leading to it and no path."

Fools cannot see the reason that guides the cosmos, but some reason (Logos) gives meaning to the random pile of dust, according to Heraclitus. Hence his darkest moments give way to a dawn of insight and meaning. These dark sayings are balanced with Heraclitus's conviction that a Logos permeates the universe, and it is open to our access, if only we look for it. Logos (meaning) is everywhere in abundance.

Heraclitus was a hermit, but he was also a warrior in spirit, who saw *ares* (war) as the first principle of existence. War is the father of all things, perhaps in that the cosmos began in strife. Fire, war, Logos, misanthropy; these came together in Heraclitus.

Absolute Nonpersistence

Absolute nonpersistence in change, perhaps the core notion of Heraclitus, is evidenced by the famous saying, variously interpreted and translated as "Those who step into the same river have different waters flowing ever upon them," "It is not possible to step twice into the same river," or "In the same river, we both step and do not step, we are and we are not." This image of a river suggests time as a flow, and in a single direction; hence, the notion of an arrow of time. But the river may well be thought of as the flow of motion through space; there are no eternally existent elemental parts; the entire process of the universe in change absolutely does not persist; each smallest particle, as well, is itself consumed by change and ceases to be.

"The sun is new each day" suggests that each day is a whole relative unto itself, and that there is no highest order of time period. And so a human epoch would be an instant to a god; the size of the sun is the breadth of a man's foot. No two moments are alike, nor does time seem to repeat itself, if this saying be taken literally. Day and night are one; there is no essential difference between days. Hence the quality of time is uniformity, perhaps an indefinite nature, too.

Time Is Fire

Time is a transformation in things from one element to another, continually (re)mixed. Yet fire somehow rests from change in man. What marks off day from night is the sun. Equinoxes and solstices of the sun mark off the seasons, "the hours that bring all things." And the sun stays within the solar ecliptic, "otherwise the Furies, ministers of justice, will find him out," according to Heraclitus. The sun is no wider than a man's foot, perhaps, it might be added, from a man's earthbound vantage point. But surely the sun, seen much closer, would be enormous. Hence (apparent) size is relative to vantage point. Or perhaps he meant to suggest a macrocosm-microcosm relationship—that there may be universes containing our own at indefinite orders of magnitude, in which our own sun would be as wide as a man's foot. . . . But what is the sun, if not fire?

Time is not merely *like* a universe-sized conflagration slowly burning out, it *is* exactly that. Time is the fiery consumption of the universe even until man and earth perish, as measured by the rate of conflagration. All manner of corruption, degeneration, passing away, are manifestations of fire, however minute. Time is itself an elemental force like water, air, and earth or metal, but destructive, corrosive, annihilating of the others. Hence fire ultimately turns all to ash. It dries up the water of Thales. It uses up all the air of Anaximines, which purportedly surrounded the universe. It burns up all the earth and wood and melts all metal until only ash remains. All the elements are exchanged for fire, and then fire yields to the various other elements. Perhaps at this time the entire selfsame affair begins again. Or perhaps he meant that there is a cycle of fire similar to a nitrogen cycle. These fragments may have required initiation into a mystery or esoteric teaching to become comprehensible.

Reciprocal Time

Sleep and waking, life and death, youth and old age, are measures or periods of time that Heraclitus used to show the reciprocal nature of time. Opposites gradually develop into each other. Sleep gives way to waking, which eventually gives way to the former. There are different temporal phenomena in reciprocal states; distortion of time in dreaming, the quickened pace of time in old age, and so on. Each might be said to run according to its own unique clock. Hence, we may reasonably read Heraclitus to mean that time is epicyclical change.

The basis of Heraclitus's ontology is the notion that existents "scatter and again combine" and "approach and separate." These processes mark time or even constitute it. But they are coals in the wind, slowly burning out, like the universe at large. There is a relativity in sequence between the points of a circle in space. Surely it occurred to Heraclitus that points in circular time would be equally relative. Every moment would be the beginning and end of time, consequently. And hence, every day is the same, and astrology, consequently, is fundamentally faulty.

Fragment 52

"Time is a child playing a game of draughts; the kingship is in the hands of a child." This simile is Heraclitus's most explicit word on time, as distinct from "change" or "universe." Time is a child playing because it plays at random, not by strategy and tactics. Hence a child playing at draughts would be moving the pieces without rules and only at whim. Time is the kingship at stake. Why is time a kingship? It is the very being of life, its fire.

Heraclitus is said to have spurned the company of adults and played games with children. But he did not romanticize youth; rather he only believed adulthood to be worse. In another fragment, he shed some small light onto how he envisioned children in charge of a kingship. "The Ephesians would do well to hang themselves, every adult man, and bequeath their city-state to adolescents. . . ." So time has been handed to the least capable out of default by miserable, failed beings, or so it would seem, if the parallel is sound. How is it consistent, though, to say that time is random or worse, and yet the cosmos (which, after all, is only the spatial-material complement to that same time) is guided by Logos? This is evidently another of Heraclitus's antinomies, which will end by saying that they are both random and not random, both according with Logos and not according with it.

Parmenides

Parmenides was born around Olympiad 53. Parmenides was at his acme in his early 60s, at the same time that his antipode, Heraclitus, was also in his prime (as was Pythagoras). Parmenides was one of the most influential of the Presocratic thinkers. At roughly 20 years of age, he was instructed by Anaximander, who at that time was at his acme, or prime of life. The metaphysics of Parmenides took from Anaximander the distinction between being and nonbeing, the distinction between eternity and measured time, and the distinction between the unlimited and the limited. Anaximander apparently considered all six terms as real. Parmenides, however, identified being and truth with eternity and the unlimited, and identified nonbeing and illusion with measured time and the limited. Few known thinkers in the Presocratic world had doubted the testimony of the senses until the figure of Parmenides. And Anaximander's cosmology of three distinct spheres nested in each other was amenable to Parmenides' vision of a spherical "one."

When he was 30, Parmenides met the itinerant Xenophanes of Colophon in Elea. They shared a religious mysticism and a love of poetry. Xenophanes criticized polytheism and anthropomorphism, and Parmenides was a metaphysical monist and a mystic. Close in time to these events, Melissus of Samos became a student of Parmenides. Though the particular dialectic employed by Melissus differed from that of Parmenides, the conclusions were the same: Being is one, eternal and unmovable. Melissus denied time, using a dialectic of negation, like the master, but evidently without achieving a novel contribution, as did Zeno, the better known student of Parmenides. And thus the school of Parmenides at Elea was founded.

Parmenides and his school at Elea evidenced three influences: Anaximander, Xenophanes, and the Pythagoreans. The students of Parmenides may have been influenced by a Pythagorean named Ameinias. However tempting it may be to see in Pythagoras's monad an equivalent of Parmenides' "one," this seems unlikely. Rather than distinct cosmological or ontological doctrines, the similarity between the schools of Elea and Croton is one of lifestyle. The Parmenidean way of life probably resembled the Pythagorean way in that both were lives of religious mysticism and contemplation.

The "Prologue" by Parmenides, which has survived apparently complete, is an exquisite example of inspired philosophy, putting the audience at a spiritual crossroad as spellbound spectator. And the subsequent metaphysical teaching is crystal clear: Being can only be a timeless unchanging thing, perfect and eternal. "For there is not, nor will there be, anything other than what is, because indeed destiny has fettered it to remain whole and immovable."

Because "thought and being are the same," and because "it is necessary to speak and to think what is; for being is, but nothing is not," Parmenides concluded that only reason can bring us to the truth. This reason is the immortal higher path on which Parmenides found himself at the beginning of his "Prologue," and to which he was brought by the "daughters of the sun."

Nonbeing cannot be thought, and therefore is unreal. Nor can we know change; coming-to-be and passing-away are delusions of the senses. What is changeable is temporary and unknowable. Change is unreal, and hence also any notion of measured time. The apparent omnipresence of change is an illusion created by the senses, according to the teachings of Parmenides. Many humans believe the testimony of the senses, but that path is one of darkness and mere opinion. And so Parmenides adopted the Pythagorean opposites of unlimited/limited; one/many; rest/motion; and light/dark. But he identified the unlimited, one, rest, and light with being, while he identified the limited, many, motion, and dark with nonbeing and opinion. In this manner Parmenides collapsed the Anaximandrian and Pythagorean tables of opposites; they are mere names, for him, rather than categories of being.

Anaxagoras

Anaxagoras of Clazomenae wrote one book, and his acme was around 460 BCE. He was born in 500 BCE and came to Athens at 20 years of age. He philosophized in Athens after fleeing the Persians and was active at the same time as Empedocles, with whom he shared many ideas. Anaxagoras set about his mission early in life and pursued it in Athens, perhaps for 50 years, at which time he was forced into exile on charges of "impiety." His life mission was to create a natural history of the heavens. He adopted Anaximines' notion of stars as burning objects fixed on a wheel, but advanced it by suggesting that they are masses of burning stone or metal, which can detach and fall to Earth (as an explanation of the comet at Hellespont). He suggested that there is an ether surrounding the universe and that by the force of the rotation of this ether, vast stones are pulled into orbit, set afire, and recognized as heavenly bodies. Without a clear concept of momentum, Anaxagoras conceived of this force as speed. He hypothesized that Earth is closer to the moon than the sun. He compiled facts on eclipses and suggested that the light of the moon came from the sun and not the moon itself. He hypothesized that the sun is larger than the Peloponnesus, and that the moon has ravines and plains and is made of earth. He even suggested that the Milky Way comprised the light of many stars, which are shaded from the sun by the earth.

Anaxagoras had a clear notion of elemental entities, called *homeomeries,* which are originally mixed, but then separate off in a winnowing motion, like unto like. This primal mixture is a chaos of countless elements, because the elements are actual qualities rather than abstract categories of qualities (an infinite number of seeds in no way resembling one another). In contrast, Empedocles waxed poetic about this primal union. They shared the proposition that elements always have been and always will be. This implied an infinity of the past during which all elements still existed, and in precisely the same number. And it is logically consistent to say that these elements existed in a primal confusion only if there is a directionality of time, and a sense of a *point of origin.* Infinite time is consistent with directionality, but infinite time seems paradoxical with a sense of primal origin. Time, for them both, was an awkward mixture of cyclical and linear notions.

Anaxagoras was evidently very concerned about drawing the metaphysical implications of his vision; a set of propositions of great/small, mixing/separating, and infinite/finite compose several of the fragments, but so far as we may judge, there is no driving dialectical discipline behind it. Indeed, the account of separation told by Anaxagoras is a tissue of contradictions that would drive a careful logician to distraction. Anaxagoras, we might say, saved Zeno the work of reducing his position to contradiction. This must suggest that he was only partially concerned with systematic consistency and far more concerned with communicating a vision of the world and how it operates at its farthest and highest reaches, presumably, the enlightened natural scientist's view.

By emphasizing mind, Anaxagoras was still something of an echo of Anaximander. Empedocles used mind as an explanation but sought to account for the motions of the heavens more than the motives of love and strife. He studied the heavens as Socrates studied Logos, or as Empedocles studied earthly nature: methodically, minutely, patiently, and with an open mind. Yet, by including mind, Anaxagoras surely implied that there is a purpose or design to the universe. Otherwise, why would mind be necessary, if we are explaining the orbits of masses of molten metal? The essence of mind, in contrast to the elements, is purpose. The universal mind had a purpose, presumably, behind the mixture and separation, the formation of orbits, and the rise of life on heavenly bodies, though the fragments spare few details.

As for Earth itself, it is flat and hovers on air it has compressed underneath itself. Thus Anaxagoras required the notion that air was constrained (as in a clepsydra) and tremendously pressurized under the weight of Earth. Unfortunately we lack a fragment explaining *what* constrains the air under Earth, and so on. Here Anaxagoras may have relied on the analogy, drawn by Parmenides, between Earth and a pillar (but once again, what holds up the pillar?). Such analogies did little in the face of Zeno. Most notably, Anaxagoras could not seem to decide whether the whole is one or many.

Zeno

Life

Melissus of Samos was an important follower to Parmenides, but beyond question, the most famous pupil was Zeno of Elea. Conflicting stories have been told of Zeno having been a resistor against tyranny and a victim of torture, but facts are scarce. If Plato's account in his dialogue *Parmenides* is not fictionalized, then a young Socrates heard a middle-aged Zeno and an elderly Parmenides hold forth. (But since so much scholarship has rested on that passage, if Plato's account in *Parmenides* is just good fiction, as one alternative careful chronological calculation suggests, then a much different sequence to the Presocratics must be conceived.) One source suggested that Zeno wrote his book in his youth, but even this is uncertain. The traditional date of his acme is 450 BCE. Almost nothing trustworthy is known of Zeno's life, but his enormous contribution to Western thought, especially logic, could hardly have been greater, for Zeno should be recognized as the discoverer of dialectical thinking.

Unfortunately, only fragments from Zeno's literary production survive. It is part of an ongoing debate about Zeno as to whether he wrote one or more books. And there exists no reliable way to reconstruct his arguments into a single logical system, though it seems likely that there was such a scheme. Testimony about Zeno of Elea comes from Plato's *Parmenides* and Aristotle's *Physics,* yet a complete image of Zeno the logician must always escape us. Reportedly, Zeno had some 40 dialectical syllogisms (*epicheirêma*) to indirectly support various Parmenidean teachings. He began each dialectical syllogism with a hypothesis such as "things are many," and then he reduced the assumption to absurdities. Because the initial hypothesis resulted in a contradiction, we are justified in concluding its opposite proposition. In short, he assumed the proposition of his opponent and showed that it yielded a contradiction, and then he concluded his own proposition, a technique called "indirect proof" or *reductio ad absurdum* by later logicians.

A Sample Epicheirêma

In Fragment 3, Zeno argued that if things are many, they must be both (a) finite and (b) infinite in number:

> (a) If there are many things, it is necessary that they are just as many as they are, and neither more nor less than that. But if they are as many as they are, they will be limited.
> (b) If there are many things, the things that are, are unlimited; for there are always others between the things that are, and again others between those. And thus, the things that are, are unlimited.

The conclusion to Zeno's dialectical syllogism is that if we assume that there are many things, the same thing will be both limited and unlimited. We may feel justified in assuming that Zeno would then have drawn the consequence that such a contradiction is absurd. And so the supposition which inspired the dilemma—that things are many—must be rejected.

Zeno's Paradoxes of Motion

Aristotle seemed to suggest that Zeno posited four principle paradoxes in the conclusion that motion does not exist. But how these paradoxes fit together with other parts of his logic is unknown.

1. *The Stadium.* Zeno argued that before a runner can traverse the stadium, he must reach the halfway point, and so on (presumably, that the runner must reach half way to the half way mark, and so on). But this would mean that the runner would have to cover an infinite number of points to traverse the stadium. Yet it is absurd to think he would cover an infinite number of points in a finite amount of time. Therefore the runner can never really traverse the stadium. Zeno's paradox of the stadium means to reach the conclusion that *motion does not exist.* It seems entirely likely that this notion would have led, by a dialectic of being and nonbeing, to the Parmenidean proposition that all things are one. Aristotle, the sole source, commented that Zeno ignored the difference between points *infinite in their extremes* and points *infinite in their divisibility.* Though a runner cannot traverse the first sort of infinity, he can traverse the second such infinity (and hence indeed traverses the stadium), Aristotle concluded, at least preliminarily. The runner presumably touches each point he passes over (i.e., the track), Aristotle worried, so if the track is infinitely divisible, it still poses a problem that he would cover an infinite number of points in a finite amount of time. Aristotle would finish his remarks in the *Physics* by saying, "In a way it is but in a way it is not" possible to touch an infinite number of points in a finite time.

2. *Achilles and the Tortoise.* Apparently Zeno proposed the paradox that Achilles would never be able to overtake a tortoise, even though he were moving at a much greater speed. Zeno arrived at the paradox by the same line of reasoning that he used with the stadium argument. That is, Achilles would have to reach the midway point between himself and the tortoise before he could overtake the tortoise. But by the same logic, Achilles would also have to reach the midpoint between himself and the midway mark, and so on. Achilles would never be able to touch an infinite number of points to get to the tortoise. And so, paradoxically, Achilles will never be able to overtake a tortoise.

3. *The Arrow.* Relying on Aristotle's account of the paradox of the arrow, Zeno started with the premise that anything occupying a place exactly equal to its own size is at rest. Zeno then added only one additional premise, that at any present moment, what is moving occupies a space precisely equal to its own size. Zeno concluded from these two premises that at any present moment, what is moving is at rest. To this conclusion Zeno added a new premise, that what is moving always moves at the present moment. Zeno drew his conclusion that what is moving is always at rest. Another source, Diogenes Laertius, told his readers, "Zeno abolishes motion, saying, 'What is in motion moves neither in the place it is in nor in one in which it is not.'" Thus, the arrow shot from a bow and seeming to travel at high speed is at rest!

Aristotle's evaluation of Zeno's arrow paradox proved highly valuable to subsequent philosophy of time. For Zeno's paradox of the arrow relied on the assumption that time is a succession of discrete *now*s. But Zeno was wrong, according to Aristotle, precisely because "time is not composed of indivisible *now*s, no more than any other magnitude." His idea was that a continuum, a line, for example, is not composed of indivisible points that somehow touch and make the line continuous. In short, there are no indivisibles in time, or no time atoms, because *time is not composed of points in a line.* The implications of this rejection of atoms of any sort would require centuries, and even millennia, to play out, though. For, if time does not consist of a succession of discrete *now*s, of what *does* it consist?

4. *The Moving Rows.* Zeno's fourth and final paradox requires the following diagram and legend:

AAAA

Δ BBBBE→

←ΓΓΓΓ

A	stationary bodies
B	bodies moving from E toward Δ
Γ	bodies moving from Δ toward E
Δ	starting place
E	goal

By Aristotle's rendition, Zeno presumed two equally spaced columns of men (Β and Γ) marching in opposite directions in a stadium. One group marches from Δ to Ε, while the other group marches from Ε to Δ. They march at equal speeds past a set of stationary columns of men (Α). Apparently Zeno then argued that the marching columns would pass each other twice as fast as they would pass an equal number of men in a stationary position. From this Zeno inferred that "the half is equal to the whole," meaning that the marching men were, paradoxically, moving both half as fast and fully as fast, at the same time. But this is absurd. Therefore, the marching men were not really in motion.

It seems likely that Zeno presumed that each marching row would be across each stationary column for an equal period of time, as Aristotle suggested. But Aristotle then went on to claim that Zeno's fallacy lies in ignoring that the amount of time required to pass half of the A's was equal to half of the time required to pass all the Γ's. But things are not so clear-cut, as Kirk, Raven, and Schofield brilliantly demonstrated: "Zeno needs only to get us to accept the plausible idea that if a body moves past *n* bodies of size *m*, it moves a distance of *mn* units; simple arithmetic will then show that moving *mn* units will take half the time of moving 2*mn* at the same speed." And so Zeno would have been able to show, after all, that the men are marching at full speed and half speed, at the same time.

Or Zeno might have answered Aristotle's criticism by assuming, instead of columns of marching men, indivisible bodies moving at a speed such that each would be across from a stationary body (another indivisible body) for but an instant. This would escape Aristotle's comments (for what would it mean that each B must pass each Γ in half of an indivisible time?) while raising interesting questions about space, time, and atomic bodies.

Evaluation of Zeno

Even as fragmented isolated arguments of a larger system of logic, what did remain of Zeno's work(s) has caused thinkers headaches for centuries, however, and Zeno's paradoxes of motion remain awe inspiring in a timeless way.

From the Parmenidean point of view, Zeno's project was highly successful. It showed the absurdities implicit in the hypothesis of motion, as our five senses testify to it. To combat Zeno's challenge, Aristotle attacked the rather commonsense notion of time as a continuum composed of discrete present moments. But this already gives the victory to Zeno, because he has proved his point of logic: Motion, as it is given to us by the senses, is not what it seems. Now the modern mind hastens to translate Zeno's paradox of marching rows into relativity theory. But once again Zeno has already won, for Einsteinian relativity defies common sense and the testimony of the senses, and so motion is not what it seems. And an additional devastating Zenonian point of logic came from Kirk, Raven, and Schofield: "If the distance a body moves is simply a function of its position relative to other bodies, is there any absolute basis for ascribing movement to *it* at all?"

Or to use the Parmenidean idiom, mortals fooled by the illusion of motion "wander knowing nothing, two-headed . . . carried along, deaf and blind at once, dazed, undiscriminating hordes, who believe that to be and not to be are the same and not the same."

Empedocles

Life and Influences

Empedocles of Agrigentum (Sicily) lived from 484 to 424 BCE, according to the traditional chronology, and was born into nobility. He was evidently an orator, scientific thinker, poet, and democratic figure in the face of tyranny. Regal in dress and imposing in manner, Empedocles built a legend around himself, claiming to have a golden thigh and to be divine. He wrote two poems, "On Nature" and "Purifications," both of which survive in fragments. Empedocles was in his acme around 450 BCE. His exact relations to the other Presocratics are unknown.

In the surviving fragments, he claimed to have been inspired by "much-wooed white-armed maiden muse." And he suggested that he had an elixir of life against old age; it could also bring the dead back to life.

As a general observation, Empedocles wrote, we come to be familiar only with what we immediately experience, and each of us takes our own sum of experience to be the totality of knowledge. But we learn little to nothing of the whole, and when we die, our knowledge dies with us. Only by the muse's inspiration, presumably, was Empedocles able to shake humankind out of this ignorance. And so Empedocles created his own version of the ageless philosophical distinction between ignorance and true knowledge and indeed gave voice to an ancient skepticism about human knowledge by painting humankind in a fallen state of knowledge.

What we can infer from the fragments of Empedocles, it seems, is a rather naive (uncritical) realism toward change and motion, which, like his natural science, is most reminiscent of Anaximander. A chronological question then raises its ugly head: Which, if either, was the teacher of the other? There is no philological way to settle this issue.

Yet there is no evidence of a clear distinction of eternity and measured time, as would be found in Anaximander's ideas, unless Empedocles' obscure "realm of piety" counts as eternity. Indeed, in Empedocles there is a world of change at the expense of a world of eternity. If so, this would have been an irreconcilable difference from Anaximander.

Some ancient authors reported that Empedocles was a Pythagorean, and there is significant evidence for the claim. While the surviving fragments from "On Nature" seem inspired by the natural science of Anaximander, those from "Purifications" suggest a strong Pythagorean influence on the ethics and religion of Empedocles. Allegedly, Empedocles publicized the secret doctrines of Pythagoras and was expelled, as was Plato. Or perhaps Empedocles was an itinerant member of both Pythagorean and Parmenidean communities for however long a period.

Many scholars see a parody of Parmenides' poem in the verses of Empedocles. (If Empedocles was reacting to Parmenides' challenge against motion, he should be placed contemporary with, or after, perhaps immediately after, Parmenides.) But other ancient authors claimed that Empedocles was lampooning Xenophanes. One story held that he jumped to his death into Mt. Etna.

Account of Nature and Change

Empedocles lived in his own world of the elements (earth, air, fire, water) but also the Olympians (Zeus, Hera, Hephaestus, Aphrodite, "sharp-shooting Sun and gracious Moon"), "Titan Aether," and the realm of piety, as well as the cosmic forces, love and hate. His world was further populated by an array of nymphs ("Sunshine, Speed, Delay, Beautiful, Ugly"), goddesses (Iris, Chthoniê), and the like ("lovely Infallibility" and "dark-eyed Uncertainty"), all anthropomorphized and personified in a rather naive way. Evidently, Empedocles identified Zeus with fire, Hera with air, Aïdoneus with earth, and Nestis with water.

These primal elements and forces work through the world by a "double process"; scattering (moving from one to many) and gathering (moving from many to one). This beginningless and endless scattering and gathering is the objective natural course of the universe. Thus Empedocles' fragments give evidence of a rather detailed observational natural science. His remarkable speculations about the origins of the species have resulted in him being considered as something of an ancient Darwin. But his natural science was always interwoven with the fantastic. So far as his geography went, Earth is most comparable to a "roofed cave," this term having, doubtless, an ethical meaning, as well. As to physiology, the blood around the heart, according to him, is "thought in mankind," put there by fortune. The body decomposes at death into the elements, he said, but Empedocles evidently also believed in metempsychosis, as did Pythagoras, and claimed to already have been a girl, a bird, and a "dumb sea-fish." The destiny of a soul can thus be said to be divided into a long sequence of lives.

Empedocles held that the elements never came into being and can never pass away, suggesting that *time is infinite both in the past and in the future*. More explicitly, in fragment 16 he referred to "infinite time," which will never be emptied of love and hate. In this sense he has broken with the ancient mythical notion of cyclical time in favor of a rather linear conception of time.

Time is an objective force of nature, not a figment of the human mind. If there were no "infinite time," all of nature would be at a standstill, forever. But the elements are real and pervasive, for Empedocles. These elements appear most closely related to what modern metaphysics calls "concrete universals." Thus Empedocles adopted a sort of naive realism about *time and motion as they appear to the five senses*. He did not doubt the testimony of his own eyes, gifts from Aphrodite, who, having built "tireless eyes" from the elements, "fastened them together with clamps of affection." His own unique prototype of qualitative pluralism implied that *time can be measured by the double processes of scattering and gathering.* Perhaps the transformations of individual elements would provide us, in theory, with elemental clocks, too, but that is speculative.

Unfortunately, Empedocles gives a rather contradictory account of *how time operates.* Some fragments suggest that time operates by strict necessity; there is an "oracle of necessity." Yet his account of the origin of species implied that time operates by chance, "for things can be mingled at random." Motion occurs without a mechanism (i.e., from the cosmic-force love) yet leads to mechanical results (events and things of nature). This paradox is typical of the worldview of Empedocles.

Significance

Now if Empedocles really was responding to the Eleatic school, he did not enter into a dialectical battle with Zeno, his contemporary; he did not, at least in the surviving fragments, directly confront Parmenides' theory that motion does not exist. He offered no defense of the senses vis-à-vis the arguments of Parmenides. Rather, he developed his own account of time and change—qualitative pluralism—in isolation; if he had serious rivals, he did not name them or hint at their theories.

Indeed, it may be correctly noted that Empedocles took the way of opinion, as described in the poem by Parmenides, but in an uncritical way, leaving him without having refuted or moved beyond the problem of motion.

The only way to interpret any remotely Parmenidean influence in the writings of Empedocles would be to take his elements as όντα (self-existing, eternal, incorruptible "thing")—a stretch, because Parmenides took there to exist only one όντα. Rather, it seems that Empedocles was most engaged in the thoughts of Anaxagoras. Anaxagoras took countless qualities to be elemental homeomeries; Empedocles allowed only four. But both believed that macroscopic objects comprise masses of microscopic particles.

In his atomic speculations, Empedocles went well beyond Anaxagoras. Now the absolute number of particles of each element in the universe, and hence the total amount of particles, remained finite and constant; now time operated by a conservation of matter and a constant motion. Similar notions of mixing and blending linked Anaxagoras and Empedocles, of course. With the introduction of infinite time in the past, there is no sense of mind as the author of an original motion in the sense of Anaxagoras, however (unless love and strife are theoretical remnants of mind; but why, then, are love and strife necessary, if mind suffices?). Empedocles' theory of effluences (microscopic openings in matter) allowed him at least the possibility of a remarkable insight into time and change at an atomic level. If time is matter in motion, then microscopic motion would require a microscopic scale of time. And his acceptance of a void in the effluences certainly second-guessed Anaxagoras and tested the waters for Democritus and Leucippus.

Indeed, Empedocles certainly set the stage for the subsequent atomists. Yet his insistence that love and strife are authors of motion is a hard doctrine to resolve with an atomistic understanding of motion, unless the atoms themselves are energized by these cosmic forces (an equally speculative claim).

Leucippus and Democritus

Many thinkers laid groundwork for the atomist school of thought in Athens. Leucippus and Democritus, both of Abdêra, were preceded by the so-called Milesian school of natural philosophy (Thales, Anaximines, Anaximander); the Pythagorean cosmology of number; the elemental ontology of Empedocles and Anaxagoras; and the dialectic of Zeno and Parmenides, along with their notion of όντα. Each source provided an idea or principle for constructing an elegant theory of atoms.

Leucippus reached his acme around 430 BCE, and Democritus did so around 10 years later. Leucippus may have coined the first terms or concepts of atomism: *atoms* (literally, indivisible), *great void, contact* (arrangement), *aspect* (position), and *rhythm* (form), among others. Leucippus wrote one book, *The Great World Order,* and possibly a brief work called *On Mind,* from which this important principle comes to us as fragment 2: "Nothing happens at random; everything happens out of reason and by necessity." The fact that an atomist would write anything "on mind" suggests he believed in a mind behind the cosmos of atoms and void, but we know no details.

Democritus may have plagiarized from Leucippus; either way, we should consider Leucippus as the earliest known atomist. Democritus produced an evidently enormous literary estate. His works were arranged into the categories of ethics, natural science, mathematics, music, technical works, and a long series of monographs on causes, all of which are known only by title in various fragments. According to fragment 5, in *Small World Order,* Democritus apparently attacked Anaxagoras as an original thinker and as a student of nature. Another work carried as its title *Pythagoras,* but nothing is known of it. It is certain that Democritus invented an astronomical calendar, and evident that he saw in nature a periodic cycle of seasons, migratory birds, weather patterns, (mis)fortune, and more. The fragments of his calendar that remain show a highly scientific mind working with a folk wisdom of unknown antiquity. We are told in fragment 12 that the "great year" of Democritus (and Philolaus the Pythagorean) was considered to be 82 years with 28 intercalary months. Democritus was, then, familiar with the problems of calendar making and timekeeping in general.

Fragments on Atoms

Perhaps the most famous declaration of Democritus is, "Atoms and void [alone] exist in reality." This first historical formulation of atomism remains readily understandable into the 21st century, even if the current idioms are quarks and space. Democritus had discovered, for the Greeks, the notions of elemental particles of matter and of empty space. He envisaged atoms as indivisible chunks of matter existing in space. These smallest particles, in great numbers, constitute the object of sensory experience, that is, macroscopic objects. Though they were microscopic, Democritus imagined his atoms to have many of the same characteristics as the macro objects; extension in three spatial directions; arrangement; position; and duration in time, motion, speed, and form. Thus the microscopic or microcosmic particles are the indivisible, smallest parts of a whole physical body. It was not until Sir Isaac Newton and his contemporary Roger Joseph Boscovich later came to question this extended particle ("corpuscular") assumption in the theory of atomism (though Newton retained his commitment to the existence of some extended matter in the universe) that such reasoning would become suspected of a fallacy of division.

Democritus's affirmation of a void goes far more against common sense than does his affirmation of atoms. Indeed, some sort of atomism makes common sense, but the notion of a void was roughly that of vacuum; common sense believes nature abhors one, and thus a void cannot exist. Earlier thinkers from Anaximines onward gave a metaphysical stature to air or vapor. And where space between bodies was considered by the Presocratics, it was considered to be filled by the ether. Even the effluences of Empedocles sealed up and left no void. And so the genius of Democritus becomes evident even in the paltry number of his fragments.

Atomism poses its own epistemological problem: If atoms truly are beyond our senses, how do we know their nature, characteristics, or even their actual existence? Democritus faced the epistemological challenge head on by allowing his theory to remain just that, a theory, rather than involve himself in contradictions. And so he wrote, "We know nothing accurately in reality, but [only] as it changes according to the bodily condition, and the constitution of those things that flow upon [the body] and impinge upon it." Applied to his own atoms and void, this meant that we cannot know atoms directly but only through their physical effects at a macroscopic level. Until the instrumental period of science, thinkers would be able to do little more than theorize about atoms.

Yet this, for Democritus, is ultimately true knowledge. For there are two types of knowledge; sensory knowledge, which he called the "bastard," and "one genuine" sort of knowledge, which is mind comprehending ideas. The encyclopedic knowledge Democritus evidenced in his literary corpus suffices to show his regard for learning and abstraction. But he denigrated the testimony of the senses, a tradition among such diverse men as Heraclitus, Parmenides, and Pythagoras. Our senses alone will only mislead us. And so it must have been something of a puzzle to him as to how to reconcile his blanket rejection of the senses with his own attribution of properties in macroscopic (sensory) bodies to microscopic bodies. An equally vexing problem could be posed; if Democritus is certain of the existence of his own mind in the process of discerning physical affects of atoms, then something more than just atoms and the void exist.

What seems certain is that Democritus envisaged *time as the motion of matter through space*. This is far more elegant than the vision of any predecessor. He discovered the dependence of knowledge on a specific level of being; "humanity is a microcosm." Certainly, the universe as a whole is the final macrocosm; but humanity finds itself to be a miniature universe unto itself. So much more so is the atomic world; it is a microcosm at a second remove, and the final one, for Democritus. Applied to time, then, we would expect an entirely different frame of reference for time at micro- and macrocosmic levels.

Thus there must have been an uncertainty principle built into his theorizing about atoms, as about everything else: "We know nothing in reality; for truth lies in an abyss." Nor can we know causality, even in a world of physical bodies; "I would rather discover one cause than gain the kingdom of Persia," said Democritus. These epistemological concerns about natural science made Democritus a timeless philosophic and scientific figure.

Atomic Time and Zeno's Paradox

Democritus discovered the notion of the smallest, indivisible particle. He envisaged the atom as extended, and thus likely also considered a line to be composed of points with no space between them. If this is so, then he likely also believed time to be composed of a succession of discrete present moments. This would all mean that Democritus would have been susceptible to Zeno's paradoxes in both space and time. In short, Democritus was dependent on Euclid's conception of space and time, but therein lay the paradox. Almost certainly Democritus referred to Parmenides and Zeno when he wrote, "It has often been demonstrated that we do not grasp how each thing is or is not." But no fragment offers a hint of reply.

Again, the problem Democritus faced was due to his notion of corpuscular matter, and likely a notion of discrete present moments. The solution here, as with Zeno's paradox of the moving rows, would have been to envision the atoms as dimensionless points, not extended in space but emitting forces or powers. Unless Democritus took that route, though, he would have been saddled with Zeno's paradox, for his atoms would not be able to move, and the void could never be crossed. In fact, he would have been unable to show how time ever began in the first instant. To leave corpuscular atomic theory, though, would have meant crossing over to point-particle theory, a move we have no evidence he made.

Zeno's paradox is ultimately mathematical in nature, and the discovery of the calculus of infinitesimals finally silenced him, but only many centuries later. And so calculus was of no help to Democritus. What Democritus did achieve was to create the scientific type—entirely liberated from mythology and metaphor—within his theory and his own person. After his appearance, science would continue a relentless, if halting, progress. In the meantime, Socrates and his followers, including the young Plato, were already taking their places on the stage of philosophy, and thus the so-called Presocratic period of Greek thought came to an end.

PRIGOGINE, ILYA (1917–2003)

It is unusual that a winner of the Nobel Prize in chemistry succeeds in arousing a continuing interest of nonscientists in his research. Ilya Prigogine, who won that most prestigious award in 1977, is the exception that proves the rule. His study of the thermodynamics of irreversible processes not only is important in the history of science but also may have far-reaching implications for the philosophical understanding of time, which Prigogine discussed in a series of popular books read by a wide audience.

Ilya Romanovich Prigogine was born on January 25, 1917, in Moscow. Because his family had trouble with the Soviet regime that had been established after the October Revolution, the Prigogines emigrated in 1921 to Germany and in 1929 to Belgium. Prigogine studied chemistry at the Free University in Brussels, where he also became professor after the Second World War. In 1959, he was appointed director of the International Solvay Institutes in Brussels and professor at the University of Austin in Texas. There he also founded, in 1967, the Center for Statistical Mechanics and Thermodynamics. For his scientific work, Prigogine was honored not only by the Nobel Prize but also by more than 50 honorary degrees as well as by a Belgian title of nobility, viscount. On May 28, 2003, Prigogine died in Brussels.

Prigogine's principal field of research was thermodynamics, the science of energy and its transformations. Classical thermodynamics studies closed systems—systems that are thermically isolated from their environment and whose entropy can, according to the second law of thermodynamics, only be constant or increase. On a macroscopic level this means that closed systems become more and more disordered. Yet everyone can observe physical systems that, at least temporally, show an increase in order, for example, organisms. These are open systems; that is, systems that, by constantly exchanging energy with their surroundings, increase their internal order. To develop and maintain the complexity of their bodies, organisms must eat, breathe, and excrete. It is, however, not the case that every open system is able to increase its own complexity; only open systems that are far from thermodynamic equilibrium self-organize (*equilibrium* means a state in which the forces acting on the system are in balance). Prigogine called nonequilibrium systems *dissipative structures,* and he tried to apply their thermodynamic analysis not only to organisms but also to social systems.

A characteristic feature of dissipative structures is that they are historical systems: The processes by which they originate, develop, preserve themselves, and dissolve are irreversible. Prigogine's theory of nonequilibrium systems can thus be regarded as a physics of history. He considered his model of dissipative structures to be more realistic than the classical models of closed systems and near-equilibrium open systems. Consequently, regarding the basic ontological categories of natural science, Prigogine argued passionately for a revolution whose maxim is succinctly expressed by the title of one of his books on philosophy of nature, *From Being to Becoming* (1980). In this work, two concepts of time are distinguished. The concept of external and universal time refers to time as a parameter of motion; it is used when we want to communicate about processes and use clocks as instruments to quantify the succession of events by counting conventionally fixed units. The concept of internal and individual time refers to time as a property of the development of physical systems; it is used when we want to determine the intrinsic age of a system by counting the number of irreversible transformations of a certain type that have been generating the present state of the system.

In the tradition of philosophers like Peirce and Whitehead, Prigogine criticized the standard worldview of physics for being founded on the conceptual separation of the arbitrary initial conditions of a system from the dynamical laws its behavior follows: This way of objectifying nature cannot capture the essentially historical nature of all that is existing. Because dissipative structures are continuously exchanging energy with their environment, Prigogine thought that we humans, after having understood that we are such structures, will be able to develop a new understanding of ourselves as insolubly being a part of nature. The anthropological implications of his new ontology of nature Prigogine explained in his most famous philosophical book, which he wrote with the philosopher Isabelle Stengers, *Order out of Chaos: Man's New Dialogue With Nature* (1979). Whereas his philosophical convictions are, to say the least, quite controversial, Prigogine's far-from-equilibrium thermodynamics has become one of the cornerstones of research into complex systems and their natural historicity.

Prime Meridian

The prime meridian is an imaginary half-circle reference line extending north and south from one pole to the other and passing through Greenwich, England. It marks 0° longitude and divides the western and eastern hemispheres of the earth. The line that meets it at both poles and is exactly 180 degrees away from the prime meridian is the international date line. The prime meridian is the standard basis for determining time throughout the world. It is the starting point for all the world's time zones. This meridian is the location of UTC (universal time coordinated) as well as Greenwich mean time (GMT). Noon GMT is defined as the time at which the sun crosses the Greenwich (prime) meridian.

An international agreement in 1884 established the prime meridian in its current location. This line runs through the transit circle telescope, built in 1850 by Sir George Biddell Airy, the seventh astronomer royal, at the Royal Observatory Meridian Building in Greenwich, England. The crosshairs in the eyepiece of the transit circle telescope precisely define 0° longitude for the world. It is located at 51° 28' 38" north latitude. As the earth's crust is moving very slightly all the time, this exact position moves very slightly.

Longitude is a measure of both time and location on the earth. As the earth spins on its axis, a specific location and time can be determined relative to the prime meridian. This north-south line marks noon of the day that begins at the international date line and is the origin from which east or west longitude is measured. One degree of longitude equals 4 minutes of time the world over, but the distance of 1° longitude varies depending on the latitude of the location. Every 15° east measured from the prime meridian marks another hour later; every 15° to the west marks another hour earlier.

History

Lines of latitude and longitude appeared on maps at least 3 centuries before the Christian era. Hipparchus was the first astronomer to determine the difference in longitude and chose Rhodes as the location for his prime meridian, that is, his 0° east or west. By 150 CE, Ptolemy plotted grid lines on 27 maps of his first world atlas. The equator was set from previous astronomical observations, and he chose a line running through the Canary Islands as the prime meridian for his maps.

Later mapmakers moved the prime meridian to the Azores, Cape Verde Islands, Rome, Copenhagen, Jerusalem, St. Petersburg, Pisa, Lisbon, Rio, Tokyo, Paris, and Philadelphia. This placement of the line that marks 0° east or west is purely political, as it is not based on any natural phenomenon.

Beginning in 1667, and continuing for over 200 years, French cartographers used the longitude line running through the Paris Observatory to be the prime meridian. Other meridian lines were given names such as the Rose Line but were never used universally. The English king Charles II founded the Royal Observatory at Greenwich in 1675 for the purpose of improving navigation, and its longitude became another prime meridian.

The development of the accurate chronometer by Englishman John Harrison made it possible for English ships to determine their location based on comparison of their time and the time at a known longitude. Harrison was a clockmaker and not an astronomer, but he was able to solve the problem of determining longitude at sea. This was recognized in 1773.

Ocean charts drove the need for one internationally agreed-upon prime meridian. In 1871, the first International Geographic Congress (IGC) met in Antwerp, Belgium. The general view was that the navigation passage charts for all nations should use the Greenwich meridian as zero, so when ships exchanged longitude at sea, locations and times would match. This did not apply to land maps and coastal charts. In 1875, the second IGC met in Rome. France was willing to accept the Greenwich prime meridian if the rest of the world would accept the metric measurement system. In October 1884, at the invitation of U.S. President Chester Arthur, the International Meridian Conference was held in Washington, D.C., and 41 delegates from 25 nations voted 22 to 1 for Greenwich as the location of the prime meridian. Santo Domingo was against it, and France and Brazil abstained. The United States had already chosen Greenwich as the basis for its national time zones. Seventy-two percent of the world's commerce already used sea charts that used Greenwich as the prime meridian.

International commerce and communication required one standard. Since 1884, the world has had only one prime meridian.

PROGRESS

Progress is most easily defined as forward movement toward a destination. The theory of progress, however, is commonly defined as the forward, irreversible pattern of change throughout human history, the destination being the future. In its simplest form, progress is known to be change for the better. Although it may seem like an easy concept, it is widely debated and easily refuted based on its reliance on subjective matter—a lack of empirical proof about what is indeed better.

A critical aspect of progress is time. History is critical in evaluating progress, and history would not have been written without change. Without looking back in time on the condition of human life, science, and morality, it is impossible to know if advances have been made; thus, all progress must be measured relative to the past. Progress throughout history is not continual but rather takes place over time through setbacks and dissonance. In addition, goals, hopes, and dreams change over time, making what could have been measured as progress a century prior, now obsolete.

Progress is a relatively recent idea as applied to society as a whole. In ancient times, the idea was foreign, and in fact, most civilizations viewed the state of being as declining rather than improving. The idea was that life had been perfect in a former golden age and slipped into the silver, then bronze ages, identifying a downgrading of humanity. French historian Charles Perrault said in 1687 that there appeared to be little left to learn and that there was no reason to envy future generations.

The idea of progress took hold in the 18th century in the work of philosophers, scholars, and theorists such as Immanuel Kant, Marquis de Condorcet, and Georg Wilhelm Friedrich Hegel, among others. Prior to this, there was little hope that the world was in fact on its way to becoming a better place. This was the shift from the idea that man had been created perfect, and there was a push to live up to that standard to the idea that intelligence equaled progress, and the more knowledge each generation could obtain, the more forward movement, or progress, would be seen. Most of these thinkers agreed that progress had been made throughout history and was continuing in their respective times. They did not, however, share opinions on the ultimate goals of society and what was to be the ultimate goal.

Hegel saw history as progress toward freedom and the chaos of history as having great purpose toward the future. Kant wrote about a human race looking into the future and advancing to a "universal civil society," with maximum individual freedom afforded to all. Condorcet used mathematical methods in his approach to the social and moral sciences and believed in progress and perfectibility. His Enlightenment theory specifically addresses the likelihood and reality of perfectibility being attained within human history.

The theory suggests that the movement of change is irreversible in direction and that although it is not considered to be a continuous stream of forward change, due to occasional regression or stalled movement, the ultimate result is positive change. The pace of progress is not easily defined, as it varies widely with such fluctuations in direction and cannot be adequately measured in terms of time.

The opposition to this idea of eventual forward movement is quickly dismissed by the cliché "history repeats itself." There are those who subscribe to the thought that history is in fact cyclical, and events, or basic forms of events, reoccur over time. For this reason there is a school of thought that does not accept the idea that history is an upward climb toward that which is better; rather, this school holds that history will return in a similar form in the future. And then there are those still who agree that there is a definitive pattern of history that also moves in an irreversible direction but who argue that change is for the worse.

Among its supporters, many wonder whether progress is eternal, or if at some point it will level off to a point from which no further advancement can be made. Progress is also proven to be poorly defined in that there is no solid agreement as to the breadth of progress. Some argue that it is limited to human inventions, productions, and intellect. Others would say that it also should be inclusive of the improvement of the very nature of man himself.

Many who disagree with the theory on the whole have varied reasons for its dismissal.

The idea of progress is sometimes debated as immeasurable, and therefore its legitimacy is questioned. The argument does not center on the facts of history, which are knowable, but that the determination that an improvement has been made over earlier times is subjective. Many factors can complicate the ability to identify progress, including but not limited to the subjective nature of any determination of what is better. Some may see the automobile as evidence of human progress, while environmentalists may argue that its role in pollution and its drain on the natural resources of the earth actually make things worse.

In science, at least, it is commonly understood that there is progress. Seldom is it disputed that advances have been made, and it would be difficult to argue that curing disease and prolonging life through scientific research and newer medicines are not to be viewed as positive. Although their value is largely undisputed, even scientific advances cannot be seen to represent unequivocal progress; they are simply the closest thing to measurable progress that exists.

Prophecy

Prophecy has played a significant role in world religions, laying the groundwork for fulfillment of both religious and secular expectations of the future. The term *prophecy* derives from the Greek *pro-,* meaning "before" and *phanai,* "to speak," implying a foretelling. The term has become closely associated with supernatural abilities, and the word *prophet,* derived from the Greek *prophete,* has come to mean "one who speaks for another," usually understood to be a divine entity. Prophets channel revelations that include predictions of the future as well as admonitions to return to the laws of a belief system in order to avoid disastrous consequences. Often referred to as "seers," prophets receive their messages through various means, including trancelike states, dreams, visions, or agitated conditions induced by music or dance. Others receive special knowledge through the interpretation of physical signs, including astrological signs. Prophets have also been viewed as teachers and religious leaders. Three of the world's major religions describe their most venerated leaders as prophets. Judaism and Christianity revere the prophets of the Hebrew Bible, and Islam regards Abraham, Noah, Moses, and Jesus as respected prophets but Muhammad (571–624 CE) as the last and greatest prophet.

In the ancient world, the Persians, Assyrians, Chinese, Celts, Indians, Egyptians, and others sought out prophets who were often associated with temples and royal courts. During the later Hellenistic period, prophets, called oracles, were attached to shrines, one of the most important being the Oracle of Apollo at Delphi. The word *oracle,* derived from the Latin *orare* meaning "to speak," particularly in a public forum, refers both to the seer and to the shrine, and the term can be used interchangeably. The temple at Delphi was dedicated to Apollo, the Greek god of medicine, healing, poetry, music, and prophecy. Unlike most other Greek gods, Apollo had no direct Roman counterpart; however, later Roman poets often referred to him as Phoebus. The archaeological remains of this site are located near Mount Parnassus in the valley of Phocis, which the Greeks considered the center of the earth and the universe. The name Delphi is believed to be derived from the Greek *delphus,* meaning "womb," reinforcing its sacred origins.

The priestess of the oracle at Delphi was known as the Pythia and was consulted before all major undertakings, particularly battles. However, the oracle did not directly predict the future but rather gave advice and counsel, usually couched in ambiguous language that might be interpreted in various ways. Historic records dating to the 9th century BCE recount visits to the oracle by important Greek leaders, such as Lycurgus, Solon, Croesus, Lysander, and Philip II of Macedon. By 191 BCE the shrine at Delphi had come under Roman power, and the oracle continued to be consulted by Roman leaders, including Nero and Hadrian. It has been estimated that the pronouncements of the oracles at Delphi and other shrines had an important effect on the shaping of the Greco-Roman hegemonies.

Prophetic teachings play a particularly essential role in Judaism, Christianity, and Islam, which emphasize a personal relationship with God and a sense of individual moral responsibility resulting in future judgment. Judaism is based on the Hebrew Bible (*Tanach*), which is traditionally divided into three parts: the Law (the first five books, called the *Torah*); the Prophets; and the Writings or Wisdom Books. Particularly important are the later prophets, men of position such as Isaiah and Jeremiah, who spoke against religious hypocrisy as well as secular practices of their times, setting them in opposition to established religious tradition. Writing between the 8th and 3rd centuries BCE, they pointed to threats by Assyria, Egypt, and later Babylonia as God's sign that Israel needed a return to more ethical conduct to avoid disaster. The so-called minor prophets, men of humble origins, such as Amos, Hosea, and Micah, also spoke out against social inequality and served as the moral conscience of the community. Other important prophets of the Hebrew Bible (in Christianity, the Old Testament) include Daniel, Samuel, and Elijah.

The Old Testament book of Isaiah is particularly significant in Christian theology and contains the foretelling of a young woman who shall conceive a son and call him Immanuel, Hebrew for "God is with us" (Isa 7:14). Christians consider this a reference to Jesus Christ, the Messiah; however Judaism contends the prophecy has not yet been fulfilled and that believers await the first coming of a savior. The Hebrew prophets solidified the concepts of a messiah and a millennial period that is incorporated into Christianity and, to some extent, Islam. The only purely prophetical book of the Christian New Testament is The Book of Revelation, also referred to as the Apocalypse of St. John, in which John describes the events culminating in the Second Coming of Christ, the final judgment, and the establishment of a new world of peace and justice. Islamic tradition holds that prophets were sent by God to each nation, and all received revelations from God. The prophets who received *Sharia* (a divine code for life) that was ultimately written down and collected into holy books are also referred to as messengers. More than 25 prophets are mentioned in the Qur'an.

Prophecy is an important component in spiritual traditions throughout the world. Prophets pronounce visionary accounts of the future, which may or may not be predictions, but are rather interpretations of consequences based on present action. This particularly applies to beliefs regarding the ultimate future of humanity, and most of the world's major religions contain Messianic prophecies. Judaism, Christianity, Islam, Hinduism, Buddhism, and Native American religions all contain spiritual traditions that foretell the coming of a savior who will return, or send another in his place, to restore justice to the world.

In some beliefs, such as Taoism and ancient Mayan belief, time is cyclical rather than linear, and prophecy is based on predictable recurring events. In the contemporary secular world, researchers continue to investigate claims of some persons' apparent ability to access secret information and predict future events through means not scientifically explainable. Parapsychology is an academic field of study that seeks to determine the nature of those abilities by which some individuals are evidently able too see, hear, or predict events that are not apparent to others; these phenomena include clairvoyance, telepathy, extrasensory perception, precognition, and regression in time. Whether such powers are divinely inspired, supernatural, or scientifically explainable, or whether they turn out to be merely hoaxes, the desire to ascertain the future remains a powerful human motive.

Some modern scholars and theologians look for prophets in the contemporary context. In the tradition of Old Testament prophets and teachers, modern-day visionaries are often social activists, such as Martin Luther King, Jr. and others worldwide who call upon society to reform and promote peace, justice, and tolerance. In this view, then, the future is not to be foretold to passive listeners, but rather created by concerted action.

Proust, Marcel (1871–1922)

The French novelist and essayist Valentin Louis Georges Eugène Marcel Proust wrote essays and reviews as well as two novels before he became famous for his novel *À la recherche du temps perdu* (translated variously as *Remembrance of Things Past* or *In Search of Lost Time;* in this entry, *Recherche*).

Proust was the son of Adrien Proust, a prominent physician of that time, and his wife Jeanne née Weil, daughter of a wealthy Jewish family. In 1881 Marcel suffered his first attack of asthma, a disease that was to accompany him from that time onward and that finally led to his death at the age of 51. After baccalauréat and military service, he began to study law and political sciences in Paris. He finished these studies in 1892 and 1893, respectively, but against his father's will decided not to start a career in the foreign ministry and instead to begin a new study of "lettres," which could be described as a general study of humanities. Proust chose philosophy as his main subject and received his licentiate in 1895. In 1896 *Les plaisirs et les jours,* a collection of prose writings, was published but not widely recognized. In the same year, he began to write his first novel, *Jean Santeuil.* He stopped working on it in 1904; the fragments were not published until 1952. Many themes of the *Recherche* can already be found in these fragments.

Between 1896 and 1908 Proust published some translations of the British art historian John Ruskin. In 1907 he began the essay "Contre Sainte Beuve" (published posthumously in 1954), which today is considered to be his preliminary stage of the *Recherche.* "Contre Sainte Beuve" gradually changed its nature to finally become *À la recherche du temps perdu* from 1909 onward. The novel consists of 15 volumes, which are divided into 7 parts. The first, *Du côté de chez Swann* (*Swann's Way*) was published 1913, to be followed by *A l'ombre des jeunes filles en fleurs* (*In the Shadow of Young Girls in Flower*) in 1918, *Le côté de Guermantes* (*The Guermantes' Way*) in 1920, and *Sodome et Gomorrhe* (*Sodom and Gomorrah*) in May 1922. Proust died in November 1922, leaving enough material behind to publish three more novels posthumously. The fifth part of the novel, *La* *prisonnière* (*The Prisoner*) was published in 1923; the sixth, *Albertine disparue* (*The Fugitive*) in 1925, and the last, *Le temps retrouvé* (*Finding Time Again*) in 1927.

The main subject of the *Recherche* is time. The novel describes the life of the protagonist Marcel from his own perspective. The protagonist is not identical with Proust, but there are many similarities to Proust's own life.

The novel wants to give an answer to the question, "What happened to the time lost?" Proust is influenced by the model of time described by the French philosopher Henri-Louis Bergson (1859–1941). Bergson divides memory into two parts, which are named *memoire* (memory) and *souvenir.* Memoire is the cold intellectual side of the memory, while souvenir is an involuntary evolving memory. This *memoire involontaire* (involuntary memory) is often caused by sensations such as a smell or a stone touched by the foot. The perhaps most famous example for souvenir in the *Recherche* is the moment in which Marcel eats a madeleine (small French cake) dipped into tea. This trivial experience triggers a revival of the protagonist's whole life in Combray. Time therefore is not simply a linear experience; it is possible that "lost time" may be brought back to life again by an involuntary remembrance. The lost time comes back as it really was for the one who experienced it.

The *Recherche* itself is an *édifice immense de souvenir,* in which the reader follows Marcel on his way through time described from his perspective. Time is preserved in the memory of the people, and the time they are preserving is lost for the world once they have died. In the last part of the novel, *Le temps retrouvé,* Marcel decides to write down his memories, and with them the world as he knew it, in a book. The novel thus contains a kind of circle, in which the reader finds out that he was following Marcel's search for a way to preserve time, which is found in the end. The solution found is to write a novel, which Marcel decides to do. The work to be written after the story of the novel ends is the same novel that was read by the reader.

For Proust, then, the only way to preserve lost time and all of its souvenirs is through the making of art. The *Recherche* is such a piece of art and the answer to the protagonist's question. It lets the reader relive Marcel's memories, or at least grants access to a version of them, thereby retrieving the time as experienced by the protagonist.

Psychology and Time

The dimension of time is essential for human cognitive functioning. Because events are perceived over time and actions evolve over time, the ability to process temporal information is essential to monitor the environment and control our behavior. Although we speak of a "sense of time," there exists no sensory organ for the perception of the passage of time or duration comparable to our sensory perception of colors or shapes, sounds or melodies. Time is not a concrete entity in the world we experience. Our brain must actively construct temporal relationships from the sensory information we perceive.

The Experience of Time

In his *Confessions,* Saint Augustine thus concludes his analysis of the experience of time: "It is in thee, my mind, that I measure times." He saw the perception of time as constructed by our self; that is, the experience of time represents the mental status of the beholder, reflecting one's cognitive state and emotional well-being. The accuracy and precision of subjective time estimation is linked to overall cognitive functioning, that is, to attention and memory processes. Our sense of duration depends on the degree of attention we pay to the passage of time and memories of comparable time intervals. Our subjective well-being also strongly influences how time is experienced. Time seems to fly during pleasant activities, but to drag during periods of mental distress. Our sense of time depends on an intricate interplay between specific cognitive functions and influences of our momentary mood states.

The perception of time can be classified in numerous ways, but two concepts form the building blocks of our temporal experiences—*succession* and *duration*. The perception of succession refers to the sequential characteristics of events; in other words, their temporal order. The perception of duration refers to the time interval subjectively experienced between two events or to the persistence of an event over time. The taxonomy of elementary temporal experiences derives from these two basic concepts and comprises the perceptual phenomena of simultaneity, successiveness, temporal order, the subjective present, and duration.

The first three of these experiences relate to the temporal properties of two events that are perceived as happening simultaneously or nonsimultaneously. For instance, our sensory systems have different temporal resolutions for the detection of nonsimultaneity. The highest temporal resolution (the lowest threshold of detection) is observed in the auditory system, where acoustic events 2 to 3 milliseconds apart are detected as nonsimultaneous. The somatosensory system has a slightly higher threshold, whereas the visual system has the lowest temporal resolution, with a threshold approximating 20 milliseconds. Interestingly, the detection of nonsimultaneity of stimuli is not perceptually sufficient to indicate their temporal order. Although we may be aware that two events did not occur simultaneously, we are still unable to tell which one of the two events occurred first.

The temporal-order threshold is more comparable across senses. The onset of two events, independent of sensory modalities, must be at least 20 to 40 milliseconds apart before an observer can reliably indicate their temporal order. The temporal-order threshold thus represents a fundamental perceptual limit. The temporal succession of events over time (the order in which they occur) can only be perceived if they occur approximately 20 to 30 milliseconds apart.

Regarding the perception of duration, a perceptual mechanism that integrates separate successive events into a unit or perceptual gestalt has repeatedly been suggested. We do not just perceive individual events in isolation, but automatically integrate them into perceptual units (or *gestalts*). While listening to a metronome at a moderate speed, we do not hear a train of individual beats but automatically form perceptual units, such as 1–2–3, 1–2–3, etc. These are mental constructs—physically speaking, they do not exist. The duration of this temporal integration mechanism, referred to as the subjective or specious present, seems to be limited to 2 to 3 seconds. Experimental investigations have demonstrated that temporal intervals can be accurately reproduced when their duration does not exceed 3 seconds. Intervals longer than 3 seconds are usually reproduced shorter than the presented interval.

In sensorimotor synchronization (a task in which a sensory signal has to be precisely synchronized with a motor act), if the interstimulus interval is longer than approximately 2 seconds, performance breaks down. Anticipation of the signal is no longer possible. Other examples come from bistable perception (e.g., the Necker cube), where a single stimulus leads to two mutually exclusive perceptual interpretations that alternate in time. The spontaneous rate of perceptual alternation approximates 3 seconds. Based on these findings, researchers have established the categorical distinction between *perception of duration* (for intervals up to 3 seconds) and *estimation of duration* (for longer intervals). Events lasting only a few seconds are processed on the present perception as a whole, whereas longer intervals must be estimated from memory.

A different classification of time phenomena, which still encompasses the above-mentioned elementary time experiences, includes three interrelated dimensions: (1) time estimation, (2) time awareness, and (3) time perspective.

1. Abilities to estimate time are measured by the precision in estimating clock time, that is, in experimental settings in which subjects are requested to tell which one of two presented stimuli was longer or, in real life, when we have to judge whether water has boiled for 3 minutes.
2. Time awareness is the subjective impression of time as moving quickly or slowly, that is, the

feeling that time passes too fast when we are having fun or too slowly when we are desperately waiting for something specific to happen.

3. Time perspective refers to the conception of a past, a present, and a future.

Because we experience time in these three-dimensional aspects, time perspective is a fundamental dimension in the construction of subjective time, which emerges from the cognitive partitioning of human experience into past, present, and future. Human endeavor bridges the past, present, and future, as the memory of past events can be used to plan and act in the present to reach future goals. In this respect, present time is experienced through attention, past time is defined by memory, and future time exists as expectation and prediction.

Psychological and Neural Models of Time Perception

From a systemic perspective, organisms must interact with the environment on different timescales. Experience and behavior are interactions that span time ranges in microseconds (localization of sound in space), tens of milliseconds (detection of succession, phoneme recognition), hundreds of milliseconds (motor control, speech segmentation), seconds-to-minutes (conscious perception of duration), and circadian rhythms (the daily sleep-wake cycle). Additionally, annual cycles influence psychological states and determine an individual's physiological functions. The anticipation of future decades of human life is relevant for long-term decisions, for example, when a young person saves money in a retirement plan, thereby opting for a momentary loss of money to gain future benefits. This classification of relevant timescales between the range of milliseconds and decades encompasses two aspects of time that have been described since ancient times. Time appears to be either cyclic (it repeats itself periodically) or linear and irreversible (time flows in one direction only and one moment does not repeat itself). The cyclic aspect of time is apparent in the recurrence of days and the repetition of the seasons. Nature has adapted to these cyclic properties by establishing endogenous biological clocks in organisms. The circadian (about one day) clock as well as circannual clock regulate fundamental aspects of physiology and behavior and are entrained (synchronized) by the periodicity of light.

Over the past few years, a body of evidence has shown that different time perception mechanisms are associated with different timescales. For example, on a variety of sensorimotor tasks, temporal integration windows of around 250 milliseconds and of around 1 second have been postulated to mark the transitions between different timing systems. It has been suggested that an automatic timing system is responsible for shorter intervals (milliseconds). Such a system can measure time without attentional modulation, whereas a cognitively controlled timing system for intervals longer than a second requires more strongly cognitive circuits in the brain. Furthermore, in relation to the concept of the specious present, intervals up to 2 to 3 seconds have been shown to be processed differently than intervals exceeding this time range. Even for longer intervals, it is conceivable to assume distinct processes for different durations. For example, the estimation of a one-hour interval, but not the estimation of a minute, is related to an individual's circadian rhythm.

Cognitive models of time perception in the seconds-to-minutes range distinguish two fundamental perspectives in time estimation. In prospective time estimation, an observer judges the duration of an interval she or he is presently experiencing. The observer's attention is directed to time while a particular duration is being estimated. In retrospective time estimation, the observer a posteriori estimates a time span that has already elapsed, and, therefore, duration has to be reconstructed from memory. The most prominent cognitive models of prospective time estimation assume an "internal clock" with a pacemaker producing subjective time units (analogous to the ticks of a clock). The time units produced are registered only when attention is actually concentrated on time. As a result, an attentional gate opens, and time units are fed into a counter. When attention is distracted from time—for example, when one gets absorbed in another task—the attentional gate closes, and time units are not recorded. The number of units that have been recorded during a physical time period is then compared with a memory store. The unit counts are compared with the stored representations of time periods, which can be verbalized as seconds or minutes. If more attention is directed to time during the time interval to be estimated, duration is experienced as being longer.

In retrospective time estimation, the duration of a time interval that has already passed has to be judged. In contrast to prospective duration estimation, the observer estimates duration from the amount of processed *and* stored memory contents. In general, the more different events that occur during a time span, the longer the experienced duration. According to this model, the subjective impression of a long time interval depends on the activity of a person with diverse experiences. These two components of time estimation help explain the time paradox familiar to everyone.

The same physical time period can be judged differently, depending on a person's prospective or retrospective perspective. For example, the 10 minutes spent in a dentist's waiting room may seem eternal. We may overestimate the duration of that period simply because, under those circumstances, we pay a lot of attention to the passage of time (prospective estimation). However, when looking back at that waiting period, nothing really remarkable occurred and, therefore, this time span shrinks to a negligible period of time (retrospective estimation). In a different example, when we spend 10 minutes talking to an attractive person, we are not paying attention to time, as we are absorbed in the conversation. Time even seems to pass too quickly. However, in retrospect, we have memorized so many stimulating and emotional moments that we experience this time period as having lasted considerably longer.

The neural mechanisms underlying the perception of time have yet to be identified. Nevertheless, investigations of the neural basis of time perception in the seconds-to-minutes range support the hypothesis of the involvement of brain circuits embedded in the frontal lobes of the cortex and the basal ganglia. These circuits are modulated by the dopamine transmitter system and are thought to be critical for temporal processing.

Evidence for this anatomical hypothesis comes from studies of patients with brain lesions and from investigations using brain imaging techniques. Patients who suffered an infarction in their frontal lobes or traumatic brain injury predominantly affecting frontal brain areas display impaired estimation of time intervals. In healthy volunteers, brain activation studies using a functional magnetic resonance imaging (fMRI) technique show that the processing of duration is associated with activation in the right prefrontal cortex and the striatum (as part of the basal ganglia).

Regarding the neurotransmitter systems, animal and human studies indicate that both dopaminergic agonists (drugs that stimulate the system, like methamphetamine) and antagonists (drugs that inhibit the system, like haloperidol) influence the temporal processing by increasing and decreasing clock speed, respectively. Additional evidence for the involvement of the dopamine system in time perception comes from patients with Parkinson's disease. These patients have decreased dopaminergic function in the basal ganglia and show deficits in the discrimination of temporal intervals. Hence, overall, studies show that the integrity of the dopamine neurotransmission within the fronto-striatal circuitry of the brain is an essential component for the processing of time in the seconds-to-minutes range.

The experience of time is also influenced by hallucinogenic drugs such as LSD and psilocybin, which have similar pharmacological properties acting on the serotonergic transmitter system. People report the feeling of a slowing down of the passage of time and often overestimate time intervals, as minutes can appear to be hours, or time seems to stand still. Marijuana also affects the subjective sense of time, as the user's time estimates can become inaccurate. Individual reports are complemented by experimentally controlled investigations, which explain their findings within the framework of the dopamine hypothesis of time perception. The serotonergic hallucinogens psilocybin and LSD probably act indirectly on dopaminergic transmission. Moreover, marijuana can also influence dopamine activity via cannabinoid receptors on nerve cells of the dopamine system in the basal ganglia.

Other brain regions play a decisive role in the range of milliseconds. For example, the important role of the cerebellum in temporal processing has repeatedly been emphasized. Patients with damage to cerebellar structures exhibit severe deficits in time perception and motor timing of short intervals lasting only hundreds of milliseconds.

Psychophysical and neuroimaging studies in humans, as well as neurophysiological recordings in animals, indicate that a network of cortical areas contributes to the processing of time intervals in this short time range. In a widely distributed network spanning distinct regions of the brain, neural populations within each region may encode duration as a result of specific biological time-dependent changes. Time-dependent changes result from intrinsic neural properties, such as short-term synaptic plasticity. This view postulates that a centralized pacemaker-accumulator system (the "internal clock") is not involved in the processing of time when intervals reach up to hundreds of milliseconds.

In contrast, a stronger localization of functions (i.e., the involvement of a focal area in the brain) has been postulated for the perception of temporal order. Many studies have shown that patients with lesions in the left hemisphere and aphasia (as opposed to patients with lesions in the right hemisphere) have difficulties perceiving the temporal order of two events. These patients require longer intervals between two stimuli before they can distinguish their temporal order.

Children with specific language deficits have difficulties detecting the sequence of events in the milliseconds range. These observations suggest a causal relationship between the detection of temporal order and language processing on the phonological level. According to the phonological processing hypothesis, rapidly occurring elements in the speech signal have to be adequately processed for the identification of stop consonants (e.g., *d* in *dry* or *t* in *try*). In language-impaired individuals, a basic auditory deficit in temporal-order detection leads to impairments in phoneme identification, which is anatomically traceable to temporo-parietal areas in the left hemisphere. Such results demonstrate how intimately related temporal processing mechanisms are with other cognitive functions. In this specific case, a deficit in perception of temporal order has a detrimental effect on language processing. As will be discussed below, disturbances in cognitive functioning and emotional processing can also have profound effects on the experience of time. Any change in a person's mental status has an effect on the processing of time, as minute as the change may be.

Cognitive and Emotional Views of Time

The perception of the passage of time with changing pace is part of our daily experience. We do not perceive time as a steady-paced flow; the subjective passage of time varies considerably. The prospective model of time estimation can help explain several everyday time phenomena in relation to attention. An individual who is concentrating on the passage of time in an uneventful or unpleasant situation, such as nervously waiting for something specific to happen, experiences a slower passage of time and overestimates duration. When, however, the same person is suddenly distracted from concentrating on time, as when he or she is having fun, time seems to pass more quickly, and duration is more likely to be underestimated. According to the cognitive models, the way attention is concentrated on time during a given time span leads to the collection of more or fewer subjective time units. When we devote more attention to time, more time units are collected in a hypothetical counter. When we concentrate more on distracting events during a given time interval, fewer time units are collected, leading to the impression of a shorter duration. According to this theory, the allocation of attention determines the perception of time.

However, this reasoning does not clarify why individuals in certain circumstances actually focus their attention more strongly on the present time. It can be assumed that concentrating less on the passage of time (and perceiving it as passing more quickly) is associated with general psychological well-being. This state is associated with the ability to have meaningful thoughts and engage in self-rewarding activities.

Boredom-prone persons, for example, more often perceive time as passing slowly, even when they are busy performing a task. Institutionalized individuals, like those who live in residential homes for the elderly and whose days are highly regulated and monotonous, experience time as passing very slowly. There is ample evidence that depressed patients perceive a slowing of the pace of time and tend to overestimate durations in time-judgment tasks. Cancer patients who experience high levels of anxiety overestimate duration and report that time passes too slowly. In more general terms, these studies suggest that the overestimation of time intervals is a sign of emotional distress that draws attention away from meaningful thoughts and actions and directs it to the passage of time. Individuals who are institutionalized and/or suffering from emotional distress are not able to engage in their usual role function and have to spend much of their time in situations where they are not emotionally or cognitively engaged, like a series of waiting periods. Both the feeling of meaninglessness and the absence of a stimulating environment can manifest themselves in a state of distress or an existential vacuum that leads to the complaint of the slow passing of time.

Related to the time perspective (past–present–future), a similar entanglement of cognitive and emotional processes manifests itself in decision making. Everyday we have to make choices that have immediate, as well as delayed, consequences. A student may have to decide whether to go to a party tonight or to stay home and study for an exam scheduled tomorrow (with the possible later higher reward of passing the exam). We frequently have to make decisions based on predictions of rewards on different timescales. The process of deciding whether to opt for an immediate reward or for a delayed, but higher, reward is strongly related to scholarly and professional success. To function effectively, we must voluntarily postpone impulsive urges for immediate gratification and persist in goal-directed behavior to achieve positive outcomes in the future. Time perspective is considered a personality trait affecting cognition, emotion, and goal-related actions of an individual.

Ideally, we are able to flexibly switch temporal perspectives according to the situational demands; for example, we resist the temptation of the social gathering tonight because we can anticipate the future consequences. Some individuals, however, have too strong a focus on the present (related to stronger impulsivity and the inability to curb momentary urges) and are inadequately able to cope with everyday demands. For example, a stronger focus on the present and less on the future is highly related to risky behavior, such as gambling, careless driving, unprotected sex, or drug abuse. However, too much emphasis on the past and on the future are also dysfunctional, as they deprive one of important hedonistic features in life that can only be experienced at the present moment. A balance of temporal perspectives is healthy, both psychologically and physically.

A time phenomenon that haunts nearly every adult can be explained by the retrospective models of time estimation. A common complaint is, "Time passes too quickly!" During childhood and adolescence time seems to have a much slower tempo. People even complain that, as they age, time continuously speeds up. At least two factors, but probably more, influence this subjective perception. One lies in the time perspective of an adult, which, due to the individual's social orientation, can be characterized as continuously changing with advancing age. For the elderly, the length of the future time perspective generally decreases when measured by the number of years for which plans are made or personal events anticipated. A shorter future temporal perspective, however, can also influence the awareness of time. Studies show that elderly subjects who report fear of death feel more pressured by the passage of time. Men experiencing a midlife crisis are confronted with the shortening of their time perspective and also experience more time pressure.

A second factor that causes time to fly as we grow older lies in factors influencing retrospective time estimation. Prospective time estimation models cover the experience of the momentary passage of time. An association between age and the speed of time or the subjective duration of a time span, however, typically refers to longer intervals, like weeks, years, or even decades. A common disquieting discovery of an adult is "Have I already been working here for 10 years?" Looking at the past necessarily invokes memories and leads to a personal account of one's life. As predicted by the model of retrospective time estimation, we construct time in reference to the amount of changing information processed and stored. The more the contextual changes stored in memory during a given time span, the longer the experienced durations. Thus, time periods in one's life filled with a lot of changes are perceived as being subjectively longer than periods of time when few changes have occurred.

This provides the second explanation for why a lot of adults complain that time speeds up as they get older. During the course of a lifetime, many people get into the rut of everyday habits. The number of new experiences and openness to lifelong learning often decreases with age. If experiences do not differ significantly from day to day, they are not specially stored in memory. The routine of getting up in the morning, going to work, having lunch in the canteen, going home, watching television, and going to bed will not be stored as memorable events. Thus, in retrospect we have lost all these days, which results in a contraction of subjective lifespan.

Childhood, adolescence, and early adulthood, in contrast, can be characterized as periods of life during which new experiences occur on a daily basis, and skills and knowledge are acquired at a high rate. In retrospect these time periods are filled with many events, so the time period seems comparatively long. This explanation also offers a remedy available in a person's propensity to counteract the tendencies of repetition and custom. Although the general tendency toward routine cannot be fully avoided with increasing age, willingness to change habits and redefine one's goals throughout life will not only stimulate an individual in the here and now but will also lead to a subjective slowing down of the passage of time when we look back on a period of our life.

Applied Research in the Psychology of Time

After initial research in the late 19th century and the early 20th century, the topic of time perception was neglected in the field of psychology for many decades. However, over the last 20 to 30 years, a considerable body of knowledge has been collected regarding the processes underlying the experience of time. Diagnostic tools have been developed to assess disturbed temporal processing mechanisms in various neurological patient populations. Patients with acquired focal brain lesions following a stroke or severe traumatic brain injury, patients with Parkinson's disease or with temporal-lobe epilepsy, and patients with schizophrenia have all demonstrated specific impairments in time estimation and motor timing. These findings are discussed in relation to alterations in several cognitive domains related to time processing—specifically, a pacemaker-accumulator type internal clock, memory, and attention.

A considerable body of applied research concerning possible training procedures exists, albeit in one domain only and controversially discussed—neuropsychological training procedures for improving temporal processing abilities in subjects with language disorders. Based on the diagnostic findings that patients with aphasia and children with language-learning impairments have difficulties detecting the temporal order of stimuli, training methods in temporal-order detection have been developed to improve not only the ability to perceive temporal order but also to improve basic language competence. In these computer-based feedback training procedures, the temporal order of two successively presented acoustic stimuli has to be identified at decreasing interstimulus intervals (time between two stimuli). The interstimulus interval is lowered when the sequence of stimuli can be reliably identified. In this way, thresholds for the detection of temporal order can be sufficiently decreased. It has been shown that successful training can also improve phoneme discrimination ability, which may well depend on a high acuity in temporal resolution. It is likely that similar training procedures will be developed in the future to improve temporal processing functions in patients with other kinds of neurological syndromes. Due to the interdependence of time perception and cognition, novel time perception deficits—related to the taxonomy of temporal experience—in various neurological and psychiatric patient populations are likely to be detected.

The experience of time could become a topic in psychological assessments by providing an additional approach to diagnose the mood states of various patient groups, such as individuals with depression or cancer patients with anxiety or depressive symptoms. As outlined above, the feeling that time passes too slowly is an indicator of psychological distress resulting from an inability to focus on meaningful thoughts and to engage in purposeful actions. In contrast, individuals who are able to distract themselves during a stressful period not only experience a faster passage of time but also experience less mental distress. The reported findings in the psychology of time emphasize the need to address the search for meaning as a coping factor in psychotherapy. Time perception could, for instance, be addressed in psychotherapeutic approaches as a means to positively influence psychological well-being and related subjective experiences.

As the experience of time provides insight into a person's state of mind, the investigation of time perception could also provide crucial insight in the understanding of the mechanisms of self-control and impulsiveness, as in children with attention deficit hyperactivity disorder or in individuals abusing drugs. For example, drug abusing persons exhibit a stronger present time perspective and are more impulsive than abstainers. Existing studies show that alcoholics have a weaker future perspective than social drinkers, and heroin addicts have shortened time horizons, as they are less likely to set goals for the future. Even substance use (alcohol, tobacco, marijuana) in college students is related to a shorter future perspective and a stronger present orientation. At the same time, addicted individuals, such as smokers craving a cigarette or patients addicted to stimulants like methamphetamine or cocaine who are being treated in a drug-treatment program, perceive an indicated time interval to pass more slowly and overestimate it.

The model of cognitive time perception links these separate characteristics of interest. As individuals addicted to a drug show a stronger emphasis on the present time (as opposed to the future), they consequently pay more attention to the momentary passing of time. Allocating attentional resources to time leads to a subjective slowing of time and to an overestimation of duration. An altered sense of time could be one reason why impulsive individuals do not delay gratification and act on impulse. For such a person, the benefit of resisting temptation might lie subjectively too far in the future. Based on drug users' general difficulties with decisions that involve delayed rewards (these difficulties extend into many aspects of life), it has been suggested that treatment programs should develop intervention strategies that cognitively restructure the perception of these choices to shape more adaptive and health-promoting behavior. Moreover, in the therapeutic process, the setting of positive rewards and goals should not be extended too far into the future and should adapt to the individual's shortened time horizon.

The study of psychological time is only slowly entering mainstream contemporary psychology. The experience of time is dependent on numerous factors. Some of these are the individual characteristics of the person, the physical properties of events that mark the time intervals, mental contents that are processed during the time interval, and, last but not least, whether subjects were instructed to estimate duration before or after a target interval is presented (prospective vs. retrospective time perception, respectively). As it is hard to control for all these factors, results from simple time perception tasks are often difficult to explain. Nevertheless, the measurement of time perception will become part of the standard methodological inventory in psychology. First, and on a very personal level, the experience of time has an existential dimension for all of us, because we have only a limited time to live. Second, knowledge of the psychology of time can also pay off on a very pragmatic level.

The following is a story reported not long ago in the media. The management of a hotel had to decide whether to replace an old elevator, an action that would have been very costly. Hotel guests had repeatedly complained that the elevator moved too slowly. A little trick based on knowledge of the experience of time stopped these complaints. Mirrors were hung up in the elevator. Although the elevator still moved at the same pace, nobody complained any more. The hotel guests, now distracted by their own images, no longer focused on the passage of time and did not consider the time spent in the elevator too long at all.

Pueblo

The early Spanish explorers of North America, presumably impressed with the affinity of the southwest indigenous peoples to their great houses of multilevel apartment-like villages and cliff dwellings, gave the name Pueblo to these tribes, meaning both village and a people or nation. The Pueblo people compose 25 tribes, including the Hopi, Zuñí, Acoma, and Tao, with languages stemming from three branches: the Uto-Aztecan, the Tanoan, and the Keresan. They live in one of the oldest continuously settled regions of North America, in the asperities of the arid plateaus of Chaco Canyon and other parts of the Four Corners area (so named because it comprises the corners of four states: New Mexico, Arizona, Utah, and Colorado) and the surrounding vicinity, also known as the House Made of Dawn. They are presumed to be descended from the first group of migrants to enter the Americas. The ancient Pueblo have many nomenclatures: Desert Archaics, Hisatsinom (Hopi: "people of long ago"), and Anasazi (Navajo: "ancient enemy"). These ancestors, like many ancient astronomers, considered the celestial movements sacred and attempted to harmonize with the cosmos and the six sacred cardinal directions (North, South, East, West, Zenith, and Nadir). The result manifested into building plans and architectural locations that contained apparent stellar alignments in addition to colors and symbols with assigned directional and cosmic representations.

The Desert Archaics to Pre-Hisatsinom

From 9000 to 8000 BCE, a nomadic tribe referred to as the Desert Archaics occupied the mesas throughout the hunter-gatherer period. Their knowledge of celestial cycles appears to have been well established: Petroglyphs representing constellations line many rock walls throughout and surrounding the House Made of Dawn. Scholars posit these storyboard images to be recordings of astrological events, histories, and calendars. Upon those high plateaus is a unique view of celestial movements. It can be presumed that the various stellar patterns were observed and calculated from ancient days, for around approximately 700 CE the Hisatsinom culture, whose people resided in pit houses, begin construction on the near five-story complex archaeoastronomy dwellings, or great houses, with major structures designed with internal solar and/or lunar alignments.

Hisatsinom Culture

The great houses in the House Made of Dawn were once thought to have been haphazardly constructed, but based upon closer examination by scholars such as Anna Sofaer, it is thought that the structures in the Chaco Canyon area were planned and executed with the purpose of recording solar, lunar, and other important stellar movements. Scholars posit that these structures were low in population save for ceremonial times, when pilgrimages were made from the surrounding 150 communities (and perhaps further), which were connected via a precisely constructed set of roads. The structures of the great house are oriented north–south and east–west to form a three-community house that shares in a lunar minor alignment, representing the moon's rise, its meridian, and other occasional observances. In addition, there is a solar and lunar observatory at Fajada Butte that was used to mark solstices, equinoxes, and the 18.6-year cycle of the lunar northern and southern extremes. The Chaco Canyon phenomenon thus embodies the ancient Puebloans' worldview.

The *kiva,* a round, partly underground structure that forms the nucleus of each great house, remained part of the Pueblo religion and culture. The kiva represents the world below or sacred womb, while the kiva's *sipapû,* a hole or indentation in the floor, symbolizes the "earth navel" believed to be the entrance for the people and kachinas or spirits. Their legends of creation begin with a speculation of endless space, elucidating how Spider Woman created a web-matrix for the foundations of the earth and sky. Hopi legends tell of four cycles the humans evolved through as Spider Woman led the journey, the last journey guiding them from the world below through the sipapû.

Pre-Puebloan Culture

A mass exodus from the great houses occurred around 900 to 1300 CE. It brought about new or altered religions; for the Hopi it was the advent of the kachina celebrations, with the New-Fire Celebration in November to start the New Year. The kachina season officially commences in the halcyon days of winter solstice, with rituals for each month of the nearly 7-month season, which concludes in July. The year's remainder operated through the snake or flute season.

In the Hopi tradition, all things animate and inanimate have a kachina. The masked Puebloan dancers symbolically represent these spirits wearing celestial regalia representing the morning star, the sun, and the earth. The symbols within paraphernalia, pictographs, and sand paintings have many cosmic representations: eagle—sun or sky god; fire—life's creation; spider—earth; bear—west; mountain lion—north; wildcat—south; wolf—east, and so forth. Colors can moreover represent the cardinal directions: yellow—north, white—east, green/blue/black—west, and red—south. Like the sand designs of the Tibetans, the Puebloan sand paintings are formed exclusively for ceremonial purposes and swept away at the observance's conclusion.

There were annual, biannual, and quadrennial celebrations. The biannual festivals alternated between the snake and flute societies; the snake during odd years, the flute during even years. Quadrennial celebrations accompanied priestly initiations, and for the duration of that year each of the festivals was extended; for example, a 1-day ceremony lasted 5 days, or a 5-day ceremony lasted 9 days. The extended ceremonies possibly served as training periods for the new priests, who were educated in astrological movements and accompanying traditions.

Pueblo Culture

The Spaniards attempted to eradicate the Puebloan belief system, and so struck at the core by destroying numerous kivas, including filling one with sand and positioning their church atop it, in effect preserving the "kiva beneath the altar." Many atrocities were suffered by the Puebloans at the hands of the Spaniards during early colonization, although the Pueblo tribes held fast on several occasions, including the revolt of 1680. Despite such efforts to supplant indigenous belief, the Pueblo have continued their ceremonial observances. In the late 19th century, at Eldon Mesa, anthropologist Alexander M. Stephen witnessed a winter solstice observance of the sun's arrival at the great house called House of the West.

Contemporary Puebloans

The destruction of the sacred Spider Woman hill in 1984 during a highway construction project enraged the Puebloan communities; in response, after the Puebloans received the assistance of LaVan Martineau, assurances were given that the remaining rock images within the Clear Creek Canyon would be recorded and preserved. Similar to other indigenous peoples, the Puebloans are participating in mainstream society while holding fast to their traditional customs and actively researching their ancient culture.

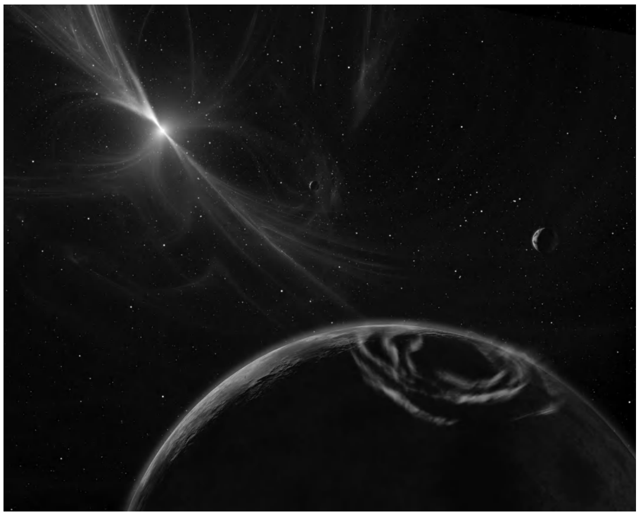
Pulsars and Quasars

Pulsars and quasars are celestial objects that often emit radio waves but can also emit energy in the visible light, X-ray, and gamma-ray ranges of wavelengths. Unlike quasars, pulsars are rapidly spinning neutron stars that often have a rotational period so regular that, as timepieces, they are more accurate than atomic clocks. Although quasars are neither stars nor timepieces, they are among the most distant observable objects in space, so distant that observing them is akin to looking at the past.

First discovered in 1967 by English radio astronomer Antony Hewish and his Irish graduate student Jocelyn Bell, pulsars are the result of a supernova explosion of a midsized star. The ensuing gravitational collapse of such a star forms a neutron star. Pulsars get their name from the regular pulses of radio waves that emit from their magnetic poles. They behave like lighthouses, but with radio waves in place of flashes of light. Each pulsar has a period, the time it takes for it to rotate once; this period can range from a millisecond to 8.5 seconds. As time passes, and the pulsar ages, the period will grow longer, meaning that the pulsar's spinning slows as its magnetic force increases. One type of pulsar is the millisecond pulsar, which has the shortest period. Its weak magnetic field allows for greater rotation speed. The periods of millisecond pulsars are stable and predictable enough to trump the timekeeping of atomic clocks. Another type of pulsar is the binary pulsar, which is one star in a binary star system in which two stars revolve around each other. Because of their atomic makeup—neutron-saturated nuclei—pulsars may have the mass of the sun but are extremely dense, sometimes less than 20 miles in diameter. For this reason, identification of their periodic pulses is often the only way these objects are discovered and observed.

Another source of radio emissions, quasars are pragmatically named, the term originating from the acronym QSRS (quasi-stellar radio source). Some can be radio-quiet, instead emitting X-rays or



This artist's concept depicts the pulsar planet system discovered by Aleksander Wolszczan in 1992. Pulsars are rapidly rotating neutron stars that are the collapsed cores of exploded massive stars. They spin and pulse with radiation, much like a lighthouse beacon.

The Hubble Space Telescope achieved its 100,000th exposure June 22, 2002, with a snapshot of a quasar that is about 9 billion light-years from Earth. The quasar looks as bright as the star, because it produces a tremendous amount of light from a compact source.

Source: NASA Goddard Space Flight Center.

gamma rays. Quasars appear starlike in that they can be observed optically as a point, or star, of light. However, their emissions are redshifted, which refers to their spectra's longer wavelengths. Redshift is a quality often attributed to objects that are accelerating away from the observer, and cosmological redshift refers to the infinite expansion of space-time and matter since the big bang. Because quasars are the most distant objects observed, their optical light appears faint. However, calculations including distance and speed led to figures of great magnitude, and quasars are sometimes posited to emit a trillion times the radiation of the sun. The most popular theory of the source behind this energy is that quasars are spinning disks of dust that surround a massive black hole. Given the great distance and theorized relationship to the big bang, quasar emissions are arriving from the cosmological past. Unlike the timepiece pulsar, the quasar is a preserver of time, displaying a picture of long ago.

Punctuality

Punctuality is defined as the act of arriving at or completing a task, event, or engagement at or before a previously designated time. Perhaps most easily thought of as being "on time" or "on task," punctuality, or the lack of, is in most cases an individual trait or tied to an individual event or task. It is, however, a more widespread problem across some cultures.

By far, punctuality is a much higher priority in countries that are largely industrialized, such as the United States, China, Germany, and the United Kingdom. For countries such as Spain, India, and those in Latin America and the Middle East, however, punctuality is a much lesser priority. When a culture relies heavily on clocks, time dictates the start of events, meetings, and the like. It is in these cultures that watches, clocks, and timepieces are generally kept in unison. In event time, the focus is less on time and more on the event itself, meaning that people living by event time will see an event through before carrying on to the next.

In fact, Latin American governments have recognized the general issues with being on time as a widespread problem that affects their ability to compete globally. Ecuador, in particular, estimates that as much as 10 percent of its GDP is lost to lateness. Ecuadorians live largely based on event time, better known locally as Ecuadorian time. In 2003, Ecuadorians were encouraged to synchronize their watches in an effort to eliminate tardiness. Similarly in Peru, a national campaign called *la hora sin demora,* or "time without delay," was launched to encourage its citizens to be more timely.

International business and travel offer further insight into the punctuality differences across the world. Detailed statistics are kept for all types of commercial travel, including airplanes and trains. Schedules and connections are dependent on their punctuality, and reputations can be damaged by excessive lateness. To that end, Japan, a country that is hypersensitive to the clock and the need to be punctual, has developed such a reliance on the adherence to schedules that its transportation workers fear reprimand for delays. Commuter trains connect with only minutes to spare before their riders must make their next connection. Such a focus on punctuality has been blamed for accidents, such as the one that occurred in 2005 when nearly 100 people were killed because the commuter train's engineer was trying desperately to make up 90 seconds.

Punctuality is to an extent a relatively modern concept. Clocks and standardized time have only been in use for little more than a century. Prior to that, there were wide variations in the keeping of time, thereby making punctuality nearly impossible. Clocks were set relative to the sun's position, making them inaccurate. It was not until a global standardized time plan went into effect that there was a gauge of timeliness.

Time is of the essence in many modernized countries, where sales of time-saving devices and gadgets have skyrocketed over the past 20 years. The pace of the industrial world has quickened, although its preoccupation with speed and attention to the clock do not necessarily mean increased punctuality.

Pythagoras of Samos (c. 569–c. 496 BCE)

Pythagoras was a classical Greek philosopher, mathematician, scientist, and mystic from the Aegean island of Samos. Known as the "father of numbers," he is best known for the Pythagorean theorem, which carries his name. Over the centuries, mathematicians, architects, artists, and musicians have built upon Pythagoras's theories, making those theories the very foundation of the modern understanding of music, astronomy, and mathematics.

Pythagoras was the son of Mnesarchus, a merchant from Tyre. As a child, he traveled widely with his father and gained a broad education from his experiences. He studied with three philosophers in particular—Pherecydes of Syros, Thales, and Anaximander. These men introduced Pythagoras to mathematics, cosmology, astronomy, and geometry. In 535 BCE, Pythagoras moved to Egypt and studied with Egyptian priests at a temple in Diospolis. The rites, rituals, and secrecy he learned in Egypt became part of the religious school he set up later in Italy. The Persians captured Pythagoras when they invaded Egypt in 525 BCE and took him to Babylon. He studied with the magi in Babylon where he learned about Babylonian mysticism, arithmetic, and music.

After his release, Pythagoras returned to Samos, where he set up and ran a school for a few years. Then he moved to southern Italy in 518 BCE, to a village named Croton where he established a secret religious society, emphasizing virtue and strict rules of conduct. The members of this society, known as Pythagoreans, were vegetarians, took vows of silence, and participated in purification rites. They believed in transmigration of the soul, meaning souls are continuously reincarnated as persons, animals, or plants. The Pythagoreans' way of life sought to release the soul from this cycle. Pythagoras lived in Croton until a village noble plotted against him and forced Pythagoras to flee. He went to Metapontum, where he died.

Pythagoras was deeply interested in mathematic principles, especially the abstract philosophy of numbers. He believed that everything, even the order of the universe, could be defined numerically, that is, in terms of harmonic ratios. He applied this theory to mathematics, music, and astronomy. He discovered that music has proportional intervals based on the numbers one through four. Therefore, he held that the universe is based upon the sum of these numbers—10. Pythagoras, or one of his followers, discovered that when the side of a square is squared, the resulting figure equals the area of the square. From here came the concept of the square root.

Although its true origin is uncertain, Pythagoras generally gets credit for developing the so-called Pythagorean theorem, that is, the hypotenuse squared of a right-angled triangle is equal to the sum of the squares of the sides ($a^2 + b^2 = c^2$). Unfortunately, none of his writings has survived to corroborate this association. Egyptian and Babylonian documents show that both of these societies knew about the theorem well before Pythagoras was born; however, some ancient sources believe Pythagoras was the first person to prove the theorem. Pythagoras believed that numbers connected music and math through ratios. Legend tells that Pythagoras discovered a relationship between tonal sound and simple ratios when he passed a blacksmith shop one day and heard the sound of the hammers beating on various size anvils. This principle of tonal harmony and size ratio is called Pythagorean tuning.

Another discovery usually accredited to Pythagoras, or his followers, is the golden ratio. This ratio is a line divided into two parts such that the longer section (a) has the same ratio to the shorter section (b) as the entire length (a + b) has to the longer section (a). In the 20th century, this ratio began to be called *phi,* named after the Greek letter in the name of a Greek sculptor Pheidias who employed the ratio. Numerically, the ratio equals about 1.618034. Since the Renaissance, many artists and architects have used the golden ratio, or its corollary the golden rectangle, in their work, believing that this measure is aesthetically pleasing.

In astronomy, Pythagoras influenced the modern understanding of the movement of heavenly bodies. He held that the planets rotated on an axis and revolved around a central point. He also held that mathematics could explain these movements. Furthermore, he was one of the first people to understand that the moon orbited the earth, that the earth was round, and that Venus was both the evening and morning star.

Pythagoras's work in mathematics, music, and astronomy was revolutionary in his day and forms the basis of much of our understanding of the universe. His discovery of timeless principles truly makes him the "father of numbers."

Q

Quantum Mechanics

Quantum mechanics is a theory in physics that was introduced by Max Planck in 1900 to solve the problem of describing the intensity of radiation emitted by a black body at a given wavelength and constant temperature. Essentially it is a modification of certain views or beliefs of the classical world, especially in relation to the motion of bodies or structureless particles. It changes in a radical way the classical view of how energy is shared in a system of particles, and it also gives properties to systems not found in classical mechanics. Classical notions of time, for example, do not hold for quantum phenomena.

Properties of Quantum Systems

One important property that has been recently discovered in quantum systems is that of entanglement, in which pairs of separate particles behave in a cooperative manner. Another very important property found only in quantum systems is particles with spin. The electron was found to have a spin value of one-half. Other particles were subsequently discovered in nature to have other spin values, and this led eventually to the grouping of the different particles of nature according to their spin value. Particles with half-integer spin values are called *fermions,* with the electron as the prime example. Others with integer spin values are called *bosons,* with the photon (particle of light) as the most well-known example. In classical systems where the laws of Sir Isaac Newton are valid, energy is distributed according to Boltzmann statistics. However, in quantum mechanical systems, energy is distributed using Bose-Einstein or Fermi-Dirac statistics. Integer-spin particles distribute their energy in terms of Bose-Einstein statistics and half-integer-spin particles employ Fermi-Dirac statistics.

In classical mechanics, the position of a particle is measured as time changes. In mathematical terms we say position is a function of time. On the other hand, in quantum mechanics, position and time are treated as independent variables on an equal footing. Position no longer becomes a function of time. In other words, there is a given probability that a particle can be at any position at any time. It is this probability that varies with position in space and time. In classical mechanics we can predict with certainty the position of a particle at any given time. This makes quantum mechanics a statistical theory, unlike Newtonian mechanics.

Black Body Radiation

A black body is defined as one that absorbs all electromagnetic energy (radiant energy) incident on it at all wavelengths. A good approximation to a black body is a closed cavity kept at constant temperature with blackened interior walls and with a small hole that allows electromagnetic radiation to enter and exit the cavity. Measurements of the intensity (total power radiated per unit area per unit wavelength at a given temperature) of radiation emitted by a black body were independent of the physical and chemical properties of the black body but varied with the temperature T. In 1879, J. Stefan found an empirical relation between the total power emitted per unit area of a black body R (total emittance) and temperature T. Subsequently, in 1884, Ludwig Boltzmann derived the same relation from thermodynamics. This relation is known as the Stefan-Boltzmann law and is given as $R = \sigma T^4$ where $\sigma = 5.7 \times 0^{-8}$. $Wm^{-2}K^{-4}$ is a constant known as Stefan's constant. It was also found that the intensity distribution at a given temperature had a well-defined maximum at wavelength denoted λ_{max}. In 1893, Wilhelm Wien showed that λ_{max} varies inversely with temperature as $\lambda_{max}T = 2.898 \times 0^{-3}$ mK, which is called Wien's law.

The first accurate measurements of the emittance (power radiated per unit area per unit wavelength) were made in 1899 by Otto Lummer and Ernst Pringsheim. The emittance is obtained from a calculation of the energy density (energy per unit volume), ρ, of electromagnetic waves in the cavity that is used to model the black body. The energy density is calculated by first assuming that standing electromagnetic waves exist in the cavity. The number of such waves or modes per unit volume per unit wavelength is shown to be $(8\pi/\lambda^4)$, where λ is wavelength. The energy density is then obtained by multiplying this number by the average energy per mode with wavelength λ. Lord Rayleigh and James Jeans treated the energy of a mode as having a value between zero and infinity and with average energy obtained from Boltzmann statistics. They calculated the average as kT, where k is Boltzmann's constant. The energy density is obtained as $(8\pi/\lambda^4)\ kT$. This is the Rayleigh-Jeans result. The emittance can be obtained by multiplying the energy density by $c/4$, where c is the speed of light. In the limit of long wavelengths, the calculated emittance follows the experimental curve for the emittance. It can be concluded that the Rayleigh-Jeans result describes only the radiation characteristics in the long-wavelength limit. It fails to exhibit the observed maximum and diverges as wavelength approaches zero, which corresponds to the short wavelength limit.

A solution to the black body radiation problem required the application of radically new ideas. The classical physics that had been applied by Rayleigh and Jeans and others failed to describe the radiation characteristics of black bodies completely. In December 1900, Max Planck postulated that the energy of a mode cannot take on continuous values between zero and infinity. He proposed that the energy of a mode in the cavity can only take on discrete values equal to $nh\nu$, where n is a positive integer or zero, h is a constant to be determined, and ν is the frequency of the mode. The average energy of a mode at temperature T was then calculated using the discrete form of the Boltzmann distribution. This new average energy was then used to calculate a new energy density. In order to satisfy Wien's law, it was found that the constant $h = 6.55 \times 10^{-34}$ Js, where J denotes joule (the unit of energy) and s stands for second (the unit of time). The constant h is a fundamental constant called Planck's constant. Using these new ideas, in which energy was treated as having discrete values, Planck was able to obtain good agreement with experimental results over all wavelengths.

Planck assumed that the sources of black body radiation were oscillators in the walls of the cavity that could only vibrate with energies $nh\nu$. Albert Einstein extended Planck's ideas and assumed that radiation consists of particles called photons, each traveling with the speed of light c and having energy equal to $h\nu$. Einstein treated black body radiation as a gas of photons in thermal equilibrium with the walls of the cavity at temperature T. A question naturally arises concerning the distribution in time of the photons emitted by a black body. Clearly, since the emission of photons from a black body is a random process, we may want to find out the average number of photons emitted by the black body within a fixed time interval. There must therefore be a well-defined probability that a certain number of photons will be emitted from the black body within some time interval. In order to detect individual photons within short time periods, photodetectors had to be developed, and a full description of such detectors needed quantum mechanics, because they were based on the photoelectric effect that we now present in the next section.

Photoelectric Effect

Many other effects required the application of Planck's ideas. Some of these include the photoelectric effect, the Compton effect, atomic line spectra, and the Stern-Gerlach experiment. Evidence for the quantization of radiation energy came as a result of an explanation of the photoelectric effect. This effect was discovered by

Heinrich Hertz in 1887 as he was in the process of confirming Maxwell's theory of electromagnetic waves. Hertz found that ultraviolet light incident on metallic electrodes caused sparks. It was confirmed that the sparks were due to the ejection of electrons from the metallic surface, and this phenomenon was termed the photoelectric effect.

Philipp Lenard performed experiments to determine the mechanism of the photoelectric effect. Lenard found that there is a minimum frequency of radiation, depending on the type of metallic electrode, below which there is no emission of electrons. Also, the maximum kinetic energy of the emitted electrons varies linearly with the frequency of the ultraviolet radiation. Such observations could not be explained using Maxwell's classical electromagnetic theory. However, in 1905, Albert Einstein proposed an explanation based on Planck's quantum theory. Einstein postulated that radiation is made up of discrete particles, called photons, which carry energy equal to Planck's constant times the frequency of the radiation. It was assumed that localized photons carrying energy are absorbed by atoms in the metallic electrodes. Electrons in the atoms gain sufficient kinetic energy to escape and are ejected as photoelectrons. Einstein's theory was confirmed later by R. A. Millikan in a series of experiments.

The theory of the photoelectric effect was developed in 1963 by Roy Glauber. Essentially, Glauber supposed that a device that measures the arrival of photons at given times was located at some point in space. He then proceeded to calculate the probability of this event over a short time interval denoted Δt. He obtained an expression that was proportional to the intensity of the radiation impinging on the photodetector and the short time interval Δt. Using this result, other researchers like Leonard Mandel were able to derive the probability for an arbitrary number of photodetections to occur within a longer time interval. They found that this number obeyed a Poisson probability distribution. Their result applied to stationary or nonfluctuating light beams.

Compton Effect

The interaction of light with matter was also an intensely studied area of research. Many researchers such as Charles Barkla in 1909 studied the scattering of X-rays, which are high-frequency electromagnetic waves. It was found that X-rays were scattered without a change in wavelength as they passed through matter. Barkla used J. J. Thomson's classical theory to explain his results. His results agreed well with Thomson's theory, but he also obtained results that were anomalous and could not be explained with the model of Thomson. The results showed that the scattered radiation had the same wavelength as the incident radiation (λ_0) as well as a component with wavelength (λ_1) greater than the incident radiation. The Compton shift, $\Delta\lambda$, defined as $\Delta\lambda = \lambda_1 - \lambda_0$, was found to be proportional to $\sin^2\theta$, where θ is the angle between the scattered and incident beams. It was also confirmed that the Compton shift was independent of both the material scatterer and the wavelength of the incident radiation.

Compton's explanation of the shift in wavelength was based on considerations of energy and momentum conservation between interacting particles. The scattering was modeled as an incident photon with momentum $\vec{p}_0$ (the arrow indicates that momentum is a vector quantity) colliding with an electron at rest and then giving rise to a scattered photon with momentum $\vec{p}_1$ and an electron with recoil momentum $\vec{p}_2$. By applying the laws of conservation of energy and momentum, Compton was able to demonstrate that $\Delta\lambda = (2h/m)\sin^2(\theta/2)$, where h is Planck's constant, m is the mass of the electron when at rest (rest mass of the electron) and c is the speed of light or the speed of a photon. This theory explained the origin of the modified component of the scattered radiation. In explaining the unchanged component of the scattered radiation, it was assumed that it originated from interactions with tightly bound electrons such that the recoil momentum of the electron was negligibly small. This would give rise to radiation with approximately the same wavelength as the incident radiation.

Spectral Lines

It was realized very early that atoms emit light when heated as well as when an electrical discharge is passed through a volume of gas. It was also observed that the visible light was not emitted at a continuum of frequencies but exhibited a certain regularity. The spectrum of the emitted light was found to be made up of discrete lines or colors. These observations among others led to the belief that the constituent atoms of matter had some internal structure that gave rise to the regularity in the emission spectrum. A seminal discovery was made in 1885 by Johann Balmer concerning the emission spectrum of the hydrogen atom. Balmer obtained a simple empirical formula that described the lines in the hydrogen spectrum. He found that the wavelength (λ) for each line was given by $\lambda = 364.56[n^2/(n^2-4)]$ nanometers, where $n = 3,4,5, \ldots$ More work by Johannes Rydberg and Walther Ritz resulted in a more general result for calculating all wavelengths of the hydrogen spectrum. This new empirical formula for the inverse of the wavelength is $1/\lambda = R_H (1/n^2 - 1/k^2)$, where R_H is called the Rydberg constant (for hydrogen), $n = 2$ corresponds to the Balmer line spectrum, and k is always greater than n. By 1925, five sets of spectral lines had been discovered. They were the Lyman ($n = 1$, $k > 1$), Balmer ($n = 2$, $k > 2$), Paschen ($n = 3$, $k > 3$), Brackett ($n = 4$, $k > 4$), and Pfund ($n = 5$, $k > 5$) series of spectral lines.

In 1913 Niels Bohr made an astonishing breakthrough in explaining the spectrum of the hydrogen atom. Following Ernest Rutherford, he assumed that electrons in atoms move in simple circular orbits around the heavy stationary nucleus of each atom. He also assumed that only so-called stable orbits are allowed. This was a deviation from classical mechanics, in which an infinity of orbits would have been allowed. Bohr further assumed that an electron in a stable orbit does not radiate electromagnetic energy. Electromagnetic energy can only be given off by the atom if an electron makes a transition between two allowed stationary states. The frequency of the emitted radiation is obtained from the relation $E_1 - E_2 = hv$, where E_1 is the energy of the initial stationary state with higher energy, E_2 is the energy of the final stationary state with lower energy, h is Planck's constant, and v is the frequency of the emitted radiation. Bohr also pointed out that the orbital angular momentum, L, of the electron moving around the nucleus in a circular orbit can only take on the values $L = nh/2\pi$, where $n = 1,2,3, \ldots$. These assumptions were then used by Bohr to derive the energies of the stationary states of atoms. By equating the Coulomb force on the electron to the centripetal force and invoking the quantization of orbital angular momentum, Bohr obtained his famous formula for the allowed energies of an electron as

$$E_n = -\frac{m}{2\hbar^2}\left(\frac{Ze^2}{4\pi\varepsilon_0}\right)^2 \frac{1}{n^2}$$

where m is the mass of the electron, $\hbar = h/2\pi$, ε_0 is a constant called the permittivity of free space, Ze is the charge of the nucleus, and $-e = -1.6\times10^{-19}$ coulombs is the electronic charge. The above formula showed that the energies of a single electron in an atom were discrete and therefore quantized. The quantum number n, which can take values from 1 to infinity, is called the principal quantum number, and the subscript n in E_n shows that there are a set of discrete energy levels E_1, E_2, $E_3 \ldots$ that depend on the value of the principal quantum number. The ground state is the state with lowest energy, that is, $n = 1$, and all other states are called excited states of the atom. Using the Bohr formula, the empirical result of Rydberg and Ritz was confirmed, as was a value for the Rydberg constant. The Bohr model of one-electron atoms gives good predictions for their energy levels. The energy quantization of atoms was confirmed in 1914 by James Franck and Gustav Hertz. It fails, however, in describing atoms with two or more electrons. Also, Bohr's assumption that electrons orbit the nucleus in circular orbits is unfounded. Using his quantum mechanics, Bohr later on tried to relate new results to well-known classical physics results. He proposed what is now called the correspondence principle, which states that the results of quantum mechanics must tend asymptotically to those obtained from classical physics in the limit of large quantum numbers.

Stern-Gerlach Experiment

A very important experiment that required quantum mechanics for its description is the Stern-Gerlach experiment performed in 1922 by Otto Stern and Walther Gerlach. This experiment was designed to measure the magnetism effect of atoms, or atomic magnetic moments. Due to the fact that electrons orbit the nucleus of atoms, they set up current loops within the atoms. This has the effect of giving atoms a physical property called a magnetic moment. The magnetic moment is essentially the product of the current and the area of the loop enclosed by the current loop. When atoms with magnetic moments are placed in magnetic fields, the atoms will experience forces if the magnetic field is nonuniform. This is the basis of the Stern-Gerlach experiment, in which they sought to measure the magnetic moment of atoms by detecting the deflection of atoms as they passed through a nonuniform magnetic field. They found that the force on the atoms was such that the orbital angular momentum of the electron must be quantized in units of Planck's constant. Thus their result again required quantum theory for its explanation.

Dual Nature of Electromagnetic Radiation

Because of the work of Planck, Einstein, and Bohr, it became apparent that electromagnetic radiation possessed both wave and particle properties. Wave properties were used to explain classical interference and diffraction of electromagnetic waves, whereas particle properties were required to explain the photoelectric and Compton effects. In 1923–1924, Louis de Broglie proposed that material particles may possess both wave and particle properties. De Broglie was attempting to extend wave-particle properties applicable to electromagnetic radiation to all particles. Einstein proposed that the energy of a photon is given as $E = h\nu$, where E is energy, h is Planck's constant, and ν is frequency. The photon momentum is given as $p = h/\lambda$, where λ is the photon wavelength. De Broglie proposed that free material (massive) particles would also obey the Einstein energy relation as well as have their wavelength related to momentum by the relation $\lambda = h/p$. This wavelength is known as the de Broglie wavelength. These ideas provided an explanation of the quantization of angular momentum used in the Bohr model of one-electron atoms and were later used to further develop the theory of quantum mechanics.

In 1927, Clinton Davisson and Lester Germer investigated the reflection of electrons from crystals. They confirmed that electrons possessed wavelike properties in agreement with the de Broglie hypothesis. Independently, G. P. Thomson examined the transmission of electrons through a thin foil of polycrystalline material. Thomson obtained a series of concentric rings when transmitted electrons struck a photographic plate. This result was also obtained in a similar experiment using X-rays in the Debye-Scherrer method used to study X-ray diffraction. Thus, electrons can be diffracted like X-rays and thus exhibit wave properties. These experiments and others confirmed the wave nature of particles and validated the de Broglie hypothesis.

Theories of Quantum Mechanics

A new theory was required to explain many of the experimental results that defied classical physics. The new theory was called quantum mechanics and was developed during the years 1925 to 1930. Two versions of this theory were created at about the same time. The first is known as *matrix mechanics* and was developed by Werner Heisenberg, Max Born, and Pascual Jordan in 1925 and 1926. This theory associates a matrix to all physical quantities, and such matrices obey a noncommutative algebra. A second version was developed by Erwin Schrödinger in 1925 in which a wave function played the central role in describing physical quantities. Later on Schrödinger and Paul Dirac were able to show that both versions of quantum mechanics gave the same results and differed only in their mathematical structure.

The Schrödinger formulation of quantum mechanics required a wave function to describe microscopic systems that could not be explained using classical physics or classical wave equations. This version of quantum mechanics had closer ties to classical physics, because the wave function satisfied a wave equation. This wave equation is now known as the Schrödinger wave equation, and it was while Schrödinger was presenting a seminar in Berlin that it was suggested to him that particles must obey such an equation. Schrödinger followed the ideas of de Broglie—that particles exhibited wave properties—and developed a wave equation to describe the wave nature of particles. The solution to this wave equation gave the wave function of the system, and it contained information about the particle's location in space and time. The wave function is usually denoted by the Greek symbol $\Psi(\vec{r},t)$, where $\vec{r}$ is the position of the particle and t is time. The wave function has a probability interpretation in the sense that the product of Ψ with its complex conjugate Ψ^*, that is, $|\Psi|^2 = \Psi\,\Psi^*$, is the probability per unit volume or probability density of finding a particle in some infinitesimally small volume of space at a given instant in time. This probability interpretation of the wave function is credited to the German theoretical physicist Max Born, and it won him the Nobel Prize in 1954.

In this new theory, we no longer calculate the exact position, energy, momentum, and so forth of a particle, but instead we compute average values for these physical quantities. The Schrödinger wave equation in its time-dependent form and for a particle with motion in one dimension along the x-axis is given as

$$i\hbar\frac{\partial\Psi}{\partial t} = -\frac{\hbar^2}{2m}\frac{\partial^2\Psi}{\partial x^2} + V\Psi$$

where $\hbar$ is Planck's constant h divided by 2π ($\hbar = h/2\pi$), $i = \sqrt{-1}$, m is the mass of the particle, and V is the potential energy of the particle. On the left side of the equation, $\partial\psi/\partial t$ is the partial derivative of ψ with respect to time, and $i\,\hbar\partial\psi/\partial t$ gives information about the total energy of the particle. On the right side, $\partial^2\psi/\partial x^2$ is the second-order partial derivative of ψ with respect to the spatial variable x. The term $-(\hbar^2/2m)\ \partial^2\psi/\partial x^2$ gives information about the kinetic energy of the particle. The final term $V\psi$ tells us about the forces acting on the particle. The special case of V= 0 represents a free particle or a particle under the influence of no forces.

It should be noted that the wave function depends on x and t. Also, the potential energy can depend on x as well as t. In the one-dimensional case, $|\Psi|^2$ gives the probability per unit length of finding the particle at a given location on the x-axis, and therefore, the probability that the particle will be found in the small interval that we call dx about the point x on the x-axis is $|\Psi|^2 dx$. This means that it is not possible to specify with certainty the location of the particle along the x-axis, but we can assign a probability for observing it at a given position in accord with Born's statistical interpretation of the wave function. Given the existence of a probability distribution for the position of the particle, the average position of the particle can also be computed. Such an average or expectation value of the position is denoted $\langle x\rangle$ and is defined by the integral

$$\langle x\rangle = \int_{-\infty}^{\infty} x|\Psi(x,t)|^2 dx.$$

Note that $\langle x\rangle$, in general, depends on time, but for certain wave functions describing particles with definite energy (stationary states), it is independent of time. Averages of functions of x, that is, $\langle f(x)\rangle$ can be found in a similar manner as

$$\langle f(x)\rangle = \int_{-\infty}^{\infty} f(x)|\Psi(x,t)|^2 dx.$$

The uncertainty in the position of the particle is denoted Δx and is defined as

$$\Delta x = \sqrt{\langle x^2\rangle - \langle x\rangle^2}.$$

Now consider the average momentum of the particle $\langle p\rangle$. Because there is no well-defined path for the particle, there is no function connecting momentum p with position x. Therefore we cannot treat momentum as a function of position, that is, $p(x)$, and use the formula for finding the average of a function of x to find the average momentum. To obtain the average momentum we use the relation

$$\langle p\rangle = m\frac{d\langle x\rangle}{dt}$$

where m is the particle mass to find $\langle p\rangle$ from $\langle x\rangle$. It can be shown that

$$\langle p\rangle = \int_{-\infty}^{\infty} \Psi^*\left(\frac{\hbar}{i}\right)\frac{\partial\Psi}{\partial x}dx$$

where Ψ^* is the complex conjugate of the wave function. The above expression can be rewritten as

$$\langle p\rangle = \int_{-\infty}^{\infty} \Psi^*\left(\frac{\hbar}{i}\frac{\partial}{\partial x}\right)\Psi dx.$$

The expression for finding the average position can also be rewritten as

$$\langle x\rangle = \int_{-\infty}^{\infty} \Psi^*(x)\Psi dx.$$

It is found that that the average value for other physical quantities (observables) as well takes the general form

$$\langle O\rangle = \int_{-\infty}^{\infty} \Psi^*\left(\hat{O}\right)\Psi dx$$

where $\langle O \rangle$ is the expectation value of the observable and $\hat{O}$ is an operator representation for the observable. In the case of position, the operator is x, and for momentum the operator is $(\hbar/i)\partial/\partial x$. Another important operator is the kinetic energy operator, which is $-(\hbar^2/2m)\ \partial^2/\partial x$. To find the average energy of the particle, $\langle x \rangle$, we sum the average kinetic and potential energies as

$$\langle E \rangle = \int_{-\infty}^{\infty} \Psi^* \left\{ -\frac{\hbar^2}{2m}\frac{\partial^2}{\partial x^2} + V \right\} \Psi dx$$

where the potential is treated as a function of x. The operator representation for energy is therefore

$$-\frac{\hbar^2}{2m}\frac{\partial^2}{\partial x^2} + V.$$

This operator has a special name; it is called the Hamiltonian and denoted H. It should be noted that when H acts on the wave function, it produces the same result as the operator $i\hbar\partial/\partial t$ acting on the wave function. It was Heisenberg who first pointed out that the uncertainty in position Δx is related to the uncertainty in the particle's momentum Δp . The relationship is termed the Heisenberg uncertainty principle and is written as an inequality $\Delta p \Delta x \geq \hbar$. The uncertainty principle imposes limits on the simultaneous values of the momentum and position. Essentially, large uncertainties in position lead to small uncertainties in momentum and vice versa. We should note that the uncertainty principle does not place any restriction on the precision with which position measurements can be made. Once we make position measurements with uncertainty Δx, possible values of the momentum will have a spread of $\Delta p = \hbar/\ \Delta x$ about an average value.

The other formulation of quantum mechanics involves the use of matrices to describe the wave function as well as all observables of a given system. For a given quantum mechanical system, we usually obtain a set of wave functions that describe the system. A particle in the system can be described by one of these functions or by a linear combination of two or more wave functions. The wave functions that describe the system can be labeled by the set $\{\psi_n\}$ where, for simplicity, n is a discrete index. The system can be in one or a combination of these basis wave functions. These basis wave functions are orthonormal and form a complete set. The orthonormality of the wave functions can be expressed mathematically by the following equations:

$$\int_{-\infty}^{\infty} |\psi_n|^2 dx = 1$$

$$\int_{-\infty}^{\infty} \psi_n^* \psi_m dx = 0, n \neq m.$$

Completeness of the wave functions means that the system can always be described by a linear combination of the set of wave functions $\{\psi_n\}$. Therefore, the wave function Ψ is given as

$$\Psi = \sum\nolimits_n c_n \psi_n$$

where the coefficients in the expansion, c_n, uniquely specify the wave function of the system. In terms of matrices, we can specify the wave function as a column matrix with entries $c_1, c_2, \ldots, c_d$, where d is the number of wave functions in the set $\{\psi_n\}$. Operators are represented by square matrices with elements, O_{mn} , given as

$$O_{mn} = \int_{-\infty}^{\infty} \psi_m^* \hat{O} \psi_n dx$$

where $\hat{O}$ is the operator in the Schrödinger formalism.

Another version of quantum mechanics, called *second quantization,* involves the use of new operators called creation and annihilation operators, which are combinations of the momentum and position operators. The Hamiltonian of any system can be rewritten in terms of these new operators as well as the wave function of the system. This version of quantum mechanics is widely used in current research.

The time evolution of a quantum system determines the wave function at later times t, given an initial wave function at an earlier time t_0. This time evolution is determined by the time-dependent Schrödinger equation. Given the initial wave function $\psi(t_0)$, the wave function at time t is $\psi(t)$ and is given by the solution to the Schrödinger equation as

$$\Psi(t) = \exp\left(-\frac{i}{\hbar}H(t-t_0)\right)\Psi(t_0)$$

where H is the Hamiltonian of the system. We remind the reader that there are two ways we can represent wave functions and operators. Operators can be in either differential or matrix form. The wave function can be represented as a normal function of space and time or as a column matrix. These two representations were termed the Schrödinger and Heisenberg representations respectively. If the wave function is time-dependent and the operators time-independent for either representation, we call this the Schrödinger picture of quantum mechanics. If the wave function is time-independent and the operators time-dependent, it is called the Heisenberg picture. These two pictures are related to each other by a time-dependent unitary operator $U(t,t_0)$. The property of unitarity is such that $U(t,t_0)$ $U^{+}(t,t_0) = I$, where $U^{+}(t,t_0)$ is the Hermitian conjugate (adjoint) of the operator $U(t,t_0)$, and I is the unit operator. The Heisenberg wave function at the later time t is equal to the Schrödinger wave function at the earlier time t_0. If $\Psi_S(t)$ is the Schrödinger wave function, then the Heisenberg wave function, Ψ_H, is given as

$$\Psi_H = U^{+}(t,t_0)\Psi_S(t) = \Psi_S(t_0).$$

Hence, the Heisenberg wave function is equal to the Schrödinger wave function at some fixed earlier time t_0. Now if A_S is an operator in the Schrödinger picture, then the corresponding operator in the Heisenberg picture is given as

$$A_H(t) = U^{+}(t,t_0)A_S U(t,t_0).$$

It is important to note that at time t_0, $A_H = A_S$. At this time the Schrödinger and Heisenberg operators coincide. Therefore, both pictures coincide at t_0, and the average value of any operator in both pictures is the same at any given time. The equation that determines the time evolution of the Heisenberg operators is called the Heisenberg equation of motion and is given as

$$\frac{dA_H}{dt} = \frac{1}{i\hbar}[A_H, H],$$

where the square bracket term is the commutator between the operator A_H and the Hamiltonian H. It is defined as $[A_H,]=A_H H-HA_H$.

In summary, quantum mechanics is a theory that has had tremendous success in describing the behavior of microscopic particles. It became a requirement because of the failure of classical physics in describing the microscopic world. It has become a useful tool that allows us to better understand the laws of nature and to create new devices to improve the quality of life.

Qur'an

The Qur'an (also Koran and Quran; from the Arabic, meaning "to read" or "to recite") is the foremost sacred writing in Islam. According to Muslim belief, the Qur'an contains the words of Allah (God) as transmitted to the prophet Muhammad over a short span of time, from 610 to 632 CE (or BH 12 to AH 10, referring to the year of the Hegira, in which Muhammad went to Medina); it is Allah's final revelation to humanity. As such, the Qur'an cannot be changed or altered over time. The Qur'an consists of 114 chapters, called *sura*s (singular, *sura* or *surah*), which are composed of 6,239 verses called *ayat* (singular, *aya*).

The development of the Qur'an is intertwined with the life of Muhammad. He was born and raised in the city of Mecca (in present-day Saudi Arabia). In the early 600s, he began to leave the city periodically and go into the mountainous area surrounding Mecca to pray. In the year 610, while in a cave in Mt Hira, Muhammad heard the voice of an angel say "recite." Muhammad protested. The command happened again, and again Muhammad protested. At the third time the angel said, "Recite in the name of the Lord who created, created man from clots of blood! Recite: Your lord is the most generous, who teaches by the pen; teaches man what he knew not" (96:1–3).

Muslims consider this interaction the beginning of the Qur'an and refer to this incident as the Night of Power (Laylat al-Qadr), which is the holiest night of the year for Muslims. Over the next 22 years, Muhammad reported hearing the voice of the angel Gabriel (or another angel) relaying the word of Allah to him. He remembered these words and taught them to others. Most scholars believe Muhammad was illiterate, so some of the revelations were written down by other followers, and some revelations were memorized. Altogether, these revelations form the Qur'an.

Muslims celebrate the initial revelation each year during the month of Ramadan; this practice is mandated in the Qur'an (2:183–185). During this month, Muslims refrain from eating, drinking, smoking, and sexual relations between sunrise and sunset.

The compilation of the Qur'an began after the death of Muhammad. The first Muslim leader after Muhammad, Caliph Abu Bakr, ordered that the Qur'an be compiled and recorded. The task involved collecting the various portions of the Qur'an that people had written down along with interviewing many who had memorized portions of Qur'an. Under the third Caliph, Uthman, the Qur'an was collected into one book.

The earthly Qur'an itself is believed to be a copy of the heavenly Qur'an. This is spoken of in 43:2–3: "We have revealed the Qur'an in the Arabic tongue that you may grasp its meaning. It is a transcript of our eternal book, sublime, and full of wisdom." Muhammad is understood to have received the Qur'an piece by piece over a 22 year period.

To Muslims, therefore, the Qur'an is the word of Allah. (Some exceptions do occur. Sura 1 consists of a prayer of man, plus Muhammad or angels speak in several places throughout the Qur'an.) As such, the Qur'an should not be translated into another language without guidance; translation yields errors, because not all words in one language have a direct one-to-one correlated word in another language. If the Qur'an is to be translated, a commentary at the bottom of the page should be included along with the original Arabic in a parallel reading on the same page or the facing page. Numerous translations into other languages do exist, although these should not be considered "official" versions.

The shortest sura is three ayat long, whereas the longest sura is 286 ayat long. Each sura has a title, which is derived from a word or idea from within the sura. The suras are not listed chronologically (as given to Muhammad) but roughly from longest to shortest. Nevertheless, the Qur'an begins with a special sura (eight ayat) which is a prayer to Allah. It begins: "Praise be to Allah, lord of the Creation, the compassionate, the merciful, king of judgment-day! You alone we worship, and to you alone we pray for help." The sura following this prayer sura is the longest sura in the Qur'an. The shortest sura (three ayat) is the 104th sura, whereas the last sura has five ayat.

The revelations (suras) were given to Muhammad while in Mecca and Medina. The suras given in Mecca tend to be shorter than the suras given in Medina; over time the messages to Muhammad lengthened. Because the suras are arranged roughly according to length with the longest first, the suras given in Medina tend to come before the suras given in Mecca. Coming as they do at different times in Muhammad's life, the suras cover a wide range of issues. Some suras are praises to Allah, some contain instructions, some relate history, some warnings, and some blessings.

Muslims believe that, over time, Allah sent numerous prophets prior to Muhammad to convey his message. In this the Qur'an is similar to the Jewish Bible, or Christian Old Testament. All three contain the figures Adam, Noah, Moses, and Abraham (along with other prophets). The Qur'an and the Christian Bible, or New Testament, both contain stories of Jesus. Yet the similarity is in name only, because each tradition's scriptures relate different stories of these characters. In addition, in the Qur'an the prophet Muhammad is supreme to all other prophets.

Practically speaking, the Qur'an is used during sermons and read by Muslims. In addition, many Muslims attempt to memorize much, and some all, of the Qur'an. All Muslims memorize at least a small portion of the Qur'an, because it is used during prayers in the mosque.

The U.S. government allows limited use of the Qur'an for official functions where a "holy scripture" is required. In 2007, a Muslim U.S. Congressman was sworn into office using Thomas Jefferson's Qur'an. Also in 2007, a North Carolina Muslim woman successfully sued the court to allow her to use a Qur'an during the swearing-in ceremony for a trial.

R

Rahner, Karl (1904–1984)

Karl Joseph Erich Rahner was one of the most influential Roman Catholic theologians and philosophers of the 20th century; his life's work was to reconcile Thomistic philosophy and theology with modern thought (Immanuel Kant, German Idealism, Martin Heidegger). Influenced by Heidegger, he stressed the importance of time: Death is always present during life, and the essence of death is completion of the human being as being in the world.

Rahner was born in Freiburg in southwest Germany on March 5, 1904. He was the fourth of seven children of Luise and Karl Rahner. In 1922 Rahner entered the Society of Jesus, and he was ordained a priest in 1932. From 1934 to 1936 he was back at Freiburg, where he frequented the lectures and seminars of Heidegger and Honecker and wrote his dissertation, *Spirit in the World.* But neither Honecker nor Heidegger accepted Rahner's interpretation of Thomas Aquinas. For Honecker it was not the true Thomas, and for Heidegger it was too transcendental. Subsequently, Rahner changed departments and successfully wrote a dissertation and postdoctoral thesis in theology. Afterwards he became a member of the faculty of theology at the University of Innsbruck, Austria, a position he held from 1937 to 1938 and again between 1948 and 1964. In 1964 Rahner transferred to the University of Muenster and in 1967 to the University of Munich, spending his last years in Innsbruck. In 1976 Rahner published *Foundations of Christian Faith,* which summed up his theology. He died in Innsbruck in 1984.

Between 1948 and 1964, Rahner developed the main principles of his influential Christian transcendental philosophy and theology. First and foremost, Rahner analyzed the conditions that make it possible for a human being to gain knowledge and to act. His main argument is as follows: Human beings transcend themselves and their world in every act of questioning and thinking. With questioning and thinking, humans encounter the mystery of existence, which Christians believe is grounded in God. Rahner developed the idea that humans are essentially oriented toward this mystery and that authentic searching into the depth of God's mystery is a transformative journey that enables humans to acquire true knowledge and to act as free persons—ultimately accepting death as the completion of their being in time and in the world. Technically speaking, God is the condition that makes every human act possible. That means that God's very existence, which surpasses everything (transcendent), is the condition that makes all human knowledge and acts of freedom possible. Rahner calls God's grace (the Holy Spirit) the "supernatural existential" of every human being; it transforms all human efforts and attracts human beings to God. In contrast to Heidegger, the human being is not *dasein* (being in the world understanding time and being), but *daGott* (being in relation to God, whereby God is the basis of their true essence). Therefore, the ultimate goal is communion with God.

How can the reality of the supernatural existential be discovered? Influenced by Saint Ignatius's Christian spirituality as well as by Heidegger, Rahner developed a philosophy and theology of time. Humans understand their death to be the end of their time on earth. In a way, death is the end of their "world." Thus humans must grasp the importance of time by reflecting on the end, even as they hope that death is not the final end. Christians believe that the resurrection of Jesus Christ reveals that death is not in vain. Transformed by this belief, they see their time on earth as God-given. Internalizing this faith-reality, Christians live "in God's time" by ordering their actions according to God's will—by doing good and avoiding sin.

Rameses II (1304–1213 BCE)

Rameses II (the Great) ruled Egypt at a time when the nation was at the height of its glory. Son of Seti I, Rameses II was the third Egyptian pharaoh of the 19th dynasty of the New Kingdom. He is one of the most famous pharaohs in history, noted for his building achievements, his major battle with the Hittites, and his connection with the biblical exodus. In addition, he was unusual in that, standing 5 feet 8 inches, he was about 5 inches taller than the average Egyptian, and he had red hair.

Rameses II has a unique connection with time in several ways. First, Rameses enjoyed an extraordinarily long life. He had the longest reign of any pharaoh, ruling more than 66 years, from 1279 to 1213 BCE and dying at 92 years old. He was born in 1304 BCE, and Seti I appointed him as coregent when Ramses was 14 years old. He came to the throne as sole ruler in his early 20s. Rameses had at least eight wives, all of whom held the title Great Royal Wife, including the famous Nefetari, two daughters of Hittite kings, and two of his own daughters, and he fathered more than 100 children.

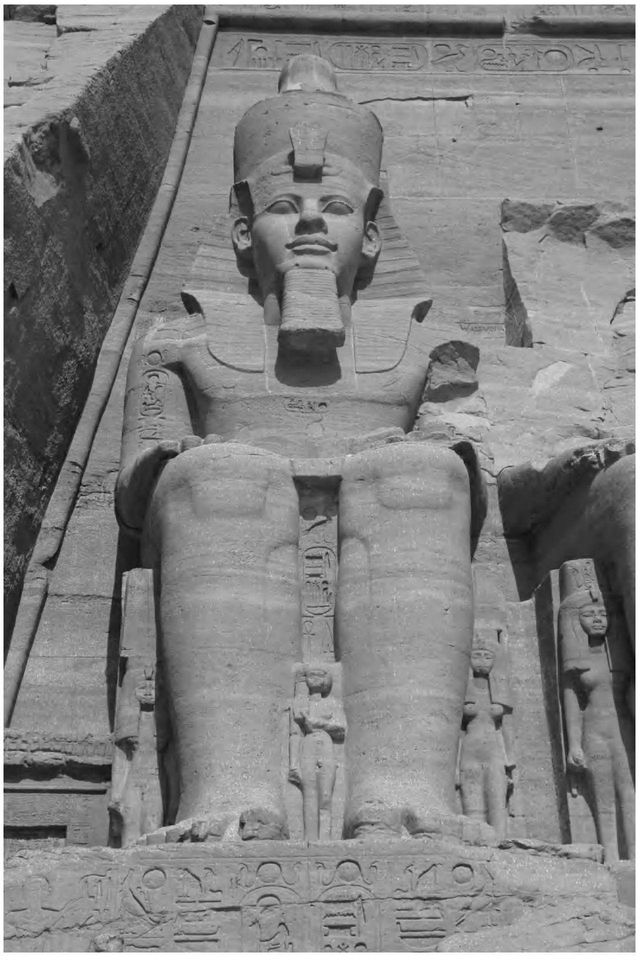
Second, Rameses II is connected with time through the sheer quantity of buildings that remain of his reign some 3100 years later. Rameses tried to make a lasting name for himself through his unparalleled building program. No other pharaoh constructed as many temples, erected as many statues, or built as many royal cities as Rameses II. He built a large mortuary complex near Thebes known as the Ramesseum. This complex, measuring 300 by 195 meters, contained a great temple, several large courts, and a colossal statue of him that stands 17 meters high and weighs over 1,000 tons. In addition to completing his father's temples at Thebes and Abydos, he built or expanded temples in Karnak, Abu Simbel, Abydos, Luxor, and Thebes in Egypt and in at least five cities in Nubia. In these complexes are pictures and written descriptions glorifying Rameses and his deeds. They show a particular interest in his battles, especially accounts of the battle of Kadesh. He also expanded Pi-Rameses, a city in the Nile delta area, and made it his new capital. This extraordinary amount of building reflects a healthy economy and a wealthy nation.

Third, Rameses II tried to make his mark on Egyptian history by being a great warrior. Even before Rameses became pharaoh, Seti I made him the commander of the army and sent him to Nubia, where he put down a revolt and gained valuable experience. His famous battle, the Battle of Kadesh, occurred near the city of Kadesh in Syria. Here, he fought the Hittite empire, a group that posed the greatest threat of the time to Egyptian expansion. Seti I had taken Kadesh temporarily from the Hittites a few years earlier, but the city quickly returned to Hittite control.

In the spring of 1274 BCE, Rameses II marched the largest professional army in ancient history, four divisions of chariots and infantry, into Syria toward Kadesh in hopes of dealing a final, crushing defeat to the Hittites. The Hittites sent out spies that gave Rameses false information, leading him to think that the Hittite army was hundreds of miles away when they really were hidden behind the city. Rameses, personally in command of the Amun division, separated his divisions. Then, he pushed his division forward and ahead of the other divisions. The Hittites sprang their ambush, routed two of Rameses's divisions, and nearly captured Rameses himself. The Egyptians were able to regroup and forced the Hittites to retreat temporarily. Both sides suffered heavy losses. The following day the two kingdoms fought another battle to a stalemate. Rameses had to return home without the decisive victory he wanted and with only a written truce. To cover over the lackluster events of the battle, Rameses had accounts of his great heroics in battle and his dubious victory written on temple walls throughout his kingdom.

After a few more attempts to push the Hittites out of Syria, Rameses II and Hattusili III, a new Hittite king, made a detailed peace treaty in 1258 BCE. Both sides agreed to the treaty due to a new threat—the Assyrians. In the treaty, not only did both sides agree to cease hostilities against each other, but they also agreed to come to the other's aid in the event of external or internal aggression. This is one of the earliest known peace treaties in world history. Archaeologists have found copies of the treaty in Hattusa, the Hittite capital, and in Egypt on the temple walls at Karnak and at the Ramesseum.

Rameses II is perhaps most renowned for being associated with the unnamed pharaoh of the biblical exodus. This tradition has strong support. The book of Exodus points out that the pharaoh had slaves working on massive building projects. Rameses conducted many building projects using slave labor, as did Seti I, his father. Also, early Christian writers, such as Eusebius of Caesarea (275–339 CE), connected Rameses II with the pharaoh of whom Moses demanded the release of the Israelites. Critics, however, point out that internal biblical chronology does not support this connection. They also point out that no Egyptian



The façade of the temple of Abu Simbel, with one of the four figures of Ramses II. Ramses II reigned for 66 years during the 13th century BCE.

Source: Matej Michelizza/iStockphoto.

writings mention an Israelite exodus associated with the time of Rameses II. This argument is dubious, because no Egyptian writings from the time of any pharaoh mention an Israelite mass departure. Although the identity is uncertain, Rameses II is as likely the pharaoh of the exodus as any (if indeed there actually was an exodus).

Rameses II continues to be prominent in Egypt. In 1955, Egyptians placed the 83-ton, red granite, colossal statue of Rameses II in Rameses Square in Cairo. However, they moved the statue in 2006 to the future site of the Grand Egyptian Museum on the Giza Plateau. Here, the image of Rameses will greet visitors near the museum's entrance. Furthermore, Rameses II has been the subject of many popular modern novels and movies, including

Anne Rice's 1989 book *The Mummy or Rameses the Damned* and the 1998 animated movie *The Prince of Egypt.*

Rapa Nui (Easter Island)

Rapa Nui is a small volcanic island in the eastern Pacific that marks the southeasternmost extent of the Polynesian Triangle, the northernmost point being Hawai'i, and the southwesternmost being New Zealand. Within the area described by these three points, Polynesians coming from West Polynesia settled virtually every island: Samoa, Tonga, and Fiji. Rapa Nui is currently part of Chile and is the only Polynesian island with this status. As one of the world's most isolated land masses, Rapa Nui has exerted fascination over the Western world for over a hundred years. This is primarily because of the *moai*—the huge monumental stone heads that are unique to that island. What is remarkable about Rapa Nui, and indeed about all Polynesian islands, is the amount of differentiation (material, cultural, and linguistic) that occurred among islands and archipelagos following colonization around 1,000 years ago—a relatively short time span for such extraordinary developments to take place.

Rapa Nui was first discovered by Europeans in 1722 and named "Easter Island" because it was spotted on Easter Sunday. Archaeology has revealed that Rapa Nui was settled roughly at the same time as virtually every other island in East Polynesia, around the 11th or 12th century CE. The Polynesians who settled the remote little island may have reached it by accident, but scholars are generally agreed that, once it was colonized, no return voyages were made to the "home" island. As they always did, the Polynesian colonists brought with them as many useful plants and animals as they could. However, few of these transplants survived both the long journey and the inhospitable terrain of the island. The only animals that endured were the chicken and rat (pigs and dogs not having been successfully transferred), and the sweet potato was the only crop that grew; the land was unsuitable for coconuts, breadfruit, and taro. The sweet potato is of South American origin (all other Polynesian plants and animals originally derive from Asia), so it is certain that Polynesian seafarers reached the American continent and transported the plant all over the Triangle.

Several centuries following colonization, the islanders began to quarry the soft volcanic tuff and to carve out the *moai,* the largest of which is 10 meters tall. Almost 900 of these statues have been inventoried on the island in various states of completion. The moai were highly standardized through the centuries and originally wore red tuff-carved topknots on the top of their heads and had inlaid coral and stone eyes. They are thought to be the representations of deified ancestors, and, while the moai are unique to Rapa Nui, stone and wood "tiki" statues are found throughout eastern Polynesia, pointing to an ancestral concept. However, nowhere else in Polynesia does anything exist to parallel the size of the moai. They are interesting because the Polynesians, using only stone tools and no machinery, were able to quarry, carve, transport, and erect these massive statues. Theories about how it was done abound, and experimentation has produced interesting results. Nevertheless the controversy continues and forms part of the island's allure. Probably before and certainly after Rapa Nui was discovered in 1722, the islanders began toppling the moai, sometimes in such a way as to break off the head from the shoulders. It is thought that this was done during the intense warfare that characterized life on the island; by the late 1800s no statues were left standing. Those that stand today have been restored in modern times.

The reasons for such intense warfare are no doubt varied, but it is generally agreed that limited land and food resources were major factors. While the island was originally forested, the Polynesians practiced slash-and-burn agriculture, resulting in accelerated erosion, which made the soil less fertile and productive. It is also thought that the islanders overharvested the lumber to transport and erect the moai. For these reasons Rapa Nui is often used as a case study for what happens when humans fail to plan ahead with respect to their environment.

Additional unique developments on Rapa Nui included the unique Birdman cult, in which the winner of an annual contest became the islandwide chief. Young men, specially chosen and trained to represent their districts, would swim out to a small offshore island to collect the season's first eggs of the sooty tern and return with the eggs unharmed. They would have had to brave rough seas, cliffs, and shark-infested waters to do so. Finally, in the 19th century Rapa Nui produced a number of wooden tablets incised with a strange hieroglyphic-type "alphabetical" writing, called *rongorongo*. All attempts at decipherment have been in vain, and most scholars agree that rongorongo was invented after its creators were exposed to European writing and that it may perhaps not be an alphabet, or indeed true writing, at all.

Rapa Nui will endure for centuries as the most mysterious of Polynesian islands, a favorite haunt of archaeologists, amateur scholars, writers, and tourists.

Rawls, John (1921–2002)

The American philosopher John Rawls's major works include *A Theory of Justice* (1971), *Political Liberalism* (1993), and *The Law of Peoples* (1999). Rawls's theory revived normative political philosophy, drew up an alternative conception to the prevalent utilitarian paradigm in ethics, and is the essential starting point for the communitarianism-liberalism debate. By developing an influential theory of just distribution between generations, Rawls points out the importance of the relation between justice and time.

Rawls sets out a theory of justice in order to determine an institutional order that should guarantee an equitable distribution of social primary goods (basic rights, freedom, opportunities, income). Following the classical political philosophers Immanuel Kant and John Locke, he develops a social contract theory that has as its starting point the thought experiment of an *original position*. This is intended to create fair starting conditions for agreeing on basic principles of social justice. The design of the original position is to stand in a *reflective equilibrium* with considered judgments of justice.

A predetermined condition for the process of negotiation in the original position is the information deficit of those involved. They have knowledge of general facts about society, politics, economics, and psychology, but the *veil of ignorance* prevents their knowing what social position or natural talents they have. Their temporal circumstances are also unknown to them, such as the stage of development of their civilization. The otherwise self-interested, that is, rational-acting, agents thus arrive at a reasonable solution to the question of distribution, because they have to abstract from their personal interests. Because no probabilities regarding one's own position within society are available, the decision is based on the risk-avoiding *maximin principle*. According to this, we choose as principles of justice those whose worst possible results are still better than the results of any other set of principles.

The first principle of justice is then that each person is to have an equal right to the most extensive system of equal basic liberties compatible with a similar system of liberty for all. An unequal distribution is allowed only in respect of the subordinated principles of social and economic justice. Inequalities are to be arranged so that they are to the greatest benefit of the least advantaged (*difference principle*), consistent with the just savings principle, and attached to offices and positions open to all under conditions of fair equality of opportunity.

The limitation of the difference principle by the just savings principle points to the connection between justice and time. Those in the original position don't know which generation they belong to. But because they know that they are contemporaries, they would have no reason to save for future generations. Rawls presupposes that the participants represent family lines. They have ties of sentiments to their descendants (original edition), or should conclude principles in the way that they would have wished earlier generations to have done (revised edition). The parties in the original position will then decide on a just savings principle for the preservation of basic freedoms, equitable institutions, and an appropriate accumulation of capital, in order to guarantee provision for the worst-off members of future generations. They ask what they could have expected from their forebears under the respective historical circumstances, and what they are prepared to pass on to their descendants. Because no knowledge of their own temporal position is available from behind the veil of ignorance, the parties must take the standpoint of every time period. They have no pure time preferences, because they have no reason to favor or discriminate against any particular position in time.

Rawls finds it necessary to put a discount on future benefit in order to avoid the consequences of a utilitarian just savings principle, which would sacrifice the present generation for the sake of future generations. It appears impossible, however, to determine the exact savings rate.

Redemption

The word *redemption* is derived from the Latin *redemptio,* which means "buy back." The noun *redemption* and the verb *redeem* are used in English Bibles to translate Hebrew and Greek terms that refer to liberation from bondage by means of a ransom. The term is used metaphorically in the Christian Bible to refer to God's deliverance of people from their slavery to sin and death by means of Christ's death on the cross. It is similar to the biblical concept of salvation in that both bear the connotation of deliverance from an unfortunate state of being. Redemption, however, implies the payment of a ransom to deliver someone or something from bondage, whereas salvation implies rescue from a danger or threat. Although the term originates in the Judeo-Christian tradition, it can be applied more broadly to any religious conception of the transformation from an undesirable state of existence to a better one. In religions with a concept of a personal God, people require the help of a savior to deliver them from their situation. In religions that lack the idea of a personal God, people can undertake certain self-disciplines to redeem themselves. Many religions include the idea that a blessed afterlife awaits those who have been redeemed.

Redemption is related to the past, present, and future. It assumes that people experienced some kind of primordial bliss that was lost at some point in the past through disobedience or error. Later, God acted on behalf of his people to provide release from the consequences of their sin. Deliverance is available in the present and results in experiencing certain blessings in the present. Redemption also opens up the hope of a greater future, either a return to the previous state of perfection or a totally new creation.

Ancient religions promoted concepts that could be characterized as redemption. The Egyptian myth of Osiris, who was slain by his brother Seth but was brought back to life by Isis, offered salvation to those who identified with Osiris. The Romans sacrificed to vegetation gods in order to appease their wrath and ensure a bountiful harvest. Zoroastrianism taught that the redemption of the world would take place when Ohrmazd finally defeated Ahriman. Mithraism offered the hope of eternal life by participation in a bull-slaying ritual. Gnosticism promised initiates who learned the secret knowledge that their souls would return to their pure state after death.

In the Hebrew Bible, the deliverance of Israel from slavery in Egypt became the archetypal image of redemption (Exod 6:6; 15:13). When Israel was exiled in Babylon, the prophets reminded them that God was their redeemer (Isa 41:14; 43:14; 44:24; 49:26; 60:16; 63:16). The past event of the Exodus sustained their hope in the midst of their present circumstances. The verbs *pada* and *ga'al* are used frequently in the Hebrew Bible with the meaning of "release by means of a payment." For example, a person condemned to death for allowing his ox to kill someone could be redeemed by payment of a ransom (Exod 21:30). The term *redeemer* (*go'el*) was used to refer to a close male relative who paid the ransom (*kipper*) to buy back the mortgaged property of distressed relatives (Lev 25:25–34) or to buy them out of slavery (Lev 25:47–52). The term *redeemer* is applied to God elsewhere (Ps 19:14; 78:35; perhaps Job 19:25). People cannot redeem themselves (Ps 49:7); only God can redeem them (Ps 130:7–8).

In the New Testament, *redemption* and *redeem* are used to describe deliverance from sin and death, made possible by Christ's death and resurrection. Two groups of Greek words bear this meaning. One group consists of the verb *lytroō* ("redeem") and the nouns *lytrosis* and *apolytrosis* ("redemption"). The nouns *lytron* and *antilytron* are translated as "ransom." The other group consists of the verbs *agorazō* and *exagorazō*, which suggest the imagery of purchasing slaves in the marketplace. In Mark 10:45, Jesus states that his life would end in self-sacrifice that would serve as a ransom for others. Paul states that Christ has redeemed people from the curse of the law (Gal 3:13; 4:5). Sometimes the ransom is mentioned but not specified (1 Cor 6:20; 7:23), but elsewhere the self-sacrifice of Christ (Titus 2:14; Heb 9:15) and the blood of Christ are specified as the ransom price (Eph 1:7; Heb 9:12; 1 Pet 1:18–19; Rev 5:9). The New Testament writers never clarify whether the ransom was paid to Satan or to God. Redemption is also used to describe the future deliverance of the world, God's people, or the body (Lk 21:28; Rom 8:23; Eph 1:14; 4:30).

Later Christian theologians attempted to explain more precisely how Christ's death provided redemption from sin and death. These are referred to as theories of the atonement, a term coined in English to refer to reconciliation with God ("at-one-ment"). The dominant view for the first thousand years was the *Christus Victor* view, which held that Christ defeated Satan and evil spiritual powers by means of his death. Anselm of Canterbury argued that Christ satisfied God's just punishment for sin. Abelard's "moral influence" theory argued that Christ's love shown in his self-sacrifice motivates others to love God and follow his ways. Calvin and other Protestants went beyond Anselm's "satisfaction" theory to develop a "penal substitution" theory: Christ bore God's wrath as the penalty for sin in place of others. More recently, theologians such as Karl Barth, Rudolf Bultmann, and E. P. Sanders have emphasized redemption through participation in Christ's death and resurrection. Most theologians do not view these theories as mutually exclusive, but they tend to argue that one represents the central or dominant idea of the New Testament authors. These theories of the atonement have in common the belief that Christ's death and resurrection was an epoch-changing event that enables people to experience the blessings of the age to come already in the present.

Although other religions may not use the specific terminology of redemption, some teach the concept of deliverance from an unfavorable state of being to a blessed state. They offer the hope of a better future that will replace the burdens and shortcomings of the past. This change of state can be achieved by one's own efforts or by relying on divine help. In Islam, people can receive the mercy of God on the Day of Judgment by following the guidance of the Qur'an. In Buddhism, one can achieve a state of *nirvana* by following the Eightfold Path. In Mahayana Buddhism, the *bodhisattva* lives in a compassionate and sacrificial way so that his limitless store of merit can be transferred to other unworthy persons in order to liberate them. In Hinduism, one can obtain release (*moksa*) from *samsara*, the cycle of death and rebirth.

Regress, Infinite

Infinite regress arguments are used by philosophers as methods of refutation. A hypothesis is defective if it generates an infinite series when either such a series does not exist or its supposed existence would not serve the explanatory purpose for which it was postulated.

The English philosopher John Locke (1632–1704) criticized the view that an act is free only if we freely choose whether to perform that act. Because freely choosing is itself an act, he argued, this commonly held theory is absurd because that act of choice must then, according to the theory, be preceded by still another act of choice that is free. It generates an infinite series of acts of free choice, one act of choosing determining the acts of another, and so on *ad infinitum*. Because such a series does not in fact occur, he argues, this account of what it is to act freely must be wrong.

Infinite regress arguments are frequently used to demonstrate that an explanatory hypothesis cannot in principle explain what it is supposed to explain. It would be absurd to suppose that the only way we can justify any of our beliefs is by appealing to other beliefs. Such an explanation is fatally flawed, because it generates either an endless chain of beliefs or a circular chain. And because we certainly don't entertain an infinite number of beliefs, the chain must circle back on itself. But a circular explanation doesn't explain anything; hence an alternative account of belief-justification is needed. The foundationalist answer is to say that the foundation of some beliefs is experience itself, not just beliefs about experience.

Some infinite regresses are linear, not circular. Suppose someone thinks the explanation as to why anything at all exists is that God made things exist. Then the God-hypothesis, when thus invoked, simply adds to the burden of explanation. On pain of infinite regress, we cannot explain why anything at all exists by invoking the existence of still another entity (God). For then that entity's existence calls for explanation.

Merely generating an infinite series is not in itself objectionable. The claim "Every natural number has a successor" entails an infinite series of natural numbers. Likewise, the claim "For every event there is a temporally precedent event that is its cause" entails both an infinite series of events and an infinite series of moments of time at which they occur. Yet the existence of an infinite series of natural numbers is mandated by logic and mathematics, and the concept of a beginningless series of events and temporal moments is not self-contradictory. There is no warrant in logic therefore for Thomas Aquinas's claim that these infinite series "cannot" go on forever. This is a misuse of an infinite regress argument.

Throughout the history of philosophy, infinite regress arguments have sometimes been used to demonstrate that ultimately some features of the universe cannot, on pain of infinite regress, be explained at all. The brute fact that some things exist is just one example.

Reincarnation

Reincarnation (also called *transmigration* or *metempsychosis*) is the religious or philosophical view that humans, and possibly also animals and plants, have multiple existences. This view is most prevalent in Asian religions of Indian origin, such as Hinduism, Jainism, Buddhism, and Sikhism. However, it also appears in the religious and philosophical thought of "primitive" religions and in some ancient Middle Eastern and Greek religions like Manichaeism, Gnosticism, Orphism; and the work of some early Christian thinkers, such as Origen, may also be interpreted as referring to reincarnation. The modern current of thought called theosophy also teaches reincarnation. Among recent philosophers, J. M. E. McTaggart (1866–1925), Sarvepalli Radhakrishnan (1888–1975), and John Hick (1922–) are prominent exponents.

In ancient Greece, Orphism held that the soul goes through multiple incarnations (in humans or through other mammals) until it attains release from the cycle of birth and death. At this stage, the soul recovers its original pure state. Pythagoras (c. 569–c. 496 BCE) and Plato (c. 427–c. 347 BCE) accepted similar views.

Reincarnation is generally linked with the moral cosmic law of Karma ("act"). Hindus, Jains, and Buddhists, for instance, hold that actions in one life can affect conditions—particularly the initial conditions—in a future life of the same individual. In Hinduism this process of birth and rebirth goes on indefinitely until one achieves *moksha,* the realization that the individual soul (*atman*) and the absolute soul (*Brahman*) are one.

Jainism puts particular emphasis on the method of nonviolence, *ahimsa,* to achieve this.

Buddhism adds the wrinkle that reincarnation occurs without the existence of an unchanging, substantial soul. Buddhists view the individual as a complex of psychophysical elements and states (*skandhas*) changing from moment to moment. Upon death, the individual who has not extinguished desires or cravings (and not achieved *nirvana*) will continue as a composite of psychic dispositions and energy. This psychic composite will then seek/require a new incarnation.

Among Tibetan Buddhists, spiritual leaders, or *lamas,* are commonly viewed as reincarnations of preceding lamas. Selection of the new lama, from a pool of child candidates, is often based on the right child recognizing unique possessions of the previous lama.

The leading scientific researcher on reincarnation, or at least on the past-lives possibility, is Ian Stevenson, head of the Department of Neurology and Psychiatry at the University of Virginia. His studies involve investigating the truth of detailed claims regarding alleged past lives, usually claims made spontaneously by children. Some of these detailed claims regarding past people, he concludes upon investigation, point decidedly at past lives as the best explanation. A recent dispassionate assessment of Stevenson's studies by the philosopher Robert Almeder affirms that the evidence these studies provide for reincarnation is strong.

One of the most fascinating versions of reincarnation is proposed by the Jane Roberts/Seth books. Seth is a "personality" that dictated the books through the American medium-poet Roberts (1929–1984). In this version, all of time is ultimately simultaneous. Hence, our historical events (past, present, and future) are like many parallel programs taking place along different electromagnetic frequencies (like simultaneous television programs). One can generally focus only on the present program/life, but in principle one's consciousness could switch programs and experience "past" or "future" ones—because these are in fact taking place simultaneously. Occasional glimpses of other "past" or "future" lives would constitute examples of such switches.

The central *moral* rationale for this theory is that it alone provides for cosmic justice. Only in some multiple-lives view could all individuals receive fair treatment over the course of their existence. Only in such a view, for instance, could humans have equal chances at mastering whatever moral or spiritual wisdom is necessary for advancement to higher "heavenly" realms. One-life theories would make this learning too chancy, given that many children die in infancy and that others face impossible circumstances.

Critics have responded that reincarnation does not really help here because of the lack of conscious memory of one's past lives' deeds, mistakes, and lessons. Not remembering one's past makes learning across lives impossible. Defenders of reincarnation reply that improved wisdom and increased moral sensitivity can occur across lives even in the absence of memory of past lives. For instance, one could find oneself in one's current life more attuned to the needs and suffering of others—human and nonhuman—without knowing *how* one has become so compassionate. The *how* could be due to one's past inner and outer accomplishments—even if they are currently forgotten.

A second standard philosophical objection to reincarnation questions the metaphysics of the vehicle carrying multiple personalities across lives, given the fact of bodily discontinuity. What makes the current "I" the same underlying being as the "I" of a person who lived in, say, the 1700s? Is it the same "soul-substance"? But what is that? What would make our two souls two, as opposed to one, other than a memory connection between them? And even if there were a seeming memory connection, how could this be separated from one's having knowledge of another person's inner life acquired in some odd, but non-memory, way? Do *genuine* memory links (across persons in different bodies) not require first establishing numerical sameness of souls? Does this, in turn, not first require genuine memory links? This looks like a vicious circle.

Defenders of reincarnation generally hold that the memory links between lives may indeed be retained but at a subconscious level during those lives, so as to prevent memory overload and to allow for a fresh perspective in each new life. Moreover, such memory links might become conscious (to the underlying soul) during the span "in between" lives, or at the end of the multiple lives series. As for what makes two apparent souls the same single soul, the answer could be some indefinable unique inner feel, much like two sets of fingerprints or of two DNA samples that turn out to point to one person. The individuality of a person, defenders claim, remains rather inexplicable even over a single life.

Relativity, General Theory of

The theory of general relativity (GR) is one of the main milestones of modern cosmology. Derived by Albert Einstein at the beginning of the 20th century, it encompasses the description of the motion of bodies within a gravitational field. Furthermore, its postulated predictions have been tested and supported by many observations and make GR therefore a widely accepted theory. General Relativity describes many phenomena, such as the relativity of time and cosmic evolution, within a gravitational field.

Meaning of Relativity

As in special relativity (SR), the term *relativity* corresponds to two or more observers who make measurements with respect (relative) to each other. This means that there exists no absolute point or frame to which measurements can be referred. To picture this, consider a passenger inside a train that passes by a station. This passenger observes a trolley travel inside the train with a velocity of about 0.3 meters per second. To an observer standing at the station, that trolley appears to have the velocity of the train plus the 0.3 meters per second. The two measurements of the velocity of the same object differ, depending on the position of the observer. This example demonstrates that there is no independent point from which the observations appear to be the same; they can only be regarded relative to each other. In terms of physics, there is no absolute preferred frame (position) in which physical processes are measured and described. Every observer located at an arbitrary position, like the train or the platform, describes the movement correctly. The most important aspect is that, for all freely moving observers, without the presence of any other forces the physical laws are the same independent of their respective relative velocity. Another fundamental fact of SR and GR is the constancy of the speed of light. In each frame, it has the same value.

The Equivalence Principle

In GR, the argument of relativity is extended further in order to include gravity. Einstein's realization was in understanding that the gravitational force is equivalent to an inertial force and in thereby concluding his *principle of equivalence*. (An inert force appears if movements are described in accelerated frames, like standing in an accelerated subway.) Imagine a free-falling elevator in a building. To a person standing within it, it seems that there is no gravity, because the inert force counterbalances the gravitational force. However, to an observer standing outside, it is clear that the elevator is accelerated toward the ground by the gravity field of the earth. Inside the elevator, the person does not feel the gravitational field, and all physical laws within this frame are written without considering gravity.

A further example to demonstrate this equivalence is given by the picture of an astronaut inside a spaceship. Let us consider two special cases, one with the spaceship standing on the surface of the earth and one with the spaceship being constantly accelerated. In the latter case, the astronaut will feel the inert force due to the acceleration, and with that a certain weight, as if a gravitational force is acting. On the surface of the earth, however, gravitational force is exerted on the astronaut inside. But the astronaut is not able to distinguish whether he or she is at rest within a gravitational field, or experiencing an inertial force due to the acceleration. Hence, gravitation can be seen either as the attracting force or the inertial force. This means that gravity can be "switched off" locally by going into a frame in which the inert force cancels the gravitational force. Such a system could be a free-falling elevator or a satellite in orbit.

Note that both examples above imply that the inertial masses must be equal to the gravity masses. This equality is stated by the so-called *weak equivalence principle,* whereas the *strong equivalence principle* comprises the indistinguishability between a free-falling or accelerated system and a system that is at rest within a gravitational field.

Naturally, most physical processes will be described in a local system without gravity. The resulting equations of motion, for the objects under consideration, can be transformed into a system that includes gravitation. In the latter system, the equations will be different from those in the local frame. This is due to the fact that gravity alters the underlying geometry of spacetime. Unlike classic physics, where time is considered as absolute, in SR and GR it is connected to the space coordinates. The gravitational field distorts this geometry and leads to a curving of spacetime. The basic idea is to connect the spacetime curvature with the gravitational attraction of massive bodies. Many consequences arise from this statement.

Gravity and Time

A massive body curves spacetime due to its induced gravitational field, as a ball will curve the surface of a stretched cloth. This distortion has many consequences—for example, the bending of light near massive objects. This feature, observed during the solar eclipse in 1919, was a further experimental proof for GR. The first experimental verification of GR was the explanation of the perihelion precession of Mercury, as predicted and described by GR. An interesting case we would like to address is the influence of gravity on time, which arises naturally in GR.

Let us take the example of the spaceship again, with two astronauts inside. One stands at the bottom, the other at the top. Both carry clocks with them in order to measure the time spans between two light impulses emitted by a laser located at the bottom. If the spaceship is floating freely in space (without being accelerated and not under the influence of a gravitational field) then the measured time span between the two light impulses will be the same, that is, the astronaut at the bottom will measure the same time among two light emissions as will the other at the top, who measures the duration between their arrivals. The same is true if the spaceship moves with a constant velocity. It will take longer for the light to reach the top, but because the spaceship does not change its velocity, the additional distance the light has to cover will be the same for both impulses. Therefore, the measured time span of both observers will be equal.

However, if we transfer this situation to a spaceship that is undergoing acceleration, the time intervals between the two clocks will differ. The astronaut at the top will observe a longer time span between the light arrivals as compared with his partner at the bottom of the spaceship (see Figure 1). To understand this, consider the time that the light needs to reach the top. In the case of the accelerated spaceship, the distance the light has to cover is longer due to the additional distance the accelerating spaceship travels compared to the spaceship with constant velocity. Therefore, the time for the first light impulse to arrive is larger. But due to the acceleration the second impulse will need even more time to arrive at the top, because the distance it has to cover is larger, as it was with respect to the first impulse. Therefore, the time span between the light arrivals will be longer.

This result is not very surprising. However, when we recall that a constant accelerated system cannot be distinguished from one that is at rest within a gravitational field, it leads to the conclusion that the same behavior will be observed in a system under the influence of gravity. Thus the time is running faster at the top of the spaceship (the measured time intervals are longer) with respect to the bottom (the measured time spans are shorter). Hence, gravity affects the passing of time!

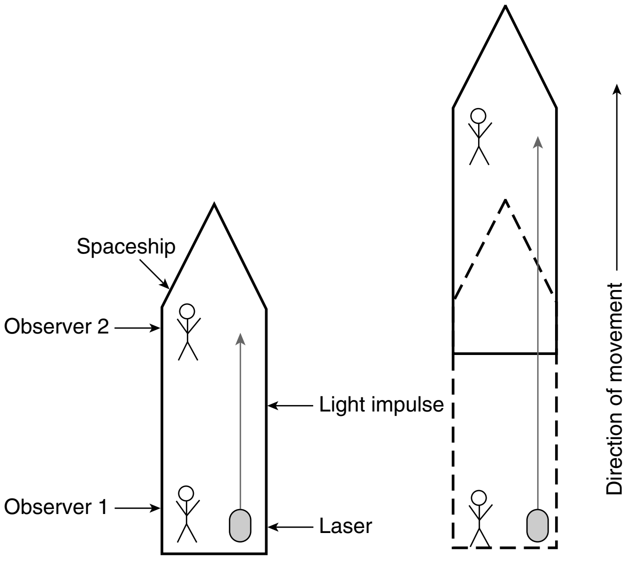

Figure 1 The case of the accelerated spaceship

Notes: Both observers measure the time interval between two light impulses. One is located at the top, the other at the bottom. Due to the acceleration, the velocity of the spaceship changes, and therefore there is a difference between the distances the two impulses cover. For the second light impulse, it will take more time to arrive at the person standing at the top. Therefore, the time intervals the two observers measure will be different. The upper astronaut will obtain a longer time span between the impulses, while the lower one will observe a shorter time span. Thus, time runs more slowly at the bottom compared to the top.

Another very famous experiment to measure the time difference caused by the gravitational field of the earth was been done by R. V. Pound and G. A. Rebka in 1960. They used the so-called Mösbauer effect to verify the time difference between two clocks, one at the top and the other one in the basement of a tower at Harvard University.

There are many more interesting features described by GR. However, one major problem that arises is the inconsistency between GR and quantum mechanics. There have been attempts to unify both theories in order to obtain a theory called quantum gravity. At the moment the most promising one is presented by string theory, but experimental proof of this theory has not yet been accomplished.

Relativity, Special Theory of

The special theory of relativity (STR) is a fundamental theory of space and time that was formulated and published in 1905 by Albert Einstein (1879–1955). The theory gives up the notion of the absolute and independent character of space and time. Length and time measures change according to an observer's state of motion. Special relativity is based on the assumption that the laws of nature have the same form in any uniformly moving frame of reference (the *principle of relativity*). As a most popular result of the STR, Einstein derived the famous relation $E = mc^2$, which states the equivalence of matter and energy. Over the years the STR has been confirmed in many tests and experiments. Along with the quantum theory, it is considered a foundation pillar of modern physics.

The Principle of Relativity and Inertial Systems

Any quantitative law of mechanics, or rather physics, is expressed with respect to some fixed spatial and temporal frame of reference represented by three spatial coordinates plus a time coordinate. This can be realized in a terrestrial laboratory providing the frame for a measurement. An experiment may be performed equally well in a racing car, cutting a corner at high speed. Quite obviously these two systems are not equivalent: Due to the permanent change of direction (i.e., the velocity vector), pseudo forces appear within the racing car. These prevent, for example, a body, thrown straight upwards by the driver, from following a simple straight trajectory as it would in the stationary laboratory of an institute. The trajectory within the racing car reference does not follow the simple Newtonian law of motion. Among all possible frames of reference, physical laws take the simplest forms in so called *inertial systems*. These are systems in which bodies that are exposed to no pseudo forces whatsoever, like centrifugal or Coriolis forces, rest or move uniformly; that is, with constant speed and direction. To a good approximation, the earth's surface can be regarded as an inertial system. Although any point on it is moving in a complex way, the appearing pseudo forces are negligible.

Four centuries ago, the Italian naturalist Galileo Galilei (1564–1642) stated that uniform motion is not an inner property of a body but rather a quantity that is to be defined relative to a framework or an observer. Galileo illustrated this by the example of a body resting on a uniformly drifting boat on a silent lake. The question as to whether the concerning body is moving has to be answered in different ways, depending on whether an observer is sitting in the boat or resting on the bank. Both systems, boat and bank, can be considered as inertial systems in an idealized case. Isaac Newton (1642–1727), though sharing Galileo's view in considering relative motion as relevant exclusively, nevertheless assumed the existence of absolute space. He argued, however, on the basis of spiritual rather than physical criteria and admitted the impossibility of proving the existence of absolute space.

The Principle of Relativity Beyond Mechanics

After centuries of empirical research, classical electrodynamics—the theory of electromagnetic fields' and charged particles' dynamics—was brought to its early perfection in the 1860s by the Scottish physicist James Clerk Maxwell (1831–1879). In an accomplishment similar to Newton's reduction of classical mechanics to just three fundamental laws, Maxwell succeeded in expressing the nature and dynamics of electromagnetic fields with a system of just four equations. Following these Maxwell equations, the propagation of light should always occur with the same universally constant velocity. This was, however, in disagreement with Galileo's principle of relativity: The migration velocity of a light beam should certainly have different values depending on whether a resting or a moving observer is watching it. Furthermore, a constant universal speed of light should have the consequence of an absolute space, defined as the frame within which the light velocity adopts the well-known value of 300,000 kilometers per second.

Michelson-Morley Experiment and the Abandonment of "Ether"

It had long been presumed that, like sound waves, which cannot propagate without substantial material, electromagnetic waves should run within some medium of unknown nature, the so-called ether. This picture is clearly accompanied by the concept of an absolute space, namely the ether rest frame. In 1881, for the first time, the physicist Albert A. Michelson (and repeatedly later together with Edward W. Morley) performed a historical experiment to verify or exclude the existence of ether. For this purpose Michelson constructed a set of mirrors placed on two perpendicular tracks, along which he sent two light beams that would finally superpose on a screen. As is well known in the context of waves, one expected to observe some characteristic pattern of interference. The experimental geometry was set up so that one of the beams ran along the earth's orbit around the sun, and the other ran perpendicular to it. This meant the first beam would have to propagate against the ether drift, like a swimmer against the stream, while the other was not affected this way. According to the ether concept, this should have caused the two light beams to have slightly different velocities. If the whole gadget is turned by 90°, the roles of the beams—as well as their velocities—must exchange. This must inevitably lead to visible modification of the interference pattern on the screen. The experiment, conducted with highest accuracy and precision, did not show any such modification, however; the run time of the beams was evidently not influenced by some ether drift. This important result caused scientists to doubt the existence of ether.

The Lorentz Transformations and Einstein's Principle of Relativity

Nevertheless most scientists at that time were not willing to give up the idea of absolute space and time. The Dutch mathematician and physicist Hendrik A. Lorentz (1853–1928) conceived a mathematical gimmick to reconcile the Michelson-Morley result with the ether concept. He suggested any object moving with respect to the ether would contract by a tiny amount along the direction of motion. For this he postulated some mechanism of electromagnetic nature, acting on an atomic scale, but not yet determined in greater detail. Furthermore he invented a purely mathematically motivated new time coordinate, the *proper time,* as well depending on the reference system's velocity against the ether. With his *Lorentz transformation* rules it was perfectly possible to describe any physical scenario from any inertial system's perspective and still preserve the principle of relativity for electrodynamics. The Maxwell equations are, purportedly, invariant against the Lorentz transformation.

In the first years of the 20th century, Albert Einstein, then a "3rd class expert" in the Swiss patent office, started to address the physical and philosophical problem of space and time. Presumably without knowing about the Michelson-Morley result, he was convinced that absolute concepts of space and time would not be maintainable. He further postulated a universal version of Galileo's (mechanical) principle of relativity. According to Einstein, not only the rules of mechanics but rather any law of nature should keep the same form in any inertial system. This theory again assumes the universal constancy of the speed of light independent of the observer. He published his epoch-making work "*Zur Elektrodynamik bewegter Körper*" ("On Electrodynamics in Moving Bodies") on September 25, 1905. Therein he interpreted in a revolutionary manner Lorentz's mathematical preparatory works in terms of really varying spatial and temporal measures, depending on the observer's state of motion. Distances should reduce with increasing velocity, just as do time intervals. The speed of light acts as a universal limit: Neither matter nor information can propagate faster than light.

A Train, Tracks, and the Relativity of Simultaneity

It is possible to demonstrate the relativistic concept of time in a vivid manner using the term *simultaneity.* As a thought experiment, we consider a train passing over a track with considerably high velocity. Let the train be open along its complete extension, so that the light of a bulb at the middle of the train can reach both the front (F) and the back (B) inside. There in each case a photocell is located, activating a signal when a light beam is detected. Let the train have the length L. We denote the signal event at the front/back end by S_F and S_B respectively. At some time t_0, a passenger switches on the light, located exactly at the halfway point M *(middle)* between the detectors at F and B. The observer inside the train and in motion along with the train is called the train observer. He will observe that the light beams approach both of the train endings F and B with identical speed and that the signals S_F and S_B are activated at the identical time $t_1 = t_0 + ½\ L/c$ (where c is the speed of light). Thus the events S_F and S_B appear *simultaneous* to the train observer. We call the time interval $\Delta t = t_1 - t_0 = ½\ L/c$ the runtime of the light beams in the train inertial system.

Let us now take the perspective of a person resting on the track (the track observer) and repeat the simple experiment. Both observers synchronize their clocks at the time t_0, when the light bulb in the train is switched on. Further we choose the time t_0 so that the bulb at M is just passing the track observer exactly at time $t_1 = t_0 + \Delta t$ (that is, the time when the signals are activated in the train inertial system). After the light bulb is turned on, the light beams in each direction are propagating with identical (light) speed c. During the time interval Δt, the beam approaching the front end covers the distance $c\Delta t$ towards F. During the time change Δt, the train (and so F) is moving on by a distance $v\Delta t$, where v is the speed of the train. Thus the front signal S_F will not yet be activated at $t_1 = t_0 + \Delta t$, because F, moving forward at the speed of the train, tried to "escape" from the light beam moving forward behind it. On the other hand, the back end signal S_B will move a little toward the light beam traveling backward during the same time and will thus be activated a little earlier than t_1. From the track observer's view, this obviously means that the signal event S_B occurs earlier than S_F—while it was simultaneous for the train observer. Nevertheless both inertial systems—train and track—are equitable in the physical sense. The concept of simultaneity is in fact dependent on the observer.

The Light Clock in the Express Train

In a similar way it is possible to demonstrate a consequence of the Lorentz transformations, according to which the clock of a moving observer is running more slowly than a resting clock. For this purpose we construct a light clock in the following way. On both the ceiling and the floor of a train car we fix mirrors that face each other, their reflecting surfaces adjusted horizontally face to face. At time t_0 we send out a very short light signal (say one photon) from the floor mirror to the ceiling mirror; this signal will then be reflected up and down between the mirrors for an arbitrary time. We denote the train velocity by v and the distance between the mirrors by d. The situation is trivial in the train inertial system. The photon starting at t_0 reaches the upper mirror at $t_0 + d/c$, is reflected, arrives at the lower mirror at $t_0 + 2d/c$, gets to the ceiling mirror again at $t_0 + 3d/c$, and so on. We call the time interval between the two reflections Δt.

Next we analyze the light clock from the view of an external observer, resting on the track again, whose clock is synchronized with the clock of the train observer at t_0. Because the mirrors move along with velocity v, the movement of the photon also has a forward velocity component, as it remains between the mirrors. If it continued to move up and down with light speed c, the photon would obtain a total velocity $c' = \sqrt{(c^2+v^2)}$ that is, the vector sum of the horizontal and the upright components of its movement), in clear contradiction to the universal constancy of the speed of light. The upright velocity component must be lower than c by a small amount in order to not exceed a total velocity of c. Necessarily, due to the slowed perpendicular velocity, the time intervals $\Delta t'$ between two reflections increase. As $\Delta t' > \Delta t$, the light clock is "ticking" more slowly in the track observer's frame.

The existence of time as a relative quantity is confirmed today by a multitude of experiments. Well known are the measurements with the help of atomic clocks, covering long distances in airplanes. When they return to the place from which they departed, these clocks show a delay by a tiny fraction of a second compared with the clocks resting at the airport. Another proof for this so-called *time dilation* is the fact that certain elementary particles, *muons*, created in high layers of the atmosphere by cosmic rays, reach the earth's surface at a much higher rate than one might expect according to their tiny average lives. In the relativistic framework, this result is interpreted in terms of a considerably slowed run of the muons' "clocks." Thus the muons obtain significantly longer average lifetimes and can easily reach the ground instead of decaying halfway to the earth's surface.

Analogous to the effect on time intervals, spatial measures are also subject to relativistic effects at high velocities. As recognized by Lorentz prior to Einstein, length scales in a moving frame of reference are contracting from a resting observer's perspective, an effect called the *Lorentz contraction.* Whereas Lorentz considered this as a real electromagnetic effect on an atomic scale and a result of motion against the ether, in Einstein's interpretation it was generated purely by the change of reference frame. The above-mentioned argument, whereby muons reach the earth's ground due to their enlarged lifetimes, is quite obviously useless from the muons' own perspective: In their view, rather, a clock resting on the earth's surface is running more slowly than their own! Nevertheless the muons *do* reach the earth. The reason is that from their perspective, the thickness of the atmosphere—the distance they have to pass down to the earth—is greatly shortened due to the Lorentz contraction. This explains again conclusively the high rate at which muons are detected on the ground.

Effects of relativistic nature lack any relevance for our daily lives. This is simply due to the enormously high speed of light compared with any human experience. Relativistic effects of noticeable degrees only occur in frames of reference moving against each other at at least 10% of the speed of light. Muons from high up in the atmosphere arrive at more than 99% of this speed. Our lives would be considerably different if the speed of light were much lower, perhaps 200 kilometers per hour or so. Then a motorcyclist would confront relativistic effects, and a fast car driver could travel the entire length of US Route 66 and back while aging only a few minutes.

Space, Time, and Spacetime

In the framework of special relativity, space and time lose the absolute character that has been considered self-evident over millennia. The German physicist Hermann Minkowski (1864–1909), who was devoted to a stringent mathematical formulation during his last years, suggested that we should understand space and time henceforward as components of a four-dimensional spacetime. In the common three-dimensional position, space—the distance *d* between two points—is calculated employing the appropriate *x*-, *y*- and *z*-coordinates as

$$d^2 = (x_1-x_2)^2 + (y_1-y_2)^2 + (z_1-z_2)^2 = (\Delta x)^2 + (\Delta y)^2 + (\Delta z)^2.$$

In the four-dimensional *Minkowski space,* the spatiotemporal "distance" between two events (i.e., between points in spacetime) is determined in an analogical manner using the formula

$$\Delta s^2 = (c\Delta t)^2-[(\Delta x)^2 + (\Delta y)^2 + (\Delta z)^2].$$

The light speed c in the first summand of the right-hand side guarantees the time coordinate to obtain the dimension of a length and can thus be directly compared with the spatial components. Δs is of special interest, because it is invariant against Lorentz transformations. This means that the spatiotemporal distance $(\Delta s)_A$ between two events measured by some observer A is the same as $(\Delta s)_B$ observed from a moving system B.

The Equivalence of Matter and Energy

The day following the submission of his work "On Electrodynamics of Moving Bodies," Einstein sent a follow-up paper to the journal *Annalen der Physik* titled "*Ist die Masse eines Körpers ein Maß für dessen Energieinhalt?*" ("Is the Mass of a Body a Measure for its Energy Content?") Therein he discusses the consequences of momentum (i.e., the product of mass and speed of a body) in a theory of relativity. In this context Einstein shows in a simple mathematical derivation that the mechanical energy E of a body and its mass m are always connected via the relation $E = mc^2$. Mass and energy are thus nothing but distinct realizations of the same physical quantity. This plays an important role in physics, for example, in the study of nuclear bonds. A helium nucleus, for example, has a mass lower than the sum of its constituents' masses (two protons plus two neutrons). The mass difference corresponds to the amount of energy needed to dismantle the nucleus to its parts. Equally, the Einstein formula explains the destructive power of nuclear weapons, which are based on the release of the very same binding energy.

Religions and Time

Religious beliefs and cultural traditions set the tenor for the way humans conceive the individual self, the world, and the relationship between the two. Integral to these beliefs are the various conceptualizations of time, a necessary element in any attempt to explain human existence. Although each religious culture's understanding tends to have unique aspects, nevertheless most follow one of two basic ways in which time has been and continues to be conceived. These are time as a line and time as a circle. Linear time is apparent in daily life. Birth is followed by growth, aging, decay, and death. Time always seems to move ever forward in a straight line. Yet the cycles of life, as seen in stars, seasons, animal migrations, and so forth, are also readily apparent. Nature exists in cycles. Both images thereby play important roles in the way humans conceive time, and in the vast majority of traditions, there is a blending of the two, with one tending to be dominant. While linear time commands the greatest attention in the Abrahamic religious traditions, in the Westernized urban world, and in science, cyclical time has been integral to most indigenous and most Asian religious and cultural traditions. This entry examines the roots and basis for these conceptualizations of time in various religious traditions and how they effect the beliefs and practices of the people who adhere to them.

Indigenous Traditions

Indigenous peoples have typically lived in a world in which the physical and spiritual realms are closely connected. Their cosmogonic myths, or origin stories, explain their beliefs regarding Creation and validate their own origins as well as their connection to each other, to their homeland, to the creator spirit or spirits, and to the spirits of their ancestors. These and other myths validate traditional practices, social mores, and even political order, and provide members a sense of belonging to a community and a place, a sense of order and consistency, and a set of religious beliefs and behavioral guidelines. This is why land, ethnicity, culture, and religious beliefs all intertwine with indigenous peoples. Time and space are a part of most Creation stories as well, and each has its sacred characteristics. Often associated with origin stories are eschatological beliefs regarding end times, and together they form an integral part of most religious traditions and indigenous cultures. Such stories and beliefs in nearly all traditions derive from the basic longing in humans to have some sense of their origins, identities, and destinies. In speculating on both beginnings and finalities, there also tends to be an understanding of time that mixes linear and cyclical elements. These are not confined to indigenous traditions and can be found in nearly every religious belief system, in one form or another.

The homelands of indigenous peoples are typically marked by sacred space and infused with the presence of spirits. The intimate relationship between individual and land is vital to self-identity. To the extent that this relationship is physical and material, it exists within time, has a beginning and an end, and is temporal. To the extent that it exists as connection with the world of spirits and ancestors, it exists outside physical time, and is secure, more permanent, and sacred. It enhances both stability and a sense of timeless belonging. Traditions help maintain this relationship, for through them each subsequent generation forms an unbroken connection back to the original ancestors and their primordial beginnings.

Rituals also play an important role in this connection. During ritual, the linear motion of time is suspended, and a communion with the eternal is made. Some rites, known as rituals of return, may take participants back to the time when scared events occurred or may bring the past into the present with Creation happening again and sacred events being replayed. They afford the opportunity for individual and community to experience the original state of purity and a reaffirmation of oneness with the eternal and ever-present world of the unseen spirit. Such rituals display a belief either in the ability to reverse time or that sacred time is eternal and can be experienced at any moment. Scholars have speculated that the Mesopotamian peoples chanted their Creation myth, the *Enuma Elish,* every new year for this purpose, for even the recitation of sacred stories is believed to return individuals to sacred moments and sacred time. This cyclical understanding of time is reflected in several ancient calendars in cultures as diverse as those of the Aztecs, the Babylonians, the Chinese, and the Norse.

This close-knit relationship between the spiritual, natural, and human realms and between past and present helps confirm individuals as members of their communities and provides them a sense of belonging to the world in which they live. Rituals and myths work together to reaffirm this connection, and also to take one beyond the limits of linear time and give one access to the realm of eternity where the sacred becomes manifest. Adherence to tradition maintains the relationship and keeps members of the community inoculated from the dangers and evils that exist outside. However, it may also close adherents to those who exist outside their communities and belief systems.

Abrahamic Traditions

In the ancient Middle East, there were a variety of religious cults and cultures that followed the indigenous modeling of time, seeing it cyclically, and that also believed in a close connection between the world of humans and that of the spirits and ancestors. In early Greece, several time concepts were prevalent. Both Pythagorus and Plato saw time as cyclical and repetitive. Hesiod viewed it as cyclical, repetitive, and also episodic, believing that the present universe will come to an end after humans pass through five different stages, only to begin again. Pherecydes of Syros, a 6th century BCE Greek philosopher and cosmologist, developed his own views of the beginning of the universe and was the first in the Western world to elaborate a concept of transmigration of an eternal soul. He presented Chronos (time) as one of the three eternal divinities in his writings, which clearly suggest a cyclical view of time.

With the development of Judaism, the first of the major Abrahamic religious traditions, the concept of time as predominantly linear began to gain acceptance in the Middle East. This view originates for Jews in the biblical Book of Genesis. Yahweh, most likely a clan deity who eventually came to be seen as the one almighty, created the universe and everything in it in 6 days. Although humans are created during this time, they are shown to stand apart from the rest of Creation, not a part of it. Once Creation is complete, it is the duty of humans to oversee it and keep it functioning within the framework of Yahweh's commandments, while he oversees Creation's linear progression. He is very much a part of the historical process, is affected by human actions and events that occur in his Creation, and occasionally becomes involved in influencing outcomes. On one hand, he is shown to be loving and compassionate, but on the other, he also gets angry and revengeful. He has favorites, whom he blesses, and others whom he condemns.

As a consequence of the belief in the Divine's intimate involvement in the world and in time, all three Abrahamic religions conceive of a sacred history, especially when revelations and/or special events have happened in the development of their respective traditions. Their growth and their contemporary manifestations are tied to their understanding of sacred time and history, and its chronological unfolding factors heavily into their belief systems as well as their respective understanding of self, community, and relationship to their conception of the Divine. It is no coincidence that the counting and measuring of time became an important point of focus for the scientific thinkers and theologians within these religions. In the 6th century CE, the Christian calendar was formulated to begin with what 6th century Christian scholar Dionysius Exiguus thought to be the year of the birth of Jesus (1 AD). The Muslim calendar begins with the year of the departure of Muhammad from Mecca to Medina and the official beginning of Islam (1 AH). The implication is that whatever happened before is, at best, of little relevance in comparison to what has happened since. Significant and sacred time begins with religions' respective beginnings.

Judaism

The Abrahamic approach to time and the Divine begins with Judaism, which was the first of the major religious traditions to formally adopt the linear concept of time. One of the purported reasons the ancient Hebrews rejected the prevalent concept of cyclical time was to separate themselves and their tradition from the polytheistic beliefs of the day. Unlike the pagan gods of other religions, Yahweh was believed to manifest himself to his people in historical time, giving it a sacred dimension. As Judaism crystallized into an established religious tradition in the region, its beliefs came to have a great influence over subsequent generations of both Jews and non-Jews.

Early biblical interpreters believed that time has always existed, while medieval Jewish philosophers held that time began along with universe at the moment of Creation. Not only did Judaism present its own approach to time, it also asserted a special relationship between its followers and Yahweh. This relationship is expressed in the concept of Jews as chosen people, a belief that has long been fundamental to Jewish self-identity as an ethnic and religious community. Yahweh has singled them out for a special purpose, and thus all subsequent events in the history of the Jews are key to the history of the world and of humanity. The concept of linear time is fundamental to explaining the evolution of this relationship and of the pivotal events that occur in history. Jewish prophecies have suggested that all the sufferings their community has experienced in the last two millennia have had a greater purpose, for the Jews are God's chosen, and God will use them to eventually establish his wisdom and righteousness on earth.

The Hebrew peoples of the first millennium BCE lived in independent theocracies in the lands of Israel and Judah and were free to practice their beliefs. However, once those lands were taken over by surrounding empires, they began to hold forth hope for a messiah, a Jewish king and spiritual leader, to return control of their homeland and reestablish the supremacy of their beliefs there. The messiah was to be God's vehicle for ending their oppression, hunger, illness, and death, and to bring about happiness for Jews and the rebuilding of their temple in Jerusalem. Their sacred stories assured them that when the messiah makes his presence manifest, barren land will be made fruitful, all weapons will be destroyed, and peace will prevail for the entire world. His appearance will validate biblical prophecies, prophecies that are embedded in linear time. This expectation continued for more than 2,000 years for most Jews, and for many it continues up to the present day. It has been a unifying concept and a hope that has been instrumental in the Jewish community's survival.

Christianity

Amidst the social and political turmoil of the Middle East 2 millennia ago, Jesus was born in the Jewish community that was under Roman rule in the land of Judah. The influence of his Jewish upbringing on his thinking is obvious. The New Testament's presentation of his views shows a similarity in many ways to those of the Hillelite Pharisaic school of Judaism, and the understanding of time is clearly linear. Like the Jews, he saw God as functioning within historical time, although his description of God's personality traits suggests more compassion and less strictness in judgment. Nevertheless, the view of a historical, revengeful, and preferential God who condemns is there as well. Many of the early followers of Jesus believed him to be the Jewish messiah, and thus expected his imminent return after his crucifixion, as per his own apparent prophecies and teachings. This belief came to be a bedrock of Christianity, and like the Jews, Christians await their messiah's return as a fulfillment of historical prophecy. Because Jews did not recognize Jesus as the messiah predicted in their scriptures, Christianity taught that Jews lost their status as chosen people, relinquishing it instead to Christians as the true inheritors of the biblical label and of the special relationship with God in history and in prophecy.

Although they separated from Judaism, Christians nevertheless continued to adhere to many elements of Jewish thinking, including the view of time as linear, the belief that humans are uniquely separate from and above the rest of Creation, and the view that God functions within time and with human characteristics, including such traits as revenge, hatred, and condemnation. They also adopted the concept of a divine plan for the world, one in which good will ultimately overcome evil. Such a view is predicated upon the belief in a linear time and the fundamental role that God has given the chosen people in fulfilling that plan. Among the theological and doctrinal additions of Christianity was the eschatological belief in an eternal heaven and an eternal hell, the former reserved for faithful Christians, the latter for everyone else. Integral to this belief and process is the expectation of the return of Jesus as messiah, although Christians differ among themselves as to when and how. During the last 2 millennia, heightened anticipation of the return of Jesus has happened at a rate of more than once every generation, and these have been especially prevalent at the end of each millennium. Toward the end of the 1990s, for example, there were dozens of such expectations. Most were quite benign and resulted only in disappointment for their followers. A few, such as the Heaven's Gate cult, led to deadly consequences. Begun in the 1970s in Oregon, the followers of this cult believed that Jesus would return along with a comet just before the end of the millennium. In order for their souls to unite with him, 38 members committed suicide in conjunction with the appearance of the Hale-Bopp Comet in 1997.

Currently, there are two primary Christian eschatological interpretations of time. The first is known as *premillennialism,* and it has been the more prevalent view in the vast majority of the more recent messianic expectations in the last century or so. Its adherents tend to draw heavily on an interpretation of the Hebrew Bible (Daniel 9:24–27) and the New Testament (Revelations 20:1–7) in believing that Christ, as the messiah, will return to the earth to defeat the Antichrist, reign here for 1,000 years before the final judgment of humanity, and then return to heaven with the saved. As they have countless times in the past, many premillennialists see the signs that foretell the imminent reappearance of Jesus occurring today, and various publications interpret these signs and events as proof of his impending return. Among these is the Left Behind series, a set of novels by Tim LaHaye and Jerry Jenkins, that supports a premillennialist view and has attracted countless Christian followers who hope to witness the glory of Jesus and the kingdom of God on earth in their lifetimes.

There are several *postmillennialist* beliefs as well, and each finds justification for its eschatological views in alternate interpretations of the same section of the Book of Revelation mentioned above. Generally speaking, postmillennialists believe that the return of Jesus will happen after 1,000 years (some understand this number symbolically) of gradual increase in the power of Christ and Christianity to bring about the kingdom of God in the world. The powers of Satan will be overcome, and he will be defeated for eternity. Jesus will then participate in final judgment, and there will be an end to history.

Islam

Muhammad was born in the late 6th century CE in the city of Mecca, and in 622 he began the religion of Islam, which is based primarily on his teachings as written in the Qur'an and the Hadith. The latter is a collection of stories about and teachings of Muhammad that were not included in the Qur'an. Both texts reveal the influence of Christianity and Judaism in his thinking as well as his reactions to them and their teachings. Like the Jews, he considered Abraham as his ancestor and Jerusalem as a holy city. Initially, he had his followers face in the direction of Jerusalem when they prayed, but later, due to a subsequent conflict with Jews, he had Muslims face toward Mecca for their prayers instead. Muhammad accepted essential aspects of the Genesis Creation story, strict monotheism, the ability of humans to receive divine revelation, the existence of angels and demons, many Jewish dietary rules, and the linear understanding of time. Like Jews, he rejected image worship and polytheism. With regard to Christianity, there are many stories about Jesus in the Qur'an, including his birth to a virgin, his teachings, and his miracles. Muhammad considered him a special prophet of God, and Mary, the mother of Jesus, is given great praise in the Qur'an, where she is mentioned more than in the New Testament. Islam accepts the concepts of a paradise and a place of damnation. Both are seen to exist in time, for eternity.

Prior to Islam, the tribes who lived in and around the Arabian peninsula followed time through observations of the solar and lunar cycles. However, they did not have a formalized concept of the year, nor did they count years as such. The past was marked by significant events. Like the Jews, Arabs considered sunset as the beginning of a day. Muhammad initiated a strict adherence to the 12-month lunar year, and ever since the time of his second successor, Umar, it has been followed by the religious orthodox in Islam. Some scholars believe Muhammad did this because the periodic interdiction of a 13th month to bring lunar and solar calendars together was important to the various "pagan" cults and festivals in and around Mecca at the time, and he wanted to end all practices associated with them. Over the centuries, there have been various attempts to adjust the Islamic calendar to align with the solar year or with the agricultural seasons, but none have been able to find a great following among Muslims.

In Islam, all reality, including time, is based on and under the complete control of Allah. Because Allah exists beyond time, he is timeless, while humans are caught in the cycle of time. History and human existence unfold relative to Allah's will, thus both are important in Islam. The Qur'an emphasizes the omnipotence of Allah and suggests a form of predestiny, or at least precognition. In the Hadith, there is reference to a heavenly book, in which everything that happens is written. This notion of predestiny became a fundamental doctrine in several Muslim schools. Allah is said to preordain what will occur in the world, while humans simply act it out. He decides what will take place in every moment with every being, from the time they are in the womb until they breathe their last breath. At the same time, however, Islam holds humans personally responsible for their actions.

Understanding and tracking time became an important function in Islam, because Allah is believed to be very much involved in time and history and is in the continual process of creation. Medieval mosques often had on their staffs an individual (*muwaqqtt*) whose job it was to measure time. Early Muslim philosophers believed the world to be temporal, while later thinkers describe an eternal physical Creation. Both views remain dependent on linear time as the vehicle through which Allah oversees and controls existence.

Like Christians, many Muslims believe that in order for the Divine Will to prevail in the world, everyone must convert to their way of believing. Time will then take on a new and spiritual dimension. This has been the justification for both traditions to proselytize throughout the world and to seek to subdue alternative religious belief systems, all of which are said to be obstacles to the fulfillment of the divine plan. Similar to Jewish and Christian messianic expectations, Twelver Shiites, members of the dominant sect of Islam in Iran, also believe in a messiahlike figure who will usher in this new reality. His name is al-Mahdi. He was the 12th *imam,* or spiritual leader, in the lineage begun by Ali, the son-in-law and younger cousin of Muhammad. Al-Mahdi is said to have disappeared at the age of 5, after leading the funeral prayers of his father, the 11th *imam.* Twelver Muslims believe that the reappearance of al-Mahdi will bring about peace and justice in the entire world. Adopting the evangelizing approach of the Christian church, Islam began its own method of spreading its version of time, reality, and the Divine, and converting the people in all the lands its armies conquered.

All three Abrahamic religious traditions believe in the importance of ordering the world toward the fulfillment of their respective eschatological expectations. This is especially so in Christianity and Islam. In the case of fundamentalists from both traditions, this desire can lead to dire consequences for those who are judged as nonbelievers. The medieval Inquisition is a good Christian example, while the more radical Muslim fanatics of the last several decades represent a contemporary example of a similar ideological mindset. Tied in with the eschatological beliefs of the Abrahamic traditions is the view that the faithful individual has a responsibility to work toward making the world a better place. "Better," however, typically means converting others to one's own belief system, be it religious, political, social, or something else. Moreover, the molding of others' beliefs and practices is, for many, necessary to help bring about or create the environment in which eschatological expectations can be fulfilled. Time, therefore, is a fundamental element in the cosmological and eschatological beliefs of both Christianity and Islam, and each generally believes that true followers will spend eternity with God or Allah in heaven, while all others will spend an eternity in a hell. Because both eternal salvation and eternal damnation would no longer have the same relevance if time were to cease, eternity is understood within the framework of a linear reality.

Dharma Traditions

Although they have much in common with indigenous traditions around the world, the dharma traditions, those that have their origins in the Indian subcontinent, tend to have a richer and more diverse conceptualization of time than is found in other belief systems. This is due in part to the long history of philosophical development in India. The typical understanding of time posits a broad and overarching cyclical movement, within which there exists a linear aspect. Whereas time is seen to move in an apparently linear fashion, in reality it moves in a circular one. It is similar to traveling down a straight road. While one appears to be heading in a linear direction, if one were to move along the road in the same direction long enough, one would return to the spot from which the journey began. In the same way, life moves in an apparently linear direction, but ultimately returns to its origin. As previously mentioned, a similar way of thinking can be found in ancient Greece.

One of the bigger differences between the dharma traditions and the Abrahamic traditions deals with eschatological beliefs. While Christianity and Islam seek acceptance of and compliance with a particular belief system and set of doctrines, such an approach is, for the most part, nonexistent in Asian religions, especially in the dharma traditions. In the latter, there is no concept of a deity who demands such compliance and who condemns to eternal hell all those who do not adhere. Instead, it is generally believed that everyone, eventually, will gain a release from the bondage of the birth/death cycle. This freedom is referred to by many names, such as *kaivalya, nirvana, moksha,* enlightenment, and liberation. Because it is a personal accomplishment, it is independent of what anyone else does. Therefore, there is no incentive to try to convince or coerce others into following one's own beliefs, practices, or way of life as a requirement to gain that freedom. There is no need for missionaries to convert others. There is no eschatological view that is dependent upon world adherence to a particular path.

Origin stories are common in most Asian traditions as well, although events from the mythological past tend to have more symbolic than historic significance, because a linear chronology of world occurrences is far less significant than in the Abrahamic traditions. The dharma traditions—Hinduism, Jainism, Buddhism, and Sikhism—all believe in karma and in rebirth, in one form or another. Good actions lead to positive results, and bad actions lead to negative results. Although the concept presupposes cause and effect, goal orientation, and existence within a linear time frame, it conforms to the overall cycle concept of the traditions. Unlike the Christian and Muslim beliefs that certain actions, or lack thereof, result in damnation that will last an eternity, most Asian traditions reject any eternal state for the individual soul, other than liberation. In this regard, one of the unique aspects of the dharma traditions is the view that any reality confined within cyclical time is a form of imprisonment, from which one must ultimately free oneself. Thus, much of the philosophy and teachings within these traditions is geared to methods of escape from this endless cycle.

Hinduism

There are a variety of Hindu concepts of time, including various cosmogonies and eschatologies, but all fit into the overall concept of a cyclical reality. The earliest views date back to at least the Vedic period, more than 3 millennia ago. One of the oldest of the philosophical schools to propose a concept of time is Samkhya, in which there is an eternal and timeless duality, Purusha (male) and Prakriti (female). The former is seen as unchanging consciousness that underlies all existence, while the latter is the material reality that is ever-changing. Other views describe an episodic characteristic, with existence moving through four *yuga*s, or cosmic ages, after which the universe and all Creation come to an end, including time. The resulting state is known as *pralaya,* of which there are several types and degrees of dissolution. Generally speaking, during this state, all form, all qualified existence, all differentiation, and all things that have a beginning will end; all that remains is Brahman, the unqualified eternal absolute. Although time ends as well, nevertheless, the state is said to last for several billion years. Here, everything that ever was and will be is in a state of potentiality. Then, Brahman again begins the Creation process, by first dividing itself into Brahma (the Creator), Vishnu (the Preserver), and Shiva (the Destroyer). The *yuga*s begin anew, the cycle is in motion, and everything starts over again. According to some schools of Hindu philosophy, this will go on for eternity. The Puranas, a series of ancient texts, each have their own cosmology, but all tend to draw from the pattern above. Because of this, the goal of individual life is to get beyond attachment to the temporal, to all that comes to an end and to identify oneself instead with the deathless and endless absolute Divine.

Jainism

The Jain tradition acknowledges neither beginning nor end to the cosmos. Physical and nonphysical reality has always been and will always be. It continues in long cycles, during which there is a gradual fall of moral and physical existence followed by their reassertion. This process is believed to continue for eternity. All beings are bound within these cycles except those who are able to escape and become liberated. This can result only from the extinction of the interaction of the eternal soul with all that is nonsoul. The latter consists of time, matter, space, and inertia and is also eternal but constantly in flux. Karma is produced with every interaction and weighs down the soul and imprisons it. Once all karmic residue is annihilated, the soul becomes eternally liberated in the state of *kaivalya.* This freedom is the ultimate goal of life in Jainism, so methods for accomplishing this are essential aspects of Jain teachings. Those who are believed to have attained this state are the most revered beings within the tradition and are considered divine.

Buddhism

Gautama Buddha lived in the middle of the 1st millennium BCE in India, and the tradition that follows him represents an important source of non-Brahmanical thinking in India in those early days. However, the Buddha wrote nothing, and in the 1,000 or so years that followed his death, a great number of texts were written that all claim to contain his teachings. As a consequence, there is a diversity of views regarding origins, destinies, and time within the tradition. Some texts have elaborate cosmologies; others either do not address the issue or present a fairly simplified version. Some schools within the tradition see these stories as metaphorical; others as real. However, all Buddhist schools traditionally see time as cyclical and liberation from the birth/death cycle as the ultimate goal.

As an example, the *Agganna Sutta,* a Theravada Buddhist text, tells of existence going through cycles of expansion and contraction, creation and dissolution. Desire, ego, and other such traits are what lead to creation and what bind an individual to countless rebirths. When one follows the teachings of the Buddha, such as the Eightfold Path, then one is able to step outside the cycle of birth and death and attain *nirvana,* or liberation. Pure Land Buddhism, one of the largest of the Mahayana schools, believes in a heavenly realm known as the Pure Land, where those who remember Amitabha Buddha with faith will be reborn, rather than returning to the birth/death cycle on earth. Once there, they will remain to work out all their karma and will eventually gain the wisdom that will lead them to liberation. The Tibetan Buddhists have elaborated their view of cyclical time, which is expressed in the concept of *bhavachakra,* the "wheel of time." In paintings, the wheel is held by Yama, the lord of death. It depicts the eternal cycle of life through which all beings pass until they reach liberation.

Sikhism

The Sikh tradition draws its cosmogonic views from the Guru Granth Sahib, the primary scripture of Sikhism, and one can see the influence of various Hindu concepts therein. There is the belief in a singular transcendent Divinity who is infinite and exists beyond time and place. At the same time, the Divine pervades all Creation and is omnipresent. Existence goes through countless cycles of creation and dissolution. When there is no creation, the Divine exists as the One. Because of Divine Will and through Divine Sound, creation occurs, and all existence becomes manifest. Eventually, all that is created will end, and only the one truth, the one Divine will remain. The goal of human life is to end lust, greed, anger, pride, and attachment to the material world, and to find spiritual union with the One.

Other Asian Traditions

Buddhism, and to some extent Hinduism, has had such a predominant effect on thinking throughout Asia that it is sometimes difficult to separate its influence from those of the indigenous traditions in many Asian religious cultures. However, the pre-Buddhist traditions of Confucianism and Taoism in China have definite non-Buddhist approaches to time.

Confucian time follows both a 12-month lunar cycle and a 12-year cycle, with each year associated with an archetypal animal. The number 12 is also important in the I Ching, one of the Five Classics in the Confucian religious tradition, and is connected with the zodiac and 12-year cycle. It is believed by many Chinese that learning to live in accordance with the changing energy and influences that occur throughout the 12 years will bring harmony and success to one's life.

Lao Tzu, the founder of Taoism, had a very different approach. He wrote that the Tao preceded all existence. First there was the Tao, and from it came the One, then the two and the three, then the myriad of things—all Creation. As to what the Tao is, Lao Tzu says that no one can say; nevertheless, the goal is to be in harmony with it and to find balance of yin and yang, the dualistic aspects of material existence and nature. Taoists believe that aligning one's life and being in accordance with the Tao will raise one's consciousness of reality and experience of the Tao. There are no eschatological views in either Confucianism or Taoism as such.

The Shinto tradition in Japan reveals a blend of linear and cyclical thinking. There is a clear cosmogonic belief, as expressed in the Kojiki, the most important text in the tradition. However, there is no eschatological belief. Creation happened, it will continue, and it does so in cycles. A ritual that occurs at the most sacred shrine at Ise reveals the Shinto view of time, tradition, and change. The temple there is rebuilt every 20 years using the exact design that was used to build the original shrine in the 3rd century CE. The sacred items within the old shrine are then moved to the new one. Thus, every generation has a new shrine, but each one is an exact duplicate of the original. The newness of each generation is thereby acknowledged, but it is encouraged to be a continuation of the traditions of its elders. In this way linear and cyclical time are blended together.

Conclusion

The concept of time is understood in vastly different ways in the various religious traditions and cultures of the world. Most of these views originate in cosmogonic myths that are meant to provide their followers a sense of self and place in their social communities, in their homelands, and in their world. Along with inspiring feelings of pride of self, origin stories occasionally lead to xenophobic attitudes and may also be used to justify aggression against outsiders, but this has not been historically common. Eschatological beliefs, on the other hand, have the greatest potential for causing conflict between groups, especially when such beliefs include within them the need for followers to evangelize outside their own community of believers. Yet, with the exception of Buddhism and some elements of other traditions, non-Abrahamic religions that follow cyclical time have not traditionally manifested a need to convert others to their way of thinking and being. Moreover, many such traditions have considered outsiders as inherently unqualified to be a part of their religious and cultural communities, due to ethnic or geographic restrictions that are embedded in their belief systems.

For those who follow the linear view of time, such as the adherents of the Abrahamic traditions, science, and the Westernized urban view of the world, the situation has been quite different. These belief systems place humans outside, above, and in control of the cyclical realm of nature. They also tend to promote a similar attitude toward adherents of a cyclical worldview, such as indigenous peoples and the followers of most

Asian religious traditions. Followers of linear time have typically characterized cyclical cosmogonies as contrived and unrealistic, as the products of childish fantasy, and even as pagan heresy. They have also depicted the followers of cyclical time in a similarly negative way. Such views have usually been carried by Christian and Muslim missionaries in their in proselytizing activities around the world. Working tirelessly in their evangelizing efforts, they have often sought to diminish and even obliterate other cultures and belief systems and replace them with their own worldviews, sectarian beliefs, lifestyles, and conceptualizations of God and time. Thus, adherents of a linear view of time are gradually but inevitably replacing the cyclical view of time with their own, and many of the more extreme individuals and groups that are active in this process do so with the belief and even the hope that their efforts will lead to a fulfillment of their own eschatologies, and to an imminent end of the world as we know it.

Renan, Joseph Ernest (1823–1892)

In the 19th century, the French philosopher Joseph Ernest Renan studied and considered the theory of evolution, recognizing its obvious challenge to biblical beliefs and theistic theologies. He accepted this new framework of time and valued the advances in science (especially chemistry) over the dogmas of religion. His dynamic worldview became future-oriented, expressing a deep concern for the survival and fulfillment of our species in the distant ages to come.

Renan had been educated in ecclesiastical colleges and seminaries, but he began to doubt Roman Catholic scholasticism. Instead, his interests shifted from theology to philosophy (particularly the thoughts of G. W. F. Hegel), mathematics, and philology. Becoming very skeptical of religious beliefs and being most liberal in his own thoughts, Renan left the faith in order to embrace a scientific understanding of and rational appreciation for the splendor of this universe. He is best remembered for his controversial book *Life of Jesus* (1863), which enraged the religionists of his time because of its strictly human portrayal of the Nazarene. His voluminous writings also included such daunting topics as the history of Israel and the origins of Christianity. However, Renan's amazing speculations on the future of humankind within cosmic immensity are found in his volume, *Philosophical Dialogues and Fragments* (1871).

Even though Renan foresaw the persecution of scientists by a religious society, he nevertheless anticipated the triumphs of science and reason in the future. He maintained that the remote past demonstrates the ever-increasing consciousness of our species. And, for him, the ongoing progress of the human mind held the key to comprehending the directional evolution of this universe. Therefore, with critical optimism, Renan envisioned a gradual ascent of humankind within the evolutionary development of the natural world. Consequently, he held that an immense advancement of consciousness would result in the emergence of a group of superior individuals who far exceed the human beings of today. His imagination saw these forthcoming divine beings to be as far above our present species as the human beings of today represent an advancement over those lower animals that are found in the deep fossil record.

Within his organismic interpretation of the evolving universe, Renan suggested that sidereal reality would eventually become a cosmic zygote. Furthermore, over immeasurable time, from this cosmic zygote would emerge a single being that will delight in its sensations and perceptions (just as a finite human being on earth enjoys its feelings and emotions). As the totality of reality, this ultimate being of trillions of finite beings will have evolved into an organic unity out of the awesome multiplicity of a living universe (just as an organism on our planet emerges as a complex unity out of those trillions of atoms that make up its genetic information). As such, all existence will be participating in this cosmic unity of infinite diversity.

Thus, the visionary and free-thinker Renan saw the meaning and purpose of humankind fulfilled in the far distant future, when all of the matter of space, which is now the composition of endless distinct galaxies, becomes this single universal being. This thinking and enjoying final entity is the emergent God as that cosmic consciousness within which everything will be preserved and experienced throughout all eternity.

REVELATION, BOOK OF

The title of the last book in the canonical Christian scriptures, the Book of Revelation or Apocalypse of St. John, lends its name to an entire scriptural as well as popular literary genre of end-time scenarios called "apocalyptic." One of its opening words, *revelation,* translates from the Greek, ἀποκάλυψις. Here, the sense of the word *revelation* includes an uncovering of things previously unknown or possibly unknowable and has nothing to do with the end of time as such. Yet it is through the Christian Book of Revelation that apocalyptic literature became defined as those narratives that include catastrophic end-time scenarios.

Although it is by no means the first end-time religious narrative, Revelation became the standard for defining apocalyptic literature. This genre includes the many canonical and noncanonical apocalypses of Judaism and Christianity, apocalypses of other religious traditions, and even secular narratives that continue to be produced.

The Book of Revelation brandishes a dense if not impenetrable poetic imagery. It addresses the specific historical needs of a particular group of people in a particular place and time and at the same time provides sufficient allegory, and opacity, to invite wide interpretation from believers in whatever place and time it has been read.

As obscure as the imagery may be, the structure and content are fairly straightforward. The book begins with salutary, epistolary, and testimonial opening remarks typical of early Christian writing, including establishing the authority of the writer who self-identifies as "John," a "servant" of Jesus Christ and "brother" to his readers. Sometimes referred to as "John the Revelator," the writer follows his opening remarks with angelic messages to seven Christian churches. In Jewish and Christian numerology, the number seven represents completion. That the writer addresses seven Christian churches would have been sufficiently understood by early Christians to have meant that the complete Christian church was being addressed.

After the messages to the churches, the narrative launches into a vision of how the end-time will progress. The vision begins with God and "the lamb" on two heavenly thrones. Seven seals of seven scrolls are opened, and seven trumpets are blown, heralding the penultimate struggle between good and evil. Imagery includes evil epitomized in the dragon, the whore, the evil city, the monster from the sea, and the beast from the land. All these are set against the good represented by God, heavenly angels, the lamb, and God's people who number the numerologically significant 144,000 (12 × 12 × 1,000).

After more angelic messages, the "son of man" arrives in the clouds and is told by angels to reap the sheaves and to press the grapes with God's wrath. When he follows their command, blood flows from the presses. Then come praises from the conquering holy ones in heaven while those unbelievers left behind are visited by seven plagues from seven bowls. After the plagues follows the judgment of the great whore (the antivirgin), the beast (the Antichrist), and Babylon (the anti-Jerusalem). Babylon falls as heaven rejoices and God's enemies are defeated. A dragon is chained for 1,000 years during the worldly reign of righteous, believing monarchs. After this millennial reign, there is the final war and its defeat of evil. At the conclusion of this final battle, Satan and the beast are bound and tormented forever. All the dead are resurrected and judged, with the righteous being given the new heaven and new earth, while the unrighteous are either made new (21:5), die a final death in the lake of fire (21:8), or are simply left outside of the new Jerusalem (22:15). The book closes with blessings and curses and Jesus's assurance that he and all this is "coming soon."

The book is heavily indebted to its prototype, the Hebrew scripture's Book of Daniel, for its inspiration, structure, and content. From the very first verse, Revelation invokes a mystical world of divine mandate, messianic revelation, angelic message, and ecstatic vision, all capped with blessings and curses.

Mystical numbers figure prominently and add to the book's allegorical nature. In addition to the familiar numerology of 7s and 12s, the infamous number 666 (or 616 or 665, depending on the scribe) in Chapter 13 identifies the "monster from the land" in the dramatic struggle between divine and evil forces. Scholarly consensus holds that the number reflects a Greco-Roman name-code device from the early Christian era, with most agreeing that in this case the code refers to Caesar Nero. Last, if perhaps somewhat less famously, the millennial number of 1,000 years (or possibly 2,000 years, depending on how liberal the interpretation) also figures prominently in the narrative. This fact resulted in high apocalyptic expectations among some Christian groups around the turn of the 1st and then the 2nd millennia CE.

In addition to mystical visions and numerology, other elements in Revelation that are common to apocalyptic narratives of the time include the cosmic struggle between divine good and supernatural evil reflected in cataclysmic earthly wars and plagues; tropes of court drama with thrones, sealed communiqués, witnesses, prosecution, judgment, and punishment; general resurrection with special status for resurrected martyrs; and the appearance of a transformed earth and a heavenly city.

Whether the author was intentionally obscure or time has obscured the book's meaning, the cultural context of Revelation and even its authorship offer their own levels of obfuscation. The text provides often conflicting clues as to its historical origin, indicating possible assembly, revision, or redaction over time. From the elusive identity of its author (or authors), to doubts about its Christian provenance, to struggles for its reception as part of the Western Christian canon that continued well into the 5th century CE, to early and ongoing internal Christian debates as to whether it is properly understood as literal, allegorical, historical, or prophetic, the Book of Revelation holds a rich and varied, if somewhat checkered, history and an unquestioned influence on the theological, political, and artistic imagination when anticipating the end of time.

Ricoeur, Paul (1913–2005)

The French philosopher Paul Ricoeur, who taught at the Sorbonne and the universities of Nanterre and Strasbourg as well as at the University of Chicago, attained an international reputation for his work, particularly in the fields of phenomenology and hermeneutics. He is widely regarded as among the foremost philosophers of the 20th century.

The main part of Paul Ricoeur's reflections on time is presented in his three-volume work *Temps et récit,* published in French between 1983 and 1985 (in English translation, *Time and Narrative,* 1984–1988). Everyone is familiar with Saint Augustine's famous remark: "What, then, is time? I know well enough what it is, provided that nobody asks me; but if I am asked what it is and try to explain, I am baffled" (*Confessions,* XI, 14). Ricoeur took Augustine's statement very seriously, maintaining the irremediably aporetic character of philosophical reflection on time: There is an aporeticity of temporality, which means that when philosophers think about time, they run up against aporias—that is, insurmountable difficulties that cannot be resolved through standard philosophical frameworks. In fact, *Time and Narrative* presents three theses at once. The first is expressed negatively: There is no philosophical answer to the nature of time. Even contemporary phenomenology, begun by Husserl, failed in its attempts to resolve the aporias raised by the problem of time. Moreover, Ricoeur himself gives no general definition of time in his work.

Ricoeur's second thesis—this time expressed positively—claims that it is narrative, the act of retelling, that provides an answer to the aporias of the problem of time, an answer that is poetic and not speculative. This explains the title *Time and Narrative*. Narrative is the guardian of time. It is defined with the help of two concepts borrowed from Aristotle's *Poetics*. These are *mimesis,* that is, the representation of action, and *muthos,* the "emplotment," the synthesis of aims, causes, and chance brought together under temporal unity in a complete action. To tell a story is to unify through a single narrative thread successive events that are, at the outset, distinct or even disparate. Narrative is therefore the "guardian of time" in the sense that it transforms anonymous time into human time. Narrative gives a consistency, a cohesiveness to our experience of time.

The third thesis is that this role of narrative is as valuable for historical narrative as for fictional narrative (literature). There is a crisscrossing between history and fiction that is not reducible to a mere fusion of genres. Far from being two completely separate genres, history and literature share a common center, which is the activity of telling stories with reference to temporality. History is a true narrative of the past. Fiction is an imaginative narrative that can take time as its object. (Here, Ricoeur analyzes three examples: Thomas Mann's *The Magic Mountain,* Virginia Woolf's *Mrs. Dalloway,* and Proust's *Remembrance of Things Past*). The time of narration is "narrated time." In one respect, it is about time having become the object of the narrative, being actively involved in a story (fiction), practically becoming a character in the novel. In another respect, narrated time is the time of events reinscribed in a chronology (history).

Time, Natural and Phenomenological

The main aporia of time concerns the opposition between subjective time and objective time, between the time of consciousness and the time of nature, between psychological time and cosmological time. This is the most obscure aporia of time. On the one hand, time seems to be an element of nature independent of our existence. On the other hand, time seems to be a process that is inseparable from consciousness. There is no succession without memory, and no memory without consciousness. Ricoeur illustrates this aporia using Saint Augustine's theory, which he opposes to that of Aristotle. Augustine analyzes psychological time in Book XI of the *Confessions.* The past is no longer, the future is not yet, and the present unceasingly slips away. Time as a whole tends toward nonbeing. What gives existence to time, in fact, are the operations of the mind. Therefore, one must say that there are, in fact, three times: the "present of the past," the "present of the present," and the "present of the future." These three times are present in our mind, corresponding respectively to memory, intuition (*contuitus*), and expectation. Time here is reduced to the consciousness of time. It is an "extension of the mind" (*distentio animi*).

As a counterpoint to Augustine's position, which is taken up by Husserl, there exists another approach to the problem of time: Rather than seeking it in the mysteries of our consciousness, we observe time in nature, at the very heart of the world. On this point, Ricoeur refers to Aristotle's *Physics* (IV, 10–14), which studies the time of nature. For Aristotle, time is not only in the soul; it is in all things: in the earth, the sea, and the heavens. Time is connected to movement, for all movement occurs in time, but it is not the same as movement, of which it is the number and the measure. Being in time means being measured or measurable by time. In this perspective, time is defined as "the number of movement according to the before and after." Time is a measure of movement. But, in order to measure movement, time itself must be measured by a movement, which provides it with an objective unit of measurement. That is why, Aristotle explains, we measure not only movement by time but also time by movement. In order to obtain the most universal measure of time possible, we must not use just any movement, but choose the circular movement of the heavenly bodies (the sun and moon), the movement with which we are the most familiar and that is the most regular. In this way, we determine, with the help of movement of the planets, units of measurement that are more and more precise (year, month, day, hour, etc.) by which we can measure all other movements, calculate their speeds, and compare them to one another.

For Ricoeur, the two approaches to the problem of time, through nature and through consciousness, are incompatible. One cannot reconcile the theories of Aristotle and Augustine. The cosmological approach of Aristotle can only lead to cosmological time and never fully grasp psychological time, which is not reducible to measured time. But the approach to the problem of time by consciousness is incapable of taking into account the fact that time cannot be reduced to a structure of human subjectivity, as has been suggested by philosophers such as Augustine, Kant, and Husserl. If such were the case, the history of the universe and of the earth before the appearance of human beings—which lasted several billion years—would simply be inconceivable. For Ricoeur, it is as impossible to generate natural time from phenomenological time as it is to proceed in the other direction, and it is impossible to include phenomenological time in natural time.

After having shown the aporetic character of philosophical reflection on time, Ricoeur concludes that philosophy cannot escape the maze of the aporetic nature of temporality. His position consists, then, in recognizing the powerlessness of philosophy to resolve the problem of time, whose solution must be found outside of its specific field. In Ricoeur's estimation, it is narrative (historical or fictional) that acts as Ariadne's thread, allowing us to leave the maze of the aporetic nature of temporality. In its historiographic and literary forms, narrative is the "guardian of time"; it unifies our temporal experience and allows us to work out a "third time," which connects lived time with cosmic time. It is through narrativity that cosmic time becomes human time. To narrate an event is to reinscribe a fragment of lived time into the universal calendar of the world's time. Ricoeur's idea is that narrative weaves a link between our lived times, which are all different, and the world's universal and common time. Narrative presupposes a particular form of time; it unfolds in the context of "calendar time," which is dated time, a universal framework that allows us to make the events of the world coincide with human events. This dated time involves a zero point, chosen by convention (e.g., the birth of Christ), a line that can be traveled in both directions, and regular intervals (hours, days, years, centuries), calculated as a function of the movement of the planets. In fact, narrative involves three elements: dated time, duration (measured time), and place.

Narrative

Narrative, then, is a third time, a bridge connecting lived time and world time. This thesis of Ricoeur seems to work better with historical narrative than fictional narrative. Literary narrative is, in fact, fictitious; it is free from the problem of including lived time in cosmic time. Fiction, then, seems to be a work closed in on itself, cut off from the world, and not a bridge between us and the world. Ricoeur's answer to this objection is the following: Literary narrative is never a pure fiction cut off from the world, a totally self-contained text. Fictional narrative is a description of the world or of certain experiences in the world. In this sense, there exists a "world of the text." The world of the text is, on the one hand, a fictitious world, but on the other hand, a virtual world, a possible world that offers a totally new experience of the world.

Certain narratives describe in this way a specific experience of time, which Ricoeur calls "fables about time." In this type of narrative, time is narrated in the sense that it is the object itself of the narration. Authors of fiction, unlike historians who are bound to tell the truth, have tremendous freedom. They can make imaginative variations on time; move from one flow of consciousness to another as in *Mrs. Dalloway;* escape the measured time of the calendar like Hans Castorp, hero of *The Magic Mountain;* or travel in the past, like the narrator of *Remembrance of Things Past.* Regarding this last work, analyzed in detail by Ricoeur, the experience of time and of lost time, which means wasted time and past time, has forever sunk into the past. This novel describes, at the same time, the experience of time rediscovered thanks to involuntary memory, through which a present sensation awakens an identical past sensation, which emerges with everything around it; and thanks also to art, which aims at rediscovering lost time, restoring these extratemporal experiences through style and metaphor. The time rediscovered is the time saved by the work of art. For Ricoeur, the world of the text contained in the narrative is therefore a new experience of temporality, that is, an invitation to reconfigure one's own temporality. The reading of a text is that through which the work returns to the world.

Ricoeur notes that historical narrative is not fundamentally different from fictional narrative. They are made of the same fabric, because both are about narratives, emplotments, and syntheses of temporal experience. They all have the same objective: In both cases, narrative refers to a temporal experience. History and fiction are intertwined. History contains fiction. On this point, Ricoeur gives the example of the analysis of the trace. There is a paradox of the trace, of the vestige. It is an object that is both present and past. It is there, present before us, and yet it belongs to the past; it is no longer there. Ricoeur mentions Heidegger's solution, which consists in saying that the object is not what is past but the world where the object was created and to which it belongs. In order to interpret a trace, to understand it, the historian has to imagine its context in the past, its former world, and, in this operation, the imagination plays an essential role. Inversely, the narrative contains the historical. Fiction is virtually history to the extent that it often makes reference to history; for example, in *Remembrance of Things Past,* Proust refers to the Paris of 1914–1918, even if this reference is not bound by the truth.

There are, of course, differences between historical narrative and fictional narrative. Historical narrative aims at the truth. It seeks to represent the past as it really happened. That is why it strives to inscribe lived time into cosmic time by means of calendar time. Ricoeur calls this relationship between historical narrative and the past *représentance. Représentance* is not imitation, but the fact of representing, of referring to the past.

In *Time and Narrative,* there are not two but three forms of narrative. Narrative is the guardian of time. This is true for fictional narrative, historical narrative, and the narrative one might call everyday or ordinary. There is a narrative of ordinary life. Individuals talk about their lives, they reconfigure their stories, and they constantly synthesize their temporal experiences. In talking about his life experience, the individual works out his "narrative identity." Narrative identity is retrospective; it is woven from accomplished actions to which it is, by nature, posterior. Narrative supposes action. At the beginning of his work, Ricoeur emphasizes that the operation of emplotment by which he defines the narrative always refers to actions. He distinguishes "*mimèsis* II"—strictly speaking, the act of recounting—from "*mimèsis* I," the prenarrative experience of action. Before talking about one's life, one must live it. But to live one's life, one must recount it. Narrative identity is the history of a life; it is formed by narratives that individuals make regarding their own lives through a dynamic process of unending rectification. It is both fictional and historical, for even the fictions that individuals recount about themselves are part of their identities. This concept of narrative identity, which functions as well for the individual as for the community, is the solution to the paradox of individual identity, which is defined neither by identity-substance given once and for all (Leibniz) nor by always fluctuating identity-fiction (Hume). Narrative identity is an evolving identity; it never ceases to construct and deconstruct itself. To complete the notion of narrative identity, all that remains is to introduce the decisive role of memory, neglected in *Time and Narrative*. This gap will be filled in the last major work of Ricoeur, *Memory, History, Forgetting*.

Ricoeur begins this book by developing a phenomenology of individual and collective memory that inquires into the notion of the "duty of memory." He then offers an epistemology of the historical sciences that brings out three distinct stages in the work of the historian: the documentary phase (testimonies, archives), the explanation and understanding phase (research into causes, be they social, cultural, political, or other) and the representative phase (establishing the literary form of the narrative, periodization). Far from being closed in on itself, the historical narrative is a representation of the past; it refers to a past that no longer is but was. In the third part, Ricoeur develops a hermeneutic of the historical condition that analyzes in particular the complementary notions of historicity and forgetting. The work concludes with a reflection on "difficult forgiveness," which is situated halfway between memory and forgetting.

Rip Van Winkle, Tale of

The tale of Rip Van Winkle, written by Washington Irving (1783–1859), is a time-honored classic in both its theme and historical context. Through this piece of American folklore, Irving reminds his audience that indolence and unawareness of sociocultural and political change can lead to disaster. Time is the major theme in this tale.

The tale was published as part of a collection of stories in 1819. The collective work, known as *The Sketch Book of Geoffrey Crayon,* also includes Irving's other famous tale, *The Legend of Sleepy Hollow.* "Rip Van Winkle" is set in a small Dutch village in the Hudson River Valley in New York State. The village is situated at the foot of the Catskill Mountains, which play an integral role in the story. The Hudson River Valley would not only be immortalized through Irving's two most famous stories but also would become his later home. The time period is set both before the American Revolution (in the beginning) and afterwards, when Rip awakens.

In the beginning, the audience is introduced to the titular character as a well-liked member of the community. However, in Rip's own house, misery seems to stem from his henpecking wife, Dame Van Winkle. Dame Van Winkle is simply upset with Rip's natural aversion to labor within his own house. One day after a characteristic barrage of nagging from Dame Van Winkle, Rip sets off into the Catskill Mountains to escape. Accompanied by his equally henpecked dog, Wolf, Rip originally seeks to shoot some game, but instead runs into the spirit of famous explorer Henry Hudson.

After helping his new acquaintance to carry a keg of liquor he was struggling with further up the mountain, Rip encounters the rest of Hudson's

This illustration of a scene from Washington Irving's 1819 Rip van Winkle shows a group of people outside the George Washington tavern as they crowd around, point at, and otherwise inspect an old man with a long white beard and a walking stick.

Source: Getty Images. Engraved by T. Doney from a drawing by T. H. Matteson for the *Columbian Magazine,* 1850s.

crew entertaining themselves in a game of ninepins. Initially uneasy with the unsmiling crew, Rip settles down to sample some of the liquor in the keg. After many samples, Rip finds a nearby grove and falls into his renowned 20-year slumber.

Not knowing that he has slept 20 years, Rip awakens on what he supposes to be the next morning and heads back down to the village, unable to locate Wolf. That is, he cannot locate Wolf until he enters the village. There he finds an aged Wolf, who does not recognize his master. As if that weren't enough for the bewildered Rip, he soon discovers that he has arrived on an election day. Confused at the inquiry of his political allegiance from a passerby, Rip mistakenly cries "God bless the king!" After shouts of outrage from the newly liberated populace, Rip Van Winkle explains his identity, which is confirmed by a kindly old neighbor. Rip is welcomed back to the community and sees the effect of time upon everything he remembers before his famous slumber. His children are now grown up; his wife has died, as have many of his former friends.

Washington Irving's tale is a response to the rapidly advancing times of political and social change that characterized the American Revolution. Perhaps even more, it is a reminder that idling away one's own time in such a turbulent historical period can be disastrous. The so-called sleepers or more appropriately named "Rip Van Winkles" need to honor their proverbial "wake-up calls."

There is no doubt that Irving was inspired to pen "Rip Van Winkle" by taking direction from an earlier German folktale known as "Peter Klaus the Goatherd". The tale also bears a strong resemblance to another German folktale collected by the Brothers Grimm known as "Karl Katz". In fact, the postscript written by Diedrich Knickerbocker, Irving's infamous narrator throughout the *Sketch Book* and some of his earlier works, mentions a German superstition.

The tale of Rip Van Winkle inspired others in turn to produce further works based on the story. There have been successful stage adaptations of the tale, as well as operettas and animated films featuring Rip Van Winkle. The earliest screen adaptation is the short film entitled *Rip's Twenty Years' Sleep* (1896), starring Joseph Jefferson as Rip Van Winkle and now housed in the National Archives.

Rites of Passage

Rites of passage are rituals or ceremonies that individuals in many societies must endure in order to pass from one stratum of life to another. Some examples of rites of passage include naming ceremonies, initiation into adulthood, marriage, childbirth, and funerals.

Arnold Van Gennep described rites of passage, or *rites des passages,* in his 1906 book of the same name. Van Gennep discussed the significance to individuals and society of certain ceremonies or life events that act as a doorway from one stage of existence into another. While passing through this doorway, the initiate found him or herself in a dangerous stage or interface (in some cases literally) of liminality, after the Greek for "threshold." Van Gennep further subdivides rites of passage into rites of separation (preliminal rites), for example, funerals, transition rites (liminal rites) such as initiation, engagement, and pregnancy, and rites of incorporation (postliminal rites) like marriages. These three stages of rites not only transform the individual but reinforce the validity of the social group as a corporate whole by its participation in the events, as well as by the *transformé*'s desire to become part of it.

Victor Turner argues that if the basic model of society is a "structure of positions," the liminal phase is an interstructural situation. During this stage the initiate is separated from the society as a whole by physical means, clothing, or behavior, as he or she is neither what was nor what will be. By analogy we might compare this to a pupa stage between larva and adult in entomology—neither what was nor what will be, but an inchoate form in between. It is during this phase that the individual is intentionally remolded into something different from before by rituals that can cause the initiate to be made to look foolish (as in the Bemba *chisunga*) or ultrapious (as in Holy Orders), or in some manner is stripped of the previous identity and becomes structurally invisible. As an example, when one joins the military, one's old identity is stripped away—literally—as such personal statements as clothing and hair are removed, the name is replaced by "recruit" or "private," and one is subjected to humiliating public medical examinations and torturous training exercises. Eventually the recruit is accepted into the society in the new identity as "soldier" (or "marine," etc.). By passing through these rituals together, the group members feel a sense of cohesion that may outweigh those of kinship bonds, as when age mates (those who have been initiated into an age set at approximately the same time) are compelled to protect each other even against their own kin, as described by Laura Bohannan.

Among the most often described rites of passage are initiation rites from childhood into adulthood, which Turner finds to be core periods in social instruction. In the modern Western world, this often takes the form of a driving license examination or the bar mitzvah and bat mitzvah found in Judaism. In other cultures these can be painful and dangerous genital surgeries such as the subincision found among the Arunta of central Australia, in which a boy's penis is split lengthwise along the urethra, spread flat, and bound to an object to keep it that way until it heals. One of the boy's incisors also is knocked out. Among the Nuer of the Sudan, boys between the ages of 14 and 16 who wish to become men must have a series of parallel incisions called *gar* carved into their foreheads so deeply that it is said that they can be detected on the skulls of dead men. Following the ceremony, the new man takes a new name from his favorite ox, and thereafter is known by his "ox name." These men then belong to a named age-set of men of similar age who form a fraternity for life. Bruno Bettelheim argues in *Symbolic Wounds* that, at least in the male case, bloody rites of passage give men the right to take credit for giving birth just as women can. Women give birth to children, but men give birth to men.

In the early 21st century, more is made of female genital mutilation in the literature than is made of male genital mutilation, as was done in the mid-20th century. An example of female genital mutilation as part of a rite of passage can be found in clitoridectomy as practiced by the Ibibio of southeastern Nigeria, described by John C. Messenger, Jr. An older woman sponsors a girl who has had her first menses and oversees the excision of her clitoris. She then recovers and is instructed in womanliness in a fattening house. After sufficient healing and weight gain, the girl is released from the fattening house and, following a ceremonial leap from a large boulder, is considered to be a woman when her feet touch the ground. She then is known as *mbopa*–fattening girl, or debutante. According to Messenger, the Ibibio claim that clitoridectomy makes women far more libidinous than men.

Somewhat less bloody rites of passage include the vision quest found among Native Americans of the Plains culture area. Although there are variations, the core idea is that for a boy to become a young man, he must have a sacred vision that will guide his path in life. In the vision the boy will meet his spirit companion and receive several symbols that will resonate like wave harmonics with small objects put in a spirit bag that will serve as his soul. Some of the ordeals that boys go through in order to have their visions include fasting to induce hypoglycemia, praying in a sweat lodge to induce dehydration and loss of electrolytes, going naked into the wilderness alone for up to several weeks and risking exposure to the elements, and staring at the sun all day to induce sensory deprivation. One would be surprised if, after enduring all the ordeals, the boy did not have a vision.

Somewhat similar is the walkabout found among some Australian Aboriginal groups. The Zambian Bemba sing and dance the *chisunga* ceremony following a girl's first menses. As described by Audrey Richards, it is designed to give a girl access to supernatural power through her knowledge of symbols that will bring her from "unproductive girlhood to a potentially dangerous but fertile womanhood" and prepare her for marriage.

Some rites of passage are required for initiation into religious groups as well, such as the tonsure ceremonies found in monastic communities. Zora Neale Hurston described her initiation into New Orleans Hoodoo, a syncretistic religion combining Christianity with West African spirit religion primarily found among the Yoruba and Dahomeans and closely related to Haitian Vodoun. Hurston was required to lie naked under a cloth overnight on an altar in preparation for her initiation ceremony as a member of Hoodoo. This is reminiscent of the "mourning" ceremony found among the Spiritual Baptists of Saint Vincent described by Jeannette Henney, and it allows one to come naked into the world again from a dark place, that is, to be reborn.

Rome, Ancient

Rome was a highly developed society that remained a distinct nation-state for more than 12 centuries. Throughout all that time, there was continual social and political evolution. In the beginning, Rome was ruled by kings. It developed into a republic with elected leaders and a senate and then became an autocratic empire ruled by a series of emperors. In the earliest years, there was little interest in anything more than "local time." Every city had its own calendar and its own way to reckon time. As Rome evolved into a more complex society and absorbed more neighboring cultures, elaborate calendars, astronomical knowledge, and historical recordkeeping developed. At the same time, however, for centuries there was a lack of timekeeping to regulate the workday. Everything was measured relative to sunrise and sunset, and there was no division of time shorter than an hour.

Concept of Time

The era of kings and the early republic are the most poorly documented periods of Roman history. Historical writing by Romans did not occur until Rome had conquered all of Italy and Greece recognized Rome as a world power.

Greeks began to synchronize time in the 3rd century BCE. By charting Olympic Games and their victors in relation to the reigns of kings, a chronology was established. Two Alexandrian scholars, Eratosthenes and Apollodorus, continued and expanded this work through the middle of the 1st century BCE.

As Rome grew and expanded into the Republic, Hellenic synchronization of time changed to accommodate the Romans. The first Roman writer of chronography was Cornelius Nepos. He systematically attempted to place Roman events into the framework of Greek chronology. His *Chronica* was written in the mid-50s BCE. Nepos synchronized events and people from Greek and Roman history. The foundation of the city of Rome, which had had a mythological beginning to this point, was calculated to have happened in the 2nd year of the seventh Olympiad (751 BCE). From this fixed point of reference, he assigned dates to past events. Later historians continued his work. Varro finished a work titled *De Gente Populi Romani* in 43 BCE; it quickly became the canon of chronology. Varro calculated the date for the founding of Rome as 754 BCE.

Establishing a Calendar

Romans numbered their years by labeling the founding of Rome by Romulus, the first king, as year 1. By today's reckoning, the date 753 BCE is used. Years were not numbered. Events were remembered by the names of the two consuls in charge of the state when the event occurred. This method was exceedingly cumbersome, because two consuls were elected each year, and some served more than once. The list of consuls was called the *fasti consulares*. The word *fasti* refers to the Roman calendar and almanac. The word evolved to refer to lists or registers that had to do with keeping time. The *fasti diurni* was a yearbook of religious ceremonies, market days, and court dates. *Fasti dies* were the days in which legal business could be transacted. The *fasti* would be posted in the Forum and other public areas. The word eventually came to be used generally to refer to annals or historical records. The poet Ovid wrote an epic work titled *Fasti,* using the months of the calendar as a frame to weave together Greek and Roman stories and events. There was a book for each month, but only the first six have survived. In Ovid's *Fasti,* festivals are described chronologically and traced to their legendary origins, in verse. While brilliantly written, the poem is also full of patriotism and flattery toward the imperial family.

The earliest Roman calendar began on March 1, and lasted for 10 months; Martius, Aprilis, Maius, Junius, Quintilis, Sextilis, September, October, November, and December, followed by two unnamed winter months. The months were calculated on the lunar cycle. Numa Pompilius, a later ruler, is credited with naming the winter months Januarius and Februarius and adding them to the calendar. Having 12 months based on the lunar cycle resulted in a year of 355 days. Astronomers were aware of the solar year, and periodic adjustments were made to the calendar to stay in line with the seasons by adding a 13th month every other year. This month was called Mercedonius (Latin for wages). For 600 years, politicians used Mercedonius to their advantage. The month would be shortened or lengthened, added or removed arbitrarily to further their personal political goals.

When Julius Caesar came to power, he decided to stabilize the calendar. By 46 BCE, the calendar was so out of sync with the seasons that he added Mercedonius and two additional months. This 455-day year became known as the Year of Confusion, but it did synchronize the calendar with the seasons once again. New calculations based on the earth circling the sun were used to determine the months. The new moon, an object of reverence to the Romans, occurred on January 1 in 46 BCE. Caesar declared it to be New Year's Day. His new 12-month calendar was so improved over the previous one that it remained in use, essentially unchanged, until 1752, when it was determined to be 11 days off.

The names of the months are still in use today except for Quintilis, the fifth month, which was renamed Julius in honor of Caesar after his calendar reform. Similarly, Sextilis, the sixth month, was changed to honor Augustus in 8 BCE. Other emperors tried to make similar changes, but they did not last.

Romans did not number each day in their months consecutively. Each month was divided into three parts, and days were counted in relation to these three fixed points (except for February, which had its own system). The Kalends fell on the 1st day of each month. The Nones fell on the 5th or 7th day of each month, and the Ides on the 13th or 15th day.

The Julian reform of 46 BCE gave our calendar the 12 months as well as their order, length, and names. Astrology introduced the division of the months into units of 7 days. Each day of the week was considered subordinate to one of the seven planets whose movements were believed to regulate the universe. One minor modification in the 3rd century CE renamed the day of the sun, *dies solis,* the day of the Lord—*dies Dominica.*

Finally, each day of the week was divided into 24 hours, which were reckoned from midnight, as we do today.

Measuring the Time of Day

Romans had no way to measure the passage of hours in a day. Time was calculated generally from sunrise and sunset—two fixed moments that were the same for everyone. Romans divided the daylight hours into 12 equal units, with midday occurring when the 6th hour became the 7th. Midnight was the moment at the beginning of the 7th hour after sunset. Romans calculated daylight hours from sunrise and nighttime hours from sunset. Days are longer in the summer than in winter, so the actual length of the hour fluctuated through the year. Hours were not subdivided into any smaller unit of time, so the variation in length was of no concern.

The Sundial

At the end of the 4th century BCE, Romans were still content to divide the day into two parts: before midday and after. By the time of the wars against Pyrrhus, the day was further divided into early morning, forenoon, afternoon, and evening. The concept of "hours" was finally introduced to the city in 264 BCE during the First Punic War. The Greeks had been measuring the sun moving across the sky with sundials since the 5th century BCE. Valerius Messalla, one of the Roman consuls that year, brought the *horologium* (sundial) of Catana back from Sicily as war booty and set it up on the *comitium* (a public meeting place), where, for almost 100 years after, it provided artificial time. The Romans did not understand that the vertical stylus in the center of the sundial that casts the shadow had to be calibrated for the latitude where it was located. However, most individuals probably looked on the sundial as a novelty and continued to go about their business as they always had.

In the year 163 BCE, Romans were finally given their first sundial accurately calculated for their latitude. As reliance on more precise time measurement grew, sundials were set up in public places. They were expensive, so only the wealthy could place such a status symbol in their homes. While sundials were useful tools, they were useless on cloudy or foggy days. This difficulty was remedied a few years later when water clocks were also imported from Greece.

The Water Clock

The water clock, or *clepsydra,* was fairly simple in concept. Water would be released from a container steadily to mark the passing of time. The container would have lines measuring the passage of each hour. A sundial was used initially to grade and calibrate the water clock. After the hour marks were made, one simply refilled the reservoir at sunrise and sunset. From the time of Augustus, after 10 BCE, water clocks grew more elaborate and precise. The presence of a water clock in a private home was a status symbol.

Punctuality was still impossible, even in Imperial Rome. Both sundials and water clocks depended on the hours of the day being divided into 12 equal parts, but there is fluctuation in the length of the day throughout the year. Timekeeping for the Roman was a hit-or-miss activity.

Ancient Romans were profoundly interested in the concept of timekeeping. Methods to track, organize, record, and measure time are seen repeatedly in their history. However, Roman life was never scheduled with precision to the extent it is today. The inaccurate methods for measuring hours remained empirical, and daily schedules remained fluid and elastic throughout the course of the empire. The study of ancient Rome provides a fascinating look at a complex urban society filled with cosmopolitan people who maintained the rural, agrarian pace of their roots in their daily lives.

Rosetta Stone

The Rosetta Stone is an artifact from the 2nd century BCE that was found in Egypt in 1799. It is a fragment of a carved stone decree. The message on the tablet is written in two Egyptian language scripts—Demotic and Hieroglyphic—as well as in Greek. By studying the known Greek, 19th century scholars were eventually able to translate the mysterious hieroglyphs that had baffled their predecessors for centuries. With the translation of hieroglyphic script, the secrets of an ancient and powerful society could be read from firsthand historical accounts for the very first time.

The word *stone* is somewhat misleading; it evokes thoughts of a geological and not a cultural artifact. The object we see today is only a fragment of the original tablet that dates back to 196 BCE. Inscribed on the black granite stone is a decree of the Greek government, which ruled over Egypt at this time. Hieroglyphics were rare after the 4th century BCE but were still used for some religious and governmental purposes. This is why the decree on the stone is written in three different languages: hieroglyphs, because it was a government document; Demotic, which was the common language of the Egyptian people at the time; and Greek, the language of the foreign government. It is believed that such stones would have been placed outside of temples for public viewing.

After the death of Cleopatra VII in 30 BCE, Egypt became part of the Roman Empire. As the Romans converted to Christianity, so did the Egyptians. As time went by, religious importance shifted away from the temples of the old cults, and they began to close. In 392 CE, the Byzantine emperor Theodosius issued an edict to close them all. The Rosetta Stone was most likely damaged during Justinian's reign in approximately 535 CE. During this time temples were being destroyed and their stones recycled for construction projects throughout Egypt. The piece of the stone we see today was eventually moved to Rashid and was used to build a fortress around 1480 CE. Time reduced this stone from a highly regarded object to just another building block.

The stone was discovered in Rashid (Rosetta), in July of 1799. There is some dispute among scholars as to who actually uncovered it. Pierre Francois Xavier Bouchard, a French soldier, is most often credited with the find. The French soldiers immediately realized the importance of the piece and brought it to the Egyptian Institute in Cairo. This establishment had been founded to house the ancient artifacts gathered by the French scholars who accompanied Napoleon on his expedition to conquer northern Egypt. These scholars were recording the relics of Pharaonic Egypt and sending this information back to Europe.

The discovery of the Rosetta Stone was announced to the world on Sept. 15th, 1799. Copies were made and sent to Paris in 1800. The stone was then moved to Alexandria for further study. After Napoleon's defeat in 1801, the Rosetta Stone was surrendered to the British as part of the Treaty of Alexandria signed that same year. The French were allowed to make a cast of it before they were forced to leave Egypt. When the stone first arrived in England, it was housed at the Society of Antiquaries in London. Casts were sent throughout the UK for study. In 1802, it was officially donated to the British Museum by King George III. It has been on display there for more than 2 centuries.

It would be nearly 20 years before someone would solve the mystery of the hieroglyphs written on this artifact. At the time of its discovery, the written language of the Egyptian people was Coptic, which uses Greek letters, along with a few additions, to spell out the Egyptian language. By this time, Demotic was a long-forgotten dialect, and so this part of the text on the stone was also a mystery to modern scholars. It was not known if it was an alphabetic language like Coptic or a more symbolic language like hieroglyphics.

Two scholars are associated with the translation of hieroglyphs. Thomas Young was an English scientist and researcher. He mastered many subjects during his long and successful career. By 1814 he had completely translated the Demotic text of the Rosetta Stone. In the next few years he had achieved a basic understanding of hieroglyphics, although it was later determined that many of his findings were incorrect. Some of Young's conclusions appeared in the famous article "Egypt" he wrote for the 1818 edition of the *Encyclopedia Britannica*. However, he did not publish his complete findings until 1823.

Jean-Francois Champollion is the name usually associated with the Rosetta Stone. Today, he is also credited with being the father of egyptology. Champollion was born on December 23, 1790, at Figeac in France. At the age of 10 he began formal study at the lyceum in Grenoble. By 1806, he spoke a dozen different oriental languages, including Coptic. At just 16 he published a paper that theorized that the Coptic language of the modern Egyptians was the same verbal language as that of the ancient Egyptians. This theory would be the basis of his later work translating the Rosetta Stone. It is thought that Champollion's immense interest in this topic came from the Napoleonic campaigns in Egypt during his childhood. He dedicated his career to studying the Pharaonic times of Egypt linguistically and archaeologically. He traveled around Europe studying Egyptian collections and taking extensive notes of all of his observations. He was appointed curator of the Louvre's Egyptian exhibit when it opened in 1827. In 1828, Champollion traveled to Egypt for the first and only time. It was an extensive 2-year journey mapping and studying ancient artifacts throughout the Nile region.

By 1818, Champollion had succeeded in figuring out that some signs were strictly symbolic and that many others had phonetic value. Therefore, the ancient Egyptian script was at least partially alphabetic. This breakthrough allowed Champollion and other scholars to crack the code of the ancient Egyptians. A language thought to be lost in time was now legible. The ability to read hieroglyphic carvings has allowed scholars to study and understand the documents of an ancient civilization that are nearly 5,000 years old.

Rousseau, Jean-Jacques (1712–1778)

The cultural critic, political philosopher, novelist, pedagogue, and composer Jean-Jacques Rousseau was born June 28, 1712, in Geneva, Switzerland, and died July 2, 1778, in Ermenonville, France. Rousseau is regarded as one of the most important critics of modernity. In analyzing modern society, he discusses various aspects of time, such as the origins of humankind and its basic traits and the acceleration of civil life and time as a political factor. According to Rousseau, processes in modern society are too rapid and ought to be slowed down.

Rousseau attained fame with his *Discourse on the Arts and Sciences* (1750), which was a response to a prize question by the Academy of Dijon, asking whether the sciences and arts contribute to the corruption or to improvement of morals. Rousseau's essay presents a radical critique of the idea of social progress that appears in the Age of Enlightenment. Sciences and arts, he argues, will not bring about a better society. They have their origin in human vices and are symptomatic of a lack of virtues. In all eras, the attempt to escape from ignorance leads to slavery and intemperance. Rousseau appreciates the virtues of the plain man who condemns sciences. In his criticism of contemporary society, he contrasts it with the ideal of an earlier, golden age of mankind when life and virtues were supposedly pure.

Rousseau's second discourse, *On the Origin and Basis of Inequality Among Men* (1754), seems to intend a reversal of modernity, too. He describes the development of human species, which at the same time is a process of degeneration. In doing so he is interested not only in giving a history of humankind but also in analyzing the timeframe when the basis of human traits emerges. Reason and language are not essential for human beings. They are not consistent in time; they are rather the results of a random process.

The thesis of Rousseau's essay is that the origins of social inequality and human corruption are to be found in the structures of civil society and not in human nature. As a proof, he develops a unique concept of the state of nature. At the same time he makes clear that philosophers such as Thomas Hobbes who have analyzed the state of humankind have not taken their analyses far enough back in time to show humankind's real nature.

Rousseau describes the transition from the natural man (*homme naturel*) to civilized man (*homme civilisé*). What distinguishes the first humans from animals is the mere fact that humans are free agents. The idea of freedom remains central to Rousseau's work as a criterion for a legitimate political order. However, freedom is in danger when human beings leave the state of nature. Social inequality and dependency arise together with the emergence of private property and the division of labor. This situation has been transferred into civil society by introducing a contract, initiated by the rich to perpetuate their profitable position.

The transition can be understood as antiteleological and anti-Aristotelian. There is no immanent end in time. Human nature does not find its perfection in culture. It ends up in a cultural state due to random circumstances.

In Rousseau's second discourse, he seems to have in mind a time when human existence had found an ideal form of life. He describes a bygone age when development of human species should have stopped: the *golden age.* It is not the time of the first isolated living human beings, but that of pastoralists (*homme barbar*) living in a free and loose society. However, Rousseau's golden age is a moment outside of time. He is quite clear about the hypothetical character of the described history of the human species. The state of nature probably never existed. Furthermore Rousseau's contemporaries could not return to this early stage of development, because human nature cannot go backwards. Hence Rousseau has another approach, which is supposed to be valid for his contemporaries, and which can be found in his political writings.

Rousseau's political main work, *The Social Contract* (1762), deals with the possibilities for maintaining human freedom in civil society. For that purpose Rousseau introduces the idea of a social contract that, unlike the contract in the second discourse, keeps humankind free. Natural freedom has to be transformed into civil freedom by submitting oneself to the general will (*volonté générale*). Rousseau's perfect form of government is a republic. To establish such a government, some exact conditions must be fulfilled. For Rousseau, Corsica was the only place in Europe where his republican state could have been established.

A republic can only be founded at a certain point in time. The people have to have the need for socialization, but they should be in a quasi-uncultivated state. Similar to Émile, the boy in Rousseau's pedagogical writing, the folk are in their youth. At this time they can be taught. Rousseau strives for the forming of a civil ethos through a kind of national education and religion to protect civil freedom. According to Fetscher, Rousseau's philosophy is especially concerned with the possibility of slowing down progress. Although, over time, humans give in to vices, a well-ordered government can hold back this kind of depravity.

Rousseau is ranked as one of the first and most radical critics of modernity. His work can be understood as a reaction to the ideology of social progress, the acceleration of civil life, and a new experience of space and time in the modern world. He sees the life of modern humans as a whirlwind (*tourbillon social*) in which it is vital for them to maintain their freedom and naturalness. *Saint-Preux,* one of the main figures in Rousseau's famous novel *Julie, or the New Heloise* (1761), experiences the accelerated life in the city. He suffers from modern relativisms, the need for various truths, values, and identities for different places and different times. Rousseau, on the other hand, praises the calm life, a contemplative life in nature as it is described in his unfinished book *Reveries of a Solitary Walker.*

Rousseau has been read in various ways. He is regarded as the main figure of the French revolution, as a socialist, and as a liberal; some see him as the mastermind of totalitarianism. Moreover, Rousseau was a romantic conservative. He attempts to protect humankind against the dangers of modern society. His ideal was a native life in close communion with nature. He was clear, however, that this form of life is an anachronism. Hence he hopes for education to protect people against corruption and the transformation of human beings to virtuous citizens in a well-ordered republic.

Russell, Bertrand (1872–1970)

Bertrand Russell was born into the English aristocracy and went on to become an outstanding philosopher, public intellectual, and social activist. His parents died when Russell was very young, and he was brought up by his widowed grandmother. He studied at Cambridge University and, along with his colleague G. E. Moore (1873–1958), was instrumental in overturning the prevailing orthodoxy of Hegelianism in English philosophy at the time. His early works of philosophy, in particular *The Principles of Mathematics* (1903), had a profound effect on trends in logic and in understanding the importance of language.

The most productive years of Russell's life as a philosopher were devoted to producing, with Alfred North Whitehead (1861–1947), the monumental three-volume *Principia Mathematica* (1910–1913), which was designed to show that pure mathematics follows from logical premises and uses only concepts that are definable in logical terms. This project was never completed, as the proposed fourth volume never appeared. This was due partly to the authors' exhaustion and partly to growing doubts as to the validity of what was being attempted. As Kurt Gödel went on to show, at a certain point the inexorable logic of some mathematical propositions was less clear than originally supposed. And Ludwig Wittgenstein had persuaded Russell that some of the demonstrably logical mathematical demonstrations were little more than tautologies. As Russell said late in his life: "I think that the timelessness of mathematics has none of the sublimity that it once seemed to me to have, but consists merely in the fact that the pure mathematician is not talking about time." Nevertheless, the *Principia* remains one of the most daunting monuments to raw intellectual power ever produced.

It was during the First World War that Russell felt the need to write a new sort of book, one that could extend beyond academic philosophy to reach the general citizen. The first of these works was *Principles of Social Reconstruction* (1916), a series of lectures on issues surrounding postwar reconstruction. This book was enormously successful and established a wider audience for Russell than philosophers had hitherto thought possible, or desirable. During this time Russell lost his position at Cambridge, due largely to a campaign led by J. M. E. McTaggart (1866–1925), who opposed his pacifist views. Russell went to prison for several months in 1918 for his opposition to the war.

The most important of the later technical works were *Analysis of Mind* (1921) and *Analysis of Matter* (1927), *An Inquiry Into Meaning and Truth* (1940) and *Human Knowledge: Its Scope and Limits* (1948). The themes that were constant in Russell's work were analytical method, empiricism, realism, and the relations between things. The best of his popular writings are *The Scientific Outlook* (1931), *Religion and Science* (1936) *History of Western Philosophy* (1946), and *Why I am Not a Christian and Other Essays* (1957). Russell's mathematical ability meant he had a clearer understanding of relativity than most philosophers, then or now. He put this to good effect in popular accounts like the *ABC of Relativity* (1925).

An important element of Russell's writing, particularly in his general works, was his focus on placing humanity squarely back in nature. He outlined this development in a late essay, revealingly titled "The Retreat From Pythagoras." His departure from pure mathematics was an important component of that "retreat." Part of his strong opposition to Kant, Hegel, and pragmatism lay in his suspicion that, in their various ways, they were attempting to place humanity back at the center of the universe, thus reversing the trajectory begun by Copernicus. Russell did not say anything fundamentally new about time, but he did take seriously his responsibility to incorporate time, as understood since Einstein, into a naturalistic outlook on life. The Idealism of Kant and Hegel, as well as pragmatism, struck Russell as variations of hubris. So too did notions of personal immortality, which struck him as "aristocratic." Instead, he pleaded, mainly rhetorically, for a life of moderation in matters intellectual alongside a capacity for extremes of feeling and compassion.

Much of Russell's later career was spent as a public intellectual, with occasional forays back into technical philosophy. Reversing the usual trend, Russell became increasingly radical as he got older. In 1955 he wrote what became known as the Russell-Einstein Manifesto. Albert Einstein cosigned it as one of the last things he did before his death. The Russell-Einstein Manifesto laid the foundations for the peace movement. In 1958 Russell was instrumental in setting up the Campaign for Nuclear Disarmament, serving as its first president. Two years later he founded the even more radical Committee of 100 to participate in civil disobedience against Britain's nuclear policies. Russell led from the front, going to prison in 1961 for the second time in his life. In 1963 he established the Bertrand Russell Peace Foundation as a vehicle to further world peace. During these years of social and political activism, Russell frequently resorted to apocalyptic metaphors of time running out, or the race between disarmament and catastrophe.

Russell was married four times. The first, to the American Quaker Alys Pearsall Smith (1865–1951) ended in 1911, although they were not divorced until 1921. The second, to Dora Black (1894–1986) ended in 1932. The third, to Patricia Spence, ended in 1952. Russell's fourth marriage, in 1952 to Edith Finch, was the happiest of the four and continued until his death in 1970.

S

Sagan, Carl (1934–1996)

Carl Sagan, born in Brooklyn, New York, was an American astronomer, astrophysicist, and exobiologist who wrote the introduction for the first edition of Stephen Hawking's *A Brief History of Time,* published in 1988. Around age 5 Sagan became interested in astronomy, and his curiosity was further kindled by reading a library book about stars. He became an avid reader of science fiction, especially the Edgar Rice Burroughs books about John Carter of Mars. Sagan graduated from Rahway High School in New Jersey in 1951, named in the yearbook as the male "most likely to succeed" and "class brain." He went on to complete his B.A. with general and special honors in 1954, his B.S. in physics in 1955, and his M.S. in physics in 1956, all from the University of Chicago. Sagan completed his Ph.D. in astronomy and astrophysics in 1960, with a dissertation titled "Physical Studies of Planets."

From 1960 to 1962, during his postdoctoral fellowship at the University of California, Berkeley, Sagan helped to develop an infrared radiometer, which was sent to Venus aboard *Mariner 2*. He then spent a year as visiting assistant professor of genetics at Stanford University School of Medicine. In 1963 he began a joint appointment as lecturer (and later assistant professor) of astronomy at Harvard University and as an astrophysicist at the Smithsonian Astrophysical Observatory. Upon being denied tenure at Harvard, Sagan went to Cornell University where he became director of the Laboratory for Planetary Studies at the Center for Radio Physics and Space Research and David Duncan Professor of Astronomy and Space Sciences.

Sagan's research interests included the greenhouse effect on Venus, the seasonal changes on Mars due to dust storms, the origin of life, and the search for extraterrestrial intelligence. His mentors included Gerard Kuiper and Nobel laureates H. J. Muller and Joshua Lederberg. Sagan maintained a close association with NASA beginning in the 1950s, working with the Apollo, Mariner, Pioneer, Viking, Voyager, and Galileo programs. He was author, coauthor, or editor of more than 20 books and published more than 600 scholarly and popular articles. Sagan was a successful popularizer of science, most notably with the 1-part series "Cosmos: A Personal Voyage," which was first broadcast in 1980. He also wrote the science fiction novel *Contact,* published in 1985 and adapted as a major motion picture released in 1997.

Honors awarded to Sagan include the NASA award for distinguished public service (twice), the NASA Exceptional Achievement Medal, the NASA Apollo Achievement Award, the Leo Szilard Award for Physics in the Public Interest, the Sidney Hillman Foundation Prize, the Public Welfare Medal (the highest award of the National Academy of Sciences), and the Pulitzer Prize for nonfiction, as well as many others. He was a fellow of the American Institute of Aeronautics and Astronautics, received 22 honorary degrees, and Asteroid 2079 Sagan was named in his honor.

Sagan was married three times and fathered five children. He was married to his first wife, Lynn Alexander (later Lynn Margulis), from 1957 to 1963. They had two sons, Jeremy and Dorion. His second marriage was to Linda Salzman, from 1968 to 1981. They had one son, Nicholas. His third marriage, which lasted from 1981 until his death, was to long-time collaborator Ann Druyan. They had one daughter, Alexandra (or Sasha), and one son, Samuel.

Sagan suffered from the blood disease myelodysplasia and underwent extensive treatment, including three bone-marrow transplants. He died of pneumonia in a Seattle hospital in 1996.

Saltationism and Gradualism

In the explanation for the origin of new life forms throughout organic evolution, the temporal framework is very important. Two major positions have been offered to account for the process of speciation. Darwinism maintained that the emergence of a new species occurs slowly over a vast period of time in terms of slight variations and natural selection; as such, biological gradualism supplements geological gradualism in natural history. This interpretation upheld the continuity of organic evolution. In the 20th century, neo-Darwinism also supported biological gradualism, claiming that the process of speciation results from the slow accumulation of favorable minor changes in the genetic makeup of an organism. Over time, these positive slight alterations enhanced the adaptation, survival, and reproduction of a species in a changing environment. In sharp contrast, most sudden major mutations in genetic makeup are usually harmful to an organism and result in its sterility or death. If no members of a population can adapt to changes in the environment, then the population becomes extinct. Because biological evolution has been occurring for about 4 billion years, it is generally held that there has been sufficient time for organic history to account for the staggering creativity of life forms in terms of biological gradualism. Nevertheless, the fossil record attests to the fact that most of the species that have ever existed on the earth slowly or suddenly became extinct.

There is no consensus among naturalists concerning the conceptual issue of time and speciation. Although Charles Darwin supported evolutionary gradualism, his contemporary Thomas Henry Huxley argued for a form of saltationism. Huxley maintained that the appearance of a new species represents a major leap, or saltation, in organic evolution. Therefore, in sharp contrast to Darwin himself, Huxley did not claim that biological history represents an organic continuum. To some naturalists, the incomplete fossil record suggested that species both appear and vanish suddenly throughout evolutionary time. In the middle of the 20th century, the saltationism position was revived by Richard B. Goldschmidt in his controversial book *The Basis of Evolution* (1940). In this work, the geneticist claimed that the change from species to species cannot be explained in terms of the accumulation of atomistic changes in an organism (microevolution). Instead, Goldschmidt favored macroevolution with its quantum speciation. Consequently, he put forward his “hopeful monster” hypothesis, which argued that macroevolution (not microevolution) resulted in the instantaneous appearance of a new species and even higher taxonomic groups.

More recently, Niles Eldredge and Stephen Jay Gould presented their “punctuated equilibrium” hypothesis, which claims that a new species appears in a small isolated population during a relatively short period of geological time (only several tens of thousands of years). Unfortunately, this interpretation of “rapid” evolution, along with the incomplete fossil record and alleged lack of transitional fossils in the geological column, provided biblical fundamentalists and religious creationists with a basis they can use for discrediting the immense age of the earth in general and the process of organic evolution in particular.

For scientists, however, geological time and biological time are linked in organic evolution and the process of speciation. This remains the case regardless of whether or not rates of evolutionary change have varied greatly throughout those vast eras of time represented by earth history.

Salvation

Salvation comes from the Latin *salus,* which means "sound, safe." The study of salvation is called *soteriology*. Salvation in a religious sense indicates an ultimate safety. Initially a person is in a state of spiritual danger, which indicates a future (or also present) punishment in some form; therefore the significance of salvation changes over time. Through the intervention of a deity or spiritual awareness, the individual is removed from spiritual danger and receives a spiritual reward. This turn from danger and punishment to safety and reward is salvation.

Note that the word *salvation* has European roots (Latin) and therefore is foremost a Christian concept. Most religions teach that nonpractitioners face danger and punishment, whereas adherents receive safety and reward. That similarity is expressed in a variety of methods depending on the religion. The word *salvation* is found almost solely within Christianity, yet the idea of turning from spiritual punishment to spiritual safety runs constant in all religions. For this reason, the concept of salvation has been used to describe other religious belief systems. Christianity makes the strongest use of the idea of salvation. Christianity focuses on Jesus Christ, whom Christians believe to be both a physical man and God incarnate. Christian salvation teaches that an individual needs to accept Jesus Christ as coming from God and follow Jesus's teachings in order to receive salvation. The reward for the adherent is eternity in heaven with God. The punishment for nonbelief is an eternity in hell apart from God. This is a broad characterization of Christianity, which itself has three main groups—Catholic, Orthodox, and Protestant—each with a different understanding of salvation. All three believe that Jesus is the cornerstone of salvation. Catholic Christians believe salvation is most properly practiced within the confines of church membership. Therefore Catholics receive salvation from within the Catholic Church. Orthodox Christians believe salvation is most properly practiced within the desire for a holy life. Orthodox Christians receive salvation from Jesus as they grow in holiness. Protestant Christians believe that salvation is most properly practiced as the individual accepts Jesus in a one-to-one experience with God. Protestants receive salvation from Jesus when they accept Jesus as God of their life and follow this through in action. These three Christian aspects of salvation developed over time, with Catholic and Orthodox developing concurrently and the Protestant aspect developing later.

The idea that salvation can be represented in an experience (or experiences) is found only in Protestant Christianity. This experience is known as "being saved." Christian Catholicism and Orthodoxy do not have the experience of "being saved"; instead, both teach that the experience of God should be manifested within the Church. Because Christians believe that nonbelief results in an eternity in hell, they proselytize.

Judaism does not focus on salvation as an act of believing or accepting. Instead, Jews escape spiritual danger and receive spiritual safety in trying to live a life focused on God (in Hebrew, *Yahweh,* often transliterated as Jehovah) coupled with a desire to combat sin, which is described in the Tanakh, or Jewish scriptures (which Christians refer to as the Old Testament). Yahweh will reward those who follow him through spiritual and physical blessings. Conversely, Yahweh will punish nonadherents, although the manner of punishment differs among the different Jewish religious groups. Traditionally Judaism has not proselytized because the religion teaches that Yahweh has chosen the Jews as an example to humanity of how to live.

Islam teaches the doctrine of salvation. Within Islam, Muslims will go to heaven (paradise) whereas non-Muslims will go to hell. In this sense, Islam and Christianity are similar. Yet the two religions differ in that the doctrines of God are different. In Islam, salvation occurs when one accepts Allah as the only God and Muhammad as his greatest prophet, strives to follow Muslim precepts, and strives to defeat sin. Islam focuses dually on both the acceptance of Allah and the life lived in service to Allah. Islam promotes proselytizing.

Hinduism and Buddhism, being Eastern religions, share the ideas of karma (actions) and transmigration (reincarnation). In these religions salvation is not achieved by believing in a god (Christianity and Islam) or living out a life in obedience to a god (Judaism), but by being personally responsible for one's actions.

In Hinduism, one is aided in reaching spiritual knowledge, or even purity, by a plethora of gods. Negative actions can be erased through positive actions with the result that karma is negated, and the Hindu reaches *moksha,* or release from the stream of rebirths. This can be considered salvation in the sense that a person has escaped from the continued punishment of rebirths: The *atman* (soul) has joined with Brahman, an impersonal Spirit that is beyond the illusion of life. Time, therefore, plays an important aspect because the adherent moves closer to release through the passage of accumulated lives. Hinduism teaches that all humans are part of the Hindu religious system, and Hindus therefore do not proselytize. One who is not aware of Hinduism and therefore does not adhere to the Hindu faith is living an ignorant life as a result of negative actions in past lives; once the nonadherent develops good karma (actions), the person will be rewarded by being born in an environment that teaches Hindu practices.

In Buddhism, one is guided by the teachings of the Buddha (Siddhartha Gautama). The Buddha is not worshipped as is the Christian God, Islamic Allah, Jewish Yahweh, and Hindu gods. Instead the Buddha participates in the act of salvation through instruction of how to reach total spiritual awareness, which leads to entering Nirvana (a place beyond suffering and the importance of individually lived lives). Buddhists can be said to have salvation in that one can move from spiritual punishment (reincarnations upon the earth) to spiritual reward (move into Nirvana). Thus, just as in Hinduism, the salvation aspect is dependent on time as one progresses through numerous lives. This instruction is found in the Four Noble Truths taught by the Buddha. Buddhism is further divided into two major groups, which view the Buddha's teachings in slightly different ways. Theravada Buddhists hold that each Buddhist is responsible to him- or herself alone and can draw on only him- or herself for a realization of the Four Noble Truths. Mahayana Buddhists believe that individual Buddhists are aided by bodhisattvas, individuals who have been enlightened and have chosen to remain in earthly lives for the purpose of helping others to reach spiritual awareness.

Sandman

The Sandman is a mythological character, which, at least from the 17th century on, has associated with time, especially the time for children to go to bed. A parallel can be drawn from the Sandman to Hypnos, the god of sleep. Hypnos's mother is Nyx, the goddess of night; his twin brother is

Thanatos, the god of death. As the donor of sleep, Hypnos has power over gods and humans. In Homer's *Iliad* Hypnos usually appears in human shape, but to hide from Zeus, Hypnos disguises himself as the bird of the night. Hypnos can make people fall asleep with his pure appearance, but he sometimes uses the noise of his wings or juices out of a horn to put people to sleep.

The oldest known source of the Sandman is from Sweden. In 1691, a Sandman-like figure, called Jon Blund, was mentioned there. The *Oxford English Dictionary* contains an entry on the Sandman from 1772: "sandman noun (the sandman) [sing.] an imaginary man who is said to make children fall asleep." A German dictionary entry from 1777 describes the Sandman in two versions: First, it is a man transporting and selling sand. Second, in fun, parents say to their children that the Sandman is coming when they become tired and rub their eyes, as if one had put sand into them. This explanation refers to another root of the Sandman history, the Sandmen and Sandwomen, who lived in the German Vogtland. The sand they prospected was used as scouring powder for cleaning.

In the 19th century, the Sandman character found its way into various areas of literature and music. In 1815, E. T. A. Hoffmann wrote the narration *The Sandman*. One of its main characters is Coppelius, a cruel man who scatters sand into children's eyes until they are bleeding and even tears them out of their sockets. Like the earlier version of the Sandman, Coppelius appears in the evening time. Hans Christian Andersen's *The Sandman* was published in 1841. In the original text, the Sandman is called Ole Lukøje, meaning "Ole, shutter of eyes." He sprinkles sweet milk into the eyes of children. While they are sleeping, he comes and opens his umbrella with pictures on it for the children who have behaved, so that they will have pleasant dreams. The others don't dream anything. In music, the character was used by the composer Robert Schumann, who set music to the poem "The Sandman," by Hermann Kletke. In Engelbert Humperdinck's opera *Hänsel und Gretel* (Act Two, Scene Two) from 1893, the Sandman appears to the two frightened children who stay in the forest during the night and he sings: "The little Sandman am I. . . ." He wants to bring some grains of sand for their tired eyes.

Between 1988 and 1996, the American author Neil Gaiman wrote a famous comic book series called *The Sandman*. The protagonist of the series, who was also called Morpheus, is the ruler of the world of dreams. Also, in the 20th century, the Sandman appeared on radio and television series and shows. Every Tuesday since 1923, the radio station KHJ (Kindness, Happiness, Joy), situated in Los Angeles, has broadcasted bedtime stories with the title "Sandman." On May 22, 1956, Radio DDR (Radio German Democratic Republic) began with the program "The Sandman Is Coming." On television, the Sandman had his first appearance on November 22, 1959, at the DFF (German Television Broadcasting). Since then, *Unser Sandmaennchen* (Our Little Sandman) is watched by millions of children and adults every evening at 6:50 p.m. in various countries. It is probably the most famous children's program on German television.

The figure of the Sandman manifests an interesting time structure concerning his age of appearance and his moment of emergence. One cannot say how old the Sandman is, because he is often described and represented as a little man, sometimes with a beard but also with a young face. However, the age of his Ancient Greek ancestor differs between an old and a young person. The Sandman combines old age and youth, often has a wise personality, and stays in contact with children. From today's pedagogical point of view, the Sandman stands for continuity and steady recurrence, and he ends the day with a nice, calming evening greeting.

Sandpainting

Sandpainting (also referred to as "drypainting") remains a significant and well-known feature of religious ceremonies in a number of cultures, especially among Native Americans in the U.S. Southwest, Tibetan Buddhists, and Australian Aborigines. These colorful, symbolic images serve different functions in different parts of the world but also share some common features. As the name *sandpainting* implies, the artists and religious functionaries generally work with simple materials, but their work involves intricate patterns that follow age-old designs. Because sandpaintings depict meaning on a supernatural or cosmic level, they provide insight into ways by which various peoples view time and eternity, key intellectual and spiritual frames of reference in all cultures. Although sandpaintings are more important for their original roles in ritualistic contexts, connoisseurs and collectors also recognize the aesthetic qualities of sandpaintings, which have acquired commercial value in some regions. As a result, the religious origins of these ancient artistic traditions have become better known, at least on a rudimentary level.

Although practiced among the Pueblos and other indigenous peoples of the American Southwest and Great Plains, sandpainting has assumed its highest profile in the Navajo traditional religious system. The Navajos use sandpaintings while performing ceremonies to invoke blessings from the supernatural world (e.g., rain, crops, health) and also in their famous curing ceremonies. In the traditional manner, the Navajo discover the causes of problems or illnesses through divination and then determine the appropriate ritual procedures—or "ways"—to remedy the situation. These elaborate ceremonies, called "chants" or "sings," include many ritual components, and drypainting procedures play a critical role. Whereas the chants survive in limited numbers, scholars have documented many hundreds of sandpaintings to accompany curing ceremonies. The singers who lead these rituals are highly respected professionals, and they determine—in consultation with other people who are involved in the ceremony (including the patient)—the precise combination and order of features. Such ceremonies can last up to 9 nights, and each day has a traditional set of procedures, all of which purify the place and patient/client for this special occasion and invoke the presence and aid of the gods, the "Holy People." Singers and their assistants often require many hours to prepare a painting, which can be small or so large that it requires the construction of a special hogan. They prepare a background of sand or buckskin and dispense the colorful materials (e.g., crushed minerals, charcoal, dried and crushed flowers, cornmeal, and pollen) with their hands to create the detailed pattern, which includes geometric images, lines, and figures—a diagram of reality, the visible and normally invisible realms. Even colors have symbolic meaning, and each scene includes figures that relate to mythology; the singer's attention to every detail makes the painting powerful. As the patient sits in the painting and comes into physical contact with its symbols, the image provides an actual place for human beings to encounter cosmic forces. Navajo refer to the sandpainting, in effect a cosmic map, as *iikaah*—a place where the gods come and go. In fact, the paintings portray Holy People, sacred animals and plants, and astronomical bodies. Because these images contain sacred power, which is subject to abuse, singers destroy paintings when the ceremonies end. Sandpaintings help the Navajo restore and maintain balance and harmony between the natural and supernatural worlds, which are intertwined in their traditional worldview.

The portrayal of cosmic images also serves a vital role in a number of Hindu and Buddhist traditions, but the most famous sandpaintings in these traditions relate to Tibetan Buddhist (Vajrayana) beliefs and practices. Although much of the Tantric Buddhist teaching remains esoteric to outsiders, the Dalai Lama, head of the Tibetan Buddhist community, has promoted their views by distributing knowledge about the most famous aspect of Tibetan Buddhism, namely, the *mandala*. The mandala (Sanskrit for a "circular" or "round" shape or container), often made of richly colored sands and other materials, conveys a wide range of symbolic significance. In its essence, the mandala is a picture or diagram of the universe, a representation of the deities that inhabit the cosmos, that serves as an aid to meditation for those on the path to Enlightenment (Nirvana). The ceremony surrounding the creation of a mandala, which includes music and chanting, has a purifying effect and plays an important role in the initiation of Tibetan monks and the pursuit of spiritual blessings. As a place of spiritual encounter—an actual sacred space and something more than a mere picture—the mandala channels positive energy to both beginners and experts in Tantric practices.

The Tantric artists refer to the sand mandala as *dul-tson-kyil-khor,* a mandala/diagram composed of colored powders (e.g., sands, plant materials, gemstones). The practitioners follow traditional patterns and carefully control the distribution of the mandala's tiny components with a small hand-held device. Depending on its size and complexity, monks can take up to several weeks to complete a sand mandala. The deities that populate the finished painting point to various aspects of the Buddhist quest and aid the contemplative process. One of the most famous mandalas, the so-called Wheel of Time (Kalachakra), reminds adepts about the transient nature of time. Like all such cosmic diagrams, the wheel helps contemplatives focus on the relation between the finite and the infinite. Like the Navajo artist/singer, Tibetan artists/monks also destroy the mandala after the ceremony ends—in this case by pouring its transportable components into a body of water. This destructive act distributes blessings from the mandala and vividly symbolizes the impermanence of life, one of the pivotal principles of Buddhism. According to Buddhist tradition, Siddhartha Gautama—the Buddha himself—taught his followers the value of sandpaintings.

Certain groups of Australian Aborigines also practice a form of sandpainting, often called "dot painting." With a patch of desert surface as a background, they use various materials (e.g., sand, stones, plant materials, and feathers) to depict various accounts (e.g., their creation account, clan history, sacred sites). Accompanied by ceremonies of song and dance, some dot paintings portray scenes from the most sacred history, what the indigenous Australians call "Dreamtime" or "Dreaming"—the time of Origins that remains immanent. In other words, these simple ground paintings have functioned as a primary medium to depict the sacred beginning of time and history, to connect Dreamtime with the present. While the designs perpetuate motifs in use from remote times, some artists now use new media for these images and have begun to market portable versions of these paintings.

Sankara, Shri Adi

Shri Adi Sankara was a philosopher-theologian of the Advaita Vedanta (nondual) school of Indian thought. His dates are disputed, although he probably lived and worked in the early 8th century. Besides his distinguished career as an influential thinker, he played several roles: Hindu reformer, founder of monastic centers, commentator on ancient texts, and author of original works of philosophy.

Medieval Indian culture recognized two types of time: linear historical time, often associated with dynastic rule, and cyclic cosmic time, which was depicted as four *yugas* (ages) of descending longevity. In the ancient Atharva Veda text (19.53–54), time is identified with the deity Prajapati. According to the Maitri Upanishad (6.14–16), the sun, a source and support for all living things, is also identified with Brahman, and time is, by extension, identified with Brahman, or the highest reality. In the cosmic level, time is a power that brings about the evolution and involution of the entire universe. Time is depicted in the Upanishads as cyclical, with an inconceivable beginning and end. Being described as all-inclusive and rolling on endlessly, time is conceived commonly as a destructive force. Time is, for instance, compared with the six seasons, which swallow up creatures, or cook all creatures, according to the Maitri Upanishad (6.15), making them ripe enough to be swallowed by death. Other metaphors of time depicted it as a noose that binds one and tightens as one grows older; time is imagined to be a winged horse that carries away all creatures, or time is like a ceaselessly revolving wheel. Moreover, time is connected to the cycle of birth, death, and rebirth, which is interpreted as an endless cycle of suffering that only ends with the attainment of liberating knowledge and status of one liberated while alive (*jivanmukti*).

The conception of time as four yugas is found in the worldview of the Puranic texts (c. 4th century CE). The term *yuga* is derived from the throws of dice and suggests that life is similar to a gigantic dice game. The primary or golden age is the *krita* yuga, which lasts 1,728,000 years, and it is represented by a four-legged mythical cow, which is a symbol of the social and cosmic order (*dharma*). The second age, the *treta* yuga, lasts for 1,296,000 years and is a period of time when the mythical cow stands on three legs. This silver age is followed by the copper age of the *dvapara* yuga, a period when the mythical cow stands on two legs and which lasts for 864,000 years. During the final age, or *kali* yuga, the mythical cow stands on one leg for a period that lasts for 432,000 years. During this last period, the mythical cow symbolizes the idea that humans can no longer perform good deeds during a final age characterized by strife, quarrel, dissension, war, and evil. Each cycle of the four yugas is called a *mahayuga* (great age), which represents a *kalpa* (eon) at the conclusion of which there occurs a dissolution of the world and return to cosmic nondifferentiation. After an unspecified period, the cosmos is recreated, and the cyclic process begins again with the dawn of a golden age and a repeat of the entire cycle.

These two notions of time were inherited by Sankara, who, among his other accomplishments, is arguably most renowned for his commentary on the Vedanta Sutras. Originally composed around the 2nd century BCE by Badarayana, the Vedanta Sutras were revived by Gaudapada and his disciple Govinda, who initiated Sankara into the text. During their transmission, the texts were influenced by ideas from the Vijnanavada and Madhyamika Buddhist schools, whereas Sankara attempted to purge the text of their distinctive Buddhist traits. Sankara's intention was to construct a philosophical edifice based on a direct interpretation of the older Upanishad texts that he considered part of the divine revelation to ancient Indian seers. These ancient revelatory texts helped Sankara to grasp reality, world, and the self from a nondualistic perspective.

Sankara makes a distinction between reality, appearance, and unreal. Reality is that which cannot be sublated by any kind of experience, whereas appearance can be sublated by reality, which Sankara identifies with Brahman. The unreal can never become a content of experience; it is thus that which neither can be nor cannot be sublated by other experience. For Sankara, sublation is a mental process in which an object or content of consciousness is cancelled because it is contradicted by a new experience. You perceive an object in your path, for instance, that you imagine to be a snake, but on closer inspection it turns out to be a piece of rope. Sublation represents a change of one's judgment because a new experience rectifies one's previous erroneous belief.

The notion of sublation in Sankara's philosophy possesses important implications for time, which is a category of empirical experience or only of the phenomenal world. Sankara recognizes six types of empirical or lower forms of knowledge: perception, comparison, noncognition (judgments of absence), inference, postulation (assuming of a fact in order to make another fact intelligible), and testimony (accepting as true information that one receives from a reliable person). The basic problem with these six instruments of knowledge is that they are all subject to ignorance because, in part, they presuppose a distinction between knower and object, which is a dualistic mode of knowing, and thus do not allow the individual to grasp the nondual nature of Brahman. The six forms of knowledge are valid as long as the intuitive vision of Brahman is not achieved by means of higher knowledge, which is an intuitive type of knowledge that is unique, immediate, and self-validating. The six types of empirical knowledge are rendered invalid because one can see that they are tainted by ignorance and are sublated by the higher form of knowledge.

This distinction between lower empirical knowledge and intuitive higher knowledge means that time is something to which everything is subject, and it is thus fundamental to the objectification of human existence. Simultaneously, it is our temporality that gives us a chance to know the eternal Brahman, which is defined as both time and eternity. Because of the notion of sublation, time is ultimately illusory for Sankara because it can never sublate Brahman.

Even though time possesses a lower reality when compared with Brahman, time is in us as pure subjects, and we are in time as empirical egos. The self (*atman*), which is identical to Brahman, is timeless, does not arise in time, is not subject to a present, and does not have an end in time. The self (*atman*) exists in an eternal now without past or future. Thus the phenomenal world, which can conceal and distort reality, is illusory and is produced by illusion, a metaphysical power (*sakti*) of Brahman. This illusion is beginningless, unthinkable, and indescribable, although time arises only within it. For Sankara, time is only real on the level of appearance, but it is ultimately unreal and illusory because it can be sublated by a higher reality.

Santayana, George (1863–1952)

Philosopher, poet, novelist, and critic Jorge Agustín Nicolás Ruíz de Santayana was born on December 16, 1863, in Madrid to Spanish parents and was brought to Boston at the age of 9 and educated at the Boston Latin School. He studied at Harvard University under William James and the idealist philosopher Josiah Royce. His academic career was also at Harvard, where he was a professor of philosophy. But he became progressively more estranged from American life and, once he could afford to do so in 1912, he left the United States and migrated to Europe. In 1924 he settled in Rome, where he remained for the rest of his life, dying there on September 26, 1952.

Santayana is best remembered for two works: *The Life of Reason* (five volumes, 1905–1906), which is deeply imbued with the ideals of the naturalism and humanism of ancient Greece, and his novel *The Last Puritan* (1936), a study of New England attitudes and values. Other important books he wrote include *Skepticism and Animal Faith* (1923), wherein he revised some of the ideas expressed in *The Life of Reason* and refined others. During World War I, he expressed support for critical realism, contributing to an important collective work called *Essays in Critical Realism* (1920). A feature of Santayana's work is his extraordinary fluency with prose writing. He has been described as the finest writer of philosophy since Plato.

Santayana's views on time altered imperceptibly as he got older. In *The Life of Reason,* he articulated a meliorist view of progress, which opened the possibility of things improving, but only with concerted human effort. As he got older he became more conservative in political matters and less sure that even the modest forms of progress he had endorsed as a younger man were either possible or desirable.

During the first half of his philosophical career, until about 1923, he was broadly naturalistic and humanistic. But after that date he felt the need for a more systematic exposition of his naturalism, one that inserted ontological categories he called "essences" into the fabric of nature. These essences had a negative effect on his notions of progress. Athough this second half of his career was more Platonist in style, it was still fundamentally naturalistic. But throughout his philosophical career he eschewed dualism and advocated what he called the Aristotelian principle: All ideals have a natural basis but all natural processes are capable of ideal fulfillment. By reason, Santayana simply meant a higher-order impulse.

Although he was an atheist and materialist, Santayana could see good in religion, when understood properly. He saw little value in literal belief and supernaturalism, but as a way of memorializing and celebrating what matters in life, religion was of inestimable value, he believed. Santayana's legacy is mixed. Ironically, it is in the United States, the country he felt least at home in, where he is best remembered and exerts the greatest influence, particularly among aestheticians and proponents of American philosophical naturalism.

Satan and Time

The term *Satan* (Hebrew: ןָטָשׂ, Greek: Σατανάς, Aramaic: אנטס, Arabic: ناطيش) comes from the Abrahamic religions Judaism, Christianity, and Islam, those derived from Semitic origins and traced back to the patriarch Abraham. Satan is often represented as an angel, minor god, or the Devil himself. Modern Christianity commonly conflates Satan with Lucifer and Beelzebub, among other malicious beings. In these traditions, Satan represents a force of evil within humanity.

Satan is a figure often designated by an assortment of aliases and roles. He has been called, variously, the Prince of Darkness, the Devil, the Accuser, the Prince of Hell, the Evil One, the Tempter, the Wicked One, Old Nick, Old Harry, the Dragon, the Fallen One, and Mr. Scratch and has been identified as the Ruler of Hell, Hades, the Lake of Fire, the Inferno, Styx, the Everlasting Fire, and the Realm of Pluto. These roles and names reflect the incorporation of demonic figures from several ancient religious and belief systems.

Islam's main devil figure, or Shaitan (Satan is the English equivalent), is Ibis, who was created out of smokeless fire by Allah (God). After the creation of humankind, Ibis was expelled from the graces of God to Jahannam, or hell, due to his self-pride and jealousy. In response to his pleading, Allah granted him the right to roam Earth, as the ruler of all jinns and tempter of humankind, to the end of his days. It was he who tricked Adam and Hawwa (Eve) into eating the forbidden fruit, but they repented and God removed their misdeed. Allah, after granting forgiveness, then warned them of the trickery of Ibis and the hell fires that await those who fall to the deceptions of the Devil. Unlike within modern Christianity and Zoroastrianism, Ibis is merely the servant of God, who is the supreme ruler and savior of all.

Within Zoroastrianism the figure Angra Mainyu, or Ahriman, is the opponent of the sole god figure, Ahura Mazda. According to Zurvanite Zoroastrianism, Ahriman, and Ahura Mazda were twins created by Zurvan (time). Today the Parsis of India hold that Mainyu is the "destructive product" of Mahura, and instead of battling Mahura himself, Mainyu battles the creative product Spenta Mainyu.

The Bahá'í Faith refers to Satan as a metaphor for the "insistent self" or the self-serving desire of humanity. Bahá'u'lláh wrote of the insistent self being the "evil one," the symbol of which is Satan. They hold that evil is simply the absence of goodness, making the existence of evil powers impossible. Consequently Satan is not evil personified in the world, but the evil ego and lower self of all of humanity.

Within the Hebrew Bible the prosecuting angel *Ha-satan,* the accuser, is the closest reference to Satan. Ha-satan is the one who questions man's loyalty and plagues Job with disease to test his faith. The Hebrew Aprocrypha also holds references to a Satanic-like figure being tossed from heaven.

It is this story of a rebellious angel being tossed from heaven which composes the mainstream understanding of Satan in Christianity. Satan's original name is said to have ended in *-el* like the great angels Michael, Raphael, and Gabriel. Having become consumed by pride, Satan challenged God for supremacy of heaven. God then cast him and other rebellious angels out of heaven. Due to his former stature, Satan became ruler of all Devils and disobedient souls. Christianity additionally regards Satan as the serpent in the Garden of Eden, the tempter of Christ, and the Dragon in the Book of Revelations. The common belief is that at the Apocalypse, Satan will wage a final war against Jesus, whereupon he will be defeated and banished into the Lake of Fire alongside all sinners. The Unification Church, however, believes that Satan will be returned to his former angelic form.

The Devil is supposed to be capable of taking any form to carry out his deceptions. As Martin Luther mentioned in *Table Talk,* the Devil holds two forms. He may appear as either a serpent (to scare us) or a lamb (to deceive us). Depictions of Satan have varied throughout the centuries. In the Middle Ages the common devil icon is that of a figure with horns, hooves, and a pointed tail. Medieval art depicts a figure with bat wings, a twist on the traditional angelic figure. Kabbalists, however, show him as a former angel with the moon upon his feet, denoting the ability to change. His wings are severed to show his fallen state, a star on his forehead denotes him as the former morning star, and he carries a torch symbolizing him as a destroyer. Some have depicted him in the form of an animal, such as a black dog, goat, or snake. These forms are often riddled with deformity due to his inability to duplicate God's work. Others have even depicted him as a beautiful creature, referring back to his former stature and ability to deceive humanity.

Many minor demons are commonly confused with Satan due to their nature. Lucifer is a leader of the rebellious angels who is expelled from paradise. He is commonly confused with Satan himself:

> "How art thou fallen from Heaven, O Lucifer, son of the morning!" (Isaiah 14:12)
>
> "I beheld Satan as lightning fall from Heaven." (Luke 10:18)

The demon Beliel or Beliar, commonly referred to as the Prince of Trickery, is another fallen angel. He is confused with Satan due to Saint Paul's decree:

> "What Concord hath Christ with Belial?" (2 Cor. 6:15)

Beelzebub, "the Lord of the Flies," is a former Philistine god. He is one of the chiefs in the nine hierarchies of hell, and is regarded frequently as second in command to Satan. The Evangelists Matthew, Mark, and Luke refer to Beelzebub as the chief of the demons, and in Matthew 12:24 Beelzebub is called the "Prince of Demons"; however, he is not Satan himself. Mephistopheles is a servant of Lucifer who is closely associated with Satan because of his role in the literary works *The Tragical History of Doctor Faustus* by Christopher Marlowe and *Faust* by Johann Wolfgang von Goethe.

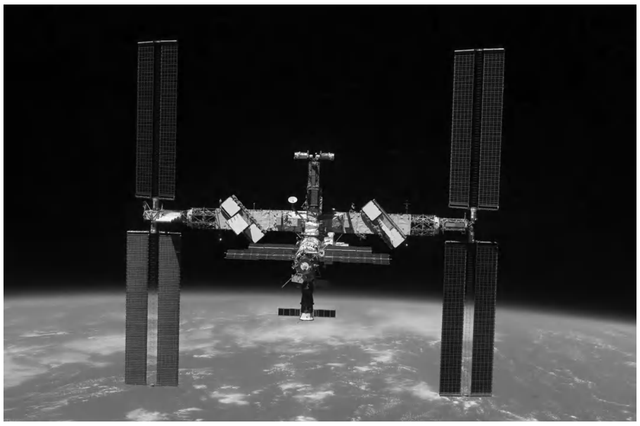
Satellites, Artificial and Natural

A satellite is a small or secondary body that revolves around a larger one in the solar system. There are both natural and artificial satellites, which revolve and rotate at different rates of speed. Consequently, they may be used to measure time on Earth and to determine extraterrestrial occurrences. In the future, time-measuring satellites will be used to aid space travel and to predict cosmic events.

Natural planetary satellites are classified according to either their composition or their type of orbit. Nearly 100 have thus far been observed and identified in our solar system, and a great deal is known about their size, composition, and other physical properties. Our moon is Earth's only natural satellite; some planets have many such objects circling them. Jupiter, for example, has 49 officially named satellites. The rotation of most natural satellites about their respective planets is west to east, the same as the rotation of their planets. Some outer satellites, however, rotate in the opposite direction.

Artificial satellites are human-made objects that typically orbit the Earth, gathering data that are used for a multitude of purposes. There are six main types: (1) scientific research, (2) weather, (3) communications, (4) navigation, (5) Earth observing, and (6) military. Because their design is dictated by their intended use, satellites come in a variety of shapes and sizes. Some artificial satellites also orbit the moon, the sun, asteroids, and the planets Venus, Mars, and Jupiter, gathering information about the bodies they orbit. All artificial satellites are subject to the same physical laws as their natural counterparts. The first artificial satellite, *Sputnik I*, was launched in 1957 by the Soviet Union; today, according to estimates by the National Aeronautics and Space Administration (NASA), more than 8,000 satellites are in orbit. All the major industrialized nations use satellite technology.

Satellite observations provide a unique vantage point from which to study Earth, and they have provided researchers with a critical means for studying the solar system. This is the only way to make in situ measurements of Earth's atmosphere, without having to contend with the affects of the atmosphere. Previously, such measurements could only be made on the ground or on ships or airplanes.



The International Space Station (ISS), the largest human-made object ever to orbit Earth, is shown here after separation from Space Shuttle Atlantis*, June 19, 2007.*

Source: NASA.

Most satellites are launched from rockets at fixed sites; in the United States many are launched from Cape Canaveral, Florida. Such sites provide logistical support for the assembly, check-out, and launching of satellites, and these sites possess the technology necessary to support these activities, including radar, optical tracking equipment, and meteorological equipment.

The launching of a satellite is achieved by propelling the object at a high velocity that allows enough energy to be imparted so that the object can remain in orbit without the need for additional energy. Orbits exist in a variety of shapes, from circular to highly elliptical and from high altitude to low altitude. A higher-altitude orbit leads to longer orbital periods (i.e., time required to complete one orbit). Satellites with a low-altitude orbit, on the other hand, orbit more quickly but are more likely to decay and enter Earth's atmosphere sooner than those orbiting at a higher altitude.

Artificial satellites are powered by solar cells, by batteries that often are charged by solar cells, and in many cases by nuclear reactors, or by generators in which heat produced by the decay of radioisotopes is converted into electricity.

Scheler, Max (1874–1928)

Max Scheler was among the most prominent and widely discussed philosophers of the

German-speaking world in the early decades of the 20th century. Though Scheler did not explicitly outline a specific philosophy of time, the concept of "timelines" of life and being is important for his phenomenological and anthropological work and needs to be understood in the context of the general development of his thinking.

The Life

Born within a predominantly Jewish family background (his mother was orthodox Jewish, his father had converted from Protestantism to Judaism), Max Scheler developed an interest in Catholicism in his youth in Munich and formally became a member of the Catholic Church in 1899 at the age of 25.

After briefly studying medicine and psychology at the universities of Munich and Berlin, where he also studied under Wilhelm Dilthey and Georg Simmel, he changed to philosophy, which he continued to study in Jena. At the University of Jena he studied mainly under the philosopher and Nobel Prize winner (for literature) Rudolf Eucken (father of the later influential economist Walter Eucken). There Scheler also finished his Ph.D. and taught from 1900 to 1906. During that time he met Edmund Husserl and came in contact with the philosophical thought of the phenomenological circles, to which he became more closely connected after 1907 in Munich, where he had moved after a private crisis that forced him to leave the University of Jena in 1906. From 1907 to 1910 Scheler taught in Munich and was in close contact with phenomenological thinkers Alexander Pfaender, Dietrich von Hildebrand, Theodor Lipps, and others. After Scheler lost his position in Munich, he gave private lectures in Göttingen, where Edith Stein was among his students, and worked later for the German government. During that time Scheler published some of his major works, including *Phenomenology and Theory of Sympathy* and *Formalism in Ethics and Nonformal Ethics of Values*. Defending a value ethic and a view on humankind as characteristically related to a theistic-understood God (and creator), Scheler became one of the most influential Catholic intellectuals. After World War I the mayor of Cologne, Konrad Adenauer, later chancellor of Germany, was involved in Scheler's appointment as professor of philosophy and sociology at the refounded University of Cologne, where he taught beginning in 1919. In that time a major shift took place in Scheler's thinking; he turned from the Christian and Catholic tradition, denied the concept of a personal creator-god, and developed the idea of a god in the process of becoming, for which humankind is crucial (highly important for that concept is his famous *Man's Place in the Universe,* in which Scheler outlines his late anthropology). In 1928 he accepted a new position in Frankfurt but died early in that year. His work was actively suppressed under the Nazi regime, but in the postwar period it underwent a revival and has been translated into many languages.

The Work

Scheler did not explicitly outline a specific theory of time in his oeuvre, so that his comprehension of time needs to be understood in the context of the general development of his thinking. Despite the discontinuities in his thinking, Scheler emphasizes that the understanding of anthropology is the steady center of his interest and his philosophy. In his first important period he holds a specific phenomenological view, which leads him to an understanding of man as primarily an *ens amans,* a loving being, characterized by his *ordo amoris,* or order of love, that directs him to the sphere of values. This core dimension of human existence follows his own—intelligible—"logic of the heart." Prior to all other forms of cognition is the perception of value in a specific act of feeling (*wertnehmen*). Scheler distinguishes five strictly hierarchical ranks of values: (1) an absolute sphere of holiness; (2) a sphere of values of person, culture; (3) ethics, vital values; (4) values of utility; and (5)values of sensual pleasure. His ethical concept is based on the ethical good being realized by a creative process of intending the realization of higher values as preferred to values of the lower spheres, whereas evil results from a "disorder of preferences," mistaking lower values for the sphere of the absolute. In its leaning and orientation to the realization of value, human life is a *werde-sein* ("being in becoming") and the experience of time is primarily the medium of a process of becoming, developing, and growing. In his later period Scheler embedded his concept in the idea of a great "drama," in which a value-connected but originally powerless spirit forms and directs the vital *Drang* (urge, impulsion), both being original aspects of the ground of being. This process of *Durchdringung* (penetration) of spirit and vital *Drang* is the evolution of a yet unfinished, "becoming deity," which can be observed in the spiritual development of humanity.

In this context of his late philosophy, Scheler speaks of "absolute time" as the origin of the phenomenon of timeliness, which is given with this evolutionary character of being as a cosmic "becoming." The concept of absolute time results from this evolutive constitution of being (as *werdesein*) as a "space" for the process of development. Measurable, objective time, the "clock-time" of our day-to-day understanding, derives from the experienced phenomenon of "absolute time" by an act of extending the tendency to self-alteration and resistance against it to a general concept of reality.

Schelling, Friedrich W. J. von (1775–1854)

Friedrich Wilhelm Joseph von Schelling was born on January 27, 1775, in Leonberg, Württemberg, Germany. He was perhaps the most important German idealist philosopher who lived after the time of Immanuel Kant and before G. W. F. Hegel. With them, he shared the principle of idealism, namely, that the essence of an object is the objectified essence of a subject.

In his *System of Transcendental Idealism* (1800), Schelling began by adopting the seminal notion of time as the intuition of inner sense, developed by Kant, but developed it into the doctrine that "the self itself is time conceived of in activity." In his metaphysics, Schelling identified "being" with "process," that is to say, to be is to produce. The self is the process that produces itself; that is, the self is simply the activity of producing its own world. This process is itself time and space, as they are nothing other than the process which creates them. The self begins unaware that it produces the world and only gradually becomes conscious of the fact.

Greatly influenced by Kant's late notion of "force" in *Metaphysics of the Natural Sciences,* Schelling developed an idealism that took into account the natural sciences. The resemblance between the theories of Schelling and Roger Joseph Boscovich is due to the fact that Kant largely adapted Boscovich's concept of force in *Metaphysics of the Natural Sciences.*

Schelling wrote in the verbose and dense terminology of the German idealists. He constructed a "system of transcendental idealism" in considerable detail, which cannot be entered into in this entry.

In *On the History of Modern Philosophy,* Schelling criticized his immediate forerunner in German idealism, Johann Gottlieb Fichte. Schelling had studied at the prestigious University of Jena, becoming close friends with the well-established and famous Fichte, who had already developed a subjective idealism of the ego. Schelling began as a follower of Fichte but moved on through a series of developmental stages. Beyond Fichte's subjective idealism, Schelling found his way to his own philosophy of nature and his own philosophy of identity. Another student at Jena and a close friend of Schelling, Georg Wilhelm Friedrich Hegel, was also an idealist in the manner of Kant, but Hegel eventually succeeded in surpassing Fichte and Schelling in logic and much else. Though his junior, Hegel seemed to mentor Schelling. In his *Lectures on the History of Philosophy* (Vol. 3), Hegel criticized, but also praised, Schelling. Still another Jena student, Arthur Schopenhauer, became an immediate lifelong opponent to Schelling, however. Much later, the University of Berlin gave Schelling a teaching appointment as a sort of counterbalance to the Young Hegelian movement there. Yet, Schelling's star never shone as bright as Hegel's, although Schelling had followers in Schleiermacher, Schlegel, and others.

Problem of Idealism

As was true of the idealists generally, philosophy was defined by Schelling as the history of self-consciousness. Schelling chose to divide this history into epochs. The first epoch is one from original sensation to productive intuition. The second epoch runs the course from productive intuition to reflection.

As his problem, Schelling took to explain how the self comes to intuit itself as productive. His "Solution III" in the *System of Transcendental Idealism* was derived from the nature of space and time. One cannot say of the self that it exists, it begins, precisely because it is being-itself.

Schelling continued by defining the self as the "eternal, timeless act of self-consciousness . . . which gives all things existence, and so itself needs no other being to support it."

The self bears and supports itself, instead. Viewed objectively, the self is "eternal becoming." And viewed subjectively, the self is a "producing without limit." One implication of this is that the self produces infinite time from itself.

Schelling observed that consciousness of an objective world is implied in every moment of consciousness. He concluded that something objective must already enter into the synthesis of self-consciousness from the beginning, meaning a stream of intuitions which comes, presumably, from outside the self.

This same stream of intuition must emerge as the developed form of the object, meaning that the intuitions issue forth as objects in a world of time and space. Indeed, time and space themselves come from a development of the intuition. But, Schelling asks, how does the philosopher know this second, constructive stream to be identical with the original, absolutely free one? When intuitions are structured into a world, in other words, how do they compare to the original sensations? For Schelling, this was the central problem of idealism. To do so involved him in problems about time and space.

Time and Process

Schelling rephrased, and attempted to solve, the problem of idealism in terms of time. If it is through self-consciousness that all limitation, and thus all time, originates, then this original act cannot itself occur in time. This is a problem stemming from Kant's metaphysics; the transcendental structures cannot be described as having any of the a priori categories, because they *are* those categories.

And so the structures cannot be spoken of in terms of "temporal sequence," and so on. The transcendental ego is, therefore, entirely outside time and space, Schelling argued. One can no more say that the transcendental ego has begun to exist, than that it has existed for all time.

The self as such is eternal, meaning outside time altogether. "The self, once transposed into time, consists in a steady passage from one presentation to the next; yet it remains, after all, within its power to interrupt this series by reflection. The absolute interruption of the succession is the beginning of all philosophizing. . . . Nothing else can arise for me save what comes about for me originally and beyond all time."

Retreating to a more comprehensible Kantian formula, Schelling founded his solution to the problem of idealism by claiming that "time is merely inner sense becoming an object to itself."

This "becoming an object" occurs when an awareness of inner and outer worlds arises, that is, when the self experiences what it considers to be an inner world while at the same time experiencing a world it considers to be outside itself.

Time is the inner intuition, whereas space is the outer intuition. Thus space and time arise from limiting each other. Again, as the self becomes aware of itself as such, a dual experience of the inner and outer objects arises.

The self is none other than the process of producing a time and space. "Time is not something that flows independently of the self," concluded Schelling, "the *self itself* is time conceived of in activity."

An object is nothing else but "fixated, merely present, time," and yet time is fixed simply and solely by the space occupied. Substance and accident, however, are attributed to the object. The philosophical observer sees that space and time may be distinguished in the self, and substance and accident in the object.

History as Sacred Time

Schelling's notion of history owes much to Fichte but also to Johann Gottfried von Herder. Even before the appearance of Kant, Herder had insisted that history is entirely sacred; there is no secular history and no secular time. History is not a pointless, merely human parade of events. Rather, history is the evident Divine Plan unfolding through human agency. Fichte had echoed these sentiments of Herder, and Schelling's philosophy of history further resonated with those tones.

Time as a Point

A fundamental problem remained, though. *How* does the self become an object to itself as inner sense? Ultimately, Schelling explained that the self becomes aware first of the space before it and, in reaction, comprehends its inner space, which is not the outer. At this point in his argument, Schelling insisted on distinguishing time as it is "already externally intuited" from time as a "mere point, a mere limit."

This latter notion is a moment in which the self knows itself as "*pure intensity,* as activity which can extend itself only in one dimension, but is at present concentrated at a single point; but in fact this uni-dimensionally extensible activity, when it becomes an object to itself, is time."

Aside from the rather circular form of his thinking here, Schelling has taken time to be a point and taken a line to be an extended point, whatever that may be. (He perhaps means, rather, that a line is a point in motion.) But unfortunately the entire use of geometry explained the obscure by the still more obscure. Or Schelling may be taken to merely *assume* that time is one-dimensional and unidirectional, though both seem suspect.

For Schelling, in this one dimension of time, the intensity of the self is infinite, pure intensity; that is, the self would produce infinite time out of itself if it were not constrained by space.

Time and Causality

Consider the simplest possible model of time, a succession of events A and B, in which the observer takes A to be prior to B and the cause of B. Because the observer judges the relation to be temporal, the observer takes it to lie in the objects themselves and not just in the observer's subjective locus of consciousness. That the succession is considered "objective," means, for Schelling, that "its ground lies, not in my free and conscious thinking, but in my unconscious act of producing. That the ground of this succession does not lie in us means that we are not conscious of this succession before it takes place; its occurrence and the awareness thereof are one and the same." Schelling took the succession, as well as the objects A and B, to be "independent" of our representations but also "absolutely inseparable" from them. More understandably perhaps, the observer's rational intuitions identically correspond with the events in things.

Evaluation and Influence

Schelling's works present a Gordian knot of logical flaws, including several concerning time. Most fundamentally, Schelling had committed the fallacy of circular argument. "If we begin with intellectual intuition," reasoned Hegel, "that constitutes an oracle to which we have to give way, since the existence of intellectual intuition was made our postulate." Instead, Hegel felt the point of idealism was to prove that intellectual intuition exists, not merely presume it: "It must be shown that the subjective signifies the transformation of itself into the objective, and that the objective signifies its not remaining such, but making itself subjective." Thus Schelling's advance was hardly one of logic, but rather in moving from Fichte's subjective idealism to a sort of objective idealism, the idealism of nature. Hegel took Schelling to have begun at the same point as Fichte, but without any dialectic to move from object to subject, and back again. As a corrective, Hegel developed his own system of absolute idealism, building on the advances of Schelling over Fichte.

Schopenhauer, Arthur (1788–1860)

Arthur Schopenhauer has been eclipsed in the history of philosophy by "the three evil geniuses of the nineteenth century," as Albert Camus called G. W. F. Hegel, Karl Marx, and Friedrich Nietzsche. Schopenhauer is rarely studied as an independent figure: The usual treatment is to consider him as an antipode to Hegel or as a precursor of Nietzsche, or as a Kantian (all three of which are partial truths). This oversight is far less common in Germany, where Schopenhauer is regarded not only as worthy of independent study but also as one of the nation's greatest philosophers; during the postwar period in Germany, he was widely held to be a greater thinker than Nietzsche.

Schopenhauer was born in Danzig on February 22, 1788, to Heinrich F. Schopenhauer, a wealthy merchant, and his wife Johanna, an exceptionally well-educated and renowned novelist. Schopenhauer studied medicine at the University of Göttingen, where he became acquainted with the writings of Plato and notably Kant, two authors who powerfully influenced his own ideas. Schopenhauer first became a philosopher in Göttingen, but in 1811 he left there for the University of Berlin, the newly founded hub of philosophy for the entire nation. He attended lectures by Johann Fichte and theologian Friedrich Schleiermacher. Schopenhauer was impressed by neither, and the former became one of his most frequent objects of attack. In his eyes, Hegel was a "clumsy charlatan," Fichte a "sophist" of "chicanery and nothing else . . . humbug"; they existed miserably among many unnamed "Hegelians and other ignoramuses."

When Napoleon's troops shut down the University of Berlin in 1812, Schopenhauer withdrew to Rudolstadt (in Thüringia) and independently wrote his thesis, *On the Fourfold Root of the Principle of Sufficient Reason* (published in 1813), which earned him a degree from the University of Jena. His idea of time may be found in its earliest formulation in his thesis. During this period, he also met Wolfgang von Goethe and conversed with that polymath concerning Goethe's recently published theory of color and vision. While in Weimar and its vicinity, he also met the Orientalist F. Mayer, who alerted him to the philosophy of ancient India. Schopenhauer found a Latin translation of the *Upanishads* soon afterward. Schopenhauer left the area around Weimar for Dresden, where he lived for 4 years. In Dresden he studied Indian philosophy and wrote the first version of his most famous work, *The World as Will and Representation,* which was published the next year. In this grand production, Schopenhauer's erudition encompassed Hinduism, Buddhism, the Roman and Greek classics, and much more, also reflecting a long-running interest in natural science.

When the cholera epidemic of 1831 swept through Berlin, killing Hegel among many others, Schopenhauer left for the university town of Frankfurtam Main, where he lived for 28 years (living 1 year, 1832–1833, in Mannheim) with his wife, Caroline Medon, the operatic singer, until his death.

While in Frankfurtam main, Schopenhauer published two books: *On the Will in Nature* (1835) and *Essays and Aphorisms* (1852). He also published two essays, one of which had won a prize from the scientific Society of Drontheim in Norway, as *Two Fundamental Problems of Ethics* (1841). But most importantly, he added 50 new chapters (Part II) to *The World as Will and Representation,* for a second edition, finishing that work as it is known today. His mature ideas on time may be found in Volume I, Chapter 4 and Volume II, Chapter 4 of his magnum opus. By 1853 the fame of the philosopher was ensured, when an anonymous article on him, titled "Iconoclasm in German Philosophy," appeared in the *Westminster and Foreign Quarterly Review.* But he lived to enjoy it for only 7 more years, dying in 1860.

Schopenhauer's General Orientation Toward Time

Schopenhauer came from the Kantian tradition, which interpreted time as the inner form of intuition (space being the outer form). These forms structure the "phenomenal world"; our experience of time and space comes from these transcendental ideal structures, along with a stream of sensations. Schopenhauer accepted Kant's theory of forms of intuition but took them to be under the control of the Will; or more precisely, the forms of intuition were developed for the purposes of the Will (to make sensations comprehensible). Schopenhauer accepted Kant's "thing in itself," too, but he identified it with the Will behind the transcendental idealist structures. Schopenhauer's thing in itself creates a world of representations for itself. The thing in itself, the Will, does so by a schema of structures transcendental to space, time, and matter: the a priori categories, forms of intuition, faculties of pure reason, practical reason, and judgment, and the faculty of representation or imagination (*Vorstellung*). The world perceived as an independent entity is an illusion that Schopenhauer identified with the *maya,* the "veil of deception," of the Vedic philosophies of India; the world only appears as an object independent of one's own rational processes.

Indeed, Schopenhauer was more at home with the Brahmins, ancient Greeks, and Romans than with his contemporaries, with the exception of the scientists, as he was well-read in science. As a product of his milieu, too, Schopenhauer inherited transcendental idealism from his fellow German Immanuel Kant, but without choosing the path of the many Hegelians around him. For him, the transcendental ideal structures connect the individual locus of consciousness with a universal Will identical to that of Divine Cosmic Will in the Hindu and Buddhist religions. And so, for Schopenhauer, these transcendental structures took on a deeply moral and religious significance that they did not enjoy in science. Time, space, and the whole material world are illusions that serve the purposes of the cosmic Will, he believed, though to the subjective locus of consciousness they seem entirely external and objective. Sooner would Schopenhauer believe in Shiva, the dancing god of destruction, than the rational unfolding of Hegel's Absolute Idea or the Christian God of love.

Schopenhauer's tenets, taken together, provide a clear and distinct image of a world created through rational processes in the intellect, given immediate sensation. Where time and space meet is in the object. Material objects are those interstices between space and time. Thus the material world, composed of countless objects, is all a construction of the cosmic Will within the individual. Time, space, and the entire material universe are subjective representations that the intellect constructs to understand its own sensations. Time does not exist in and of itself; it exists only as the internal form of one's rational intuitions. And more so, the rational sense of "time" does not apply to the Will in and of itself; questions as to its beginning or end, or lack thereof, simply make no sense.

This becomes a spiritual notion because the only liberation from suffering is through a realization that the intellect creates the world. Schopenhauer combined ancient Sanskrit wisdom with the German idealist principle that the essence of an object is the objectified essence of the subject. The essence of any object is the self, the subject, which projects itself onto the world and creates representations that are objectifications of its own inner workings. Thus it is not truly an object but the objectified essence of the subject.

When the individual ego finds its way to the transcendental ego, through the transcendental deduction, it experiences a transindividual rational process, which Kant identified as science, but which Schopenhauer identified as a largely irrational force, the Will. It is this realization that Hindus express as *tat tvam asi.*

As a creature of the intellect, time is merely a representation of sensations that cannot be interpreted otherwise. The Will-in-and-of-itself is not susceptible to the a priori categories of quantity, quality, relation, or modality. It lies beyond the distinctions between and within these categories.

Thus the cosmic Will can be known only immediately, directly as swirling chaotic sensation.

Time and the Principle of Sufficient Reason

Schopenhauer will forever enjoy an important place in the philosophy of time. He held these main tenets about time: (a) Time is a representation of a cosmic Will at work in the world. (b) Time and space intersect through matter, and matter is the perceptibility of time and space. (c) Time is the inner form of intuition. (d) Time is only the principle of sufficient reason. (e) Succession is the form of the principle of sufficient reason in time.

The "principle of sufficient reason" may also be referred to as the "law of causality": For every effect, there is a cause or causes sufficient for its actualization. The cause must precede the effect in time. Schopenhauer stipulated that causality occurs between states, not things. "It is not one thing which is the cause of another thing," he wrote, "but one state which is the cause of another state." This principle is the basis of the understanding, or more precisely, it is the understanding itself. The principle has a "four-fold root," for it is expressed equally well in knowing, being, willing, and judging. But relations of time are peculiar to willing and judgment.

Time is "the simple schema of all the other forms of the principle of sufficient reason, and this schema contains only what is essential; indeed time is the prototype of all finiteness."But Schopenhauer qualified this by noting that the relation of time has no meaning in the faculty of knowing ("before" and "after" make no sense to knowledge). Time is meaningful to the faculty of reason, instead. Nor does the relation of time find any place in geometry or arithmetic, because neither simultaneity nor succession applies to numbers (their being is determined by the "identity of indiscernibles" alone). At the root of being, time and space are representations that are sensuously perceived as matter. Time and space are pure intuitions and matter is the perceptibility of time and space. Schopenhauer alternately defined time in this regard, as "causality that has become objective," because we take these material bodies to be real objects. Matter is whatever cannot be reduced to subjective form; it is the "material from without," from "organs of sense."

Understanding and Empirical Reality

The function of the understanding alone constitutes the foundations of empirical reality. Empirical reality arises from the union of time and space. Time alone cannot represent coexistence, and so space is needed in addition. And space alone cannot allow for change, for there is alteration or change only in time. Thus Schopenhauer defined time in this regard as "the possibility of opposite conditions in the same thing."

The law of causality is "a mere form of understanding" by which the material world is constructed. In the understanding, space and time are so thoroughly mutually related that every part of one is conditioned by another part. Thus the understanding cannot grasp this complex as a whole, and space and time must be known by pure intuition a priori.

Time exists infinitely in the past, since a first cause is as incomprehensible as the limiting points of space. The law of causality concerns itself exclusively with changes. Each and every change is an effect.

Schopenhauer regarded change as taking place in time; like Aristotle, he argued that no change occurs instantly (as Plato had entertained in *Parmenides*). All change requires a certain time. Between any two points on a line, there is infinite divisibility and thus no immediate contact between points. A line may be constructed between any two points, but a certain space will always lie in between. Two indivisible things, such as geometric points, cannot be contiguous with each other. (To the extent that the imagination represents two curved boundaries touching, it represents the zero-dimensional point-three dimensionally.) Now the same principles hold in time. To the extent that we imagine time as a line, each point would correspond to a discrete "now." Yet these nows are not contiguous, and an infinitely divisible certain distance exists between them. As a change occurs over a range of these points, an infinitely divisible amount of time becomes the time of a change. Changes thus come about infinitely gradually and not instantly. Further, every entity coming into existence is made of an infinite number of parts, as Aristotle had deduced. As these parts change, time is required, which arrives gradually, and not instantly. Just as a line is not composed of indivisible discrete points, time is not composed of a succession of instantaneous nows. (This was the solution Aristotle had proposed in the face of Zeno's paradoxes.) What we must assume are two states, one the cause and prior in time, the other the effect, which gradually changes into the other. This chain of causality has no beginning or end, and is, in Schopenhauer's terminology, the "root of becoming."

Conclusion

Arthur Schopenhauer will forever enjoy a unique place in the history of the philosophy of time. It was obvious to him that a Will exists within and without each individual human being. This cosmic Will is universal, immanent, transcendental, and absolute; it is prior to all the qualities contained in the a priori categories. The Will within each human being is imperceptibly intertwined in a collective consciousness, or more precisely, the Will in and of itself is neither one nor many. And likewise the Will has neither spatial nor temporal attributes. The Will only creates representations of time internally and those of space externally. Schopenhauer always insisted that our intuitions are already rational; that is, we cannot know the ultimate nature or origin of those sensations. Time is the internal intuition of the self and world, whereas space is the external intuition of the world. Time and space intersect as material bodies. These are mere representations by the Will for itself, a process of reflection that creates its own subjective locus of consciousness. The Will operates to fashion a world out of time, space, and matter in order to understand its own stream of sensations. The world, therefore, is this foundational Will and its representations of time, space, and matter.

Schopenhauer and Kant

Arthur Schopenhauer (1788–1860) was, at the turn of the 20th century, the most widely read philosopher in Europe. He exerted an influence on art, literature and psychoanalysis, and philosophy, especially with regard to Friedrich Nietzsche's and Henri Bergson's ideas of time. Even if he claimed to follow Immanuel Kant in his theory of time and space as being a priori forms of perception, there are also other lines in his thought on time that led to significant differences.

In his thesis *On the Fourfold Root of the Principle of Sufficient Reason*, Schopenhauer refers to Kant's transcendental idealism when he presents time and space as the class of objects that is ruled by the principle of sufficient reason. Time and space are the formal parts of representations. Whereas space is the form of outer sense, time is the form of inner sense. Neither can be perceived on its own; instead they are conditions of the possibility of perception which precede experience and are thus called a priori forms. So far, Schopenhauer's considerations agree with Kant's transcendental aesthetics. But during the preparation of his main work, *The World as Will and Representation,* he deviates from Kant's conception.

According to Kant, perception is completed by sensation as the matter of representation. Form and matter constitute human sensuality, which is the receptive part of our faculty of cognition. With regard to time this means that we perceive any impressions on our senses in time. Time itself, however, is merely a subjective condition and not a quality of things in themselves. Kant makes a sharp distinction between sensuality and intellect, which is the spontaneous part of the faculty of cognition. Therefore something must be given to the receptivity on which the intellect can act and complete the sense perception to an object of experience.

Schopenhauer refuses this distinction and combines sensuality and intellect to yield "intellectual perception": A complete representation, even an object of experience, is created by the intellect whose function is to connect time and space. Matter consists in this connection and is identical with causality. Nothing is presupposed that is given to the subject from outside, and the whole "world as representation" seems to be totally subjective, a "dream" or an illusion created by the "veil of Maya." But these considerations, which are based on Kant, stem from an abstraction in Schopenhauer's eyes; they have to be complemented by consideration of the "world as Will." According to Schopenhauer, Will is the thing in itself outside of time, space, and causality. Taking the concept of a thing-in-itself from Kant, Schopenhauer emphasizes that Will is subjective and is the one essence that objectifies itself in terms of time and space as a manifold of appearances; in that sense, time and space are the "principle of individuation." With this metaphysical assumption the fact corresponds that the function of the intellect in creating the world of representation as subject to the principle of ground depends on Will: The intellect is serving the Will supplying it with motives; if it does not, tormenting boredom arises. Already in the dissertation Schopenhauer had called time the "prototype" of all forms of the principle of sufficient reason because it has only one dimension and one direction: Every moment is caused by a previous moment. In his main work he writes that the principle of sufficient reason is "the most general form pertaining to all objects of cognizance that stands in the service of Will." By connecting time and space, the intellect places the present into a net of structurally defined moments that constitute past and future. With this, the present, which is the only true reality of existence, becomes the unextended and insubstantial boundary between past and future, immediately annihilated by the following moment. Thus temporality originates, which is the reason for pain, as any satisfaction of Will is always vanishing and making way for new desires, while having death in prospect. Temporality has an existential and ethical significance, for it is dependent on Will and there is a possibility for the intellect to resign from its service to Will. In such cases the present is viewed as eternal existence of the thing in itself (the idea) because it is realized that the difference between present, past, and future merely belongs to the form of perception. Eternity in that sense does not mean infinite time but that which is beyond time at all.

A concern with the ethical meaning of temporality can be traced back to the earliest manuscripts of Schopenhauer. Under the influence of his Pietist education and taking up Platonic and mystical elements he had developed the idea of "temporal" and "better consciousness." According to this thought, temporal or empirical consciousness is characterized by the fear of death and the striving for pleasure in order to make the most of whatever time remains. It causes pain not only because its striving is in vain in the face of the transitoriness of life but also because it tries to shift pain onto others and thus becomes morally bad. By contrast better or eternal consciousness has been relieved from all that through religious and moral conduct as well as through aesthetic contemplation. Later on Schopenhauer connects this idea with transcendental idealism, the doctrine that objects of experience are dependent on the subjective forms of perception and understanding and with the metaphysics of Will. Unlike Kant, for whom these subjective forms simply belong to the nature of human mind, in Schopenhauer they again have a condition in the will to live. Whereas temporality stands for the will to live and its correlate, the world as representation, the release from it now is formulated as denial of Will.

Transcendentalism remains basic, however, for Schopenhauer's theory of cognition: Even the philosophical cognizance of Will as thing-in-itself is dependent on time for we cannot grasp it immediately; we can only perceive singular acts of Will and interpret them as expressions of the timeless essence. Self-cognizance is therefore tied to the inference from bodily actions, which are the developed and elaborated appearance in time of a universal extratemporal act of Will. Using Kantian terms, Schopenhauer calls the latter "intelligible character" while the sum of the bodily actions make the "empirical character" of an individual.

In its maturity, Schopenhauer's thought on time emphasizes time's circularity and the insignificance of history, which is nothing but the return of the same in different modes. The crucial significance of temporality, which Schopenhauer identifies, by explicit reference to Christian tradition, with worldliness involves further conceptions, like that of temporal and eternal justice and a number of psychological considerations that anticipate modern thinking in several respects.

Scopes "Monkey Trial" of 1925

The epic "Monkey Trial" (*Scopes v. State*, 152 Tenn. 424, 278 S.W. 57 [Tenn. 1925]) pitted high school science teacher John Scopes and the American Civil Liberties Union (ACLU) against the Butler Act, a 1925 ruling that made it illegal to teach evolution in Tennessee schools. The resultant court battle received widespread public attention, in part, for the theatrical grandstanding of its participants, though today the trial is remembered for its impact on our understanding of human rights and development.

John Scopes's actual role in the "Monkey Trial" seems one of test subject more than actual defendant. The ACLU had sought out an educator to front its contesting of the Butler Act, which prohibited the teaching in Tennessee's public schools of ideas (including evolution) that disputed the Bible; Scopes answered the call. In actuality, there are questions as to whether or not Scopes truly taught evolutionary theory at the time. This aside, Scopes, defended by the ACLU, was charged with violating the Butler Act and quickly thrown into the circus of accusations and grandstanding worthy of reenactment in films such as *Inherit the Wind* (1960). The trial became a forum for a variety of concerns regarding civil rights of the few and religious beliefs in public education, as debated hotly by one of the prosecuting attorneys, William Jennings Bryan, former U.S. Secretary of State and three-time candidate for president, and prominent defense attorney Clarence Darrow. Ultimately, although Scopes was found guilty of violating the Butler Act, his conviction was overturned due to procedural errors tied to the establishing of Scopes's fine.

Sensational as the trial itself was, little was settled by the verdict although, arguably, its effects continue to reverberate in American culture. The ACLU failed in its effort to have the verdict overturned by the Supreme Court of Tennessee in the hope of refuting the Butler Act and similar pieces of legislation. Other states, Arkansas and Mississippi, subsequently passed laws forbidding the teaching of evolution, though similar bills were rejected by a number of other states. The trial also frightened some educators into avoiding further discussion of evolutionary theory within their classrooms for fear of losing their jobs or worse. Additionally, Scopes's trial stirred up national emotions regarding evolution versus creationism, two viewpoints exacerbated further by divisions within each respective camp and its place in time. The trial brought to light the right of individuals outside the majority to hold to their values and perspectives, scientific or otherwise. It has also been observed that the trial ultimately helped speed public awareness of evolutionary theory and its impact on our understanding of the progression of life on Earth.

Seasons, Change of

The Greek naturalist and mathematician Pythagoras, around 529 BCE, presciently believed the earth to be a sphere and divided it into five zones: two frigid areas, one at each pole; one torrid area at or near the equator; and two temperate areas, located between the equator and either of the poles. In this, Pythagoras was essentially correct. As we now know, with the earth's axis pointing toward Polaris, or the North Star, at a 23.5° angle from the perpendicular of its orbit, the sun's rays strike the earth's surface at various angles during its yearly revolution. The only area of the earth that receives direct rays from the sun is between 23.5° north latitude and 23.5° south latitude, known as the tropics, or the torrid zone. These parallels are known as the Tropic of Cancer and the Tropic of Capricorn, respectively. The march of the sun's direct rays between these two extremes sets up a seasonal variation within the tropics; that is, the rainy season and the dry season. It also tends to define the other climates of the world.

Climate and Geography

According to the Koeppen climate classification, generally torrid or tropical climates include the tropical rainforest, the tropical savanna and the tropical monsoon, all of which have rainy and dry seasons. The rainy season in the tropics tends to follow the sun's direct rays between the tropics of Cancer and Capricorn. The direct rays bring about convection currents in the atmosphere from the heating of the earth's surface, and as the heated air rises it cools. When the air cools sufficiently, condensation occurs and clouds form. Once the clouds become saturated enough with moisture, rain occurs, bringing with it the rainy season. At this time in other parts of the tropics, the dry season occurs; sometimes, depending on location, there are two dry seasons and two wet seasons. However, even during the dry season, varying amounts of rain will fall occasionally during the afternoon. The dry season (or seasons) in the tropics occurs where the sun is not directly striking the earth's surface, resulting in a significant decrease in convection currents and very little, if any, precipitation.

The temperate zones are located in the northern and southern hemispheres and vary with the position or angle of the earth as related to the sun. Thus, when it is winter in the northern hemisphere, it is summer in the southern hemisphere, and vice versa. The transitional seasons between winter and summer are spring and fall. The temperate zones as mirrored as the hemispheres exhibit several temperate climates. Nearer to the tropical zone, the humid subtropical, marine West Coast, and Mediterranean climates occur. The humid subtropical climate tends to have four seasons, with mild winters and hot summers. The marine West Coast climate is cool and rainy most of the year. The Mediterranean climate has a cool, wet winter and a hot, dry summer. Nearer to the polar zone, but only in the northern hemisphere, are the humid continental with a warm summer, the humid continental with a cool summer, and the Subarctic climate. The humid continental climates exhibit the well-known and typical winter, spring, summer, and fall seasons. Winter snows, spring rains, summer breezes and colorful falls dominate the landscape. The subarctic climate, adjacent to the polar tundra, is commonly known as the taiga biome, with stunted conifers that survive a harsh winter and a short growing season. The continental climate types do not appear in the southern hemisphere, where there is more water than land, the underlying reason being that water heats and cools more slowly than land.

Also in the tropical and temperate zones are the dry climates, brought about mostly by the position of the land in relationship to the oceans with cold currents. Here, the prevailing winds are cooled by the adjacent waters, resulting in deserts, or the distance from the oceans tends to produce deserts farther inland. Lastly, some deserts occur on the leeward side of mountain ranges. Among the most prominent deserts in the world are the Kalahari and Sahara in Africa, the Baja and Sonoran in North America, the Patagonian in South America, the Arabian in the Middle East, the Gobi in Asia, and the Great Sandy, among others, in Australia. Arid areas contain deserts as well as steppes, the latter being transitional areas between deserts and more humid areas. The steppes exhibit some precipitation during the warm period, whereas the cold period is very dry.

In the frigid zones, north and south, there are two polar climates: the polar tundra and the polar ice cap. Here, too, there are only two seasons as related to cool and cold, and day and night, respectively. In the winter there are 24 hours of darkness at one pole, while there are 24 hours of daylight at the other pole. Extremely cold weather occurs during the dark winters, with temperatures commonly below 0°F; during the warmest summer month, the average temperature is still below 50°F but above 32°F. Adjacent to the ice caps is the tundra biome, with its mosses and lichens—too cold and dry to support much vegetation.

In addition to the previously described climates and their related seasonal attributes are the highlands and the metropolitan areas of the world. Due to elevation, highlands take on a polar appearance. For example, the ice-capped Kilimanjaro on the equator in Africa and Mauna Loa on the island of Hawai'i show snow and ice year round. But like the glaciers, they are receding as the earth proceeds into another interglacial stage, tending to redefine climates and the seasons. Urban places tend also to modify climates and seasons. Commonly known as urban heat islands, the large cities, at least in the northern hemisphere, tend to be warmer and wetter in the summer and less cold in the winter compared to rural areas worldwide. The intensification of heat among streets and buildings in the city, compared with the adjacent rural areas, brings about this climatic and seasonal modification. How much these heat islands contribute to global warming is not known, although it is believed to have some effect.

Patterns of Seasonal Change

Throughout the world, native peoples tend to follow seasonal change. In the tropics, shifting cultivation or ladang ("slash and burn" cultivation) is practiced, as with each growing season there is a move to another location, usually on a 7-year cycle. The practice of transhumance in mountainous areas is well known, where summers are spent in the high mountain pastures and winters are spent in the valleys below. In the desert areas of the world, the nomadic peoples follow the seasons always seeking better moisture and vegetation. Farmers around the world plant their crops in the spring, cultivate during the summer, harvest in the fall, and hopefully provide a ground cover during the winter. There are many examples of adhering to seasonal changes, including the urbanites. The practice of taking vacations during certain seasons is common. Skiing in the winter, boating in the summer, watching or playing football in autumn, and planting gardens or at least window boxes in the spring are just a few seasonal rituals in which people engage. It is likely that people will respond, although perhaps slowly, to future seasonal changes, as well as changes within seasonal changes. As the earth continues toward a warmer global condition, weather conditions and patterns will tend to be more erratic, and climatic conditions and areas will change. Over time, some species will adjust more easily than will others.

Sedimentation

In geology, sedimentation is the process of deposition of previously eroded and transported material (sediments), and it includes such processes as the separation of the rock particles from the source rock, their transportation to the site of deposition, the settling of the sediments in layers, and the diagenetic processes that occur until the sediment is lithified. The processes involved occur on a geologic timescale that spans millions of years. It was the meticulous and systematic observation of the layers, or strata, of sedimentary rock that enabled 18th- and 19th-century scientists to appreciate the immense age of the planet.

Sediment is any material that settles to the bottom of a fluid. *Sedimentation* describes the motion of particles in suspension or molecules in solutions as a response to an external force, and it takes place when the energy of the transport agent decreases (e.g., when a river reaches the sea). Water plays a major role in sedimentation in most areas, whereas wind is the main parameter in dry sedimentary environments such as deserts. Although sedimentation often takes place in minute reactions and quantities, its effects are magnified by time. Given sufficient time, the material accumulates layer upon layer in sedimentary basins after going through geological, physical, chemical, and biological processes. Sedimentation thus involves the erosion of rocks or minerals from the earth's crust, their transportation, and their recombination as sediments. After sediments are deposited, they are commonly compacted by the weight of overlying sediments, and they are altered or affected by *diagenesis*. Diagenesis is characterized by low pressure and temperature conditions, and it should not be confused with metamorphism. Because many diagenetic processes originate during transportation, the study of sedimentation also must include the analysis of lithification (conversion of loose sediment into sedimentary rocks). Geologic time is important in the study of sedimentary rocks: Although the rocks' properties may appear permanent at any time during the study, they are constantly changing through geologic time.

Mechanisms of Sedimentation

The four key physical aspects of sedimentation are *gravity* (force that acts to attract two masses, in this particular case, pulling a grain into the earth), *shear stress* (component of gravity acting along the surface), *normal stress* (component of gravity acting into the surface), and *friction* (acts parallel, but opposite, to shear stress; the coefficient of friction is a constant for a given surface material). Hydraulic physical properties of the mobile medium determine turbulence and current velocity, which control the composition, size, and shape of the sediments that will be eroded, transported, and settled.

The different minerals that form as weathering products have different characteristic grain sizes that determine the distances to which they are typically transported and the environments in which they are deposited. The size of the particles and the velocity of the fluid are combined in Hjulstöm's curve (Figure 1), which concerns the minimum shear stress to get a grain to move in a flow. This curve shows the mean flow velocity required to initiate movement on a flat, uniform bed, for a flow depth of 1 meter. Flow velocity required to sustain movement is less (Figure 1, lower curve). As a result of transport, there is a sequence of sedimentary rocks that represents the various weathering products of rocks and the distance that they can be transported from their source areas. Whereas coarse products (boulders, gravels) require fast-moving water to be moved, and they are not transported far from their sources, often retaining their source mineralogy and chemistry, intermediate-sized particles such as sands normally consist of quartz grains, which are relatively resistant to chemical weathering processes that affect the particles during their transport by rivers and wind and during their deposition at coasts or in deserts. The fine grains such as silt and clay are transported to off-shore environments and

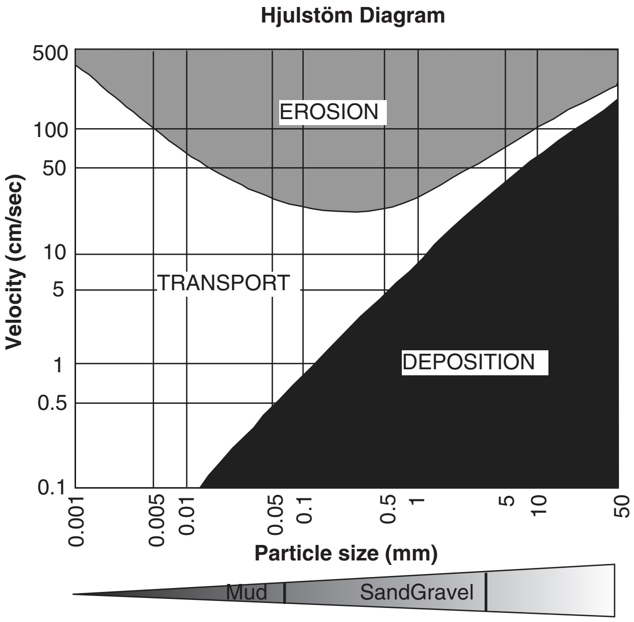

Figure 1 Hjulstöm's curve

Note: The Hjulstöm's curve illustrates the size of the particles and the velocity of the fluid.

consist of clay minerals resulting from weathering of feldspars and ferromagnesian minerals. Finally, the finest material is carried farthest in dissolution and deposited in evaporation areas as evaporites (e.g., calcite, gypsum, halite).

The geochemical aspects of sedimentation include the study of chemical properties of the mobile medium and the sedimentary particles, as well as the reactions that occur between them during sedimentation. Rates of sedimentary chemical reactions are greatly influenced by the temperature of the mobile medium. Biological aspects have an influence on, and are regulated by, chemical parameters, which control the abundance of nutrients or the metabolic functions.

The characteristics of sedimentary deposits depend on the nature of the mobile medium. When the mobile medium is the wind, rivers, or the sea, particles are settled when velocity decreases. When the mobile medium is ice, deposition takes place when the ice sheet reaches its maximum spatial extension or when it finds an obstacle.

There are two types of sedimentation or accumulation of sediments: *clastic* and *nonclastic*. The former consists of sedimentation of solid particles produced by weathering (e.g., formation of sands and sandstones), and it is controlled by physical parameters. Sedimentation takes place when the velocity at which particles settle is greater than the velocity of the mobile medium, and this situation happens when the transportation stops (in the sedimentary basin) or during transportation (selective sedimentation, which is a function of the dynamic conditions). Nonclastic sedimentation depends on chemical properties and corresponds to the deposition of dissolved material such as chemical or biological sediments, which are known as nonclastic sediments (e.g., limestone).

Sedimentary Environments

A different classification of sediments is used in geomorphology, depending on the characteristics of sediments that are deposited in continental or in marine environments. Continental sedimentation (glacial, fluvial, eolic, or lacustrine) originates coarse and angular sediments, and marine sedimentation (littoral, neritic, bathyal, or abyssal) results in finer and more rounded sediments.

The places where the sediments are deposited are called sedimentary environments, and their study provides information on the transport and erosion processes that affected the sediments, as well as on their origin. A sedimentary environment is a region on the earth's surface that is characterized by specific physical, chemical, and biological parameters. Although the surface of the earth is varied, there is a limited number of sedimentary environments. This allows us to define each sedimentary environment and its characteristics. The main physical parameters are precipitation, temperature, dominant transport agent and its velocity, currents and their direction; among the chemical parameters, the composition of the rocks and of the water is most important. The biological parameters refer to the flora and fauna and to their interaction with the sediments. Each sedimentary environment is unique and is affected, to a greater or lesser degree, by erosion, transport, and sedimentation processes. For example, sedimentation dominates in marine environments and transport dominates the slopes, whereas deltaic systems are dominated by sedimentation or erosion depending on the season and the precipitations, which determine the river flow. Sedimentation results in deposition of the sediments, originating the stratigraphic record. The successions of sedimentary rocks are studied by sedimentologists, who attempt to infer the sedimentary environments from the past, based mainly on the principle of uniformitarism, which holds that the present is the key to the past; that is, the present processes are similar to those that occurred in the past.

Senescence

Senescence, or aging, is a biological term deriving from the Latin root word *senex* ("old man" or "old age") and refers to the period following the development phase of a living organism, during which various processes cause it to age, deteriorate, and die. The period of senescence begins when an organism reaches sexual maturity and ends with the organism's death. For humans, senescence begins at about age 28 and ends at about age 85 under optimal living conditions.

The length of senescence is in large part genetically determined and is species-specific, correlating closely with the average life expectancy for any given species, with longer-lived species having a more prolonged period of senescence. One theory of aging states that this innate aging process is caused by the release of highly reactive molecules called "free radicals," which arise from the processes of normal metabolism as well as from such external sources as chemical exposure, sunlight, smoking, or other environmental damage. Over time, these unstable compounds interact and bind with other molecules in the organism, gradually and cumulatively causing irreversible harm to cellular DNA, mitochondria, and cell membranes.

Senescence occurs at the cellular level when cells lose their ability to divide, or suffer "replicative senescence," as the organism steadily loses the ability to respond to, or repair, damage caused by stress, injury, or disease. In humans this natural biological limit occurs after about 50 cell divisions, and is called the "Hayflick limit" in honor of the scientist who first observed this phenomenon in 1961. In contrast, for mice (a shorter-lived species than humans), cells typically divide only 10 times. In both plants and animals, each chromosome has at its end a specialized nucleoprotein complex (a "telomere"), which helps to protect, replicate, and stabilize the chromosome ends, allowing them to be repaired when damaged. Replicative senescence is thought to be caused in part because the telomeres at the ends of cells become shorter each time the cell divides, until it can no longer divide and replicate itself. Senescence progresses as more and more cells across the organism reach their Hayflick limits and the body's cells are increasingly unable to reproduce or repair themselves. The remaining length of an organism's telomere sequences at any given point in time therefore serves as a natural "clock" or measure of how far senescence has progressed for that individual.

In addition to being affected by inherent aging processes, the length of senescence is also affected by the level of cell and tissue damage (and resulting DNA damage) that an individual organism experiences during its lifetime due to such environmental factors as food availability, temperature or light changes, disease or injury, or predation. For all living organisms, then, better nutrition, shelter, treatment of diseases, and safety from physical injury will help to reduce cellular damage and to allow the upper natural limits of the senescence period for that species to be reached.

Seven Wonders of the Ancient World

In ancient times, monuments and structures with the power to redefine environments or landscapes gained renown. The classical era (roughly 8th century BCE to 5th century CE) produced seven of these, noted by travelers and sightseers of the times who roamed the shores of the Mediterranean. The ancient Greek poet Antipater of Sidon included the Seven Wonders of the Ancient World in a poem written around 140 BCE and is thereby credited with naming them: the Great Pyramid of Giza, the Hanging Gardens of Babylon, the Temple of Artemis at Ephesus, the Statue of Zeus at Olympia, the Mausoleum of Mausollos at Halicarnassus, the Colossus of Rhodes, and the Pharos or Lighthouse of Alexandria. Of these seven, only the Great Pyramid of Giza remains.

The Great Pyramid of Giza

Built by the Egyptians between 2650 and 2500 BCE and therefore the oldest of the Seven Wonders, the Great Pyramid of Giza is the only one that still stands. It is believed to be the tomb of the pharaoh Khufu or Cheops, who ruled between 2589 and 2566 BCE, the second pharaoh of Egypt's Fourth Dynasty. This dynasty is known for pyramid building, with its founder Sneferu—Khufu's father—commissioning at least three pyramids during his reign. At a height of 480 feet, the pharaoh Khufu's tomb remained the tallest structure in the world until 1300 CE, when it was surpassed by the soaring spire of the Lincoln Cathedral in England.

The Great Pyramid, or Pyramid of Khufu, rests on the Giza Plateau just outside Cairo, Egypt, in a complex called the Giza Necropolis. Included within the necropolis are the Pyramid of Khafre (Chephran) and the Pyramid of Menkaura (Mykerinus), as well as the lesser pyramids of queens. Watching over all, is the Great Sphinx, the head of which some current-day Egyptologists believe to be a representation of the pharaoh Khufu; others claim the likeness is of his son, Khafre. One of the smaller pyramids contains the tomb of Khufu's mother Hetepheres, who was both a sister to and a wife of Khufu's father, Sneferu.

Some believe that the architect of the Great Pyramid of Giza was Hemon (Hemiunu), who was Khufu's vizier. Typically, viziers were top executives in ancient Egyptian culture who controlled taxation. Considering the resources needed to construct a single pyramid, a vizier was perhaps in the perfect position to accomplish the task. Scholars and scientists estimate that Khufu's pyramid consists of more than 2 million blocks of limestone taken from a nearby quarry, with each block weighing an average of 4 tons and some weighing as much as 15 tons. Blocks of granite that weighed as much as 80 tons were brought from Aswan for the pharaoh's inner chamber. Although various theories have been proposed as to how these pyramids might have been built, not knowing how they actually came to be constructed does not diminish the finished masterpieces that resulted. The Great Pyramid was so brilliantly constructed that, to this day, even a piece of paper cannot be slipped between the stones. The fact that this wonder of the ancient world is both the oldest of the seven and the only one that has withstood the ravages of time speaks unequivocally to its prominence in the history of the world.

Hanging Gardens of Babylon

A woman's longing for the trees of her homeland may be the reason that the Hanging Gardens of Babylon made it to the Greeks' list of the Seven Wonders of the Ancient World. Near the present-day Iraqi city of Al Hillah, these gardens and the walls of Babylon were built around 600 BCE by Nebuchadnezzar II, reportedly for his wife, Amytis of Media, who left her Iranian home when she married the king of Babylon. Whether Amytis planted the seed or whether King Nebuchadnezzar simply followed his father's lead, he created more than gardens as he rebuilt Babylon, devastated by years of conquests and rebellions. In addition to constructing the terraces that held the Hanging Gardens of Babylon, the king restored temples, completed the royal palace, built a bridge over the Euphrates to connect citizens of Babylon, and built the Mede wall to protect citizens from any invasion of their northern borders.

Because the Hanging Gardens did not appear in documents that chronicle the history of Babylon, some have questioned whether the gardens were mythical. The earliest mention was in 4th-century BCE; subsequently, Greek historians Strabo and Diodorus documented their existence. They wrote that the terraced gardens were irrigated by water drawn from the Euphrates, and they mentioned stones, towers, and stairways, tiers of fully grown trees, lush plants that thrived in a theater-like setting. An earthquake is cited as the reason for the garden's destruction around 1 BCE. Recent archaeological excavations along the banks of the Euphrates show promise of revealing thick garden walls that may ultimately put to rest the question of whether the Hanging Gardens of Babylon were historical myth or fact.

The Temple of Artemis at Ephesus

Turkey is the site of this wonder of the world: the Temple of Artemis at Ephesus, a city of ancient Lydia. In Greek mythology, Artemis was a female twin of the male god Apollo; both were children of Zeus and Leto. As Apollo was associated with the sun, so was Artemis associated with the moon. Her counterpart in Roman mythology was Diana, the huntress, and Artemis, too, was often represented graphically with bow and arrows.

Begun by Croesus of Lydia, the Temple of Artemis was built over a 120-year period, completed in 550 BCE. Its architect was the Greek Chersiphron. Many Greek sculptors contributed works of art for the temple, including Pheidias, creator of the Statue of Zeus at Olympia. Made of marble, the temple overlooked a courtyard filled with activity—musicians, artisans, merchants, magicians—and was so stunning that, in the eyes of the poet Antipater of Sidon, it dwarfed all of the other wonders he named.

Its very beauty may have led to the beginning of the temple's demise: A disturbed young man named Herostratus chose to set fire to it in 356 BCE in an attempt to forever seal his fame. The Greeks put him to death and rebuilt the temple. Some historians claim that the temple was destroyed and rebuilt as many as seven times. Around 400 CE, the temple was eventually demolished.

The Statue of Zeus at Olympia

The Greek statesman Pericles, a general who led the city during the Peloponnesian War, commissioned this wonder of the ancient world from the Greek sculptor Pheidias circa 440 BCE: the Statue of Zeus at Olympia, Greece.

Olympia was one of four Greek sanctuaries, centers of culture and Greek life. Along with the sanctuary Delphi, Olympia hosted games and contests every 4 years in which the best Greek athletes would compete. As they did with Delphi, the games elevated Olympia's political prestige, and it became one of the most important sanctuaries in all of Greece and considered sacred to Zeus.

Although the only artistic representation of the Statue of Zeus that remains is on ancient coins, from them and from historians of the times it is known that Pheidias created the god Zeus in ivory on an ornate throne accented in gold. The statue was huge—40 feet tall—and crowded the temple that was built to house it. The construction was chryselephantine: built up on a wooden frame using ivory and gold leaf to form the image. In Zeus's hands, Pheidias placed an eagle atop a scepter and a likeness of Nike, the winged goddess of victory.

Zeus was not alone in his temple but was accompanied by his mythical son Herakles, a hero to local residents and considered the founder of the games. The 12 tasks of Herakles were depicted on friezes above the columns of the temple.

From early accounts, words failed to describe the statue's power when seen in person. It is not known for certain how it met its destruction. Some presume it was destroyed by an earthquake in 400–500 CE; others claim that armies carried it to Constantinople, where it was consumed by fire in 462 CE. Today, only fallen columns embedded in Greek soil mark the place where Zeus's statue watched over the Olympians' success at their Greek games.

The Mausoleum of Mausollos at Halicarnassus

As with the Hanging Gardens of Babylon, history credits a woman for this wonder. The Mausoleum of Mausollos was commissioned by Artemisia II of Caria, the wife and sister of King Mausollos, and built around 350 BCE in the ancient city of Halicarnassus, what is now the Turkish port of Bodrum. Artemisia's grief at her husband's death was so great that the tomb could be no less than splendid. Designed by Satyrus and Pythius, well-known Greek architects of the times, each of the four sides of the 135-foot-high-tomb showcased graphic relief works—primarily animals and armies in battle—created by prominent Greek sculptors and hundreds of lesser artists and workers. The monument to Artemisia's husband sat on a hill that overlooked Halicarnassus and became so famous among travelers and sightseers that the king's name is now an eponym for a grand and splendid final resting place: *mausoleum*.

The tomb was toppled by an earthquake in the 1490s. Crusaders used the remaining stones in 1522 to fortify their castles from Turkish attack. Today, visitors of the Knights of Malta's castles in Bodrum can see stones from the tomb in the castle walls. Visitors of Bodrum can view the tomb's remaining ruins as well.

The Colossus of Rhodes

Towering 110 feet over the Greek island, the Colossus of Rhodes was a statue of Helios, the Greek god representing the sun. It was built in 292 BCE by the citizens of the island of Rhodes, following their successful defense of the island when an army led by Demetrios Poliorketes invaded.

Chares of Lindos, a native of Rhodes who had studied under the sculptor Lysippos, was in charge of the statue's construction. Made of white marble and bronze, the statue Helios stood 100 feet tall. Its exact location has never been documented, although romantic notions place the Colossus astride the entrance to one of the many harbors of Rhodes. It existed only half a century before it was felled by an earthquake at the knee. Although offers came from abroad to pay for the restoration of the statue, the people consulted an oracle or prophet who forbade the reconstruction, and the Colossus remained where it fell for almost 800 years. In 654 CE, an Arabian army that had captured Rhodes disassembled what was left of the Colossus and sold off the pieces. In her 1959 poem "The Colossus," poet Sylvia Plath gave a voice to what is left of the ruin:

> No longer do I listen for the scrape of a keel
> On the blank stones of the landing.

The Lighthouse of Alexandria

Off the coast of Alexandria, Egypt, on the island of Pharos, the Lighthouse of Alexandria rounds out the Greek list of Seven Wonders of the Ancient World. Estimated to be as tall as 450 feet, the lighthouse was originally built around 250 BCE as a tower or pharos, a navigational landmark.

It was designed by Sostratus of Cnidus at the behest of Ptolemy I of Egypt, one of Alexander the Great's generals, although it was Ptolemy's son who actually saw to its completion. Legend has it that the son, Ptolemy Philadelphos, forbade Sostratus to inscribe his name on the tower when it was finished. Dutifully, Sostratus instead inscribed Ptolemy's name on the tower. Centuries later, erosion removed the inscription to reveal a second name and that of the true builder of the Pharos of Alexandria: Sostratus.

At the top of the tower, a mirror reflected the sun during the day and a fire lit at night. It is estimated that the light could be seen offshore as far as 35 miles. Early images of the lighthouse from Roman coins show a statue of the Greek god of the sea, Poseidon, at the top of the Pharos and a triton at each of the tower's corners.

Built of stone, the tower could withstand the sea's waves crashing against it and survived until 1303, when an earthquake damaged it. In 1323, another earthquake brought it down. Egyptian sultan Al-Ashraf Sayf used the remaining rubble to build a fort in 1480, and these stones can still be seen in the walls of Fort Qaitbey.

Likewise, stones from the collapsed lighthouse have been discovered in the sea just off the coast of Alexandria by archaeologist Jean Yves Empereur, director of the French Center for Alexandrian Studies.

The New Seven Wonders of the World

In 2007, a nonprofit organization dubbed New7Wonders conducted an extensive poll via the Internet and cell phone text messaging to update the Seven Wonders of the World list. Whereas the Seven Wonders of the Ancient World represented a consensus of Greek travelers who toured the rim of the Mediterranean Sea, today's newly named wonders represent locations around the globe. The New Seven Wonders are

- Great Wall, China
- Petra, Jordan
- Chichén Itzá (Mayan pyramid), Mexico
- Colosseum, Italy
- Machu Picchu, Peru
- Taj Mahal, India
- Statue of Christ Redeemer, Brazil

The people of Egypt protested the idea that the Great Pyramid of Giza needed to compete with modern wonders. The sponsors of the new list agreed, and the Great Pyramid retained its status as a wonder, remaining the oldest and only surviving member of the original Greek list.

Shakespeare's Sonnets

Time is a major theme throughout most of the 154 sonnets that William Shakespeare wrote. It is referred to variously as "ould Time" (Sonnet 19), "wastfull time" (Sonnet 15), "bloudie tyrant time" (Sonnet 16), "devouring time," "swift-footed time," Time's "cruell hand" (Sonnet 60), "Times sieth" (Sonnet 12, meaning time's scythe), "injurious hand" (Sonnet 63), "Ages cruell knife" (Sonnet 63), "Times theevish progresse" (Sonnet 77), "times spoiles" (Sonnet 100), "times tiranie" (Sonnet 115), and "fortie Winters" (Sonnet 2) indicating the passage of time.

It is important to note that Shakespeare's treatment of time is predominantly that of an antagonist. His love defies "devouring time." Time is the enemy that is overpowered by the eternal love he bears. It is also referred to as the time that takes away his beloved's beauty even though his love remains strong and defiant. Time is seen as a harbinger of death in which it culminates. As such, the theme of time as it hastens death is recurrent in several of the sonnets. The theme of time and death appears again in Sonnet 32, when the poet refers to his own death. Sonnet 13 also speaks of the decay that time brings and the rage of death's eternal cold, a throe of time.

Sonnet 15 shows time debating with decay to change youth to night. In this sonnet, Shakespeare defies time by "ingraft(ing)" (Sonnet 15) anew what time takes away from his love; by making her immortal with his pen even though the ravages of time might take over her physical self. He is constantly in war with time (Sonnets, 15, 16, 18, 19). Sonnet 55 refers to the end of time, doomsday, until when the Bard's beloved will be kept alive in these verses. Sonnet 60 once again returns to the theme of time as the destroyer of beauty and youth, as nothing can withstand the scythe of time except for the poet's verses singing praises of his lady love. Shakespeare makes a statement that time shall never succeed in erasing the memory of his beloved (Sonnet 63), even as in the very next sonnet he worries that time will take his love away (Sonnet 64). Even though he defies time, he continues to be haunted by it. This conflict continues in Sonnet 65, in which he is agonized by the thought of time wiping out impregnable rocks while his beloved's beauty was like a flower. Yet by the end of the sonnet he gains back his confidence that his love will remain in black ink despite the ravage of time. In Sonnet 100, the Bard compares the speed of his love's fame to be faster than the destructive pace of time. In Sonnet 115, the poet, fearing time's tyranny, expresses his love in the present as the best while he harbors doubts about the times to come when he might not be in a position to do so. However, in the next sonnet (116), he writes about the unchanging nature of love, which is not "Times foole." In Sonnet 123, he once again challenges time as not the one to bring about changes. Sonnet 126 refers to time's fickle hourglass and sickle.

In "When I do count the clock that tells the time" (Sonnet 12), Shakespeare considers the day, the spring, and the summer as times to rejoice, whereas night and winter have a negative connotation showing the onslaught of time, when nature is past its prime. In Sonnet 30, he refers to the passage of time bringing him sweet remembrances of the past. Sonnet 33 refers to his hour of glory. He also looks at time as the moment that love has come because the time is ripe, or "now is the time" (Sonnet 3). In Sonnet 57, the poet bestows all the time he has to the service of his love, much like a slave. Sonnet 49 shows him preparing for the time when his love might cast him away.

Throughout Shakespeare's sonnets, time is primarily looked at as cruel and cold in combination with death. It is a knife, a scythe, a cruel hand that mercilessly takes away the beauty of youth and of the spring. Though youth and beauty cannot withstand the ravage of time, the effect on nature itself is not permanent. For instance, he mentions that the sun is new and old every day, and so time has but a limited impact on this great gift of nature. Yet, unlike the sun, Shakespeare is aware that his love, time's best jewel, cannot lie hidden from time, for it will take its toll. Hence, Shakespeare tries to defy time by immortalizing his love through these sonnets. This defiance is so strong that it is repeated variously in several of his sonnets. In fact, he is aware and even admits that he is repeating himself, but he chooses to do so nevertheless. Immortalizing his love for the dark lady and Mr. W. H. is definitely the main theme of his sonnets. Less frequently, Shakespeare also refers to sad times, when his beloved is in the company of others. On a more positive note, time is looked at as a reminder of moments of glory or love, of sweet silent thoughts as he goes down memory lane, the day, spring and April, and the summer, as times to rejoice and cherish.

Shangri-La, Myth of

The search for paradise on earth has been a recurring theme in world mythology for thousands of years. People have always been drawn to the idea that there is a place where humans live in harmony with each other and nature and where the wisdom in the world is gathered for the benefit of all humanity. In paradise, the ravages of time are slowed or stopped, and peace is eternal.

Shangri-La is such a place. Shangri-La is a modern myth invented by James Hilton in his novel *Lost Horizon,* published in 1933. In the novel, a group of westerners are rescued from a plane crash in a remote valley. The exact location is never pinpointed in the novel, but the flight had been heading northeast from Afghanistan when Hilton pictured it landing in the unexplored western region of Tibet, surrounded by the highest mountains in the world. Shangri-La is an isolated community that has a lamasery (a monastery for Tibetan lamas) headed by a 200-year-old Capuchin lama. Time is slowed significantly in Shangri-La, making life spans of more than 200 years common. The lamasery is a repository for all human knowledge and cultural treasures, gathered for posterity when the outside world self-destructs. The inhabitants of

Shangri-La are peaceful, opposing all aspects of violence or materialism. The tale becomes a meditation on philosophy and how to best live one's life, as the travelers in the story meet the High Lama of Shangri-La and engage in many conversations.

The idea of a lost kingdom somewhere in the Himalayas has circulated for centuries. Europeans first found references to a mythical place called Shambhala in Tibetan texts at the court of the Moghul Emperor Akbar in the 1580s. The tale appears to date even further back in time, to 962 CE in India. Shambhala is said to be a land behind the Himalayas where a group of isolated people live in peace and harmony waiting to save the world after its destruction. The kingdom is in the shadow of a crystal mountain surrounded by a ring of snow-covered mountains shaped like the petals of a lotus. A crystal palace housing the current king lies at the very center. It is said that inhabitants of Shambhala have made huge advances in science and technology, as side effects of the intense study conducted to attain spiritual goals. While gaining deeper knowledge over their minds and bodies, inhabitants of Shambhala are said to have achieved the ability to cure themselves of illness. Other side effects of their study include telepathy and precognition. Although the inhabitants are not immortal, they live healthy, happy, extended lives of well over 100 years.

The prophecy of Shambhala states that a series of 32 kings will rule for 100 years each. The outside world will continue to deteriorate as each reign passes. The pursuit of power will continue to corrupt until one evil tyrant rises above the rest to oppress the entire world. As the world appears to be on the brink of total annihilation, the mists obscuring Shambhala will clear. The 32nd king of Shambhala will ride forth to lead a mighty army against the tyrant, establishing a Golden Age of Enlightenment and restoring peace and prosperity to the world.

It is easy to see the appeal in this type of tale throughout history. In times of political unrest and instability, the world can be a frightening place. Stories about the possibility of places like Shangri-La and Shambhala validate this fear. The future is uncertain, and it is comforting to think that something good from the past will endure through time, after the destruction of all that is familiar.

Shintō

Shintō is the indigenous Japanese religion, based on the belief in divinities called *Kami*, reverence of ancestors, and a combination of ritual purification and food offerings. Kami can best be described as impersonal manifestations of power. They have no shape of their own but can be summoned into vessels (often trees, banners, long stones) or be communicated with through a medium (often young women called *Miko*). Usually living in a world of their own, Kami can visit the human world at certain seasons. If cared for through the fulfillment of proper rituals and offerings, then they can bring material blessings to this world. If offended, for example, by pollution brought about by blood, dirt, or death, they might curse the offenders, thus bringing disease, disaster, or famine to the culprits. Shintō faith does not hold a unified concept of time. Instead, its myths present two different understandings of time and space.

There is no historical founder and no set of holy scriptures that define the content and practice of this faith. But two Japanese classics, *Kojiki* (Record of Ancient Matters, written in 712) and *Nihon shoki* (Chronicles of Japan, 720) contain the myths central to Shintō up to the present day. According to these works, three gods appeared out of the primordial chaos and disappeared, leaving no progeny behind. More generations of gods appeared and disappeared to no greater effect. Then Izanami and Izanagi (the first pair of gods with distinct sexes) appeared, married, and created the great eight-island country of Japan. In want of an entity that could rule the universe, they begot three gods: the sun goddess Amaterasu, the moon god Tsukiyomi, and the storm god Susanoo. Whereas Amaterasu and Tsukiyomi were sent to heaven, the unruly storm god was not seen fit for a position of equal power and sent to the netherworld.

The sun goddess then decided to send her august grandchild Ninigi to reign over the Central Land of Reed-Plains (usually understood to be Japan) and bestowed him with the Three Treasures (sword, mirror, jewel). Ninigi was sent to the Reed-Plain with the parting wish that his dynasty may prosper and, like heaven and earth, endure forever. He was successful in his quest, and one of his descendants became the first legendary emperor, Jimmu, who, according to Japanese tradition, is ancestor of the Imperial Family that reigns over Japan until this day.

History of Shintō

Although Shintō only crystallized as a religious system during Nara (710–784 CE) and Heian (794–1185 CE) times, early religious phenomena can be traced back well into prehistoric times. Agricultural rites developed first during the Yayoi period (250 BCE–300 CE), when the cultivation of rice was introduced from the continent. Numerous clans (*uji*) ruled smaller and larger areas of the country, gradually forming alliances and small states. The leaders of those clans traced their ancestry to the gods revered in their domain, combining political and religious power in their hands. By the 5th century CE, these states were unified around the powerful Yamato clan, which became the imperial lineage. Japanese religion by then already displayed two characteristics: It combined a strong local character (including manifold local legends and myths) with a supraregional cult, centered around the dominant clans' ancestral gods.

Import of continental culture went to a new level, when Confucianism, Buddhism, and Chinese Taoism reached Japan in the 5th and 6th centuries. Equally important for the further development of Shintō, the Chinese writing system was introduced to Japan, and the spread of literacy among the aristocracy set the foundations for Shintō to assume formal identity as an indigenous religion. Japan was modeled after the Chinese state and furnished with a Chinese-style bureaucracy as well as chronicles recounting its legendary and historical past. *Kojiki* and *Nihon shoki*, respectively, contain myths about the age of gods and the creation and history of Japan, starting with the legendary first emperor of Japan, Jimmu. But rather than retell the oral traditions of the people, these chronicles were compiled to serve as mythological literature of the ruling elite, integrating conflicting legends from different clans according to their present position at the court. The legendary beginnings of Japan were written down not only utilizing the Chinese writing system but also Chinese philosophy. Most prominently, the emperor system cannot belie its Chinese origin. It is in these chronicles that the word *Shintō* ("way of the gods") appears for the first time.

The 8th century brought with it strong tendencies to interpret Shintō from a Buddhist point of view. Understanding Kami at first as beings to be saved from the endless cycle of transmigration, Buddhists later took them to be incarnations of Buddhas and Bodhisattvas. It was only in the 15th century that the Yoshida school reversed this *honji suijaku* theory and paved the way for a national reorganization of Shintō. The Edo period (1600–1868) witnessed a shift of Shintō from Buddhism. While some scholars interpreted Shintō from a neo-Confucianist standpoint instead and stressed the concept of imperial virtues and national ethics, others turned toward the Japanese classics in search of a pure Shintō. The philological studies of the School of National Learning (*Kokugaku*) aimed to identify the original norms of Shintō as mirrored in the beliefs of former generations.

Although the imperial lineage had continued through the centuries, the emperor's position had been a rather powerless one for many centuries. The Meiji Restoration (1868) reinstated the emperor as head of state and renewed the bonds between state and Shintō. In 1870 the government proclaimed the separation of Kami and Buddhas (*Shinbutsu bunri*), turned shrines into instruments of the state, and made Shintō priests civil servants. State Shintō played an important role in Japan's imperialist efforts from the Sino-Japanese War (1894–1895) to the end of World War II.

Accordingly, state and religion were strictly separated, and the system of state-financed shrines was abolished in 1945 by the Allied forces. Although weakened by the memories and repercussions of its not yet distant past, the emperor continues to be a symbol of the nation, and Shintō still is a vital part of Japanese religious life.

Concepts of Time in Shintō

Shintō is not based on a set of scriptures, and it has not generally accepted a creed. It is concerned with detailed legends, practical questions of life, and proper rituals rather than abstract dogmas. Just as *Kojiki* and *Nihon shoki* in places recount several conflicting versions of the same legend, they also hold fundamentally opposing concepts of time and space. These can roughly be divided into a spatial and a linear image of time, each described by different layers of the Shintō tradition.

The spatial concept of time is often described as cyclical. Indeed the appearances and disappearances of the first gods are strongly reminiscent of an agrarian life cycle. They appear, grow, and finally disappear, only to be followed by the next generation in due time. Their disappearance is often understood to signify death. In this respect a story about the sun goddess Amaterasu "disappearing" (hiding) into a cave and appearing again out of the same cave at the sound of music and laughter gains a deeper meaning. It can be interpreted as rebirth of the goddess, which also leaves the possibility for other disappeared gods to be reborn.

Renewal and purification play a very important role in Shintō. Each visit at a shrine starts with a ritual purification of the believer, and New Year celebrations require a thorough cleanup of the house. During Shintō festivals (*Matsuri*) the locally revered god pays a visit to his shrine, thereby renewing the bond between him and his followers. If all necessary rituals like dancing and food offerings are observed, the god himself is strengthened by the worship. Most prominently, shrine buildings were usually rebuilt to purify the site and renew the materials used. Most of the larger shrines followed this tradition until the Edo period (1600–1868). Today it is only preserved by the shrine of the sun goddess (Ise shrine), which is still rebuilt at an adjacent site every 20 years.

Although several traditions and legends contain elements suggesting a cyclical image of time, spatial aspects are prevalent. Day and night, life and death, different seasons as well as present and past are not perceived as different times experienced in the same location, but as different worlds. The oldest Shintō traditions describe the world as divided into a land of the living and a land of the dead. The latter is called Tokoyo and is described both as a cheerful place for heroes and as a horrible place for the ordinary dead. It is located beyond the sea, in the mountains or in the woods. In many parts of Japan, the dead are believed to dwell on holy mountains (e.g., Mount Fuji) with a characteristic symmetrical and conic shape. They watch their descendants from a distance and visit them in the plains at certain seasons. Traditionally these visits were thought to take place at New Year and at harvest time. But today the Buddhist festival of O-Bon, celebrated in mid-July or mid-August, has become the central time to welcome the dead back in the land of the living in Japan.

Passage from one world to the other is perceived as a movement in space rather than time. Thus visiting the other world might be difficult, but is possible as such. *Kojiki* and *Nihon shoki* tell the story of a visit to the land of the dead. Izanami, the first female god, was also the first one to die. When her mourning brother and husband Izanagi arrived in *Yomi no kuni* (Hades), Izanami had already eaten the other world's food and thus had lost any chance of return. Ignoring his wife's order not to look at her, Izanami lit a torch and beheld her worm-eaten body. Disgusted at the sight, he had to flee from her wrath and only just reached the world of the living again. But even when in different worlds and separated by a rock, Izanagi and Izanami argued with each other. While an angry Izanami threatened to take 1,000 souls to Yomi no kuni every day, Izanagi promised to let 1,500 humans be born everyday in return.

Although the legend is not specific about the means to reach the other side, a passage is described to be possible. The two gods even argue with each other. Although in different worlds, they obviously are within earshot.

Probably due to continental influences, later myths divide the world into three realms. Gods live in the Plain of High Heaven (*Takama no hara*). The present world, or Middle Land (*Nakatsu no* *kuni*), is inhabited by the living, while the dead go to a world below (Yomi no kuni or *Ne no kuni*). Movement between these worlds is believed to be restricted but possible. Gods can easily cross the borders, while the living are usually confined to the Middle Land.

Until the end of World War II, the emperor was believed to be a living god (*ikigami*) descended from heaven. When a new emperor ascended the throne, the god was believed to descend from heaven only to ascend again at the emperor's death. Similarly, the myths speak of Izanagi's ascension to a palace in heaven after his death.

Souls of the deceased are free to leave their world at certain times and thus retain a strong connection with their descendants. When somebody dies a violent death or is thought to hold strong resentments when dying, his angry soul may haunt the world and bring disaster to any living person. Such souls have to be cared for cautiously to be pacified and are often enshrined as gods. If cared for properly, they might use their considerable power to help the people instead. The most prominent example of this practice is the Yasukuni Shrine in Tōkyō, Japan, which is dedicated to the souls of all people that once fought for the emperor, including several convicted war criminals.

Although the legends do not describe specifically the condition of the souls in afterlife, there is a strong belief in the return of the souls into the land of the living. Even a return to the body after death was once believed to be possible. In ancient Japan the souls were thought to leave the body at death and linger between the worlds of the dead and the living. During the time of mourning, the dead were laid out in a special building. The mourners lived with them, eating and drinking, dancing, singing, and crying in front of them, thereby hoping to persuade the soul to return to its body. In 686 the mourning for emperor Temmu continued for as long as 2 years. But the Buddhist custom of cremation had already started to take hold in Japan by then, and soon all burials followed Buddhist traditions.

Legends conveying a linear concept of time probably result from continental influences. The emperor system adopted from China in the 7th century CE left its traces not only in political practices but also in the religious traditions. In historical Japan the emperor's supremacy was backed by his supposed descent from the sun goddess. Ancestor gods of other leading clans were given importance according to their respective clans' power at the time of the compilation of the chronicles. This may partially explain the existence of conflicting legends within each of the chronicles. In particular, the unruly storm god Susanoo is depicted differently in several myths. Reverence for the smallest details of each legend and a strong opposition to unifying changes to the myths seem to be other reasons.

In the legends of *Kojiki* and *Nihon shoki*, Amaterasu's order for her august grandchild Ninigi to rule the Reed-Plain is the beginning of a long and unbroken line of emperors. With this legend, history starts to unfold. According to Amaterasu's wish, Ninigi's dynasty was to prosper forever. Although there is no promised land or final stage to be reached, history always holds the promise of eternal prosperity of the imperial linage. Although after World War II the Emperor Hirohito (posthumously Emperor Shōwa) renounced his status as a living god, the national anthem of Japan still refers to Amaterasu's promise. The lyrics were taken from a Heian period (794–1185) collection of poems and express the wish that the emperor's reign may continue for 1,000, even for 8,000, generations. As the imperial lineage started with the legendary Emperor Jimmu in 660 BCE, current Emperor Akihito being the 125th emperor, fulfillment of this wish would indeed hold a very long future still.

Simmel, Georg (1858–1918)

The pioneering German sociologist Georg Simmel spent most of his life as a private scholar, sustained by a small inheritance. Although he was permitted to lecture after receiving his doctorate in philosophy from the University of Berlin in 1881, his Jewish origins sufficed to deny him an academic chair until 1914, when he was offered a professorship at the University of Strasbourg. A penetrating thinker and brilliant essayist, Simmel is best known for his *Philosophie des Geldes* (Philosophy of Money, 1907); *Einleitung in die Moralwissenschaft* (Introduction to Moral Philosophy, 1893); and *Soziologie* (Sociology, 1908).

In his last work, *Lebensanschauung* (Life Views), Simmel broaches the issue of time in order to explicate his concept of *life*, which was of central relevance for all his work after 1908. According to Simmel, time (like life) is characterized by the notion of continuity. Therefore, the subdivision of time into past, present, and future is an artificial one. The present as such cannot be experienced, just as little as past or future. Rather, the present experienced by humans "is always composed of a little piece of past and a little piece of future," which means that the concept of the present is closely linked to the concept of the experienced timely moment (*Augenblick*), which is constituted by the vital functions of remembrance and anticipation. Simmel focuses especially on the former by analyzing how remembrance constitutes the past. According to Simmel, the previously experienced moments "live in us, not as a timeless content but bound to the very special point of time." Therefore, very much unlike the mechanistic concept of time, which Simmel often criticizes, these previously experienced moments are not absorbed and dissolved in the present as the cause is absorbed and dissolved in its effect. The mechanistic conception of causality destroys the cause by dissolving it, the vital notion of time, on the other hand, *stores* the experience. Simmel holds that the mechanistic concept of time leads into logical aporia because it remains unable to explain the "continuity of changing." Thus, Simmel's theory of time is one of the first approaches toward a conception of "organic time."

It is not only this criticism of mechanism but also the vital concept of time itself which Simmel adopted from his reading of the French philosopher Henri Bergson. In his essay titled "Henri Bergson," published in 1914, Simmel states that the mechanistic conception is principally timeless "because no formula, no state would change if all motions of the world would run two times as fast or a thousand times as fast or even slower than they actually do." Thus, the physical concept of time is a relational one. Time, understood as a physical term, can be contracted or expanded (or sometimes even be reversed) without changing the underlying physical processes. In contradistinction to that, the vital concept of time Simmel has in mind is characterized by the irreversible process of life for which the timely progress is essential because, according to Simmel, "to live means to age." Time, thus understood as the central category of life, transcends every given moment—on the one hand by remembering the past and on the other hand by fulfilling voluntary actions pointing into the future (in which way the past can be represented in an instant view, as analyzed in Simmel's book *Rembrandt*). Thus, according to Simmel, the distinction between past, present, and future is an artificial one and belongs to the physical concept of time.

A different focus on the concept of time is inherent in Simmel's criticism of modern culture. According to Simmel's discussion of time in his book *Philosophy of Money* and in many other essays, modernity focuses on time as goods, as "a value determined by usefulness and shortness." The individual measuring of time (by means of pocket watches) leads to a binding time schedule, which irrevocably corrupts the vital concept of time.

Sin, Original

Original sin is the Christian doctrine that all people have a general condition of sinfulness from birth inherited from the first humans—Adam and Eve—that separates humans from God. Original sin is also called hereditary sin, birth sin, ancestral sin, and person sin.

The term *original sin* applies to both the first sin and to the inherited nature of sin found in each human. Genesis chapter 3 describes the first sin of Adam and Eve, the first humans. Initially, Adam and Eve lived in a state of immortality and in close communion with God. The humans disobeyed God when the serpent deceived them into eating from the tree of knowledge of good and evil, a tree from which God had told them not to eat. By eating the fruit, Adam and Eve discovered the capacity to know and do evil; thus, they developed a sinful nature. This capital transgression condemned the first humans as well as the human race to a life of sin that ends in death. As a consequence of the first sin, everyone born afterward inherits this sinful nature, thus corrupting the human race. This first sin is often referred to as "The Fall."

The Christian tradition of original sin is based in part upon Paul's writings to the Romans. Romans 5:12 (New International Version) says, "just as sin entered the world through one man, and death through sin, and in this way death came to all men, because all sinned." This thought is repeated in subsequent verses. According to Paul, Christ's sacrificial death was the remedy for original sin.

Augustine, Bishop of Hippo (354–430), one of the early church fathers and an early Christian writer concerning original sin, believed that every human was born flawed, that is, evil with a sinful nature, and shared Adam's guilt. He based this belief on his understanding of Psalm 51:5. He believed one must be baptized in order to remove this guilt; even infants should be baptized because they are born with a sinful nature. Furthermore, Augustine believed that a person was predestined as to whether one would accept God's grace to overcome this nature and that a person could not overcome this sinful nature without God's help.

Not everyone agreed with Augustine's view of original sin. The Pelagians, a group following the teachings of a British ascetic named Pelagius (late 4th to early 5th century), believed one could reach perfection through a virtuous life. This group believed that Adam's sin was confined to Adam alone and that he was destined to die regardless of whether he had sinned. Augustine wrote against the Pelagians in *On Merit and Forgiveness* around the year 412. Orthodox Christianity condemned Pelagius's position at the Council of Carthage in 418.

Like Augustine, Anselm, Archbishop of Canterbury (1033–1109), saw original guilt and humanity's flawed nature to be passed on from parent to child; however, he saw original sin as original in each individual rather than as a reference to Adam and Eve's first sin. He argues that all people were present in Adam and actually sinned in Adam.

Thomas Aquinas (1225–1274), a scholastic theologian, defines humans as rational beings. Although he does not use the term *original sin*, he says the consequence of Adam's sin was that a person's ability to reason was no longer subjected to God's will. Therefore, the Fall does not involve the loss of human reasoning, an ability Aquinas connected with the image of God, but rather humans gained the ability to reason outside of what God would want. Aquinas's position influenced the theology of many modern theologians such as Karl Barth (1886–1968).

According to his writings in *Institutes of Christian Religion,* John Calvin (1509–1564), one of the Protestant Reformers, saw original sin as an internal, total depravity and corruption of human nature (II.i.5). He was greatly influenced by Augustine's work. Yet, he did not see original sin so much as heredity but rather as an ordinance of God. According to his position, Adam, a representative of all humans, sinned, and God ascribed this sin to all people. Then God judged all humanity because of this sin. For Calvin, sin pollutes all aspects of the human being; there is no goodness in humankind. Humans on their own accord have no option but to choose sin (i.e., humans have no free will). Like Adam, Christ, also representing all humans, overcame sin; therefore, all humans can be made righteous through him. According to Calvin, only those predestined to this salvation will receive it. Today, several modern denominations follow Calvin's position, including some Presbyterians and some Baptists.

Jacobus Arminius (1560–1609), a Dutch Reformed pastor and the head of the Arminian movement, believed that all people inherited the sinful nature; but he also believed that each person has the free will to choose God's grace and that God's grace overcomes this condition. Out of this tradition came the modern Methodist movement.

In the Jewish tradition, Adam and Eve's actions are those of individuals; thus the sin, which is disobeying God, is limited to them alone. By eating the fruit, humanity gained the capacity to know evil. Thus, they developed free will, the ability to choose to do good or evil. Sin in itself is the responsibility of each individual based upon each individual's choices. Thus Judaism does not have a doctrine of original sin as Christianity does.

Islamic tradition of the account of the first sin is similar to the biblical Genesis account. Islam blames both Adam and Eve for the sin. However, Adam and Eve are forgiven after they repent, and they are restored. Therefore, Islam does not have a doctrine of a sinful nature passing from parent to child. Islam holds that children are born in a state of purity without sin.

SINGULARITIES

Singularities are points in spacetime that have infinite density and temperature. At these points, the known laws of physics break down or contradict each other. Singularities are found in three places: at the beginning of the big bang, at the end of the hypothetical big crunch, and at the centers of black holes. The singularity at the big bang is mathematically defined as the beginning of time, or "t = 0." Alternatively, singularities may be defined as points of infinite tidal gravity and chaotic spacetime curvature, or as being made of quantum foam, the bubbly substance governed by probability that constitutes space at the quantum level. Infinities usually identify an error or problem with a physical theory, so these definitions cannot properly describe singularities. The search for a complete grand unified theory was initiated because of this breakdown of physics.

Singularities warp the fabric of spacetime more than any other known phenomenon. Time slows to stopping at the event horizon of a black hole and ceases to have any meaning at the singularity itself. The warpage of spacetime around a regular black hole depends upon the hole's mass and circumference, according to Albert Einstein's general theory of relativity. The greater the mass and the smaller the circumference of the object is, the greater is the time dilation that results.

Black Hole Theory

In England in 1783, John Michell used Newton's laws of gravity to deduce, via a thought experiment, the possible existence of "dark stars," rudimentary black holes. Perhaps, Michell postulated, there are stars so massive that their escape velocities, the speed required to escape the star's gravity, were the speed of light. He imagined light rays, or photons, rising above the surface of the star, then being dragged back by gravity. Such a star would be invisible from a distance. Michell presented his idea to the Royal Society, which caused excitement. Around the same time, the Marquis Pierre Simon Laplace used nearly the same argument in his book *Le Système du Monde* (The System of the World), published in 1796. Without any apparent reason, Laplace later removed the reference. Because these dark stars could not be studied further, interest waned.

Some of the right tools with which to study black holes appeared in Einstein's general theory of relativity. This theory is built upon the principle of equivalence, which states that all reference frames are equally valid to view or study physical phenomena. This theory, to Einstein's chagrin, predicted a singularity at the big bang and the big crunch, despite his efforts to prove that singularities were impossible. He would not even countenance the possibility that stars many times the sun's size might implode near the end of their lives. Einstein was certain that some internal force would be found to balance the star's gravity.

More of Einstein's findings led to discoveries of singularities' properties. When researching the effect of curved spacetime, he realized that tidal gravity, the force that pulls all matter toward an object's center, was a sign of curved spacetime. His discovery explains the high level of tidal gravity near singularities; they also highly curve spacetime. Tidal gravity stretches the closest part of an object most and squeezes the sides perpendicular to the bottom. Objects that were originally moving parallel with respect to each other will collide when acted on by tidal gravity. The same mechanism can be seen looking at a globe, where longitude lines, parallel at the equator, cross at the poles.

Another advance in black hole theory was the discovery of stellar mass limits. Karl Schwarzschild, Subrahmanyan Chandrasekhar, and J. Robert Oppenheimer were primarily responsible for these discoveries. Schwarzschild created Schwarzschild geometry in 1916, which describes the degree of spacetime warpage for any spherical, nonrotating star. He calculated the critical circumference, better known as the Schwarzschild radius, at which the sun would become a black hole, about 18 1/2 kilometers. This number agreed with Michell's and Laplace's calculations. High magnitudes of spacetime warpage and densities were accepted in the physics community, but no one was willing to believe in infinities. It was known theoretically that infinitely redshifted photons were created at the horizon, which also meant that time stopped at the horizon. The amount of a wavelength shift equals the amount of time dilation resulting from the shift. This was considered unacceptable.

Sir Arthur Eddington's and R. H. Fowler's work on white dwarfs and the end stages of stars inspired Chandrasekhar. Using one of Eddington's books, he deduced the stellar mass limit for forming a white dwarf. Eddington encouraged Chandrasekhar to develop the idea. Most physicists had no interest in the subject at the time, and Eddington later attacked Chandrasekhar's ideas openly at a conference. Chandrasekhar sent his calculations to Niels Bohr for verification and was told that he was correct: No star more massive than 1.4 solar masses could settle into a white dwarf state. Another physicist, Viktor Amazapovich Ambartsumian, told Chandrasekhar that he would have to analyze known white dwarfs to prove his calculations. This Chandrasekhar did, finding all white dwarfs to be of less than 1.4 solar masses. He eventually moved into other areas of physics. Most scientists believed that by some method, stars greater than 1.4 solar masses would either eject enough mass to become white dwarfs or settle into some unknown intermediate phase between white dwarfs and neutron stars, a denser star form.

Oppenheimer was the next physicist to add to the stellar mass limits. He was intrigued by neutron cores, which when first proposed in 1933 were modern neutron stars buried inside regular stars. Upon analyzing this hypothesis, Oppenheimer found that neutron cores were not viable, but neutron stars were. Researching further, Oppenheimer found that these also had a maximum limit, somewhere between one half and a few solar masses. Above that size, a star would certainly form a black hole. Oppenheimer then investigated black holes. He discovered a paradox: From a distance, a forming black hole would appear to be a static star shrinking to the critical circumference and then freezing there. However, for an observer on the star, the star would continue to shrink to zero volume and infinite density. The curvature and tidal gravity would not, as previously thought, be infinite, but the light would be infinitely redshifted. These unusual findings encountered a great deal of skepticism, largely because in order to analyze the imploding star, Oppenheimer had been forced to make his model star very uniform and spherical, unlike most real stars. In 1958 John Wheeler said that black holes were unlikely, while acknowledging in the same breath that implosion was necessary for stars over two solar masses. Resistance continued, but these developments nevertheless led to advances in singularity theory.

Wheeler contributed an important insight to the study of singularities, labeling them the holy grail of the physics community. He found that quantum gravity, the name for the theory incorporating quantum theory and relativity, would entail quantum fluctuations. These fluctuations occur everywhere in the universe in two types: electromagnetic and gravitational. There are always some of these fluctuations, no matter how empty the surrounding space is. They contain no net energy, but any isolated area can temporarily have positive or negative energy. Quantum fluctuations become more vigorous in confined spaces, and gain crucial importance at the Planck-Wheeler scale, about 1.62×10^{-33} centimeters. At this length, space becomes quantum foam, which is what a singularity is actually composed of. The connection of singularities to quantum fluctuations was not made for years, however.

Singularity Theory

In 1961 Evgeny Lifshitz and Isaac Khalatnikov concluded that all known types of singularities are unstable when realistic random fluctuations are introduced into their vicinity. Instability would halt a star's implosion and avoid a singularity. However, the same researchers, with Vladimir Belinsky, discovered the chaotically oscillating singularity, a new type, 8 years later. This new singularity had random forces of alternating pressure and elongation that acted on matter falling through the black hole. As matter approached the singularity, the forces gained strength and oscillated faster, remaining chaotic in pattern. Matter was always stretched in one spatial dimension and squeezed in the other two dimensions. The oscillations were chaotic both spatially and temporally, so a human falling toward one of these singularities might have one leg being pulled down while an arm was stretched sideways. Another physicist, Charles Misner, had also found the chaotically oscillating singularity, and called it the "mixmaster oscillation" because of its ability to completely destroy and combine the constituents of matter.

Roger Penrose and Stephen W. Hawking developed singularity theory directly to a higher degree in one generation than anyone had before. Shortly after Hawking received his Ph.D., the two began working together. In late 1964, Penrose used the rules of general relativity and an obscure field of mathematics called topography to prove that there was a singularity in every black hole, and conversely, that no black hole could form without a singularity. The Russians Lifshitz, Khalatnikov, and Belinsky rejected this idea on the grounds that the known singularities would be unstable, until they found the chaotically oscillating type. This is considered to be the only kind of singularity that exists, based on their work. In the late 1960s, Penrose and Hawking proved that both the big bang and big crunch scenarios entailed singularities, which all matter and energy either exploded from or converged into. From the methods and theorems that Penrose had derived, coworkers like Hawking, George Ellis, and Robert P. Geroch created the "global methods," with which they described the early universe and the centers of black holes. In 1969, Penrose made a claim known as the "cosmic censorship conjecture," broadly meaning that the universe does not allow "naked singularities" (i.e., those without event horizons) to occur. The weak version of this conjecture protects the universe from the spatial and temporal unpredictability experienced close to the singularity; the strong version states that singularities are always either completely in one's future or one's past but can never actually be reached. Despite the security this conjecture would give the outside universe, Penrose has not successfully proven it.

The next winter, Hawking discovered that black holes have an event horizon that never decreases. When matter falls into the hole, the horizon increases. Singularities were eliminated from the universe by Hawking a decade later. His development of the "no-boundary" hypothesis made use of imaginary time, which is represented visually at right angles to ordinary time. Using the concept, Hawking could explain the singularities at the big bang and big crunch without the unknowns and infinities inherent in their definitions. They became normal points in spacetime, analogues of those at the north and south poles of the earth. Looking at the history of the universe in real time, there are still singularities, but it makes mathematical consideration of cosmology simpler.

A decade after Hawking made singularities optional, Werner Israel and Eric Poisson investigated the changes that occur in old singularities. Another theoretical physicist, Amos Ori, independently carried out the same calculations. They found that the chaotic oscillations deteriorate in intensity over time and may even disappear. This work suggests that if a person fell into an old black hole, he or she may not die on impact with the singularity, or may die much closer to the singularity than the individual would have if the hole had been new. However, the tidal forces are temporarily rejuvenated upon the intake of energy.

The most recent breakthrough in singularity theory was a computer simulation carried out at Cornell University by Stuart L. Shapiro and Saul A. Teukolsky. Through the history of singularity theory, an ongoing debate has raged over whether naked singularities can be seen from a distance. Even if they could, some have argued, the state would be very unstable, and an event horizon would form swiftly. Most physicists have sided with Penrose's cosmic censorship theory, but Shapiro and Teukolsky's simulations in 1991 created naked singularities from extremely misshapen stars, using calculations in the general theory of relativity.

Over the past 50 years, knowledge of singularities has grown exponentially. Gravitational waves carry away asymmetric matter from a collapsing star; when the star finally settles into its final state as a black hole, the singularity at the center is perfectly spherical. Both space and time stream directly to the singularity inside the horizon. A near-vacuum exists between the event horizon and the core of a black hole, due to the singularity's extreme gravity. Younger and smaller singularities destroy matter faster than do large or old holes. Atoms are pulled apart, as gravity overcomes even nuclear forces, and their constituent particles merge with the singularity. When this complete destruction happens, in 10^{-43} seconds or less, the still-incomplete theory of quantum gravity is supposed to replace current physical theory. When this occurs, time close to the singularity becomes separated from space and ceases to exist. Theoretical havoc ensues; probabilities are the only tool left to find the properties of this state. Space itself becomes frothy. It is believed that the electromagnetic vacuum fluctuations bombard a hole, ensuring that the singularity doesn't pinch spacetime off completely and drift away, creating a new universe.

There is still a great deal to learn, however, and perhaps to observe directly. Still unknown is whether or not a person would certainly die when he or she hits a singularity, especially a very large or old one. Also left to prove conclusively is whether Penrose's cosmic censorship hypothesis is correct. If it is, then there is nothing we can learn for certain about singularities, for they will always be hidden behind the event horizon. The expense of having naked singularities to study is the added danger for travelers of finding an unstable, gravitationally powerful singularity potentially around every corner.

The laws that govern singularities' activities (i.e., the theory of quantum gravity) are beyond the grasp of current physics as well. The rules and laws must govern tiny spaces and high densities satisfactorily. The theory should unravel the mysteries of the mechanisms and events that occur inside black holes and how the singularity causes them. Finally, it must settle the debate about whether a singularity can detach from its region of the universe and create a new universe.

Sisyphus, Myth of

Sisyphus is a character in ancient Greek mythology who defied death and then was condemned to an eternity of performing a repetitive, meaningless task. The myth exemplifies the concept of eternal recurrence, the notion that time in the universe is cyclical rather than linear, and that the universe recurs in the same form an infinite number of times. The myth of Sisyphus also became the foundation of a 20th-century book, *The Myth of Sisyphus, and Other Essays,* by the 20th-century French writer Albert Camus, about the meaninglessness and absurdity of life.

According to the Greek myth (partially recounted in Homer's *Odyssey*), Sisyphus was the founder and first king of Ephyra (Corinth) and the father of Odysseus. He is also credited with founding the Isthmian games in honor of Melicertes, whom he found dead lying on the shore of the Corinthian Isthmus. Legend holds that Sisyphus was a deceitful person and very crafty. He put Death in fetters when he came for Sisyphus, and thereafter no one died. Ares became frustrated because his enemies in battle would not die, so he came, released Death, and sent Sisyphus to Tartarus, a dungeon within Hades. Before Sisyphus died, he told his wife not to offer the normal sacrifice for the dead. The underworld complained that Sisyphus's wife had neglected him, so Sisyphus convinced Persephone to allow him to return and ask his wife to offer the sacrifice. She agreed and allowed Sisyphus to return to Corinth, but then he refused to go back to Hades. Eventually, Hermes took him back to the underworld. As punishment for his misdeeds and trickery (and for betraying Zeus by exposing his sexual misdeeds), Zeus bound Sisyphus to an eternity of frustration, forcing him to forever perform a meaningless task. Zeus forced Sisyphus to push a rock up a steep hill. However, just before he reached the top of the hill, the rock always rolled back down and he had to start over again. Today, people often use the term *Sisyphean* to describe a pointless or interminable task.

Sisyphus's eternal, repetitive labor serves as an example of the concept of eternal recurrence. According to this philosophy, the universe is cyclical and, over time, recurs upon itself. This was a common philosophy in the ancient world. The scarab in ancient Egypt symbolized recurrent life. This concept also appears in other Greek myths, such as the Demetrian myth of the cyclical, annual return of Persephone from Hades, a myth that explains the seasonal changes. In Western civilization, eternal recurrence lost its prominence with the rise of Christianity; however, philosophers such as Friedrich Nietzsche briefly revived the philosophy in the 19th century.

In 1942, Albert Camus wrote an essay titled *Le Mythe de Sisyphe*. Based on the myth of Sisyphus, Camus's treatise is a philosophy of the absurd and focuses on humanity's futile search for meaning in an unintelligible world without God or eternity. He concludes that such a life does not require suicide. He compares the life of absurdity with the struggle of Sisyphus to push the rock up a hill. He concludes that Sisyphus is an absurd hero, who has found happiness in his meaningless task. He is truly happy because the futility of his task is beyond doubt; therefore, any human can be content once he or she comes to terms with the absurdity of life.

Sleep

From time immemorial the ultimate function of sleep has occupied the attention of scientists, philosophers, and physicians, though little basic understanding emerged. In recent times, J. A. Hobson, a leading sleep researcher at Harvard University, succinctly observed that sleep is of the brain, by the brain, and for the brain. Recent approaches from the perspectives of efficiency of brain function and natural selection are unraveling sleep's long-standing mysteries, particularly how sleep is "for the brain."

One obtains the greatest insight into the rationale of a biological act or state through elucidating its evolution, namely, why, when, and how it came into existence. With this inherent advantage of an evolutionary perspective, sleep's ultimate function now presents little more mystery than many other phenomena of life that increasingly are yielding their secrets. In fact, it is now evident that time, in the sense of simultaneity, played a pivotal role in sleep's origin.

Time's Role in the Origin of Sleep

Merely from the fact of sleep's continued existence, an evolutionist would expect it to maintain an overall high level of efficiency of brain operation. Otherwise, how could sleep have survived the relentless pressures of natural selection? Such an overall highly efficient state of brain operation very likely has been achieved by the brain's postponing, until the new vigilance state of sleep, any nonurgent (low-priority) brain activities that conflicted with the urgent activities of wakefulness.

But which brain activities are nonurgent during waking and can safely be postponed until sleep? Here, neuroscientists have provided clear answers. The major, safely delayed brain activity carried out during sleep is memory processing, with the delay tolerated because synaptic decay rates are low. Three aspects are foremost. Enormous numbers of memory fragments, essentially meaningless taken individually, are reinforced during NREM (no rapid eye movement) sleep; new memories are "consolidated" and added to the brain's long-term memory stores; and already-stored long-term memories become "reinforced," or "refreshed," during REM (rapid eye movement) sleep.

Given that memory processing is the major nonurgent brain activity during sleep, why couldn't this processing have occurred safely and efficiently during a continuous state of wakefulness? In other words, why is postponement until sleep sometimes necessary or merely beneficial? To answer these questions, one has to turn back in evolutionary time to the early appearance of brains and relatively simple collections of nerve cells in nonsleeping invertebrates. At those times, natural selection would have favored animals whose simple brain tissues were versatile, that is, had evolved the capacity to carry out more than one function.

A given amount of brain tissue in such animals would have been able to carry out more processing than could the same amount in animals whose brain tissues were dedicated only to specific functions. These circumstances are now recognized as a fundamental dogma of neuroscience. According to this dogma, memories are stored in the same collections of brain cells involved in processing, analyzing, and controlling responses to the situations to be remembered. In a striking example of these circumstances, after severe damage to certain limited brain regions, some patients not only become blind to colors, they are unable even to remember what a color is. In other words, the damaged brain circuits were involved in both seeing and remembering colors.

While such circuits with multiple functional capacities were highly adaptive for animals with the simple, stationary lifestyles in which the circuits had evolved, this versatility could have led to conflict in a more complex, highly mobile existence. For example, if circuits were occupied with a high-priority function during waking, say the escape from a newly encountered predator, the same circuits might not have been able to carry out, simultaneously and efficiently, the lower-priority function of processing the memory of how the escape was achieved. That might have had to wait until the subsequent period of "restful waking," or primitive sleep, after the urgent escape had been accomplished.

Just such a conflict in highly mobile animals in complex environments—an inability of certain brain circuitry with multiple functional capacities to cope efficiently with more than one function at a time—is believed to have been the selective pressure that gave rise to earliest sleep, in other words, sleep's "ultimate cause." In this sense—of infeasibility of efficient occurrence of certain brain functions in the same neural circuitry at the same time—an aspect of time was responsible for sleep's origin.

Detailed Focal Vision's Role in the Origin of Sleep

The evolutionary progression toward primitive sleep is thought to have begun when animals were evolving increasingly complex, highly mobile lifestyles (control of which is one of the brain's main functions) and detailed focal vision (vision that recreates a complex scene). Such vision requires enormous amounts of neural processing. Thus, almost 50% of the neocortical neurons and circuitry (the most recently evolved portion of the brain) of the primate are devoted to representing the pictorial world. The processing is vastly more complex than for any other sense, even more so than for all other senses combined. Without focusing on any specific region of a scene, one becomes aware of the simultaneous, space-filling presence of almost limitless numbers of objects, of all sizes, shapes, orientations, positions, depths, textures, and colors—all involving tremendous amounts of information.

In those ancient times, as animals acquired detailed focal vision, their lifestyles would have become markedly altered. With sharper discriminations and engagement in multifarious new activities, including fast, wide-ranging movements and rapid actions and responses, it would have been crucial to retain greatly increased stores of memories for the long term.

In these circumstances, the parallel processing capacity of some regions of these animals' brains would have become severely taxed. It would have become increasingly difficult for brain regions with multiple functional capacities to meet demands associated with crucial, largely unpredictable hazards and routine but essential needs, while at the same time (the role of simultaneity of time) meeting needs to acquire and maintain large stores of long-term memories.

In essence, an adaptation that initially conferred great efficiency of brain operation, before the evolution of great mobility and detailed focal vision, would have become increasingly less efficient as highly mobile, more complex visual lifestyles evolved, had not compensating features evolved in parallel—first restful waking and, eventually, primitive sleep. Accordingly, the selective pressure for primitive sleep probably was the need to resolve these developing conflicts. This could have been achieved most readily through the provision of a period with a greater degree of brain unresponsiveness to outside occurrences than exists during restful waking, namely, primitive sleep.

By providing a portion of the 24-hour cycle when enormously increased needs for memory processing could be accommodated efficiently, primitive sleep obviated any possible conflicts with urgent waking brain activities, particularly the rapid processing and responding to increasingly complex and varied visual inputs.

It follows from this mode of origin of primitive sleep that entirely sessile and very slow-moving animals, such as mussels, sea anemones, starfish, and some worms, would have no need for sleep. It also follows that sleep would be engaged in only during that part of an animal's existence when danger was at a relative minimum and rapid movements usually were unnecessary, for example, during the night for day-active animals.

The long-sought ultimate function of sleep thus appears to be an "enabling" one. Sleep enables the brain to operate with high efficiency at all times. This was accomplished by the evolution of a vigilance state to which low-priority waking brain activities, particularly the enormously increased needs for memory processing, could be deferred.

This scenario for the origin and ultimate function of primitive sleep does not rule out the subsequent or accompanying evolution of secondary (proximate) functions that may have become essential. Indeed, several proximate functions besides memory processing now play important roles. These include rest and rejuvenation, as well as many deep-seated rhythmical changes that influence physiological processes.

Beyond the superficial, some occurrences that appeared to contradict this paradigm, and that long contributed to obscuring sleep's significance, are readily reconciled. These included a continuing need for sleep by blind animals and an absence of sleep in some fishes, despite their having excellent vision.

Actions of Brain Waves and States of Awareness During Sleep

Attention here is directed largely to the sleep of mammals and birds, in most of which both the REM and NREM states occur. Earliest sleep probably most closely resembled the predominantly slow-wave, arrhythmic, high-voltage spiking as it now occurs in cold-blooded vertebrates. REM sleep, which awaited the evolution of warm-bloodedness, is essentially a specialization of a portion of primitive sleep, in which certain fast and slow brain-wave components have come to predominate.

Both slow (≤ 14 cycles per second [cycles/s]) and fast (> 14 cycles/s) spontaneously generated electrical brain oscillations are present to varying degrees in human electroencephalograms (EEGs) during waking and NREM and REM sleep. The designations "slow waves" and "fast waves" for scalp EEGs are used only for convenience. It is often the global oscillatory brain states that are involved, of which slow and fast scalp-waves are merely superficial manifestations. These oscillations play roles at all levels of brain function.

The fast waves, which greatly predominate during REM sleep, are nonsynchronous, and of relatively low voltage (several-microvolt range). In most mammals the EEGs of this state are very similar to those of wakefulness, a sure indication that similar brain activities occur in both states. Not only does sleep have a role in the differing frequencies of slow and fast brain waves, but these waves likewise have a role in the origin of the cyclic alternation between NREM and REM sleep.

One of the keys to REM sleep's principal adaptive features in the adult, as in wakefulness, lies in the predominance and principal actions of the brain's gamma oscillations (30–100 cycles/s). Thus, REM oscillations in the gamma band predominantly participate in memory processing by actions first suggested by Christoph von der Malsburg. This processing is generally referred to as "temporal binding," or binding by synchrony.

In the temporal binding of a memory during sleep, the memory's circuit fragments, located in widely distributed neocortical regions, are mobilized and synchronously activated by the gamma oscillations. These actions usually result in reinforcement and transient recall of the memory. At the same time, all individual connections (synapses) between the fragments are reinforced (accomplished by their mere activation). In short, the gamma oscillations of REM sleep bring about the reinforcement of neocortical memories, often resulting in the "unconscious" awareness of them, which we call "dreaming."

This temporal binding by gamma oscillations also figures largely in the formation of waking thoughts and perceptions during cognitive processing, including their recall from long-term memory. In higher vertebrates, this formation of a memory by the temporal binding of its fragments can be regarded as the neural correlate of consciousness. However, the contents of unbound fragments of memories are meaningless.

The synchronous, relatively high-voltage (in a somewhat higher microvolt range) slow waves of sleep have three principal functions. In one function, during NREM sleep, they activate and reinforce only the synapses within the enormous numbers of memory-circuit fragments. Unconscious awareness (dreaming) of the contents of these fragments does not occur, because, as noted, without temporal binding, the contents are meaningless.

A second principal function of slow waves during NREM sleep is the consolidation of declarative memories, which involves the conscious recollection or explicit remembering of facts or events. In this process, known as "hippocampal replay," distributed hippocampal circuit fragments of recent short-term memories become established at distributed locations in the neocortex for long-term storage.

The third principal function of slow waves during sleep is carried out by highly synchronous hippocampal REM theta waves (4–8 cycles/s), the largest and most regular slow waves. It seems likely that these waves serially link selected groups of memories assembled by gamma oscillations. Groups of memories so linked often are manifested as continuous or narrative dreams.

As an example, the fragments of a visual memory would represent such characteristics as shape, size, orientation, color, texture, and so forth. Most of these fragments are distributed in the neocortex. Mobilizing and temporally binding them (which requires a period of 100–200 milliseconds) produces the conscious (awake) or unconscious (dreaming) visual memory.

Slow and fast waves are thought to act cooperatively in reinforcement during sleep. NREM slow waves reinforce synapses within enormous numbers of memory fragments and participate in hippocampal replay. REM gamma waves reinforce synapses between the specific combinations of memory fragments that yield the corresponding memories, and REM theta waves link these memories, often expressed as narrative dreams.

Predominantly slow-wave, arrhythmic, high-voltage spiking generally occurs during restful waking and sleep in reptiles. The fast and slow brain-waves that temporally bind memories and serially link the bound memories, make their appearance abundantly only during arousal and wakefulness. Reinforcement of memory fragments by slow waves during sleep probably occurs on a nightly basis. This would have been the principal primitive sleep–associated mechanism of memory maintenance in reptiles, inherited by mammals and birds as the chief action during their NREM sleep.

The stimulation of circuits controlling muscle contractions during the sleep of cold-blooded vertebrates and NREM sleep of mammals and birds reinforces the circuits but fails to produce contractions (which would disturb sleep) because the muscles have partially lost their tone. Stimulation of circuits for fragments of thoughts and perceptions in mammals and birds during sleep also reinforces the circuits but produces no awareness. To the minor extent that properties of REM sleep overlap those of NREM sleep, dreaming can occur, but the NREM dreams are mostly of the static or thoughtful variety.

While the gamma oscillations of REM sleep temporally bind circuits controlling skeletal muscle contractions, the muscles—excluding those of the diaphragm—do not contract then, either, because they are completely without tone. If, in abnormal circumstances, skeletal muscle tone is not lost, dreams are acted out with startling reality, sometimes with injury.

It follows that the most favorable time for reinforcing circuits controlling muscle contractions is during REM sleep. Further, during REM sleep there is a high degree of perceptual isolation from external stimuli, and behavioral responsiveness is reduced. Because of this, the temporal binding of fragments of motor circuitry and serial linking of the bound fragments during REM sleep do not produce contractions—only dreams.

NREM and REM Sleep Cycling

NREM and REM sleep alternate in roughly 90-minute cycles in human adults. The most efficient memory processing in most mammals and birds appears to be a multistep affair. First, memory fragments are reinforced by slow waves, primarily during NREM sleep, which accounts for 75% to 85% of total adult sleep time. The fragments then become temporally bound into memories by gamma waves, including reinforcement, during REM sleep—different ones on different nights. These, in turn, become linked by theta waves, often producing narrative dreams, also primarily during REM sleep.

The role that time plays in the occurrence of NREM–REM sleep cycling during a night's sleep can be elucidated as follows: It is reasonable to assume that some minimal time is required to achieve an effective measure of the characteristic actions that occur during each sleep state. Accordingly, one would expect 4 or 5 90-minute NREM–REM cycles occurring in sequence in humans, with the length of each sleep state fulfilling the minimum, to be more effective than one long biphasic period lasting 6 to 8 hours, with the length of each state greatly exceeding the minimum.

Because multiplication and reduction of physiological processes and structural elements are among the most common achievements of evolutionary processes, these circumstances would account for sleep having become partitioned into multiple NREM–REM cycles in most warm-blooded animals.

Sloterdijk, Peter (1947–)

Peter Sloterdijk was born on June 26, 1947, in Karlsruhe, Germany, to a German mother and a Dutch father. He studied philosophy, history, and German at the universities in Munich and Hamburg and received a Ph.D. in German literature in 1976. In 1983 he became the shooting star of German philosophy with the publication of his early main work *Die Kritik der zynischen Vernunft* (The

Critique of Cynical Reason), which is of particular importance for his views concerning time. It was translated into English in 1987. The most important work of his current period is a three-volume project titled *Spheres*. Since 2001 Sloterdijk has been the rector at the Staatlichen Hochschule für Gestaltung in Karlsruhe. With Ruediger Safranski he has been host of the television show *Philosophical Quartet* since 2002, in which leading intellectuals discuss topics of current importance. Together with Jürgen Habermas he is widely seen as the leading German philosopher alive today. Some academic philosophers regard him as a charlatan, however, claiming that he lacks academic rigor and deals with topics not normally discussed in academic philosophy. Yet, even Habermas reviewed Sloterdijk's *Critique of Cynical Reason*. Sloterdijk's views concerning time also stem from this work, still considered his most important.

Critique of Cynical Reason

Sloterdijk is a vehement critic of all abstract philosophical topics such as time; he regards it as futile to attempt to give a philosophical account of them. Only young people, outsiders, and clerics are supposed to be interested in them, according to him. Through such comments Sloterdijk's Nietzschean heritage becomes clear, as both thinkers argue against the plausibility of positions by reference to their origin. Neither of them commits the genetic fallacy, as they do not attempt to put forward the truth in correspondence with the world because they are skeptical of the possibility of grasping the truth in correspondence with the world. However, by putting forward this type of criticism, they try to undermine the plausibility of those beliefs against which they argue.

Sloterdijk's main contributions to the philosophy of time are his views concerning the Zeitgeist, the spirit of our times. In his *Critique of Cynical Reason,* he puts forward an interpretation of the Enlightenment similar to that of Nietzsche and Spengler. According to him, the Enlightenment brought about the end of the Christian domination of the Western world, a destruction of ideals, absolutes, or truths, with respect to both ontology and morality. In great detail he analyzes various types of critique with which the Enlightenment is connected: critique of revelation, religious illusion, metaphysical illusion, idealistic superstructure, moral illusion, transparency, natural illusion, and the illusion of privacy. According to Sloterdijk the history of criticism has been connected with laughter, gaiety, the affirmation of life, and the satiric tradition. However, the outcome of the Enlightenment brought about an attitude toward life that is different from that satirical tradition.

Cynicism and Kynicism

Our times are supposed to be dominated by misery, depression, and pessimism. Sloterdijk calls this attitude toward life "cynicism." He distinguishes between "cynicism" and "kynicism," and he is critical of the former but affirmative of the latter. Cynicism is enlightened false consciousness, and he regards it as a modern universal problem as it is supposed to be the dominant attitude toward life in enlightened countries. Kynicism, on the other hand, is also connected to an enlightened attitude toward life. In contrast to cynicism, it is an enlightened correct consciousness. Cynics are aware of the various types of criticisms. In addition, cynics see that they are part of institutions and bound to moralities that they cannot justify for themselves, given all the critiques of which they are aware. As a consequence, cynics are miserable. The philosopher and cultural critic Theodor Adorno (1903–1969) is seen as a prototype of a cynic by Sloterdijk. Kynics, on the other hand, are aware of the very same situation as cynics but, in contrast to cynics, kynics are able to say "yes" to it. Kynics are cheerful, life-affirming, full of vitality, and also cheeky, and they argue with the whole of their bodies, especially with its lower part, which is supposed to have been neglected throughout the history of philosophy. Diogenes is the role model of a kynic. Traditionally, the carnival, universities, and bohemians have been connected with the kynical tradition. By putting forward a critique of cynical reason, Sloterdijk tries to show why the kynical attitude is far more appealing and more appropriate for modern times than is the cynical one. In his descriptions of various cultures, Sloterdijk gives a poignant summary of the dominant Zeitgeist, and the presentation of such descriptions has been called Sloterdijk's greatest ability.

Smith, William (1769–1839)

William Smith was an English surveyor, canal builder, and amateur geologist who became known as the "father of English geology." His main achievement was the creation of the first geological map, using fossils as a tool for mapping rocks by their stratigraphical order.

Smith was born in Churchill, Oxfordshire, into a humble family, and he received a limited education, although his work as a land surveyor for Edward Webb gave him a deep knowledge of the rocks. While working in an estate's pit mine in Somerset, he noticed that the strata were arranged in a predictable pattern and that the various strata could always be found in the same relative positions. Moreover, he realized that fossils were arranged in order and regularly in strata, always in the same order from the bottom to the top of a section, each stratum being characterized by a particular type of fossils. These observations lead him to propose the principle of faunal succession, according to which strata could be traced and correlated by comparing the fossils that they contained. Smith was probably the first to suggest that strata and their fossils were displayed in a natural order of indefinitely wide extension.

While he was working as a surveyor for a canal-building company until 1799, and later unemployed or taking different civil engineering jobs, he tried to test whether the same succession of fossil groups from older to younger rocks could be found all over England and if the relationships between the strata and their characteristics were consistent throughout the country. As a result of his research, Smith produced the first large-scale geological map of the area around Bath, Somerset, showing the outcrops of the rocks and their boundaries, coloring each rock type with a different color.

In 1815, after traveling all over England, mapping and collecting samples for more than a decade, and in spite of financial problems in funding his research, he published his masterpiece, the first geological map of England and Wales. The map itself is 6 feet across by 9 feet high, representing tens of thousands of square miles, and it used John Cary's national topographic map as a base map. This geologic map helped Smith to demonstrate the validity of his principle of faunal succession. Additionally, in 1816 Smith published the "Geological Table of Organized Fossils," which completed the first map. Whereas Smith's map was overlooked by some naturalists, George B. Greenough and collaborators plagiarized it and sold it at a lower price, pushing Smith to bankruptcy and to debtor's prison in 1819. Released from prison, he worked as a surveyor for different employers, and conceived a more ambitious idea: the preparation of 60 geologic maps of individual counties in much greater detail, from which he finally prepared 21.

It was not until 1831 that his work was finally recognized. He was awarded the first Wollaston medal, the highest honor of the Geological Society of London. Afterward, his scientific achievements were widely appreciated; he was offered an honorary Doctorate of Laws by Trinity College and received a lifetime pension, awarded by King William IV. William Smith died on August 28, 1839, in Northampton, and he is buried in St. Peter's Church.

Solipsism

Solipsism (from the Latin *solus ipse* "[one]self alone") is the thesis that *I,* the one who is thinking, am the only one who really exists. The term is ambiguous, and can be taken in a metaphysical, ontological, epistemological, or methodological sense. The status of time with regard to solipsism varies depending on which sense is in use.

Metaphysical solipsism is the thesis that the world is dependent on *me.* In this case, it seems that time must be an unreal, purely subjective, phenomenon that is created by the solipsistic mind. The pragmatist George Santayana and early analytic philosopher Bertrand Russell both argue that, in order to remain consistent, any (metaphysical) solipsism must be "present-moment solipsism." If one is going to be skeptical about the induction that other minds exist, then one must be skeptical about the induction that one has a past or future too: Only the present moment is known.

The view that the structure of reality—that is, the way the world is categorized—depends on *me* is a subclass of metaphysical solipsism called ontological solipsism. This view is often associated with transcendental idealism, which was popular in later modern philosophy beginning with Immanuel Kant. The later transcendentalism of Ludwig Wittgenstein can also be understood in terms of ontology, although it may be conceived more properly as a semantic theory. For this type of solipsism, time is frequently thought of as a necessary, a priori condition for structuring the matter of the world either conceptually, as for Kant, or linguistically, as for Wittgenstein.

Epistemological solipsism holds either that *I* cannot know that my experiences do not exhaust reality or, more strongly, that *I* can justifiably believe that my experience is the only experience. This view may be taken with either of the views above in mind. Another, weaker form of epistemological solipsism is often associated with strong foundationalism: the view that the starting point for all knowledge is basic knowledge about one's internal world. This view does not seem to imply any particular view about time necessarily. Depending on how strongly one holds the position, one might claim that one simply does not know about the reality of time or that one knows it as a part of one's epistemically basic experiences.

René Descartes's method of doubt, as the forerunner of epistemological foundationalism, employed methodological solipsism. This is the view that one should suspend beliefs about the existence of other minds or other entities outside of one's own mind because this is the correct way to go about scientific or philosophical investigation. This view may be held independent of one's view about time. The investigation of time, however, would employ the method.

One of the most prominent attempts to reject solipsism is the pragmatic view that one simply cannot live as a solipsist—it is simply impossible to live without believing that other people and things exist. Other criticisms include Russell's rejection of present-moment solipsism and the later Wittgenstein's private-language argument.

Solstice

Solstice refers to the 2 days in the year when the length of daylight hours are either the longest or the shortest. The hours of daylight change because the earth's axis, an imaginary line drawn through the earth from one pole to the other, is not perpendicular to its orbit around the sun. The axis tilts from the vertical by 23.45°. As the planet moves around the sun and the earth rotates, there will be 1 day when the north pole will be pointing most directly toward the sun. A second day occurs when the south pole turns as closely as it can toward the sun.

As the north pole begins to point more directly toward the sun, the days grow longer. When the length of the daylight hours reaches maximum, this is the summer solstice. When daylight hours are at their minimum, it is the winter solstice. The times of sunrise and sunset at the winter solstice compared to the summer solstice can differ by nearly 3 1/2 hours.

In the northern hemisphere, the summer solstice occurs in June, marking the beginning of summer. At that time in the southern hemisphere, it is the winter solstice and the beginning of winter. Conversely, in December, in the north, when the day is the shortest, the winter solstice occurs. In the southern hemisphere, it is the beginning of summer. The exact days when these events occur vary between June 20 and 23 and December 21 and 22.

During the course of the year, as the time of solstice approaches, depending on whether summer or winter is coming and in which hemisphere, the sun will rise and set further and further north or south. There is a point at which, for a short period of days, this progression slows. The sun appears to rise and set in the same place. This accounts for the name given to the solstice events by the Romans, *sol stetit,* meaning the sun stood still. In primitive times, with the importance of agriculture, many cultures celebrated the summer and winter solstices.

Ancient stone structures such as Stonehenge (England) and petroglyphs (rock carvings) were ways of calculating the exact occurrence of solstices and other astronomical data. For example, at Chaco Canyon in New Mexico, a single blade of light bisects a carving called the Sun Dagger as sunrise begins on the summer solstice.

Today, most of the civilized world barely acknowledges the summer solstice. However, celebrations of the winter solstice live on in some of the traditions associated with Christmas and New Year's Day. Even the date of Christmas may have been moved from what was believed to be the Nativity (January 6) to December 25 in order to capitalize on preexisting pagan celebrations of the winter solstice.

Space

The general history of the concept of space can be divided into two epochs: the Aristotelian period and the Newtonian period. A third epoch, which is a consequence of the rethinking of Newtonian spatiality, especially by Einstein in the early 20th century, can be identified with relativistic spacetime theory. In each epoch the physical concept of space rested upon geometrical as well as cosmological concepts of spatiality, which furthermore was set in a cultural context by which certain understandings of space were encouraged and others ignored or suppressed.

Early Concepts

The dominant spatial concept in antiquity was that of place (Greek *topos*). Within his epistemology the Greek philosopher Aristotle (384–322 BCE) first classified place as a linguistic category, by which anything can be described according to *where* it is. Subsequently in *Physics* he defined the place as the surrounding border of any material object: A place has in itself no extension and is invariable. According to Aristotle it is a pure modality of things being, therefore the place itself cannot be moved; only things can change their places. By this concept Aristotle tried to solve a problem that was posed by Zeno of Elea (c. 495–445 BCE), who argued that trying to physically describe the traversing of a given distance (which is the literal meaning of the later Latin word *spatium*) leads to certain paradoxes: especially to the one that an infinite number of points to which any distance can be reduced in geometrical respect makes it logically impossible to traverse all single "spots" (for their number is infinite). In turn Aristotle tried to emphasize the physical concept of becoming as a change (of place) and to separate the concept of place from a pure geometrical definition. Nevertheless, his concept also caused theoretical problems: If place was the location of things, where then is a certain place itself located?

This problem had already been discussed before Aristotle, namely, by his teacher Plato (427–347 BCE), who argued that there has to be something which "gives place" to any possible being (including locations). Plato called this the *chora:* He defined it as an instance that is in between the realm of the eternal ideas and the world of becoming. The concept of chora can be interpreted as a forerunner of the Newtonian concept of "absolute space" insofar as it is conceived as the horizon or context of any possible existence in the physical world.

Nonetheless Plato's concept had less impact on ancient physics as well as on medieval ontology, where the Aristotelian view prevailed. The reason for this was Aristotle's cosmology (which was the background to his physics), which called for a "first mover" (which in the Christian interpretation was identified with God), located at the edge of the outermost sphere from where God caused any physical process in the world. Aristotelian physics and its cosmological framework are nevertheless typical for ancient Greek philosophy, within which scientific reflection always began with the question of an origin (*arche*), or what being is in total. In this way many Presocratic philosophers evoked a certain concept of spatiality when they tried to answer these general questions: The first philosopher, Hesiod (c. 700 BCE), for example, defined the origin as an opening or abyss (*chaos*) and thereby anticipated Plato's concept of chora. Anaximander (c. 610–c. 546 BCE) defined the totality of being as that which is without a border (*a-peiron*) in the spatial as well as temporal sense. In the same respect Parmenides (early to mid-5th century BCE) conceived of totality as a spherical entity outside which nothing exists. Like Aristotle, many ancient theorists of space agree on the idea that within the (finite) world everything is of matter or substance and that nothing like a void exists. Exceptions can be found in atomistic concepts, for example, in Leucippus (late 5th century BCE) and Democritus (c. 460–c. 370 BCE), who argued that in between atoms, in order for them to be moveable, there is a void.

Aquinas and After

The fundamental change within the conceptualization of space presupposed a turning away from the cosmology of a finite universe, which especially was promoted by Thomas Aquinas (c. 1225–1274), who had adopted the Aristotelian worldview. Against it theologians like Giordano Bruno (1548–1600) and Nicholas of Cusa (1401–1444) posed the idea of the cosmos as something infinite, indeed the universe as one of an infinite number of universes. The perspective on the cosmos with the earth at its very center got qualified as only one possible perspective among others. Especially in early Italian Renaissance philosophy, this cosmological turn was of great impact: It coincided with the new and even modern ontology of the world as something that can only be perceived or described from a certain standpoint. Likewise, the technique of linear perspective painting became established as an adequate form of pictorial representation in which a certain point of view on the world was accepted as sufficient.

The decentralization of the earth as envisaged by Nicolaus Copernicus (1473–1543) thus can be considered a consequence of the perspectival and optical theory of representation: Even though Copernicus still denied the existence of empty space, he envisaged the possibility of a viewpoint from which the planets' movements might be described. However, the final impetus for a new concept of physical space came from a theological as well as an experimental side. Already before Copernicus, the Jewish philosopher Hasdai Crescas (c. 1340–1410) argued that the Aristotelian concept of space as place is inconsistent, because a reduction of space, which is seen to be quantitatively identical with the surface of an object, could lead to an increase of the object's place (e.g., taking away a piece from a spherical object increases the outline of that body). Crescas thereby actually did not only prove Aristotle's concept of space as place to be incorrect, but also his critique showed that the epistemological basis for ancient physics had begun to erode: The new understanding of space to emerge was that of volume as the (geometrical) product of a three-dimensional extension.

But in order for volume as the definition of space to be accepted, first of all the existence of empty space had to be proven. This was done by Otto von Guericke (1602–1686), who in the 17th century developed an air-pump and demonstrated the power of vacuum in his hemispherical experiments. Guericke's demonstration gave way to the procession of the Newtonian worldview, which rested mainly on the acceptance of space as void and stood in a strong contrast to the dominant theory of matter in the baroque era, which still was committed to Aristotelian ontology. Especially René Descartes's (1569–1650) theory of physical space as *plenum* gave a strong backing to this substantialism as he defined the external world as continuous and of a material character (*res extensa*).

Newtonian Space

Against the Aristotelian–Cartesian heritage, Isaac Newton (1642–1727) established a new understanding of space. Newton was trained in the Neoplatonic tradition of Cambridge, where his teacher Henry More (1614–1687) introduced him to the kabbalistic concept of space as *makom*. That expression could stand for the divine being, but as a concept it first of all meant "indivisibility," which became the core concept for the notion of absolute space. According to Newton, space in total cannot be divided; it is not the sum of all (relative) spaces, but is spatiality as such. This new concept finally overthrew the whole Aristotelian physics in which the universe was finite and spatiality bound to the locality of an object as well as its substance. From here the Platonic concept of chora can be interpreted as a forerunner of Newton's concept of absolute space, which now includes Nicholas of Cusa's and Bruno's idea of the infinity of the universe as well as the Copernican worldview. According to this view, the earth's movement is not only relative to the sun, but any position of any planet is relative to the others. For Newton there was no center of the universe, but also no end to it. What Newton named absolute space can thus be considered a matrix: It is the totality of all measurable relations between objects. By this there was no "place" in this universe anymore for a divine creator being the cause of all movement within it. Instead Newton supposed matter (as *mass*) itself to be the cause for movement by means of attraction.

Newton's concept was widely discussed, and he was especially accused of promoting an atheistic philosophy—physics. Anticipating that charge, Newton in some exemplars of his *Opticks* wrote that space is the organ with which God "perceives" the world, stating that he nevertheless believed God existed. It was Gottfried Wilhelm Leibniz (1646–1716), in a dispute with the Newtonian Samuel Clarke (1675–1729), who argued that such a concept is not only atheistic, but first of all that it is false. In contrast to Aristotle, who implied that location is the definition of space, Leibniz argued that not the topos in itself, but the relation between the topoi is what defines space. Leibniz thereby is a forerunner of a topological concept of spatiality, which was further developed by Leonhard Euler (1707–1783) in the 18th century, Johann Benedict Listing (1808–1882) in the 19th, and Jules Henri Poincaré (1854–1912) in the 20th century. A topological description of space (Leibniz called it *analysis situs*) thereby is less interested in physics or in the motion of matter, but furthermore in a transformation of Euclidian geometry into nongraphic algebra and process geometry purely by calculation.

This was the main reason why the dispute between Leibniz and Clarke could not be resolved in either of the two fields (geometry or physics) but only on a different stage of reflection. A solution to this dispute on space was developed by Immanuel Kant (1724–1804), who stated that definition of space as an extension measurable in three dimensions is the very and only condition of any perception by the external senses. In contrast to time, which rests upon the inner condition of (memorable) succession, space (extension) is something that underlies any possible appearance ("in space"). However, the Kantian concept of space did not (yet) imply the understanding of space as dependent on individual perception; rather, Kant talks about an imaginable space, a space that can be (geometrically) constructed independently from any given situation. Therefore Kant does not talk about the construction of space by individual cognition but about the general constructability of objects or the relations between them. In contrast to the approach of Leibniz, which considered the construction being a priori to the spatial appearance, Kant conceived of spatiality as something even prior to the topological construction of it.

Subjectivity, Non-Euclidian Space, and Einstein

It was not until the 19th century when Kant's concept of space was transformed into the concept of subjectivity as it is widely understood today. Subjectivity in the post-Kantian sense rests upon a physiological understanding of perception, which implies that spatiality is subject to the condition of each species or even of each individual. Especially in psychophysics and physiology with Gustav Theodor Fechner (1801–1887) and Hermann Helmholtz (1821–1894), space was qualified as variable according to different impressions and therefore became a question of experience in the strong sense.

It was at that time that non-Euclidian geometers tried to find an alternative basis for geometry, avoiding the parallel axiom. In psychophysics the new geometrical approach found a stronghold for the idea that space not necessarily has to be defined as an extensive realm in which each place can sufficiently be located by three coordinates. For what is missing is a parameter for describing the space as something that can also appear as curved, as is the case in individual perception. Even when the Cartesian system of coordinates enables one to describe all the locations in respect to a "point zero," none of the three values depicts the qualitative form of space, neither in perception (where the field of vision is curved in relation to the viewer) nor in geodetics (where the surface of the earth is measured as a curved one). Non-Euclidian geometry and modern topological approaches began to cause a rethinking of physical space, which until then was bound to Newton's concept of space, seen as homogeneous and as an entity separated from time.

Against the latter aspect Hermann Minkowski (1864–1909) argued that time and space cannot be seen as different entities but are two aspects of the same physical event. Just as time has an extension, space is of a certain age. Minkowski's student Albert Einstein (1879–1955) then developed a relativistic theory of space, in which he claimed Newton's difference of absolute and relative space fostered an image of space as a container. Einstein's argument was that the movement of a physical body, described on the level of absolute space, implies a movement of the relative spaces themselves. However, Einstein wanted to look on (absolute) space as being relative not to another space, but to matter, which furthermore is claimed to be determined by an electromagnetic field. In consequence, on the one hand, Einstein transforms the Newtonian notion of space by claiming absolute space itself to be relative; with this, on the other hand, former concepts in physics that had been superseded became reestablished—for example, as Einstein pointed out, in the concept of a field, Descartes's idea of space as a continuous plenum returns. By looking upon space as being of a certain age, space then cannot be infinite anymore, because since the big bang, it started to expand and was transformed within its temporal development. In recent cosmology, especially in string theory, space is not only conceived of as interweaved with time, but spacetime possesses at least 10 different spatial dimensions.

Space and Cultural Discourse

In contrast to scientific and also philosophical concepts of space, the notion of cultural or anthropological space as it can be found throughout the 20th century does not ask for a definition of the origin, the essence, or the true concept of space, but for spatial practices as well as for the production of spatiality. An important figure in the modern cultural discourse on space is Ernst Cassirer (1874–1945), who claimed that in anthropological terms, it is less useful to think about space as such than to look upon different structures that have constituted cultural and aesthetic spaces throughout history. His claim directly influenced the art historian Erwin Panofsky (1892–1968), who analyzed the pictorial presentation system of central perspective as a symbolic form that first of all constituted the idea of a homogeneous space in paintings as well as in architecture. Furthermore Cassirer influenced the anthropologist Claude Lévi-Strauss (b. 1908), who analyzed archaic cultures by looking at the way they structure their material world, such as in settlements, housing, and craftwork, in respect to the structure of the intelligible world, like a specific myth or the given rules for marriage. The cultural approach to space in cultural theory was later renewed by Michel Foucault (1926–1984) who applied the structuralist description of spatiality not only to different historical forms of space but also to scientific concepts of space, stating that they share the same "discourse" or paradigm, like the corresponding structure of a given culture does.

Space, Absolute

In his 1687 work *Mathematical Principles of Natural Philosophy* Isaac Newton defines *absolute space* as something that is "without relation to anything external" and "remains always similar and immovable." In contrast to absolute space, *relative space* "is some movable dimension or measure of the absolute spaces; which our senses determine by its position to bodies; and which is commonly taken for immovable space" (Scholium II). Similar to his differentiation of "absolute time" and "relative time" in the same context, Newton's definition of two types of space fundamentally changed the basis for the physical description of movement in the field of mechanics: Until the 17th century, movement was defined as a change of place by an object. With Newton, a different definition was consolidated: Movement is movement through space. Newton defines relative space as everything that is in relation to a certain object moving and absolute space as the level of comparing two or more of these relations in relative space. Thereby both "spaces" are no longer conceived as substantial, but as a frame or matrix for describing movement. Mostly—and already by Newton's critiques—these conceptions were interpreted against the background of space as substance: Descartes in his *Principles of Philosophy* (1644), for example, defined space as *plenum;* in other words, as the substance of all things being (*res extensae*). The idea of space as void had already been considered by ancient philosophers but had not been accepted until experimental proof for its "existence" was given by Otto von Guericke, who invented the vacuum pump in 1650 and demonstrated the virtue of vacuum 13 years later by joining two copper hemispheres, from which he pumped out the air and showed that power of eight horses was insufficient to separate them. Consequently Newton did not intend to define absolute space as an absolute substance but, on the contrary, as the totality in which any substance is located and can be described according to its position. Newton was directly inspired by his Neoplatonist teacher Henry More in Cambridge, who introduced his pupil to the Kabbalist notion of *makom,* which defines space as something that is inseparable. That definition met on the one hand with the Platonic notion of space as *chora* (defined as that which "gives birth" to becoming) and on the other hand with Renaissance considerations that the universe is infinite. In accordance with this metaphysical grounding, absolute space gave Newton the framework for his interpretation of the causation of movement through gravitational forces (*actio in distans*) in between objects, or "physical bodies." From a theological perspective Newton's concept was criticized for either leaving no place for God or for turning space into a medium (*sensorium*) for God's perception of the world (as Newton himself tried to explain it in his *Opticks*). The model of absolute space subsequently became *the* concept of space in modern times. In particular, Kantian epistemology conceived of space neither as a holistic substance nor as the sum of singular spaces, but first of all as the possibility of perceiving as well as describing things spatially, that is, constructing and defining them geometrically. In the late 19th century, Newton's concept of space was questioned by physicists such as Ernst Mach and the mathematician Hermann Minkowski, who argued for the coupling of the concepts of time and space that were discussed separately in Newtonian mechanics. The resulting concept of *spacetime* then became the basis for the theory of relativity, with which Albert Einstein interpreted Newton's physics to be valid only as a special case.

Space and Time

Until the beginning of the 20th century, time and space were treated as two distinct modalities of being. It was only following the pioneering work of Albert Einstein that time and space were defined as inseparable with respect to physics, and consequently also in metaphysics. The separation of time and space can be pointed out in ancient philosophy as well as in classical physics and philosophy, namely in Aristotle, Isaac Newton, and Immanuel Kant. For all of them Einstein's physics of relativity meant a categorical break to the conception of matter in particular as well as being in total. All three conceptions of time and space rested upon a mechanical view of the world by which time was conceived as the duration a physical entity takes to traverse space. Thus, time furthermore was looked on as derivative of space, for only space allowed a definition of time in the sense of traversing a certain distance within space or to change place. For this reason, even though time and space were treated as different entities, the two concepts correspond strongly or even mirror each other.

In Einstein's era, alongside the new definition of an inseparable physical spacetime, time as such on behalf of metaphysics was then identified with lived (experienced or remembered) time. In early 20th-century philosophy, this led to a dominance of time over space, which from then on was correlated with the dead aspect of matter. This reevaluation of the former dominance of physical space over physical time started with Kant, who defined time and space as subjective forms of imagination. Until then, and in contrast to ancient physics, time and space both were still objective determinations: Aristotle defined time as the succession of a change of place—that is, the measurement of the states before and after. Even though he did not have a concept of space in the modern sense (as extension), time for him implied a form of spatial movement. Aristotle's concept of space was that of *topos,* or space as "place." Place hereby is not understood in the sense of coordinates (as in Cartesian geometry) but is defined by the surface inhered by an object: Every object is spatially identifiable by the place it occupies. In accordance, time is defined as the change of place, that is, the object occupying a different place at one moment compared to another moment. Through this, Aristotelian physics relies on the concept of "presence," which means that "being here" (in a certain place) and "being now" (at a certain time) are the two modalities of matter that cannot be explained even though they both explain what space (as place) and time (as change of place) are. To overcome this notion, the modern concept of space as volume had to be introduced into physics. Volume is described as a three-dimensional extension that is independent from an actual existence of matter in place.

Isaac Newton's concepts of time and space have to be understood against this background: Space is not the place of a certain object, but extension or expansiveness as such. Time then is the duration it takes for an object to move through space. Newton thereby defines time as well as space in two respects. Both time and space persist in a relative way as well as in an absolute way. *Relative space* is the observable space or the given extension through which an object moves. Likewise, *relative time* is the corresponding duration. Both are measurable, and relative space as well as relative time can be quantified. On the contrary, *absolute space* and *absolute time* are not measurable but are assumed to be the frameworks by which each spatial or temporal quantification is comparable. That further means that a certain time an object takes to travel a certain distance can be compared with the time another object takes to travel the same distance, or a different distance in the same time.

Since Newton, it has been heavily discussed whether absolute time and absolute space really exist. If especially absolute space were real in the sense of an endless volume ("void") there would be no place for God, who in Aristotelian cosmology was seen as the overall agent of all motion in the universe, being located at the edge of the world, and—by means of the concept of gravitation—to Newton, having no longer any physical function in the world. Even though in the long run the impact of Newton's physics indeed was to promote an atheistic worldview, the interpretation of absolute space as existent is somewhat misleading and was not intended by Newton. As Immanuel Kant pointed out, (absolute) time and (absolute) space according to Newton have to be presupposed in order for physical descriptions to be scientific, that is, universal and comparable. Kant thus defined time and space as the "pure forms" of perception or intuition by which they are a priori to any experience; that is, any experience is already spatial as well as temporal, no matter in what quantity or quality it appears. Nothing can be perceived or even imagined that is not of a certain volume and persists for a certain time. Kant never made clear whether the three dimensions of space (volume) and the dimension of time (duration) are anthropological conditions of humankind. He gives some hints that especially the three-dimensionality itself is dependent on the sense of directionality, which in turn is derived from the subjective standpoint. However, what Kant made clear is that he does not consider the number of spatial dimensions to be objectively given. Thereby Kant's theory of space as a form of perception can be seen as compatible with anti-Euclidian concepts of space, insofar as Kant distinguishes between the form and the concept that is derived from that form within physics.

Even though Einstein's concept of a spacetime continuum is interpreted as overthrowing classical physics, it was Newton's understanding of time and space that in fact was the beginning of a relativistic concept of space and time. The main difference is that, to Einstein, relative space and relative time are all that can be accepted by modern physics. To Newton, the concept of anything being absolute and free from the influence of matter—which was the root of gravitation—was wrong. Einstein, then, overturned the idea of a spatial and temporal framing and started with matter/gravitation as the benchmark for physical description: Time and space are not prior to matter, but the physical "event" affects a qualitative difference in spacetime.

Spacetime, Curvature of

The concept of curvature can be approached through examination of two-dimensional surfaces. The floor of a room is flat, the surface of a ball or of the earth is curved. What does this mean more exactly? Let us imagine two wanderers going from place P to place Q along two different paths and carrying pointers which, in the beginning, were oriented in the same direction. Let the wanderers regulate the directions of their pointers in such a way that they do not change in the plane tangent to the surface of the earth (it is possible to envision this with the help of large-scale maps). It is easy to ascertain with the aid of a globe that, in the case of repeated meeting of the wanderers whose paths taken together enclose a large area, the directions of the pointers will be different (see Figure 1).

The path of a wanderer continuing in the initial direction of the pointer will be the most upright line on the earth's surface, the *geodesic.* Two initially parallel geodesics (principal circles on the spherical surface) will gradually approach each other and will finally intersect. But the direction of the parallel transported pointers would be independent on the path (see Figure 2), and the initially parallel geodesics would remain parallel in the case of flat, noncurved space.

Great mathematicians of the 18th and 19th centuries (Gauss, Riemann, Levi-Civita, and others) elaborated the concept of curvature and extended it to the case of spaces with arbitrary dimension. In the 20th century new, more abstract formulations succeeded, but in this entry the original, more intuitive definitions are retained.

Let us have in the space two "infinitesimally near" points P, Q with the coordinates x^i, $x^i + dx^i$. Let the vector (depicted by the arrow) have the component V^i, given in the point P. By its parallel transport into the point Q, the vector V^{*i} arises with the components

$$V^{*i} = V^i + DV^i = V^i \rightarrow \Gamma^i_{jk}(x^a)\, V^j\, dx^k. \qquad (1)$$

The coordinate dependent quantities Γ^i_{jk} are called the components of affine connection. Their prescription makes it possible to transport vectors in a parallel manner along an arbitrary path and to find the parametrically expressed geodesics (most direct lines) $x^i(\sigma)$ by solving the equation

$$\frac{d^2x^i}{d\sigma^2} + \Gamma^i_{jk}\frac{dx^j}{d\sigma}\frac{dx^k}{d\sigma} = 0. \qquad (2)$$

The geometrically natural request of closeness of infinitesimal parallelograms constructed by parallel transport leads to the symmetry of the components of the connection or, in the other words, to the zero value of the *torsion tensor* field

$$S^i_{jk} = \Gamma^i_{jk} \rightarrow \Gamma^i_{kj}. \qquad (3)$$

In the case of the *Riemannian spaces* with the infinitesimal distance ds defined as

$$ds^2 = g_{ik}(x^a)\, dx^i\, dx^k \qquad (4)$$

(g_{ik} are the components of the metrical field, or the metrics), it is natural to demand the inalterability of the lengths of parallel transported vectors and the angles between them. Thus in the case of zero

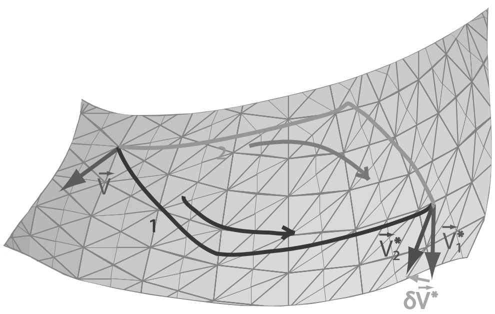

Figure 1

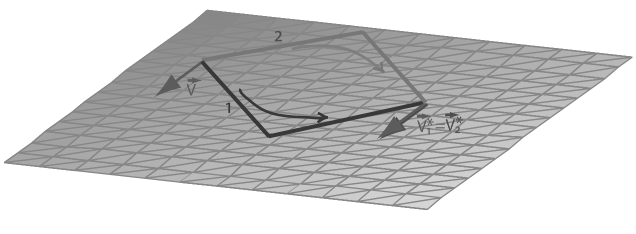

Figure 2

torsion (3), the relation can be derived

$$\Gamma^i_{jk} = \frac{1}{2} g^{is} \left(\frac{\partial g_{sj}}{\partial x^k} + \frac{\partial g_{sk}}{\partial x^j} - \frac{\partial g_{jk}}{\partial x^s} \right) \tag{5}$$

determining the components of the connection by help of the metrics (here, g^{ab} is the inverse matrix to the matrix g_{ab}). Then we speak about the Levi-Civita connection and the components of the connection (5) are called the Christoffel symbols. It is possible to introduce coordinate systems where these quantities are equal to zero in a prescribed point, with the effect that the equations of geodesics locally merge into the equations of right line. Such systems are "locally geodesic." Thus the Christoffel symbols do not determine the curvature of the space, only the curvature of the coordinate system.

To find the criterion of the curvature of the space, let us transport in parallel the vector V^i along the arms dx^i, dy^j of an infinitesimal parallelogram by both possible ways (see Figure 1). The difference of the transported vectors is given by

$$\delta V^{*i} = R^i_{jkl}\,(x^a)\, V^j dx^k dy^l \tag{6}$$

where

$$R^i_{jkl} = \frac{\partial \Gamma^i_{jl}}{\partial x^k} - \frac{\partial \Gamma^k_{jk}}{\partial x^l} + \Gamma^i_{nk}\Gamma^n_{jl} - \Gamma^i_{nl}\Gamma^n_{jk}\,. \tag{7}$$

Thus the curvature of the space is determined by the quantities R^i_{jkl}, which are the components of the curvature tensor field. Their zero values in the given point (or in some region) means that the space is flat here. They are constrained by some relations, which decrease the number of independent quantities. The one-dimensional space cannot be curved, and there are 2, 6, and 20 independent components in the two-dimensional, three-dimensional, and four-dimensional spaces, respectively.

According to Einstein's general theory of relativity, *spacetime* is the four-dimensional space of events with a special type of metrics, which allows the time coordinate to be distinguished from the space coordinate, and with the appropriate Levi-Civita connection. All relations and definitions presented above remain valid, but the square of the distance *ds* in the relation (4), now called the interval, can have a positive, negative, or zero square (which distinguishes the timelike, spacelike, and lightlike intervals). According to the general theory of relativity, spacetime is curved by its matter content in accordance with the Einstein equations (1915)

$$G_{ik} = R_{ik} - \tfrac{1}{2} R g_{ik} = (\kappa/c^2)\, T_{ik}. \tag{8}$$

Here κ is the Einsteinian gravitational constant, c is the speed of light, $R_{ik} = R^a_{iak}$ is the *Ricci tenzor,* $R = g_{ik} R_{ik}$ is the *scalar curvature*. The Ricci tensor and the scalar curvature are derived from the curvature tensor, but unlike the curvature tensor, they can be equal to zero even in curved space (or spacetime).

Thus the Einstein equations state the proportionality between the *Einstein tensor* G_{ik}, which has a purely geometric nature, and energy-momentum tensor T_{ik}, which describes basic mechanical properties of the content of spacetime—densities and flows of energy and momentum, pressures or tensions. (It is possible to include into it also the cosmological constant added later by Einstein and today usually related with the properties of a physical vacuum.) According to John A. Wheeler, "matter prescribes to spacetime how to curve itself" via the Einstein equations. The curvature of spacetime, caused by its matter content, represents the mathematical description of the gravitational interaction.

It follows from the Einstein equations that the particles of dust matter, subjected only to the gravitational influence described by the spacetime metrics and in this sense "free," trace by their motion geodesics in the spacetime (see equation [2]). So, according to Wheeler, "spacetime prescribes to matter how to move." The motion of light signals (or photons) corresponds to the geodesics of zero "length." The curvature of spacetime can be observed as changing distances of originally parallel geodesics or, physically expressed, as relative motions of free particles. In curved spacetime, one particle moves with respect to the other with relative acceleration. Consequently, gravitational influence causes the deformation of bodies. On the earth's surface, the well-known manifestation of tidal forces are marine tides. In strongly curved spacetimes in the nearness of massive bodies, the tidal forces manifest themselves more violently (the observer falling to the horizon of a black hole is deformed by them into a strip). Similarly, the influence of spacetime curvature on light rays causes an effect somewhat reminiscent of the functioning of a lens. The common gravitational force acting on bodies at the surface of the earth does not represent a manifestation of the curvature of spacetime. It is given by Christoffel symbols in equation (2), and consequently it can be "canceled" in the local geodesic system, that is, in a freely falling system from the physical point of view.

In the framework of spacetime geometry, it is also possible to consider the curvature of "space" as the three-dimensional section of spacetime. In some approaches to quantum gravity theory, three-dimensional geometries are considered as states of the quantum universe, and the task of theory is to determine the probabilities of transition between these states. In these approaches, time is a secondary construction.

In the field of cosmology, the curvature of the universe is often understood to be the curvature of three-dimensional space in a given moment of the evolution of the universe. Because this space is (on a large scale) homogeneous and isotropic according to standard cosmology, its curvature is completely determined by the scalar curvature.

The curvature of spacetime does not exhaust its unusual properties as possibly realized in spacetime. Non-Euclidean topology can be considered, with the impossibility of finding a mutually continuous map between spacetime and Euclidean space and, in such a way, to cover spacetime by one coordinate system. In spacetimes fulfilling the Einstein equations, singularities can arise, not allowing the prolongation of spacetime through them. These properties of spacetime could be important in astrophysics and in cosmology.

The concept of connection is logically independent of the concept of metrics. It is possible to consider connected curved spaces without metrics, with a connection related to metrics in another way as the Levi-Civita connection (5), or with a connection with nonzero torsion (3). Also nonsymmetric metrics ($g_{ik} \neq g_{ki}$) and various modifications of the Einstein equations have been considered.

These possibilities intrigued Einstein and other physicists and mathematicians (including Eddington, Schrödinger, Bach, Cartan, Hlavatý, and Moffat) after the rise in popularity of the theory of general relativity. They placed much hope in them: extension of the geometrical description of gravity to the other interactions (at first, mainly electromagnetic); exclusion of the phenomenological, not strictly determined energy–momentum tensor from the Einstein equations; or inclusion of the spin of matter among its fundamental properties. Many versions of unified theories of physics and of generalized theories of gravitation were derived, but—in contrast to the theory of general relativity—none of them was able to reach a satisfactory experimental corroboration. Currently, theories positing a larger number of spacetime dimensions seem to offer a hopeful direction for unifying the theories of physics.

Thanks to the work of É. Cartan (1923), Newton theory of gravity also was formulated in geometric language with the use of the concept of connection. Consequently, Newtonian gravity also can be understood as a manifestation of the curvature of spacetime.

Spacetime Continuum

The mathematician Hermann Minkowski, in his groundbreaking 1908 paper "Space and Time," stated that "henceforth space by itself, and time by itself, are doomed to fade away into mere shadows, and only a kind of union of the two will preserve an independent reality." Minkowski's insight referred to the fact that until the late 19th century, space and time in physics were treated as two separate entities. This was because traditional approaches used different ways of describing space and time, which again was a heritage of the dualistic ontology of the modern era.

Such ontology can be found especially in the work of René Descartes, who identified space with the outer realm and objects as matter (*res extensa*) in opposition to the rational interior (*res cogitans*). To Descartes the outer world furthermore was characterized as a *plenum,* which means that in his opinion there is no void, but that anything is of a certain substance: Anything that exists in the object world occupies space, because it is extended. The concept of *plenum* is not equal to space itself, but to the continuity of matter, which fills space. Descartes thus adheres to an antique notion of substance that can be found as early as Aristotle and the nonatomistic philosophies, which denied the existence of the void.

After Descartes, in Isaac Newton's physics, the concept of "absolute space" no longer implied a materialistic concept of space. Newton conceived of (absolute) space as the frame for any possible description of movement (in space), and as such the void is just as continuous as the plenum of Descartes. Furthermore, "absolute time," according to Newton, can also be continuous in the sense that there is the theoretical possibility of an endless movement—not limited by either space or time. Here the concepts of space and time include the continuity of each one, but not a continuity of both of them together.

Subsequently, Immanuel Kant, with the most serious consequences, combined Newton's physics with Cartesian dualism and defined space as the condition of the possibility (spatiality) of any perception or construction of things present to the outer senses by means of uniformity and, in opposition to that, time as the condition of the possibility (temporality) of any perception or construction of things changing shape or place—that is, the concept of movement. For more than 200 years after Newton and Kant, not only were space and time treated as separate entities, but space became identified with the unchangeable and was even attributed as "dead," whereas time, as the specific mode of inner perception, became identified with the principle of life; as such it can be found in Henri Bergson's concept of the *élan vital* and the notion of time as *durée* (duration).

Minkowski's enterprise therefore was neither purely mathematical nor physical; it thereby aimed at the heart of the predominant worldview, according to which time and space are strictly separated entities. Minkowski's student Albert Einstein interpreted this in a chiefly psychological respect: In his view, time and space are both forms of lifeworld abstractions from physical instances, as can been seen in the concept of space as a container (three-dimensional) or time as a line (fourth dimension). But the possibility of describing these abstractions in respect to space (volume) or time (interval) suggests a false understanding of matter, which is always spatially situated and is always moving. To overthrow this misinterpretation Einstein suggested defining space as something that is of a certain "age" as well as to define time as something that is extended. Therefore not only time and space are continuous in themselves, but they together form a space–time continuum: Each location in the universe therefore is a single manifold, which is qualified by the impact of gravity. In consequence the description of a manifold is no longer relative to an observer but is defined as a (four-dimensional) reality in its own, which has no gaps but rather is a "smooth" space. Any object moving in spacetime can thus be depicted according to a "world line" that is describing its unique path through the universe in respect to time as well as to space, whereby the three dimensions of space are condensed to one. Hence, in a two-dimensional diagram, all four dimensions can be represented.

Surprisingly, Einstein in his idea of continuity of space (and time) refers back to Descartes, whom he respected for not having accepted the idea of space as void. On the contrary, Einstein takes the concept of "plenum" as a forerunner of the concept of the electromagnetic "field" as it was developed by Michael Faraday and James Clerk Maxwell in field theory. Instead of defining points in a coordinate system, a field defines a homogeneity, which is caused by electromagnetic forces. According to Einstein the movement of a body is not a movement through space and time anymore but a change of states of a gravitational field, by which an object is then defined quantitatively. Thus, to Einstein the idea of plenum can even be traced back to ether theory, insofar the ether is defined as a medium of movement. But in contrast, the modern theory of a spacetime continuum takes into account that there are different qualities of several continua, which Einstein identifies as "inertial systems." In those systems a physical instance cannot be defined in spatial and temporal respects separately, but must be conceived of as an "event" in spacetime. Today Einstein's concept of the continuity of spacetime has been further developed in string theory, which defines spacetime as a continuum that is structured according to at least 10 spatial dimensions. However, dimensions higher than four only have effects on the subatomic level.

Space Travel

Space travel, the act of sending objects and humans beyond Earth's atmosphere, includes both orbiting Earth and traveling far beyond Earth's gravity. The fringes of outer space were explored as early as 1949, but only since 1957 have humans had the ability to send objects permanently beyond our atmosphere. Controlled motion in space requires the accurate use and measurement of time; the laws of physics dictate that there is only one best path from one place to another, a path available only by using precise timing. Thus, to travel successfully in space requires both an exact departure time and a way to measure time intervals with great precision.

To travel in space we must leave behind our Earth-centric concepts of time intervals and grapple with the concepts of relative planetary time and absolute time. The common definitions humans use for the passing of time on Earth change depending on the location in space. When communicating between planets, the orbits and rotations of each planet affect the success of those communications. The timing of those motions is critical to find the optimum moment to send and receive messages.

The distance between the planets of the solar systems places them minutes and hours apart. When communicating with objects in space, near-instantaneous communication changes with distance to asynchronous messages and responses. The universe is so immense that time in the form of the light year is used as a measure of distance in space travel. To travel beyond our solar system, it will take a very long time to get any place if we cannot travel nearly as fast as light.

Motion in Space

Although at extremely high speeds the theory of relativity is invoked, the basic motions of space travel are governed by Newton's laws of the motion of bodies and Kepler's laws of planetary motion. Newton and Kepler showed that orbital motions are predictable both backward and forward through time. Through careful recording of where objects in space have been, it is possible to plan the optimum moment for a future launch of a space vehicle.

Space travel is possible because of the "clockwork" nature of the universe in classical physics. Everything in the universe interacts primarily via gravity. All destinations of any significant size are traveling in specific regular orbits. These orbits behave for the traveler as asynchronous clocks. Each object revolves in a regular orbit with a regular period, but every object has its own period. Navigation in space is therefore concerned with finding the optimal time to travel from one orbit to another.

Orbital mechanics dictates that there are an infinite number of possible free-flight paths between two objects. Space navigators are concerned with the trade-off between the path that requires the least fuel and time spent in transit. Operating within these limitations has meant that, from the beginning, space travel has been associated with certain time-specific terms such as *countdown*, *launch window*, and *mission elapsed time*.

A practical example of the timing needed would be predicting the optimum time to leave Earth for the Moon. This is referred to as a launch window or orbital window. The Moon revolves around the Earth in an elliptical orbit, so there is an optimal time of the month to launch when the Moon's orbit brings it closest to Earth. The calculation also should consider that the Earth rotates on its axis. Every 24 hours there is an optimum time for the rocket to leave Earth pointing at the moon. The interaction of two cyclic clocks gives a best time and day every month to launch. The planner also needs to account for the motion of the Moon during the rocket's time of transit, aiming for where the Moon will be when the rocket reaches lunar orbit path.

To go to another planet in the solar system, the planner must consider the orbital periods of different objects around the sun. For a launch to Mars the best orbital window occurs only once every 2.2 years when both Mars and Earth are on the same side of the sun. Also, most orbits are elliptical, and so where each planet is at its apogee (greatest distance) and perigee (closest distance) in relation to the sun also can dictate the optimum time to travel the least distance. The Voyager probes in the 1970s took advantage of a so-called grand alignment, when Jupiter, Saturn, Uranus, and Neptune were all on the same side of the sun. The fortunate timing of the "window" is evident when you consider this alignment only takes place every 176 years, because these planets' orbital clocks all run at such different rates.

As we continue to travel in space, other cyclic phenomena will influence the timing of rocket launches. A short list includes the approximately 11-year solar cycle of flare activity, the orbits of various comets and asteroids, the behavior of planets with multiple moons, and the motions of other solar systems around the core of the Milky Way.

A last, now common, use of time and predictable orbital motion in space is in global positioning system (GPS) satellites. The fundamental properties of a satellite regularly orbiting Earth allow an observer on the planet to determine his or her location. An observer with an accurate clock and the knowledge of the transit time for signals from four satellites can determine location. The transmitter compares its internal clock with the ultra stable and accurate atomic clocks on each of the four satellites. The difference between the five clocks is influenced by the motion and location of the satellites and can be used to calculate a location and altitude on the planet very accurately.

Relative Planetary Time

Space travel shows that many of our common time measurements are relative to Earth. As humans travel in the solar system, they will need to redefine what terms like *noon, day, month*, and *year* mean. The case of Mars is particularly illustrative because we contemplate colonization there at some future time. Travelers in space will face the problem of choosing their own definitions. Whether the defined terms will be of where they departed, their destination, or some standard time is still not clear.

Humans have a local interpretation of when noon is. We tend to think of noon as "solar noon, when the sun is highest in the sky. That also matches with "mean noon" (what the clock says) within plus or minus 16 minutes because Earth has a very regular orbit around the sun. We experience only minor differences throughout the year. Mars, however, has an orbital eccentricity that is considerably larger, which means that the lengths of various Martian seasons differ considerably. On Mars the time of day when the sun is highest in the sky varies throughout the year. On Mars, because of its orbit, mean noon and solar noon can be plus or minus 51 minutes apart through the seasons.

A sidereal day on Earth is 23 hours and 56 minutes, and on Mars it is 24 hours 37 minutes. For an explorer on Mars this will require only a moderate adjustment. When operating missions remotely from Earth, however, more planning will be required. During missions that last weeks and months, the days on Earth will become out of sync with those on Mars. The Jet Propulsion Laboratory team running the Pathfinder missions had to modify their schedules to the Martian day in order to coordinate probe observation times with daylight on Mars, regardless of what the daylight time was on Earth. They coined the term *sols* to describe mission times and events on Mars. Any future residents of Mars will have to develop their own clocks to cope with this subtle change.

On Earth a month is defined by the motion of the Moon around the Earth every 27.3 days. With 12 to 13 orbits per year, months on Earth are 1/12 of a year. Other planets, however, may have no moon, or several moons. Residents will need to create a new calendar, with new definitions of the length and name(s) of the months. What will define a month on Mars? It has two moons, Deimos and Phobos, that whip around it every 1.3 and 0.3 days, respectively, making for very frequent months.

We define a year as 365 days, 5 hours, 48 minutes, 46 seconds (the time for Earth to revolve around the sun). In our solar system, years vary in length more than 1,000 times, from 88 Earth days on Mercury to 90,777 days on Pluto. Living year-round on Mars would require adjustment for residents to the Martian year of 687 days. Because we measure our lives in these "Earth standard" units of time, how will such basic concepts as birthdays and age change? Exploration in space will mean either being tethered to a single planet's definitions or developing new ways of naming how time passes.

Communication Timing in Space

Communication distances in space are another way that time and space travel are tied together. Objects in space are separated by huge distances, which translate into being separated by time. We need precise clocks to communicate across these distances.

Radio waves, like all forms of electromagnetic waves, travel at the speed of light. The time it takes for a message to travel a given distance can be calculated using the equation $t = d/v$ (t = time, d = distance, v = speed of light). Our Moon is so far from Earth that light (and radio waves) takes 1.3 seconds to get there. Communications between these bodies have this 2.6-second gap between when a message is sent and when the reply is received. For human conversation this is merely annoying, but for an operator remotely driving a robotic vehicle, this 2.6-second gap could be disastrous.

An additional problem is that Earth is constantly revolving and traveling in its orbit. These motions move the transmitters and receivers apart, so multiple sets are needed over the surface of the Earth to have continuous communication with an object in space. The problem is increased when communicating with probes on or orbiting around other planets which are moving too.

Consider, as an example, a robot explorer on Mars. The round trip for communications to Mars when Mars is closest to Earth is 20 minutes. When the Earth and Mars are at opposite sides of the Sun, the round trip is 40 minutes. Additionally, both Earth and Mars revolve on their respective axes, so the transmitters and receivers on their surfaces are moving constantly. Similar to orbital windows for launching, there are optimal communication windows when the communicators are facing each other. The clocks between these transmitters and receivers need to be precisely synchronized. For most space missions there are communication blackout times when communication is impossible because the transmitter and receiver do not have "line of sight."

Each planet exists within a "time island," separated from the others by the gap it takes communications to go between them. This time gap functions as an isolating element when doing real-time tasks like communicating between computers. If we choose to explore the outer solar system, the gap for round-trip communication between Earth and a moon of Saturn would be 2 hours and 12 minutes. In our world of networked computing and Internet communications, this is an unseen barrier to human colonies in the solar system. Each colony will need its own computer network and will communicate with outside systems though a built-in delay. This has had implications for remote control of exploratory probes, leading to an increase in the ability of probes to be autonomous of a human controller. For time-critical maneuvers, like entering or leaving orbit, instruction sets are sent for the robot to carry out, and highly accurate clocks are required.

As we move farther from Earth the gaps become more significant. Human and robot explorers become travelers isolated from timely assistance or instructions. An explorer on Pluto would have a round-trip communication gap of more than 9 hours. Exploration beyond the solar system will have communication gaps of weeks and months. Travelers to the nearest star (4.2 light years away) would experience a gap of almost 8 1/2 years between a sent message and a reply. Any meaningful dialogue will be reduced to asynchronous communication spread over decades. As we contemplate life in other solar systems, this gap suggests we may never be able to have a dialogue with other intelligent life, only a series of exchanged monologues.

Distance in Space

Time is used in space travel as a measure of distance. The known universe is so vast that we need a very long measuring stick to conceptualize it. The commonly used measure of space distances is the speed of light. Light is the fastest phenomenon we know of, moving at approximately 30 centimeters (approximately 1 foot) per nanosecond. In fact, the current definition of the meter is the length of the path traveled by light in a vacuum during a time interval of 1/299,792,458 of a second. In a year (31,557,600 seconds) light travels 9.46×10^{12} kilometers or about 5.88×10^{12} miles.

We can conceptually measure the relative size of space with light. In our solar system, the Moon is 1.3 light seconds from Earth, the sun is 8.3 light minutes away, and Pluto is 4.4 light hours away. The nearest star to Earth, Alpha Centauri, is 4.3 light years away (273,000 times the distance from Earth to the Sun), the center of our galaxy is 32,000 light years from Earth, and the nearest galaxy to Earth is 75,000 light years away. These distances remind us that the events we see in space are minutes, hours, and years separated from what is actually happening at a given location.

Travel Times in Space

Distances between solar systems are so large that there have been only a few objects sent beyond the solar system. *Pioneer 10* was launched in 1972 and left the solar system in 1983, aimed at the star Aldebaran, about 65.1 light years away. At its present rate of speed it will take it more than 2 million years to reach there. *Voyagers 1* and 2, launched in 1977, have also left the solar system. Because of their gravitational assists during their mission, they are traveling at a much higher velocity than is *Pioneer*. *Voyager 1* is traveling at a speed of 61,799 kilometers per hour (.000057 the speed of light) covering about 538,465,972 kilometers a year. Even at those speeds, as of February 2008, *Voyager 1* was "only" 15.7 billion kilometers from the sun.

Voyager 1 is traveling faster than any other spacecraft humans have launched, yet it will not be "near" another solar system for 6,600 years when it passes 4 light years from Barnard's Star. The closest *Voyager 1* will get to another solar system in the next 300,000 years will be 1.7 light years, 38,000 years after launch. From that point, at its present speed if it could fly straight to the system, it would take it an additional 30,000 years.

The distances in space are daunting without some way to reduce the travel time. Velocity in space is related to the amount of force one can produce and the amount of time needed to produce it. Space travel is essentially frictionless, so once a velocity is achieved, an object will continue at that speed indefinitely. An important implication is that the object will not slow down at its destination without the application of an equal and opposite force.

One solution would be greater rocket velocities with improved rocket propellants. Rocket propellants are compared by the specific impulse (Isp) they provide. Specific impulse is measured in "seconds," or the number of seconds during which a rocket engine can produce 1 pound of thrust from 1 pound of propellant. The velocity a vehicle can achieve is directly proportional to the specific impulse. Current chemical rockets such as the NASA Space Shuttle have a specific impulse of 450 seconds (burning liquid hydrogen and liquid oxygen). To achieve greater velocities for longer times, we will need to explore experimental propulsion systems like nuclear (900–1,200 seconds) and ion propulsion, which has a specific impulse of 2,000 to 20,000 seconds. The ultimate would be an engine with a specific impulse of 30,000,000 seconds (approximately the speed of light).

One of the fascinating outcomes of relativity theory is the idea that, at very high speeds, time is distorted. The amount of time that passes for a passenger is reduced as the velocity of the spaceship is increased to larger fractions of the speed of light. This effect is of interest because the time it would take to reach another solar system would be reduced for the passenger. If we could attain greater speeds, we could achieve a kind of time travel for passengers, allowing them to experience less time passing than would observers on Earth.

The second way to tackle the long to extreme travel times between planets and solar systems is to slow the passage of time's effects on human passengers. There is speculation that the existence of "hibernation" genes within mammals or the development of "suspended animation" technologies would allow the engineering of humans to travel in a state of reduced metabolism. This suspension would allow essentially little or no time to pass for the traveler as well as reduce the number of supplies the craft would need to carry or recycle. It also may be possible through advances in biotechnology to engineer humans for extended life spans allowing "near-by" flights within a human life span. Finally, science fiction has explored the concept of "colony" ships, which would carry humans for several generations.

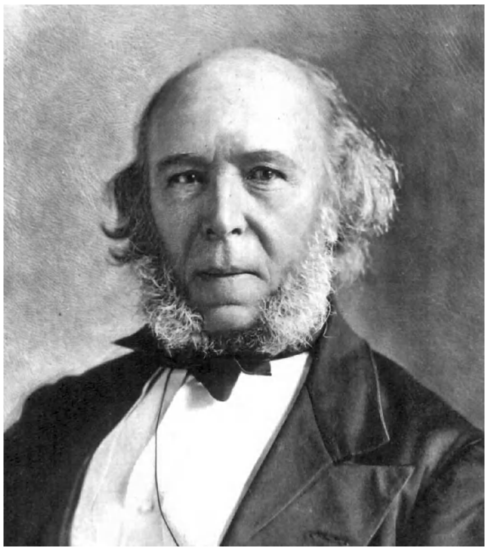
Spencer, Herbert (1820–1903)

Herbert Spencer was an English philosopher, evolutionist, and political theorist, whose theories treated the universe and time in general with scientific minuteness and a synthesis of speculation and positivism. He is often cited with coining the popular expression "survival of the fittest," which later would be used frequently by social Darwinists.

Spencer was born in Derby, England, on April 27, 1820. His early influences were chiefly his father and uncle, both of whom were teachers well acquainted with the natural sciences. Initially gaining a job as a civil engineer, to cultivate the skills learned from his father and uncle, Spencer went on to become a subeditor for the *Economist,* a newspaper noted for its liberal tone. During this time, Spencer was able to pen *Social Statics* (1851), which supported the popular notion of laissez-faire economics. In 1858, however, Spencer set out to create a synthetic philosophy, which aimed to unite the disciplines of biology, sociology, psychology, and ethics under the physical notions of time, space, matter, motion, and force. This was first presented in the 1862 work *First Principles.*

Spencer's philosophy rests upon the insolubility of the nature of reality and something he called "the unknowable." One such question that would fall into the unknowable is the idea of who created the universe. Because this is something that



In 1862 Spencer began his 10-volume System of Synthetic Philosophy*, which expanded Darwin's theory of evolution to include the entire field of human knowledge. Spencer coined the expression "survival of the fittest."*

cannot be comprehended, as it is not within one's own intellectual power to ascertain, Spencer instead concentrated on the knowable, which he believed was governed by the unified physical notions, which in turn preclude knowledge of the unknowable. These powers, too, are not completely known without a complete grasp of the unknowable.

From this, Spencer applied the idea of force as the key to understanding all other knowledge. Force is responsible for evolution to take place, of which he defined as "a change from a state of relatively indefinite, incoherent homogeneity to a state of relatively definite, coherent homogeneity." Evolution was not only a biological or cultural force to Spencer, but a cosmic force, which pervaded the time–space continuum. As life and the individual on Earth were evolving, so was the cosmos.

After Spencer laid the groundwork for his conception of evolution, he succeeded *First Principles* with the *Principles of Biology* (2 vols., 1864–1867), *Principles of Sociology* (3 vols., 1876–1896), and finally *Principles of Ethics* (2 vols., 1892–1893). Before *First Principles,* Spencer wrote the *Principles of Psychology* (1855), which was marked by Spencer's position that individual characteristics develop as a result of evolution. In *Principles of Biology,* Spencer used the expression "survival of the fittest," referring to organisms that were able to reproduce due to their self-sufficiency and ability to adapt and survive in a changing environment.

Principles of Sociology was one of Spencer's celebrated works in which he likened the progression of society to the progression of a biological organism. His use of the term *superorganic* differentiated a society as something that exists above the nature of reality, yet like an organism, it is mutually dependent and follows the process of evolution. The society evolves from being relatively insufficient and undifferentiated (homogeneous) to being self-sufficient and differentiated (heterogeneous).

Spencer also weaved his thread of evolution into the *Principles of Ethics.* Though there are stronger individuals in societies, it should be the goal of humankind to promote the longevity of our species. Instinctively, the human race has garnered certain "good" behaviors through the evolutionary process that have contributed to the survival of the species. Thus, the good behavior is one that contributes to the healthy maintenance of the species, whereas the bad behavior is conducive to the destruction of the species. This same idea would be applied to Spencer's ideas of economics; that is, the laissez-faire approach to the economy is best because there are no regulations from outside influences that would dissolve the economy.

On December 8, 1903, Spencer died, leaving behind a body of work that was to influence many later scholars and writers. He had been honored a year earlier with a nomination for the Nobel Prize in Literature (1902). His synthetic philosophy allowed writers such as H. G. Wells in *The Time Machine* to develop his themes of evolution. Charles Darwin would also use Spencer's phrase "survival of the fittest," in the fifth edition of his *On the Origin of Species* (1869). Spencer's philosophy of the universe will be remembered as both groundbreaking and diverse.

Spinoza, Baruch de (1632–1677)

Spinoza, a Dutch philosopher, is considered one of the greatest rationalists of the 17th century and one of the founders of modern Bible criticism. His works encompass metaphysics, ethics, political philosophy, and epistemology. With regard to his theory of time, the most striking feature of his ontology is the emphasis on eternity. Although the philosophical investigation of physical time plays only a minor role in Spinoza's work, he highlights the inherent striving of each thing to stay in existence for an infinite time.

As a member of a Sephardic Jewish family living in Amsterdam, Baruch (also known as "Benedictus") de Spinoza enjoyed a classical biblical–talmudic Jewish education. Because of his sympathy for the rationalistic Cartesian philosophy and due to his critical Bible studies, he came into conflict with the Jewish community, from which he was expelled in 1656. In his philosophical work he initially follows Descartes. Spinoza presents Descartes's main philosophical ideas in the fashion of the geometrical method. In his *Theologico-Political Treatise,* published in 1670, he develops a political doctrine that aims at freedom of speech and at a limitation of the power of religion and churches. In his posthumously published chief work *Ethica,* he (again in a geometrical fashion) develops an ontology, which states that there is only one substance called "God or Nature" (*deus sive natura*). Individual beings therefore do not have a separate existence of their own but rather are modes of God.

Spinoza was a Dutch philosopher of Portuguese–Jewish heritage whose independent thinking led to his expulsion from the synagogue in 1656. His philosophy was deductive and rational, as expressed in his book Ethica *(1677).*

Source: Library of Congress, Prints & Photographs Division, LC-USZ62–122962.

The striking absence of a theory of time in Spinoza's *Ethica* is characteristic of his philosophical approach. His main interest lies in the understanding of the timeless structure of the universe, insofar as all of its parts express the eternal essence of God. In Spinoza's pantheistic worldview, all finite things are encompassed in God. Everything within this world needs a reason (*causa*) for its existence; only God exists through its own power (*causa sui*). According to Spinoza there are therefore two main ways of looking at things: either as existing in relation to a given time and place or as contained in God and following necessarily from his divine nature (cf. *Ethica,* Part V, Prop. 29, Note). Thus the temporal order is only one way of looking at things that also has the disadvantage that it does not reveal the eternal truth. While the imagination is mainly directed at the spatial-temporal order, reason is the capacity to look at the relation of the individual concepts to God's infinite and eternal essence under a form of a timeless, eternal perspective (*sub quadam specie aeternitatis;* cf., Part II, Prop. 44, Cor. 2).

With regard to the concrete physical time of objects, Spinoza states that all objects are either at rest or in motion. Motion occurs at different speeds, so that our notion of time is derived from the experience of things moving at different velocities (cf., ibid., Cor. 1, Note). Spinoza ascribes to each thing the endeavor (*conatus*) to persevere itself in its being (Part III, Prop. 6). In principle every finite thing would exist for an unlimited time. It is only through external causes that it can be destroyed. So just as well as everything needs a cause to come into existence, it also needs an external cause to vanish from existence.

Spontaneity

That which develops or occurs without apparent external influence, force, cause, or treatment manifests spontaneity; a spontaneous event is one that occurs as if by chance. This phenomenon seems to permeate every facet of life. Concerning its role for existence, and in hypothesizing on what may have functioned as a catalyst to the spark of life, Charles Darwin states that a "warm little pond, with all sorts of ammonia and phosphoric salts, lights, heat, electricity, etc. present, so that a protein compound was chemically formed ready to undergo still more complex changes" may have existed in some rudimentary form. Continuing, he states "at the present day such matter would be instantly devoured or absorbed, which would not have been the case before living creatures were formed." As such, Darwin believes that the search for life must take place within sterile conditions of a laboratory, for intensely evolved present-day life would overpower the most basic of creations.

Perhaps the most fundamental, primordial case of spontaneity informs the big bang theory, which purports to explain the emergence of substance and ultimately life within the universe. In brief, the theory, as advanced by American astronomer Edwin Hubble, speculates that approximately 15 billion years ago, a tremendous explosion occurred, giving rise to all the energy and matter of the universe from one infinitesimally small point. The event was not like a conventional explosion, but rather one in which all the particles of the embryonic universe rushed away from each other, this creating—and still forming—the constantly expanding universe that exists today.

With such tremendous force of energy, the universe was, in these very early moments, unfathomably hot. As it expanded and thus cooled, at around 10^{-43} seconds after creation, there existed an almost equal yet asymmetrical amount of matter and antimatter. As these two materials originated together, they inadvertently collided and destroyed each other; luckily for us, there was an asymmetry that favored matter, and this incredibly small advantage—about one part per billion—eventually matured into an environment receptive to material growth, the commonly referred to "plasma soup" of existence. Over billions of years, abnormalities, quirks, and external factors contributed to the increased complexity of this matter, to the point where life as we know it may well trace an elongated yet ultimately undetached line back to this condition.

Another famous instance involving the question of the origins of life—abiogenesis—is the now debunked 15th-century concept of spontaneous generation, which held that life of a more complex species could be traced to the breakdown of decaying organic substances. Perhaps the best-recognized example of this idea is the erroneous belief that maggots are created from the decaying meat of a once living creature, given that they are often viewed on such material yet never on the living creatures themselves. As a result of experimentation in the mid-1800s, Louis Pasteur discredited this idea with a demonstration that only when flying, burrowing, or crawling insects are permitted access to the dead matter in which they lay eggs does the meat give rise to living creatures.

Stalin, Joseph (1879–1953)

Joseph Stalin was the supreme ruler of the Soviet Union from 1924 until his death in 1953. Upon his accession to power, he quickly established himself as the unequivocal leader of the state and chief ideologue of world communism. Although Stalin's legacy remains marred by controversy, his significance as a historical figure is undeniable, as there have been few politicians in the history of the world who have wielded comparable power, attained such a reputation for ruthlessness, and so deeply affected the lives of millions.

Joseph Stalin was born Iosif Vissarionovich Dzhugashvili on December 21, 1879, in a poor village in the Republic of Georgia. The omnipotence Stalin would enjoy throughout the latter stages of his life had its roots in his very upbringing. Soon after his father died in 1891, Stalin was sent to the seminary in the capital of Georgia, Tiflis (now known as Tbilisi). He never took to religious studies, however. A shy and self-centered teenager whose face had been permanently disfigured after a bout with smallpox, Stalin always felt inferior to his peers and, from an early age, developed a strong sense of contempt toward intellectuals, which years later would result in his merciless persecution of the Soviet intelligentsia. Driven by his lifelong desire for greatness and recognition, Stalin quickly found himself immersed in Tiflis's vibrant revolutionary life as he eagerly joined the city's burgeoning Marxist underground movement.

It did not take Stalin long to become a convinced Marxist, and he quickly rose through the party ranks. When Russian Marxism later split into two factions, he identified himself with the Bolsheviks. As loyal a Bolshevik as Stalin was (organizing Georgian and, later, Azerbaijani workers, distributing illegal literature, dodging arrests, and even robbing trains and banks), he still kept a relatively low profile within the party through the early 1900s. It was in 1913 that the young Georgian revolutionary changed his name from Dzhugashvili to Stalin (literally meaning "man of steel" in Russian), under which he became known as one of the most notorious tyrants of all time.

Although Stalin played a relatively inconspicuous role in the preparation for the Bolshevik Revolution of October 1917, his zeal and obvious organizational talents drew the attention of the party leadership. After the fall of the Romanov Dynasty and the subsequent execution of the czar and his family, Stalin was appointed in 1922 to the position of general secretary of the Communist Party's Central Committee in recognition of his work as a military commissar during the Civil War (1918–1921). As general secretary, Stalin gained control over the entire party apparatus and, within months, established himself as the second most important figure in the government after Lenin. During Lenin's last illness and after his death in 1924, Stalin's power rose even further while he served as a member of the three-man committee that conducted the affairs of the party and the country.

That formation, the *troika,* was arguably the last instance of pluralism that Stalin allowed. His nearly paranoid obsession with keeping every affair under his personal control led to the eventual destruction of the Bolshevik party as a political organism and ruling class. Through labor camps, political repressions of the late 1930s, elimination of free thought and market enterprise, treason trials and brutal executions of Communist cadres, Stalin accomplished the creation of an elaborate, completely centralized bureaucratic mechanism for the command and control of the Soviet society.

Already the leader of an unlimited autocracy, Stalin in the 1940s further solidified his political prowess when he declared himself commander in chief of the entire Soviet military establishment during Hitler's invasion. Thus, the one-party system had completely given way to a one-person system. Stalin carefully cultivated and enhanced his personality cult up until his death on November 5, 1953.

During his three-decade-long reign, Joseph Stalin greatly strengthened and stabilized the young Soviet state, transforming a country ravaged by war and famine into one of the world's most literate and industrially developed societies. Under Stalin, the German invasion of the Soviet Union was eventually turned back and the Allied powers, including the Soviet armed forces, ultimately defeated Hitler's Nazi military. For the Soviet Union, however, these economic and geopolitical victories took an unprecedented toll that many contemporary scholars consider excessive.

During his rule, Stalin's oppressive machine proved extremely powerful and overwhelmingly efficient. The imprint it left on the collective consciousness of the Soviet people was so deep that, even several years after his death, Stalin was still widely considered a national hero. It was not until 1956 that the new first secretary, Nikita Khrushchev, spoke openly of the terrors of Stalinism at the Twentieth All-Union Party Congress, thereby beginning a new chapter in Soviet history.

Star of Bethlehem

The traditional account of the Star of Bethlehem has puzzled historians and astronomers for 2,000 years. Opinion remains divided as to whether accounts of the star are based on an actual astronomical phenomenon or instead represent a fiction intended to situate the birth of Jesus within the context of prophecy. The first appearance of the star in literature occurs in the Gospel of Matthew as it guides the Magi (or "wise men") from the East to Jerusalem. Upon arriving, they are informed of the prophecy in Micah 5:2–4 that a Jewish Messiah would be born in Bethlehem. They journey to the birthplace and worship the newborn Jesus of Nazareth as "King of the Jews." The early Christian writer Luke, however, does not mention the star in his nativity account, leading some to call the portent legend. Many nonetheless accept Matthew's text as a reliable account of historical events, and countless scholars have tried through the years to identify what stellar phenomenon motivated the trek of the Magi. Exactly what event inspired Matthew's account may never be known with certainty.

Within generations of Matthew's testimony, many exaggerations arose. Ignatius's Epistle to the Ephesians, for example, claimed the star exceeded all others, even the sun and moon. This counters the idea that King Herod and his court had no knowledge of the star prior to the Magi's arrival. In an effort to sort true events from the fantastic and identify the star, modern scholars study history and Matthew's text alongside ancient astrology and astronomical records. It is hoped that this method, paired with advances in technology and astronomy, will allow researchers to establish which theories fit the existing data most closely.

The Star of Bethlehem, if successfully identified, could help elucidate a more exact time for Jesus's birth. Current scholarly consensus restricts this event in a 10-year time frame, between 12 BCE and 2 BCE, with many considering the 5-year frame of 9 BCE to 4 BCE highly probable. Reaching a more specific date for Jesus's birth helps scholars identify dates of other significant biblical events, including Herod's death, Jesus's crucifixion, and the conversion of the early Christian missionary Paul.

Some, as previously noted, relegate the Star of Bethlehem to the realm of fantasy; others elevate the occurrence over the natural, claiming that only a miraculous event can suffice. In between these views range many diverse theories. Common suggestions include simple explanations, such as the planet Venus or a comet.

The planet Venus, however, was well known and recorded as early as the Assyrian Venus Tablet, circa 1700 BCE—hardly a unique astral portent that might inspire a voyage to bring tribute. Likewise, comet theories usually receive little credit from scholars. Unlike short-lived meteors, comets provide a lengthy display. Most ancient historical writings, however, attributed comets to be signs of disaster. An appearance of Halley's comet in 12 BCE, for example, was recorded by the Romans, who applied it to the death of statesman-general Marcus Agrippa. Some nonetheless propose the comet to be Bethlehem's star, suggesting a date of 12 BCE for Jesus's birth.

Other theories have proliferated. Some have argued that the sign triggering the Magi's journey could have been a conjunction of planets or an occultation of a planet by the moon. Novas and supernovas also add to the possibilities, as the sudden appearance of a "new" star might encourage the idea of a king's birth and would undoubtedly be noticed by ancient stargazers. Most researchers consider these theories too simple but admit several simple signs occurring in close proximity might have motivated the Magi's pilgrimage.

Recent scholarly works on the subject, not surprisingly, propose significantly differing theories.

Most attempt to pull together and analyze the many existing theories and then propose a new solution. These theories are often more complex than previous attempts to explain the Star of Bethlehem. One, for example, concludes that a series of events including Jupiter and Saturn, with a triple conjunction and planetary massing, constituted triggers for the Magi, proposing that the acronychal rising of Jupiter on September 15, 6 BCE, was the exact star.

Another explores candidates such as Venus, planetary conjunctions, and meteors. The conclusion of this study argues that a long series of events may have set the Magi on their journey. The triple conjunction including Jupiter around 6 BCE may have caught the attention of astrologers. Soon after, the massing of multiple planets in certain zodiacal signs and the occultation of Jupiter twice may have led up to a nova in 5 BCE as the culmination. Supporters of this view even offer a specific nova, DO Aquilae, which might serve as the Bethlehem star.

Others have put forth the idea that the eclipse of Jupiter by the moon on April 17, 6 BCE, could serve as the long-lost star. On the basis of data from the fields of astrology, astronomy, numismatics, scripture, and history, some claim this lunar occultation of Jupiter would point ancients to a new king born in Judea, much like a horoscope. A unique side of this argument is the thesis that Ares is the zodiac of Judea, not Pisces, as most previous studies claimed.

Nevertheless, scholars know many natural occurrences that can explain the Magi's journey to Bethlehem and have added astronomy to the fields that help identify a more specific date for Jesus's birth.

Stars, Evolution of

Observing a single star through its evolutionary process with conventional time would prove to be inefficient. Instead, scientists have observed star clusters, where numerous stars of different masses, but close in age, reveal different stages of stellar evolution. The length of a star's existence, and whether its death is violent or more peaceful, is dependent upon its mass. Scientists have mapped the different stages of stellar evolution in the Hertzsprung-Russell (HR) diagram. The Hertzsprung-Russell diagram was named after its creators, astronomers Ejnar Hertzsprung and Henry Norris Russell.

Origins of a Star

Stellar evolution begins with the gravitational collapse of a cosmic cloud of gas and dust. Over a range of tens of thousands of years, the gas cloud

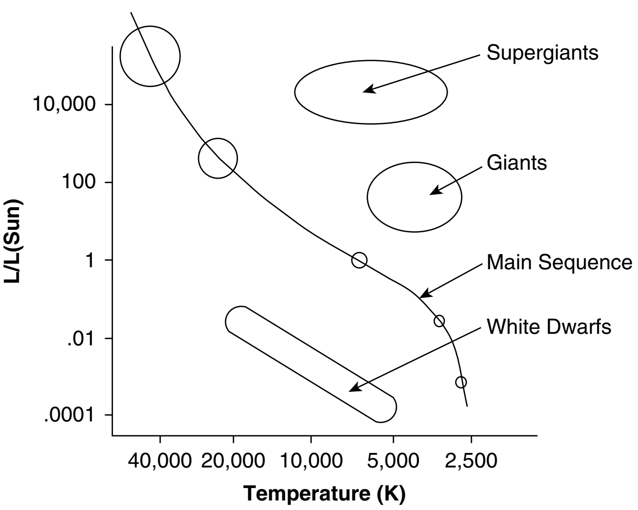

Figure 1 Hertzsprung-Russell diagram

contracts and becomes denser. If the mass reaches temperatures greater than 10 million Kelvin, it will ignite and begin a nuclear fusion reaction where hydrogen is transformed into helium. As the gas cloud continues to collapse and density builds, atoms move faster, colliding harder and more frequently, building pressure against the contracting cloud. These turbulent motions create a spin to the cloud, building the star's angular momentum. If the angular momentum is too high, this protostar, or potential star, might split off into two stars that revolve around each other and become what is known as a binary star system. If the angular momentum is too low, a nebula, or gas cloud, will form. The dust of this nebula may eventually create a planetary system that revolves around the star, similar to that of our solar system.

As the star stabilizes, the pressure inside will prevent the walls from contracting any further, and the star will settle into the evolutionary stage known as the "main sequence," where it will live out most of its existence. This is where our sun has been for the past 5 billion years and will remain for another 5 billion years. The more-massive stars burn brighter and hotter and will remain in the main sequence stage for a short amount of time, whereas less-massive stars are cooler and less luminous, conserving fuel supplies, and will stay in the main sequence stage of evolution for a longer period of time.

The mass of stars is measured in solar masses, a measurement comparative to our sun. A star that is equal in mass to our sun is said to be 1 solar mass. A star that is 8 times more massive than the sun is said to be 8 solar masses, or a solar mass of 8. A star with less than 0.08 solar masses will fail to reach a temperature required to commence a nuclear fusion reaction and become a brown dwarf, or a failed star.

Life on the Main Sequence

A star's life span is dependent upon the mass of the star. Higher-mass stars burn through their fuels much quicker than do lower-mass stars, thus going through the stages of stellar evolution faster. Stars of 1 solar mass take several million years just to reach the main sequence. This is but a blink of an eye for a star this size, for it will exist another 10 billion years. Stars of 8 solar masses will take approximately 100,000 years to reach the main sequence, with a stellar life expectancy of only 100 million years.

Throughout its rather uneventful existence on the main sequence, a star will burn through its fuel supply, transforming four hydrogen atoms into a single helium atom with energy as a by-product. Once the hydrogen is exhausted, the star will begin to collapse under its own gravitational force. The temperature of the star will begin to rise as this happens, causing the star to become more luminous. The outer gaseous layer of the star will expand, and the star will begin to cool and energy output to decrease. The star then will begin its move off the main sequence and upward to the red giant stage. For a star of only one solar mass, this move away from the main sequence will take 100,000 million years. As it moves into the red giant stage, the star's temperature will increase to 100 million Kelvin, triggering a triple-alpha reaction in which the helium will begin transforming into other elements.

If the star is massive enough, it may continue to burn its fuel supply, creating a successive chain of different elements. This cycle, if conditions allow for it, ends with the creation of iron in the core. Each successive element will require a shorter period of time to create, as well as more mass and higher temperatures, than its predecessor. A star that produces iron may exist for a day to a week. The cycle ends with iron because the creation of iron requires more energy than the process produces. The star will fail to create the amount of energy required to sustain its current needs, and it will rapidly collapse.

Death of a Star

The most-massive stars will explode violently, where as lower-mass stars will burn out quietly. Stars that are roughly the size of our sun will peacefully burn out. As the sun-sized star exhausts its fuel supply, it will begin to cool, decreasing in luminosity, and compress, becoming what is known as a white dwarf. A white dwarf is a densely compacted star composed primarily of carbon and oxygen. Over the next billions of years, the white dwarf will continue to cool and fade until completely burned out, at which point it will be nothing more than a cold, dark mass known as a black dwarf. The universe is currently too young, and not enough time has passed for the formation of black dwarfs.

A star that is greater than 5 solar masses, as it creates heavier elements during the final stages of its nuclear fusion process, will swell beyond the red giant stage and become what is known as a supergiant. As it expands, it may explode off its outer layer and may lose up to 80% of its mass. The core mass left behind, if less than 1.4 solar masses, would form into a white dwarf, and the outer layer would become a glowing cloud of unused hydrogen that surrounds the white dwarf. This spectacle is known as a planetary nebula, despite its having nothing to do with a planet.

If the core of the star is greater than 1.4 solar masses, it will form something other than a white dwarf. These massive stars violently expel their outer layer in what is known as a supernova. What is left behind is a core that compacts itself into either a neutron star or a black hole. If the core is between 2 and 3 solar masses, it will become a neutron star, a phenomenon so dense that a single teaspoon would weigh 400 million tons. Some of these neutron stars may emit pulsating radio emissions that flash in all directions, similar to a lighthouse beacon. These pulsating neutrons are known as pulsars.

If the core is greater than 3 solar masses, the star will continue to collapse in on itself until all of its mass reaches a state of infinite density, or a singularity, creating a black hole. Due to the high density of a black hole, not even light can escape from its gravity.

Statute of Limitations

The statute of limitations is a statute that originated from the common-law system, which set forth time limits on legal action in certain cases. The deadlines for filing vary, in accordance with the type of case (criminal or civil) and the circumstances surrounding the case or claim. The periods of time also vary from state to state and country to country. Statutes of limitations apply to all cases filed in courts, including state and federal courts.

The limits of time for court action is predicated on an idea of equity or fairness. There is a prevalent belief that the best time to bring a civil lawsuit or prosecution of a criminal case is as close to the event as possible, in order to have the best evidence. The more time a case or claim sits dormant, the more likely memories fade and important evidence may be lost. Also, diligence is expected by an injured party or government entity to pursue an action in a timely manner.

Most jurisdictions examine the time frame of a legal action by thoroughly scrutinizing the circumstances of the individual case and tolling the amounts of time limitations. For example, in the case of medical malpractice, in which the doctor's mistake is not immediately known, tolling of time does not take place until there is a discovery of an actual injury or harm. Minors as injured parties are also afforded extra protection in most jurisdictions: The tolling of time often does not begin until after the minor turns 18 or the age of majority.

At any time, a party to a case can assert the statute of limitations as a defense. If the statute of limitations has expired, the case is no longer litigated. In the United States and Great Britain, there is no statute of limitations for murder. An individual suspected of committing the act of murder may be prosecuted at any time with no expiration date. However, other countries do not permit the prosecution of murder suspects after certain time periods have elapsed. For example, in Japan, a murder case must be brought before the court within 25 years of the victim's death. Japan extended its 15-year statute of limitation for murder in 2005, but the new time frame of 25 years does not apply retroactively. Only new crimes committed after the time period was extended may assert a statute of limitations beyond the original 15 years.

There are a few exceptions to the strict time limits of the courts. For example, parties may extend or limit the life of a case in civil and private matters if the litigants are in agreement. The Uniform Commercial Code allows for contracts of the sale of goods to be limited in time to 1 year; however, the code does not allow the parties to shorten the time limit beyond a 1-year period. The Uniform Code of Military Justice has a 5-year statute of limitations for almost all cases, excluding those cases for which a punishment of death is a possibility.

The statute of limitations as a concept illustrates the notion of time as a means to achieve justice for an individual. Both the injured party and the accused are afforded protections through the application of time limits to a case.

Steno, Nicolaus (1638–1687)

A respected anatomist, crystallographer, and priest, Nicolaus Steno (Danish: Niels Steensen) is hailed as one of the founders of modern geology. Through his dissections, laboratory experiments, and field observations, Steno was one of the first natural philosophers to recognize the organic nature of fossils and explain how sedimentary rocks were formed. His discoveries indicated that the earth has a dynamic history and is not a static body that has changed little since its formation, as was widely assumed at the time.

Born in Copenhagen in 1638, Steno was raised in a devout Lutheran household. He was a sickly youth, spending most of his formative years indoors reading science and philosophy and experimenting in his father's goldsmith shop. At the age of 18 Steno enrolled in the University of Copenhagen to study medicine but terminated his studies amidst war. He later continued his academic work in Leiden, where he earned a medical degree and set out on a successful career as an anatomist. Steno quickly became recognized as an expert on the human heart, brain, and glands. As a medical student he was the first to identify the duct of the parotid gland, which supplies saliva to the mouth. He would later impress audiences in Paris with his legendary dexterity with a scalpel, and in 1665 he published *Discourse on the Anatomy of the Brain,* a detailed anatomical description of the human nervous system, combined with a discussion of his philosophy of science.

In 1666 Steno traveled to Florence, where he befriended Ferdinando II de Medici, the scholarly Grand Duke of Tuscany who years earlier had established the Accademia del Cimento, the world's first academy dedicated to experimental science. Soon after his arrival, Steno was commissioned by Ferdinando to dissect the head of a giant 2,800-pound shark that landed near the port city of Livorno. In what was one of the first careful dissections of a shark, Steno noticed an uncanny resemblance between the creature's teeth and "glossopetrae," a type of odd stone common on Malta that was thought to have curative and magical powers. Other experts had previously noted the resemblance but were at a loss to explain how petrified sharks' teeth were found on land, often on mountains thousands of feet above sea level.

Steno explained this paradox in his 1669 *Prodromus to a Dissertation Concerning Solids Naturally Enclosed in Solids,* now recognized as a pioneering attempt to describe the earth in terms of natural science. Noting that glossopetrae resembled modern shark teeth in every regard, Steno wrote that these odd stones must be the remains of once-living organisms. This conclusion was generalized to other fossils, such as bones and shells, and was the first coherent argument that fossils were organic. Steno also realized that since sharks are aquatic, the sediments that encased glossopetrae must have formed in the sea. Based on field excursions in Tuscany, Steno recognized that many rocks are found in layers made of different materials. This observation formed the basis for Steno's Principles, three basic laws that are taught to every beginning geology student: (1) Sedimentary rocks are deposited from a fluid in originally horizontal layers; (2) in a series of layers, younger layers lie on top of older ones; and (3) sediments are deposited as laterally continuous sheets and later truncated by erosion. These principles demanded that the earth a dynamic history in which different rock layers are formed in temporal sequences, not as part of a single event such as the Biblical Flood.

Despite his philosophical break from traditional religious and scientific authority, Steno remained piously religious and attempted to reconcile his principles with scripture. Although Steno never departed from a young-earth viewpoint, his ideas would later be used by James Hutton, Charles Lyell, and other geologists to argue for an ancient earth. Steno converted to Catholicism in 1667, was ordained as a priest in 1675, and gradually withdrew from the scientific community. In 1677 Steno was ordained as the titular Bishop of Titiopolis, an office without a see whose main duty was to minister to remnant Catholic populations in Germany and Scandinavia. As a bishop Steno took a vow of poverty and frequently fasted, a devout lifestyle that gradually destroyed his health. Steno died in 1687 at the age of 48 and is today interred at the Basilica of San Lorenzo in Florence.

Sterne, Laurence (1713–1768)

Laurence Sterne, among the most prominent English novelists of the 18th century, is best known for *The Life and Opinions of Tristram Shandy, Gentleman,* a novel that mocks traditional literary conventions. In contrast to an ordinary presentation of time as a linear process, Sterne emphasizes the relativity of time in human experience by means of exuberant digressions.

Sterne was born in Clonmel, Ireland, the son of an impoverished infantryman. On account of his father's profession, Sterne spent his early childhood in various barracks moving from place to place. The future novelist was sent to school at the age of 10. From there he proceeded to Jesus College, Cambridge, where he first encountered the works of the philosopher John Locke.

In 1738 Sterne took holy orders and became vicar at Sutton-on-the-Forest. Three years later he relocated to York, where he assumed the position of prebendary. In the same year the clergyman married Elizabeth Lumley, who suffered several miscarriages before their daughter Lydia was born in 1747. Despite the birth of Lydia, Sterne's family life was not happy. In addition, he and his wife suffered from pulmonary tuberculosis. To recover from the quarrels in his private as well as in his public life, Sterne took an interest in painting, played the violin, read widely, and spent much of his time in the company of other women.

The author lived in Sutton for 20 years. It was at the end of this period that he began to work on his most famous novel, *Tristram Shandy.* Between 1759 and 1767 the work was published in nine volumes. The first version of volumes one and two was rejected by the London printer Robert Dodsley, so Sterne had to revise them. They were finally published in 1759 in London. These and the remaining seven volumes were highly successful although they aroused indignation among some contemporary literary critics (among them Samuel Johnson).

The aggravation of his tuberculosis forced Sterne to leave England. In January 1762 a journey to the south of France was arranged which engendered Sterne's second novel *A Sentimental Journey Through France and Italy.* After his wife and his daughter had followed him, the family went to

Toulouse where they settled for 1 year. In 1763 the Sternes visited Aix-en-Provence, Marseilles, and Montpellier. One year later the writer returned to England and finished the seventh and eighth volumes of his masterpiece, *Tristram Shandy.* Elizabeth and Lydia preferred to stay in Montpellier. In 1765 the writer left England again and set out for France and Italy, a trip that supplied him with further material for the *Sentimental Journey.* The work was published early in 1768. In March of the same year Sterne fell ill with influenza and died.

The author's literary career began late. Between 1742 and 1750 Sterne wrote letters, sermons, essays on local politics, and experimented with satire. *A Political Romance* (the title was later changed into *The History of a Good Warm Watch Coat*) was published in 1759. It was Sterne's major publication prior to *Tristram Shandy* and gave evidence of his power as a humorist.

Yet, Sterne's career as a novelist could be said to begin only with the publication of *Tristram Shandy.* The success of Sterne's masterpiece is based on its highly experimental structure that results from the ironic parody of traditional literary conventions. The writer composed his novel as a fictional autobiography, that is, as a biography of the main character Tristram told by himself. In contrast to the title the reader ironically learns little about Tristram's life and knows even less about his opinions at the end of the novel. There is no consistent plot or conclusion because the primary line of narrative is constantly interrupted by florid digressions. By means of digression Sterne is able not only to mock the generally accepted form of autobiography (*Tristram Shandy* starts with the procreation of its protagonist) but also to invert the ordinary flow of time: Paradoxically the more Tristram tells about his life, the more he will have to tell because the narrator-protagonist dwells upon endless excursions about his family and friends while his own life is constantly proceeding but remains undocumented. Apart from parodying autobiography and experimenting with time, *Tristram Shandy* explores the limits of typography by including marbled and entirely black pages as well as sketches of the plot.

Many of the innovations Sterne introduced in his masterpiece influenced modern as well as postmodern writers, for example, James Joyce, Virginia Woolf, Thomas Pynchon, and David Foster Wallace. Although Sterne's literary œuvre is quite small when compared to the work of other 18th-century authors, *Tristram Shandy* continues to exert an influence on contemporary writing.

Stonehenge

The prehistoric megaliths of Stonehenge, believed by many to correlate to a calendar or other device for calculating and/or monitoring time, have held firmly to people's imaginations for centuries. Likewise, the site itself has been studied and reported on by countless archaeologists, historians, astronomers, and other enthusiasts eager to unravel the mysteries embedded in the stone edifices, embankments, and human remains found there. The results of these collective investigations have been a broad understanding of the site's stages of construction, an appreciation for the feats of Stonehenge's architects, and a hint of Stonehenge's astronomical implications. At the same time, a multitude of unanswered questions remain.

Location and Stages of Construction

Stonehenge is a multicomponent site situated in the present-day town of Amesbury, located in the county of Wiltshire in southern England. Covering several acres, the site of Stonehenge includes earthen mounds and a ditch along the site's periphery, a series of pits constructed at multiple stages over time, and megaliths of sedimentary and igneous rock, some of which were extracted

Stonehenge as it might have looked in prehistoric times. There have been many theories about who built Stonehenge and much speculation as to its function.

Source: Fortean/Topham/The Image Works.

from locations that would have required Stonehenge's architects to travel over 100 kilometers to acquire them. Although Stonehenge was long believed to be a Bronze Age construction, radiocarbon dates indicate that the oldest sections of Stonehenge date further back in time to the end of the western-European Neolithic era, circa 5,000 years before the present, and were followed by multiple stages of construction during the 1,500 years that followed.

The first recognized stage of construction at Stonehenge included the formation of embankments and a ditch, all of which were positioned toward the periphery of the site. Additionally, a series of various-sized pits encircling the interior of Stonehenge's embankments were excavated, presumably during the first stage of construction. These "Aubrey holes," which were named after the man who discovered them, are believed to have served as postholes, although questions remain as to their exact purpose and date of origin.

The second major stage of Stonehenge's construction was completed during the half-dozen centuries following the first stage's activities and saw the filling of Aubrey holes with cremated remains and the partial filling of the ditch erected along the site's periphery through natural processes and human activity. Cremated remains were also placed elsewhere at the site during this period.

The third stage of construction at Stonehenge, ending roughly 1,500 years after the initial stage of construction began, saw the erection of the megaliths that form the heart of what most people envision when they think of the site. The actual stone used for the construction of the megaliths included sandstone and "bluestone," the latter being an assortment of blue-colored igneous and sedimentary stones, including sandstone, dolerite, and limestone variants. Unfortunately, stones used in the site's construction have been rearranged, removed, and damaged throughout the centuries. Consequently, questions remain as to the original arrangement of Stonehenge's megaliths and what their purpose was initially.

Time and Stonehenge

The specific purpose of Stonehenge remains unclear, even after countless researchers have examined its burials, mounds, and megaliths. With a particular focus on the alignment of Stonehenge's main avenue in the northeastern quadrant and megaliths to celestial bodies, investigators have hypothesized that the site may have served as an observatory to calculate eclipses, track lunar cycles, and unravel the movement of other celestial objects in relation to the earth and Stonehenge itself. Of central importance to many researchers' quests to prove such assertions is the position of Stonehenge's Avenue, Heel Stone, and additional megaliths in relation to the rising midsummer sun. To date, investigations of the site have questioned all such inquiries because the alignments of Stonehenge's components to celestial objects are not exact. Owing to loss, damage, and relocation of many of Stonehenge's fixtures over time, as well as the destruction and misplacement of collected artifacts and bone material through poor management and various catastrophes, it is difficult to ascertain what precisely was the aim of the site's creators.

Recent Research

Loss and repositioning of portions of Stonehenge's fixtures pose a challenge to determining the site's role in making temporal and astronomical measurements. Yet, numerous studies have uncovered information providing suggestions that appear promising. In 1996 John North completed and published his comprehensive research, which includes a detailed study of the placement and alignment of Stonehenge's earth and stone works. North's work also considers the possible purposes behind the site's construction and its connection to other sites. In 2001 Mike Pitts published results of his extensive research of multiple sites, including Stonehenge. Pitts's text also reviews the research on Stonehenge undertaken by scholars from multiple fields. Complete with diagrams detailing the stages of Stonehenge's construction and the alignment of the Heel Stone, appendixes documenting radiocarbon dates secured for Stonehenge, discussions of previous research initiatives of and excavations at Stonehenge, and systematic photographs of the site, Pitts's book provides a thorough analysis of Stonehenge as well as other megalithic sites. It is hoped that these efforts and those of other researches will help to further clarify the ancient site's temporal significance.

Stratigraphy

Etymologically, the term *stratigraphy* (from the Latin *stratum* and the Greek *graphia*) means "description of strata." The word *stratum* (plural, *strata*) was introduced by Nicolaus Steno in the 17th century to describe a layer of rock or sediment that is delimited by horizontal surfaces with lateral continuity and which represents a unit of time of deposition. The meaning of a stratum deals not only with the geometry of the stratified rocks but also with their genesis, assuming that it is a sedimentary unit deposited under constant physical conditions. Therefore, stratigraphy is not just a simply descriptive science, but it also deals with problems related to the genesis of the strata, the description of rock successions, and their interpretation in terms of a general timescale. Stratigraphers study all attributes of rocks as strata (e.g., form, distribution, lithologic composition, fossil content, geophysical and geochemical properties) and infer their origin and geologic history.

The origin of stratigraphy has its roots in scientists trying to determine the age of the earth. It was first introduced in the geological nomenclature by Alcide d'Orbigny in the 19th century, as a consequence of the need to order processes in time, so as to establish a geological chronology. Since Amadeus W. Grabau published the first treatise on stratigraphy in 1913, the term *stratigraphy* has been used to refer to a geological science that studies the order and the relative position of the strata, the stratified rocks being its main focus. The sequence of layering of the rocks, together with the evolution of life, is the basis of the relative timescale. In addition, stratigraphy can yield information about the processes affecting the deposition of sediments, which can result in a complex layout of the strata. Thus stratigraphers study and interpret the processes recorded in the sedimentary successions in order to determine the nature and arrangement of the stratified rocks, correlate rocks and events, and order the sequences of rocks and events in a relative timescale.

Since 1917 the improvement of radiometric techniques has allowed scientists to determine the absolute age of rocks and to work out the duration of the intervals of geologic time that had been previously established by means of fossils. The development of the oil industry between 1920 and 1940 led to a significant improvement in the knowledge of lithostratigraphy and the geometry of stratified sedimentary bodies. Until the mid-1900s the French school supported a historical meaning of stratigraphy, whereas the North American school focused on a dynamic concept of this science and on the interpretation of the geometries of sedimentary bodies. It was this second concept that was more broadly accepted within the scientific community. Afterward, the advent of plate tectonics led stratigraphers to concentrate their studies on the mobility of sedimentary basins and their evolution through time. Data from international research programs on marine geology, such as the Deep Sea Drilling Project, the use of paleomagnetism, sedimentary geochemistry and seismic stratigraphy, together with the improvement of the biostratigraphical methods and the abundant studies on radiometric dating, contributed to the current meaning of stratigraphy as a science and to its subdivision into several branches. The most important of these are *lithostratigraphy* (study of the geometrical bodies of stratified rocks, their geometry and genesis), *biostratigraphy* (study of the temporal distribution of fossils in the stratigraphic record), *chronostratigraphy* and *geochronology* (determining the age of the stratigraphic units and establishing a worldwide stratigraphic scale), *magnethostratigraphy* (establishing a scale of changes in magnetic polarity through time), *chemostratigraphy* (analysis of stable isotopes and chemical elements in the stratified rocks), *sequence stratigraphy* (recognizing major events recorded in the stratigraphic record), and *basin analysis* (reconstruction of the spatial and temporal distribution of each unit of stratified rock within a sedimentary basin).

Principles of Stratigraphy

The practice of stratigraphy is based on the application of five main principles. Nicolaus Steno proposed three of them in the late 1600s, when he attempted to explain sediment accumulation. The *principle of superposition* states that in any succession of strata not severely deformed, the oldest stratum lies at the bottom, successively younger ones above; this is the basis for establishing the relative ages of all strata and of the fossils that they contain. The *principle of original horizontality* suggests that because sedimentary particles settle from fluids and experience the influence of gravity, stratification is originally horizontal and when steeply inclined must have suffered subsequent disturbance. In addition, the *principle of original lateral continuity* states that a rock unit continues laterally unless there is a structure or change to prevent its extension, such as the edges of the depositional basin. In the late 1700s, William Smith suggested that strata could be traced and correlated by comparing their fossil content, proposing the *principle of faunal succession*. Finally, in recent decades, the *principle of simultaneity of events* was proposed to explain the catastrophic events (e.g., earthquakes, volcanism, meteorite impacts, climatic changes, sea-level changes) recorded in the sedimentary rocks globally. These catastrophic events are excellent correlation criteria, even at a global scale.

These principles, together with the *principle of cross-cutting relationships* (a structure that cuts another is younger than the structure that is cut), the *principle of inclusion* (a structure that is included in another is older than the including structure), and the *principle of uniformitarism* (the present is the key to the past; i.e., processes operating in the past were constrained by the same "laws of physics" as operate today), proposed by James Hutton in the mid-18th century to compare the present-day rock cycle to the past rock cycle, help to achieve the main objectives of stratigraphy. These include the identification of sedimentary rocks (lithology, textures, structures, geophysical and geochemical properties, fossil content), delimitation of the lithostratigraphic units (and of their lateral and vertical polarity) and their relationships (conformities, unconformities), interpretation of their genesis (sedimentology), stratigraphical logging, correlation, and introduction of time (bio- and chronostratigraphical units). Finally, the main target of stratigraphy is the reconstruction of the basin, which is the main source of information for historical geology. Apart from providing a basis for historical geology, the principles and methods of stratigraphy have found application in such fields as petroleum geology and archaeology.

Stratigraphy is closely linked to other geological sciences, such as sedimentology, historical geology, petrology, mineralogy or paleontology (especially with the biostratigraphy and paleoecology), among others. Nowadays, stratigraphy is a modern science that is actively contributing to multidisciplinary studies such as plate tectonics or so-called event-stratigraphy.

STROMATOLITES

Stromatolites are a distinctive group of layered structures that form in aquatic environments through the activity of microbial communities. They are the earliest known examples of complex life on Earth, and provide evidence that life started relatively soon after the planet's formation. The dominant form of life on Earth for most of its geological history, stromatolites are now quite rare. A few colonies still eke out a precarious existence in limited and unusual habitats.

The term *stromatolite* is derived from the ancient Greek (meaning "layered rocks") and is used to describe the laminated mineral deposits produced by certain microbial communities. Like coral reef systems, they can cover quite a large area. Stromatolites range in size from flat films to domes and columns several meters high. Some types are renowned for their distinctive "living rock" appearance and aura of quiescent antiquity. A stromatolite is not a rock, however, but a thriving colony of highly specialized microbial species. There may be many species in the system, including cyanobacteria, photosynthetic bacteria, anaerobic bacteria, and even diatoms, tied to each other by a web of symbiotic relationships.

Most stromatolites are divided into several vertical zones, each containing different groups of species. The outside or growth surface is composed predominantly of filamentous and motile photosynthetic cyanobacteria. Just beneath this layer is a thin zone of photosynthetic, anaerobic bacteria called the undermat, protected from oxygen by the growth surface and adapted to use only those wavelengths of light that pass through the cyanobacteria. Together the two populations use light energy to build up organic matter near the growth surface. Beneath the undermat, there is an oxygen-depleted zone inhabited by bacteria and archaea. These organisms feed on the remnants of organic matter produced by the layers above.

The Hamelin Pool in Western Australia is one of only two places in the world with living marine stromatolites, or "living fossils."
Source: iStockphoto.

New layers are added in response to changing environmental conditions, especially those concerning the quantity of available sunlight. The photosynthetic cyanobacteria secrete a sticky mucus, which traps and binds any passing sediment into layers of inorganic particles, predominantly carbonate. Being motile, they will then move to grow up and over the sediment layer to reach the sunlight. The space created beneath them allows the underzones to move upward as well. A new layer of carbonate forms each time the photosynthesizers move to remain on the outer surface, and the whole process causes the distinct laminations found in stromatolites.

Most stromatolites can be classified into four groups based on their shape, similar to the genera used in biologic nomenclature: the flat-layered *Stratifera,* domed *Cryptozoon,* conical *Conophyton,* and columnar *Colonnella* and *Gymnosolen.* The shape of a group is thought to be governed mainly by the conditions of its habitat. Mats and flat-layered varieties form in quiet, shallow environments such as lagoons and marshes. The conical and domed stromatolites form in more energetic environments or deeper waters, where the competition for sunlight is more intense.

Stromatolites are relatively rare but still can be found at a few sites scattered around the world. Because they have few defenses and take an extremely long time to recover from damage, they tend to be found in environments that are relatively hostile to other forms of life. Bodies of water with low nutrient levels, seasonal desiccation, extreme temperatures, or strong currents may play host to these colonies. Because stromatolites utilize minerals such as calcium carbonate, they also tend to grow in alkaline waters or regions where the groundwater is rich in minerals.

The age of fossil stromatolites has long been questioned and debated; some appear to be at least several billion years old. The oldest specimens yet found come from the ancient, well-preserved rocks of the eastern Pilbara craton, near Marble Bar in western Australia. Isotopic analysis of volcanic rocks associated with the stromatolites has precisely dated some specimens to 3,490 million years in the past. These are but one excellent example from more than 30 archaean stromatolite sites discovered worldwide. Some of these structures have been attributed to inorganic processes, such as soft sediment deformation and chemical precipitation. While this may be true of some sites, the evidence for the biological origin of stromatolites has been mounting. The Pilbara stromatolites, for example, have such a complex morphology that inorganic chemical processes are unlikely to have formed them. Furthermore, their features are inconsistent with fold structures and other physical deformations, indicating a nonbiogenic sedimentary origin.

Perhaps most importantly, fossil stromatolites possess some structural details that resemble exactly those seen in living stromatolites. They can have lens-shaped layers, for example, which are thicker over the apices of cones and flanks of columns. Serendipitously, world-class examples of living stromatolites can be found at Shark Bay, only a day's drive from the stromatolite fossil localities of the Pilbara region in western Australia. It is astonishing but convincing to see living versions of these multibillion-year fossils.

Fossil stromatolites provide evidence that life appeared on Earth relatively early, within 1 billion years of its formation. Stromatolites then grew increasingly widespread and abundant, peaking during the latter half of the Proterozoic era. During this period the atmosphere included a significant amount of methane and carbon dioxide and so was unsuitable for complex life as we know it today. Earth supported an immense population of anaerobic microbes and cyanobacteria at this time, some living in stromatolites and some floating free in the oceans. These organisms converted some of the atmosphere into free oxygen, paving the way for later stages of evolution and ecological change. In this way, stromatolites played a tremendously important role in shaping the course of Earth's history. Somewhat ironically, this change in the atmosphere also heralded the decline of the stromatolites. This has been attributed to the evolution of more complex life forms, including predators, and to a range of climatic and environmental challenges resulting from the evolution of tectonically segmented continents.

Discerning the environmental factors behind the emergence of a new species is a difficult proposition at best. In the case of stromatolites, the usual obstacles are almost insurmountable because of vast gaps in the fossil record. It may be speculated that a key adaptation was the ability to accumulate carbonate layers and thereby form an anchored structure. This led to the emergence of permanent colonies, enabling further specialization and differentiation of individual microbial species. A stromatolite provides a stable platform from which microorganisms can maximize their exposure to visible sunlight while limiting their exposure to potentially damaging ultraviolet light. Meanwhile, its laminated structure allows each species to more efficiently utilize the environment. Although their outer forms and physical structures have changed little over their long history, the microbes that build the stromatolites have never stopped evolving and specializing. Indeed, their successful history on geological timescales indicates that stromatolites have been adaptable enough to withstand many serious extinction threats.

Stromatolites have revealed many fundamental and significant facts of early life's evolution on Earth. Through them we know that at least some forms of life required sunlight to survive. Their form and composition also provides information on the early environment, telling us about water levels and energy and the gaseous composition of both water and air. Finally, they reveal that fully fledged ecosystems of food producers and consumers existed in the most ancient habitats now known to have existed on Earth.

Stromatolites have taught us to distinguish the subtle signals of ancient life from similar, nonbiological structures. These skills are now being applied to the search for life on Mars and other planets. Stromatolites have led us to recognize that a wide range of environments can harbor life, improving our chances to succeed in one of humanity's most fundamental quests.

STRUCTURALISM

Almost every science has witnessed the development of the intellectual movement called *structuralism.* Ranging from logic and mathematics, to natural science, to social science and the humanities, structuralist research programs have moved in different directions depending on the objectives, aims, and methods of the various sciences. Yet the diverse structuralisms have important properties in common, the first of which is their reference to a formal concept of structure. A crucial question that always arises when a structuralist approach develops in some science is how aspects of time can be described structurally, since most critics regard structures as static entities that cannot capture the dynamic properties of scientific objects.

It is most appropriate to start a discussion of structuralism by introducing a formal, even mathematical concept of structure. The structuralist movement in mathematics has been driven forward particularly by a group of, for the most part, French mathematicians that facetiously baptized itself "Nicolas Bourbaki." Since the 1930s the Bourbakists have been working on a systematic treatise of modern mathematics, the *Elements of Mathematics,* whose general architecture is constructed according to the idea that the objects of mathematical research are structures. Bourbaki defines a structure most generally as follows. Let us start with different sets $A, B, C, \ldots$ of elements whose internal constitution is unspecified. We generate another set M containing subsets and product sets of $A, B, C, \ldots$. Each element of M has relational properties, that is, properties it has only in relation to one or more other elements (e.g., being smaller/greater than or being contained in/containing). These properties can be used to define subsets of M: An element of M having a particular relational property belongs to the subset of M that contains all elements of M having this property (e.g., all elements that can be related to each other by a "smaller/greater than" relation). If an element of M has more than one relational property, it belongs to each of the respective subsets.

Let S be the intersection of all those subsets of M. The propositions that express the relational properties of elements of M according to which the subsets of M have been defined are called "axioms of S": They contain the complete information about all relational properties the elements of S have. Now a structure of species S is definable in two equivalent ways. Either we give the scheme of how we construct the set M from the sets $A, B, C, \ldots$, or we specify the axioms of S. To the theory of S-structures belong all propositions that are deducible from these axioms—or, more succinctly, from the proposition "s is an element of S" since s

can be completely characterized by its relational properties. In this sense, an element *s* of *S* defines on *A, B, C, . . .* a structure of species *S*.

Against the backdrop of Bourbaki's abstract concept of structure, the objection of some critics of structuralist thought, such as the philosophers Jacques Derrida and Jürgen Habermas, that structuralism blends out the dynamic properties of reality, seems to be plainly true. To define a structure of a certain species *S*, we start with given sets of *A, B, C, . . .* of internally unspecified elements, and for the construction of the sets *M* and *S* we use the given elements of *A, B, C, . . .* and predetermined relational properties of the elements of *M*, respectively. If we apply the concept of a structure on a real system, how can we capture the temporal change of the components of this system and of their relations?

In this respect it is remarkable that the founder of structuralism in the humanities, the Swiss linguist Ferdinand de Saussure, was an Indo-European scholar and developed a structuralist approach for the reconstruction of the history of Indo-European languages. The French ethnologist Claude Lévi-Strauss, arguably the most important structuralist in the social sciences, developed de Saussure's approach further to investigate an object of research—cultures that do not know writing—about the history of which records did not come down to us from earlier times. Lévi-Strauss considers a structure not only as a set of elements that are relationally definable but also as a hierarchical system in which the change of an element has, according to its hierarchical position, specific effects on other elements. A structure is, thus, a member of a class of hierarchies that can gradually be transformed into each other. For Lévi-Strauss, a structure is nothing but a snapshot of a process in which the relational properties of structural elements, and thereby the structures themselves, are changing at different velocities. A structuralist analysis must describe also the transformational rules these changes follow, as structures whose elements remain unchanged for a certain period of time. Thus emerges a conception of history, developed particularly by the French historian Ferdinand Braudel, as a hierarchy of structures whose levels differ in their rate of change. The semiotician Roman Jakobson captured the intrinsically historical nature of structures by his concept of dynamic synchrony: The structural analysis of a system cuts through its history to sketch an idealized picture of one of its states but does so only to determine, in form of structures of transformational rules, the forces that led to this state and will again change it.

If we do not want to consider temporal change—and in particular irreversible temporal change, that is, history—as the effect of a supranatural force that cannot be objectified by scientific methods, structuralism should still be an important starting point of our search for a general theory of historical systems. Current scientific approaches to phenomena of irreversible change, such as complexity theory and the theory of self-organization, analyze the dynamics of natural and artificial systems by means of structural concepts whose application is not restricted by traditional distinctions between ontological levels or regions of our world. This is the reason why those research programs are more and more often called "structural sciences." Their importance for the explanation of historical processes can be exemplified by a young science called "artificial life," which is the analysis of evolutionary processes in the world of the living through use of computer simulations of the origin and development of systems that have general properties of organisms, such as self-reproduction, variation, and metabolism. This method is of utmost importance for biology because biologists are in a similar, if not even in a more difficult, position as Indo-European scholars and ethnologists: Not only do they have an incomplete record of the evolution of life on Earth, but they also know, at least at the moment, only one specimen of an evolution of life in our universe. Because we also cannot restart the evolution of life-as-we-know-it from its beginnings to test experimentally how a second run would differ from the first one, we are dependent on virtual evolutions of life-as-it-could-be in the computer. In the future it might be possible not only to understand the general principles of evolution of life but also to reconstruct some processes in the real evolution of life on Earth by computer simulations.

Sufism

The English term *Sufism* (whose Arabic equivalent is *Tasawwuf*) refers to the diverse body of religious beliefs and practices that encompass the mystical dimension of Islam. In spite of this remarkable range of doctrines and outward expressions—the product of variables in history, geography, philosophy, and psychology—Sufis have shared a common goal, namely, a direct experience of Allah (the Real, the Absolute), not normally pursued through a more exoteric Islamic orthopraxy. Some Muslim factions from medieval to modern times have criticized the Sufis' more esoteric approach, with its strong emphasis on the interior life; some Muslims have doubted that Sufism represents an orthodox expression of Islam. Nevertheless, Sufism has won adherents from all branches of Islam and appealed to people from all walks of life. Indeed, throughout its history, Sufis played a significant role in the spread of Islam across parts of Africa, the Mediterranean Basin and Middle East, and other parts of Asia. Some Sufi practices made their way into what scholars often call "folk Islam." In modern times, Sufism has also won adherents in the West, though some advocates and practitioners who claim Sufi affiliation fall outside the authentic Sufi tradition. With their emphasis on union with God (Absolute Being who transcends time) and various rituals that enhance this interior quest, Sufi teachers and writers have concentrated on ways to bridge the divine–human gap, an agenda that considers critical aspects of reality and eternity and identifies the relation between the spiritual and the temporal. To appreciate Sufism's spiritual creativity, one must understand something about its historical development, distinctive teachings, and important teachers and writers.

The designation *Sufi* probably derives from the Arabic word *suf* ("wool") and alludes to the clothing that some early Sufi ascetics wore as part of their spiritual quest. Sufism looks to the Prophet Muhammad and his successors as foundational mystical exemplars, who also sought close personal relations with the Divine. This emphasis on the interior life developed, in part, as a reaction to the materialism that accompanied Islam's rapid expansion and establishment of the Umayyad caliphate. Some scholars attribute Sufi ideals and practices to Neoplatonic, early Christian, Gnostic, and/or Buddhist and Hindu influences. Such contacts and exchanges of ideas undoubtedly took place, but the Qur'an itself supplied the main elements of Islam's mystical approach, claiming that Allah is both transcendent and immanent. The Sufi tradition places greater emphasis on God's nearness and stresses the possibility of an intimate relation between the human and the Divine. Indeed, pivotal Quranic passages emphasize God's proximity and desire for communion and worship, and the Sufi intellectuals and poets discussed this perspective in technical theological treatises and sublime poetic masterpieces, always interacting and (occasionally) conflicting with the law (*Sharia*) and the scholarly authority of Sunni and Shi'ite traditions (*ulema*). By the 12th century, Sufi orders, which eventually numbered in the hundreds, began to form around charismatic, beloved teachers (*shaykhs*) who advocated the standard practices of Islam and emphasized their own approaches to union with God. Emphasis on this chain of transmission (*silsilah*) remains a strong feature of Sufism's appeal.

The Sufi "way" or spiritual "path" (*Tariqah*) refers to affiliation with a particular religious order or fraternity and to their distinctive doctrinal and practical emphases. All Sufis have taken the Islamic mandate of *dhikr* (remembering God's name) very seriously, as they regard such recollection as the way to achieve union with the Divine. They perform some dhikr rituals (e.g., repetition of a Quranic phrase or one of the names of God) that promote remembrance in public, while other practices remain private. These communal, liturgical gatherings (Arabic *sama*) consist of music, recitation of poetry, and dance, including the famous "whirling dervishes" of the Mevlevis (*Mawlawi Tariqah*). In this instance, the dancing symbolizes the movements of various parts of the Creation and can induce ecstasy. By focusing on the Divine through such meditation, chanting, and dancing, Sufis hope to approach or see God by leaving the corruptible behind and relying on Divine love and grace.

The most important breakthrough that leads to union with the Real results from *fana* and *baqa*. The former refers to "annihilation" or "extinction," that is, a state of trance in which the mystic's earthly ties pass away through absorption into God. Although a Sufi communes and unites with the Divine, thereby restoring "unity of Being," the mystic returns to the world but always maintains union with God. Sufis use the term *baqa* to refer to the "residue" or "remainder" that maintains this special relationship with God but still allows the Sufi to maintain individuality. They often describe the interior journey to union and a return to separate identity as "intoxication" and "sobriety," respectively. The unity achieved by the worshipper removes the temporal from the eternal as the Sufi "puts on immortality" by experiencing a new manner of existence in God. Throughout their history, Sufis have held a variety of views as to what this union means, and different emphases stimulated debates about its nature and the relation between the Oneness and the mystic's individuality. Of course, many scholars have compared *fanaa* with the goals of Hinduism and Buddhism—*moksha* and *nirvana,* respectively.

A number of Sufi leaders (theologians and charismatic leaders) made significant contributions to this more mystical approach of Islam; orders (Tariqahs) or schools of thought developed around their thoughts and examples. For example, Rabia of Basra (d. 801), one of the most famous and earliest Sufi saints, achieved almost legendary status as a female poet. Her poetry emphasizes the importance of love for God above all other concerns. Junayd of Baghdad (d. 910), one of the greatest of all Sufi teachers, claimed firsthand knowledge of mystical "intoxication" but also communicated the principles of Islam while in a state of "sobriety." On the other hand, the most famous Sufi martyr, Al-Hallaj (d. 922), seemed to cross the line between orthodoxy and heresy because of his emphasis on union with God. After claiming that he had become Truth (*ana 'l-haqq*), his theological and political enemies in Baghdad accused him of blasphemy (saying that he had claimed Divinity for himself), and he was executed.

Al-Ghazali (d. 1111), a leading theologian in Baghdad, found that Sufism offered a perspective on Islam that surpassed reason alone. He combined the interior path of the Sufis with a careful observance of basic Islamic beliefs and practices. Ibn 'Arabi (d. 1240), remembered as a great Sufi mystic and saint, was another respected theologian and scholar of Islamic law. Many other theologians have reacted to the extensive body of prose works he left behind, with some accusing him of heresy because he emphasized the close relation between God's attributes and nature.

The famous Persian poet Rumi (d. 1273) fell under the influence of a mysterious wandering dervish, Shamsi Tabriz, and became the focal point of a fraternity of pupils, whose spiritual descendants have survived until today. This Turkish order, known as Mevlevis, named after their "master" Rumi, have achieved notoriety as the "whirling dervishes" because of their ceremonial dancing. In addition to this distinctive devotional technique, Rumi left behind major poetic works that emphasized love for the Divine Beloved, as Rumi sought to loosen himself from the earth's glue and become one with God.

Sun, Age of

The sun, the star of our solar system, is approximately 5 billion years old and midway through its stellar life cycle. In another 5 billion years, the sun will exhaust its supply of fuel and collapse in on itself. As with all stars, it will go through the stages of stellar evolution before finally cooling into a cold, dark mass, in which state it will remain for the rest of time.

The sun formed from a slowly spinning cloud of dust and gas. The cloud eventually began to collapse under gravitational force, compressing itself into a smaller form. As this happened, the cloud began to spin faster, as stated by the law of conservation of angular momentum. The cloud of dust, as it continued to compress, began to flatten, forming a bulge in the center. This bulge formed the sun, making up 99% of the mass in our solar system. Meanwhile, the flattened, outer areas of the cloud surrounding the sun amalgamated, forming the planets and spatial debris (the remaining 1% of our solar system) while maintaining their spin, or rotation, around the sun.

After the first 400 million years in its existence, the sun entered the stage known as the main sequence. The sun will spend the majority of its existence as part of the main sequence, where it is today. After its becoming a star on the main sequence, gases and debris around the sun formed planets, becoming our solar system, roughly 4.6 billion years ago.

In about 3 billion years from now, the change that continuously occurs in the sun's core will be seen on its surface. Its main fuel supply will be exhausted and will switch to a secondary fuel, burning brighter at hotter temperatures. This will be the beginning stages of the sun transforming into a red giant. As the sun transforms into a red giant, the sun's mass will decrease as it emits stronger solar winds.

In 5 billion years, the sun's temperature will rise to 100 million Kelvin (K). The sun will expand beyond the orbit of Mercury and Venus, and life on Earth would be rendered impossible. The outer shell enveloping the sun will be blown off, and the debris and gases will surround the collapsed sun, creating a planetary nebula. The sun, now a white dwarf, will be the size of Earth, and will continue to consume its fuel supply over several billion years. Once the fuel supply is exhausted, our sun will become a frigid, black mass known as a black dwarf.

Scientists have measured the age of the sun by observing seismic waves on the surface. These seismic waves carried information about the sun's core to the outer surface. By observing these oscillations, scientists can compare information about the sun with theories of stellar evolution and stellar structure to give an estimate of the sun's age. It was dated at roughly 4.5 billion years, which corresponds with the age of the solar system through other studies such as nucleocosmochronology.

Sundials

A sundial is a device used to display time. The position of the sun in the sky produces a shadow on a flat surface corresponding to a specific time of day. Although only functional during daylight hours and in direct sunlight, sundials can be very accurate. The majority of sundials measure apparent solar time, time determined by the angle of the sun's shadow. As the earth rotates, causing the sun to appear to move across the sky from east to west, the sun's shadow, in the northern hemisphere, moves in a clockwise direction around the object. This phenomenon is responsible for the direction that the arms of clocks spin. The longitudinal position of the sundial must also be known to accurately measure solar time because the earth tilts on its axis. As the earth revolves around the sun, it tilts either the northern or southern hemisphere toward the sun at approximately 6-month intervals, giving the earth its seasons. Because of this tilt and the curved shape of the earth, the speed at which the shadow rotates around an object is not uniform. To solve this, the *gnomon*, the part of the sundial that casts the shadow, is aimed north. As a result, the hour marks on the sundial do not fluctuate throughout the year; this makes sundials remarkably accurate.

The earliest sundials appeared in ancient Egypt around 3500 BCE. These tall, narrow, four-sided stone monuments were known as obelisks. (The Washington Monument in Washington, D.C., is an example of a modern obelisk.) Its moving shadow allowed the Egyptians to determine the time of the day. In addition, the length of the shadow at midday allowed the Egyptians to roughly determine the seasonal date. The pyramidal top of the obelisk gave the end of its shadow a point. The position of this point at midday showed the degree of the axial tilt of the earth. Although the ancient Egyptians likely did not understand this concept, they did recognize the significance of the length and angle of the shadow from the obelisk. It is from the Egyptians that the modern divisions of the day into 12 hours, the hour into 60 minutes, and the minute into 60 seconds are traced.

Over time, advances in science and mathematics led to a plethora of variations of the sundial. The simplest sundial is the equatorial sundial, which consists of a disk with a bar through its center. The bar is positioned so that it is parallel with earth's axis of rotation, making the disk parallel with the earth's equatorial axis. This style of sundial indicates both the time of day, with the gnomon, and the date, with the nodus. The *nodus* is the tip of the gnomon. Another common type of sundial is the garden sundial. Although similar to the equatorial sundial, it instead uses a disk that is parallel to the ground. This allows the garden sundial to display time all year long. The gnomon is positioned so that it is parallel with the earth's axis of rotation and therefore will cast its shadow on the hour-marked flat disk. Many forms of sundials exist, including the vertical sundial, the analemmatic sundial, the portable diptych sundial invented during the Middle Ages, the ring sundial, and the equatorial bow sundial. Sundials have even entered the modern age with the digital sundial. The two types of digital sundials are the fiber-optic sundial and the fractal sundial. Using no electricity and having no moving parts, the digital sundial displays the time with numerals formed by sunlight hitting them. As technology continues to develop, the future for sundials seems bleak, but their impact on human history is remarkable. Their simplicity affords them the ability to display time from the surface of any planet in the universe where an angle exists between it and its sun. So even though it may seem that time has passed the sundial by, its universal application may be called on again in the future.

Sunspots, Cycle of

Sunspots are areas of the sun that appear relatively dark when viewed by astronomers using special techniques. These regions are approximately 2500°F cooler than the rest of the photosphere, which gives them their darker appearance. Sunspots have strong magnetic activity that inhibits its normal convection, resulting in the lower surface temperatures. Seventy-five percent of sunspots appear in groupings of two or more. They range in size from the smallest, called pores, which are less than 100 miles in diameter, to those that are more than 100,000 miles in diameter.

Sunspots have a fairly regular cycle of activity. The German astronomer Heinrich Schwab identified a 10-year cycle of activity while studying sunspots during the years 1826 and 1843. Rudolf Wolf, a Swiss amateur astronomer, used old astronomical records going back as far as 1700 to establish a sunspot cycle database and, in 1948, refined the sunspot cycle to 11.2 years.

A period of maximum activity, in which more than 100 spots may be visible, is referred to as the sunspot maximum. The sunspot minimum, the period of lowest activity, can have few or no spots visible for weeks at a time. At the initiation of the sunspot cycle, sunspots are more frequent at higher latitudes, generally appearing at 40°. As the sunspot maximum approaches, usually within 4 years after the initiation of the cycle, the sunspots will have moved toward the equator with the majority lying at 15° latitude. Near 5° latitude they begin to fade out with new spots forming at the higher latitudes. This movement is referred to as Sporer's law. However, the activity cycles will vary. For example, sunspot records show a period of 70 years, beginning in 1647 when activity was minimal. This era was called the Maunder Minimum, after the British astronomer E. W. Maunder, who was credited with the discovery.

The earth regularly reverses its magnetic polarity, and this change induces changes in the sun's magnetic field. The reversal occurs every 11 years. Using this information, George Ellery Hale suggested that the sunspot cycle is actually 22 years and encompasses the two polar reversals of the earth's magnetic field. Horace W. Babcock proposed a qualitative model for the dynamics of the solar outer layers. The Babcock model explains the behavior described by Sporer's law, as well as other effects, as being due to magnetic fields that are manipulated by the sun's rotation. Thus, the sunspot cycle may actually be a 22-year cycle, which includes two sunspot maximums and two polarity flips of the earth.

Sunspots are correlated with various events. Intense magnetic activity, such as coronal loops and reconnection, occurs with high sunspot activity. Large sunspot groupings produce magnetically active regions from which most solar flares and coronal mass ejections originate. Magnetic storms and auroral displays are more frequent and intense during periods of maximum sunspot activity. The Maunder Minimum clearly corresponded with an era of low temperatures and longer-than-normal winters. Correlations to other events, including such things as cycles of the stock market and baseball statistics, although hypothesized, have not been demonstrated.

SYNCHRONICITY, GEOLOGICAL

Synchronicity is the state of being synchronous or simultaneous; of occurring, existing, or being formed at the same time. The term *synchronicity* is applied to the co-occurrence of any geologic features or events in time, which are called synchronous events, or to rock surfaces on which every point has the same geologic age. Rocks formed in the same part of geologic time, which have identical or nearly identical geologic ages, are called *synchronogenic*. Synchronicity of events in multiple cores across a wide area has been used, for example, to identify turbidites as seismically generated (and therefore present at the same time in different settings) and to distinguish them from other types of turbidites.

A stratigraphic surface in which every point has the same geologic age is called a *synchrone:* a zone representing equal time. Chronostratigraphy, a brand of stratigraphy that deals with the age of the geologic strata and their time relations, is the use of chronostratigraphic correlation to demonstrate correspondence in age and chronostratigraphic position between geologic units. Chronostratigraphic correlation uses *chronohorizons* (chronostratigraphic horizons). Each chronohorizon corresponds to a stratigraphic surface or interface that is everywhere of the same age, and theoretically it has no thickness. However, it commonly corresponds to a very thin and distinctive interval that is essentially isochronous over its whole geographic extent and thus constitutes an excellent time-reference or time-correlation horizon. Many biohorizons, bentonite beds, and coal beds are valuable horizons for chronostratigraphic correlation, although the most geographically widespread horizons are those marked by magnetic reversals or those caused by global events, such as the red-rusty layer with impact evidence that is commonly found at the Cretaceous-Tertiary (K-T) boundary. To explain the origin of this layer, most authors agree that a large meteorite impacted the Yucatan Peninsula in Mexico at the K-T boundary, triggering catastrophic mass extinctions, as well as an anomalous enrichment in the element iridium and other extraterrestrial impact evidence such as shocked quartz grains or nickel-rich spinels in the boundary sediments globally. The meteorite impact and the deposition of the layer with impact evidence are thus synchronous events that occurred in an almost instantaneous geological period of time, and the K-T boundary layer can be used as an excellent chronohorizon, allowing chronostratigraphical correlation globally. Therefore, this layer can be considered as an isochronous (synchronous) surface having everywhere the same age within a body of strata. Magnetic reversals are also recorded globally in the stratigraphic record, as the magnetic field has its origin in the melt core of the planet, and magnetic reversals have occurred throughout earth history.

Other methods of chronostratigraphic correlation are based on biostratigraphy, philogeny, biomagnethostratigraphy, ecobiostratigraphy, quantitative and statistical studies of fossil assemblages, chemostratigraphy, cyclostratigraphy, and event-stratigraphy. Biostratigraphical correlation compares the stratigraphic distribution of taxa in different areas. Integrated biostratigraphy is one of the main tools of bio- and geochronology; it consists of the biostratigraphical study of different fossil groups, which provide different biozonations that can be combined allowing correlation of different biostratigraphical scales, increased resolution of the scales, as well as recognizing the diachronism of some biostratigraphical boundaries.

Two of the main problems in correlation are the paleoenvironmental and paleoecological effects, such as the local appearance or disappearance of species, or the Lazarus effect (discontinuous biostratigraphical distribution of a species caused by its local disappearance in a paleogeographic area, due to sudden paleoenvironmental changes, and by its reappearance in a more recent period of time). To minimize the paleoecological problems of biostratigraphical analyses, correlation methods based on the analysis of phylogeny have been developed. Biomagnethostratigraphical methods combine the reference isochrons of the magnetic reversals, which offer synchronous horizons, with the necessary correlation provided by the biostratigraphical scales. Ecobiostratigraphical methods organize or arrange the strata into units (ecozones) based on paleoecological and paleoenvironmental data; each ecozone is characterized by purely ecological assemblages that lived together in the same area. Ecozones allow high-resolution correlation, although their validity is local. Quantitative and statistical analyses of fossil assemblages improve the resolution of the biostratigraphical correlation, minimizing the subjectivity of identification of single species and of the data processing, and providing quantitative stages that allow correlation. Chemostratigraphical methods include stable isotope analyses, which allow scientists to identify global climatic, paleoceanographic, and eustatic events. These global events can be correlated and integrated into chronostratigraphical scales. Cyclostratigraphical methods are based on the variations of Earth's orbital parameters, which are reflected in the sedimentological, geochemical, and paleontological cycles, and therefore in the paleoclimatic and paleoceanographic record in the deep sea. These orbital cycles are expressed in terms of eccentricity, obliquity, and precession cycles, called Milankovitch cycles, which trigger cyclic climatic variations. Cyclostratigraphers try to identify and correlate cyclic variations in lithology, sedimentology, isotopes, paleomagnetics, mineralogy, or in the paleontological record. Finally, event-stratigraphers aim to establish a succession of global events (eustatic, cosmic, paleobiological, paleoclimatic, paleoceanographic events) in the geological record. Event-stratigraphy plays a main role in stratigraphical correlation, as events can be globally recognized and correlated in the stratigraphical record, where they are commonly recorded as chronohorizons. From a chronostratigraphical point of view, paleobiological events are some of the most important global events because they are usually unrepeatable and respond to global causes, therefore marking isochronous horizons. In this sense, mass extinction bioevents are probably the most isochronous events worldwide. The catastrophic mass extinctions recorded at the K-T boundary, together with other sedimentological, mineralogical, and isotopical evidence, mark one of the most synchronous chronohorizons and best documented global events in the earth's history, which can be easily correlated worldwide.

Synchronous boundaries delimit chronostratigraphic units, or bodies of rocks defined to serve as the material reference for all rocks formed during the same span of time. Each chronostratigraphic unit serves as a basis for defining the specific interval of time, or geochronologic unit, represented by the referent. Chronostratigraphic units are (in order of decreasing rank): eonothem, erathem, system, series, and stage. A formal chronostratigraphic unit of unspecified rank is a chronozone, which represents a body of rocks formed anywhere during the time span of a chron, which is the temporal equivalent of a chronozone. A chronozone corresponds to an isochronous unit, and it can be based on biostratigraphic units (biochronozones), lithostratigraphic units (lithochronozones), or magnetopolarity units (polarity chronozones).

Synge, John Lighton (1897–1995)

J. L. Synge, an Irish physicist and mathematician, made important contributions to science, especially with respect to the theory of relativity. During his career he worked in various universities and scientific institutions in Canada, the United States, and Ireland. In the period 1948–1972 he was professor in the School of Theoretical Physics at the Institute for Advanced Studies in Dublin, which would grow, thanks to him, into one of the most prominent centers for the study of relativistic physics.

Synge was the author of numerous books and papers marked by a noteworthy originality in thinking. For example, he was the first physicist to seriously consider the interior of black holes. In 1950, he showed that the surrounding of the central singularity in the Schwarzschild solution (the centrally symmetric gravitational field with a "point" source) represents two separated regions, the black hole and the white hole, the first of them denoting the end and the second denoting the beginning of the time for all objects occurring there. Synge's books *Relativity: The Special Theory* (1956) and *Relativity: The General Theory* (1960) are counted among the best monographs on the subject in question. They are distinguished by their original approach, philosophical depth, and brilliant literary style.

In his books and articles, Synge presented an important contribution to the understanding of the meaning of time and its measurement. According to him, chronometry presents an essential part of the theory of relativity. The determination of the geometry of spacetime consists in the measurement of lengths of sections of world-lines performed by ideal clocks and in the measurement of intervals between the emission and the reception of light signals, which allows the synchronization of clocks in different places and the measurement of spatial distances. In this way, ideal clocks and light signals are sufficient for the determination of the metrics of spacetime and there is no need for measuring rods. Synge believed that many physical and geometric notions (e.g., mutual orthogonality of spacetime vectors) could be expressed chronometrically.

It was Synge's special distinction to have devised and popularized the use of spacetime diagrams (in, e.g., his *Relativity of Time*), which helped to make the explanation of many relativistic subjects more vivid and understandable.

He also showed the effectiveness of the use of the world function in relativistic calculations. This function assigns to every pair of events half the square of the length of the section of geodesic joining of these events. Thus, in the case of causally connected events, the world function is equal to the half of the square of the maximal time elapsed between them.

T

Tantalus

Tantalus is a character in ancient Greek mythology who is condemned to an eternity of being tempted without a way of gaining satisfaction. His name (meaning "most wretched") and myth transcend time by serving as the etymology for the English word *tantalizing,* meaning to tease or torment someone by tempting without actually rewarding him or her.

The specific details of the myth of Tantalus are disputed; however, scholars and ancient writers agree on the gist of the myth. Tantalus, perhaps the son of Zeus or Tmolus, was the king of Sipylos in Lydia, or of Argos, or of Corinth (location disputed) who had three sons: Pelops, Niobe, and Broteas. Because he was an intimate friend of Zeus, the gods allowed him to attend the Olympian banquets of ambrosia and nectar. However, one day Tantalus stole some of the divine food and shared it with mortals. He also tried to share the secrets of the gods with mortals. Then, before the gods discovered his wrongdoing, Tantalus committed a worse crime. Having called the gods to a banquet, he found himself in the dilemma of not having enough food. To rectify the problem, Tantalus killed his son Pelops, cut him into pieces, placed them in a stew, and served it to the gods. Another version of the myth says that Tantalus committed this act to test the omniscience of the gods. This action incurred the wrath of the gods, who would not eat the stew, except for Demeter who, being distraught by the loss of her daughter Persephone, ate his shoulder. The gods punished Tantalus by bringing his kingdom to ruin and assigning an ill fate to his family. They also restored the body of Pelops and gave him an ivory shoulder to replace the section that Demeter ate. Zeus killed Tantalus for his ghastly crime.

After his death, Zeus condemned Tantalus to Tartarus, a gloomy dungeon and place of torment within Hades. Here, he stood in a lake with a depth varying from waist to chin deep while hanging from the limb of a tree that teemed with perfect fruit. Any time he tried to lean over to drink the water, the water receded leaving only black mud. If he did manage to get water in his hands, it ran through his fingers before he could get it in his mouth. When he reached for fruit from the tree, a gust of wind blew the fruit so that it moved just out of his reach. Thus, he was forever "tantalized" by the water and fruit while condemned to hunger and thirst. Moreover, a large stone loomed over the tree, threatening to crush the tree and Tantalus. This constant threat was punishment for another crime, one of stealing a gold dog, which he swore by Zeus that he had not stolen.

The myth of Tantalus demonstrates that ancient Greeks abhorred human sacrifice and cannibalism, practices that once had been acceptable. Also, it teaches against deceit, especially when it is carried out against the gods.

In addition to being the source of the English world *tantalizing,* Tantalus is the namesake for the atomic element called tantalum, a gray metal that is nonreactive to acids and is used in electronics and surgical instruments. Also, American astronomer

Charles Kowal discovered an asteroid in 1975 that he named Tantalus. During World War II, the U.S. Navy had a landing-craft repair ship named the *USS Tantalus*.

Taoism (Daoism)

Taoism is an indigenous religious and philosophical tradition of China. It has no single founder, no holy scriptures, and no single key message. Central to it is the belief in the existence of a mysterious power (Tao), unchanging in itself, but source of perpetual creation and decay in the world.

The term *Tao* (or *Dao* as the Chinese character can also be transliterated) translates as "way" or "path," but can also be used to describe a school or teaching. It corresponds to the Chinese words *Daojia* ("Dao family" or "school of the Dao") and *Daojiao* ("teachings of the Dao"). Both terms came into use during the Han dynasty (206 BCE–220 CE) to describe the philosophical and religious traditions of early Taoism, respectively.

History of Taoism

The beginnings of Taoism lie in Chinese antiquity, when this stream of thought first took shape. It was an oral tradition at first, transmitted and developed by masters, but not yet recognized as a religion of its own. The first written works, ascribed to Laozi and Zhuangzi, emerged around 400 BCE. But it was not until the 2nd century BCE that historians listed Taoism (*Daojia*) as one of six religious schools in China.

The first successful attempt at organizing a Taoist religious system started in 142 CE, when Laozi appeared to the hermit Zhang Daoling to announce the end of the world, which would be followed by an age of great peace (*taiping*). Zhang founded a movement known as the "way of the Celestial Masters" (*Tianshi Dao*) that successfully established a "Celestial Master state" during the later Han dynasty. The rulers of the Wei dynasty (220–280 CE) broke up the state, thus dispersing Celestial Master followers throughout China and setting a foundation for the movement's enduring strength. More individualistic Shangqing Taoism ("way of highest clarity") and Buddhist-influenced Lingbao Taoism were other important movements of this period.

During the Tang dynasty (618–906 CE) Taoist philosophy assumed a leading role. The imperial family venerated Laozi as one of their ancestors, ordering his veneration by imperial decree. Taoists attempted to attain immortality or longevity through the ingestion of herbs and minerals (external alchemy). These studies led to the death of numerous followers and to the invention of gunpowder as a side effect.

Taoist philosophical tradition also provided the foundation for the reception of Buddhism in China. Buddhists' ideas such as the concept of karma, rebirth, and hell were accepted into Taoism, and the Buddhist sect of Chan (in Japanese, Zen) shows strong Taoist influences.

As Confucianism grew stronger during the Five Dynasties (907–960) and Song periods (960–1279), the different religions interacted increasingly. Taoists tried to harmonize the "three teachings" (Taoism, Buddhism, and Confucianism), most prominently in the Taoist Quanzhen school ("complete perfection school") founded by Wang Chongyang (1113–1170). Taoists created monasteries and started to adopt monastic ways of life as displayed by Buddhist monks.

Instead of external alchemy, Quanzhen Taoists turned to internal alchemy in their pursuit of longevity. Through internal cultivation, the followers tried to harmonize themselves with the Tao, thus postponing or even avoiding death.

The relationship between Taoism and the Chinese state remained strong during the Five Dynasties and Song periods. Throughout the empire, a tightly knit network of temples was created; they served religious as well as political needs. The temples' Taoist masters did not confine themselves to religious studies and teachings but also served as government officials.

Favorable treatment of Taoism by the state ended during the reign of the Mongol emperor Kublai Khan (who reigned from 1260 to 1294). Buddhism was used to weaken the Taoist position of power. When the Taoists were defeated in a number of debates by the Buddhists in 1281, numerous Taoist texts were burned. Laozi's classic was the only work to be exempted.

After the expulsion of the Mongols and the establishment of the Ming dynasty (1368–1644) the Taoists regained a position of power. The Taoist canon (*Daozang*) was compiled under the patronage of the Yongle Emperor between 1408 and 1445. Almost 1,500 texts of great importance to Taoist faith were chosen, including texts on medicine and astronomy, as well as works that displayed Buddhist or Confucian influences.

The decline of the Ming Dynasty also marked a decline in fortune for Taoism and its followers. The Manchurian tribes that founded the Qing Dynasty (1644–1911) were influenced by conservative Confucians. The Celestial Masters, who had held a position of power at the Dragon and Tiger Mountain, lost their influence at the court. Taoism had exerted remarkable influence over the Chinese elite until this time. Now its impact on popular religious culture became more noticeable.

In the 1780s Christian missionaries arrived in China and started to spread their faith among the people. Around 1847 Hong Xiuquan, who claimed to be Jesus's younger brother, founded a Christian millenarian sect. In 1851 he proclaimed himself king of the Kingdom of Great Peace (Taiping). Government officials now were tested on the Bible instead of the ancient Chinese classics, and Hong's army destroyed Taoist temples as well as texts. But even after the defeat of the Taiping army, the decline of Taoism continued. By the beginning of the 20th century, almost all copies of the Daozang had been lost or destroyed.

The Great Proletarian Cultural Revolution (1966–1976) under Chairman Mao Zedong constituted another attempt at the destruction of Taoism. Temples were destroyed, and Taoist masters were killed or reeducated. In 1979 the overt suppression of Taoism ended. Many temples have been rebuilt since, and Taoist traditions can be openly practiced once more.

Concept of Time in Taoism

Taoism saw many changes and developments in its philosophical as well as religious traditions over the centuries. What was considered to be essential to Taoism at one point in history might have been contradicted squarely only a few years later. The classics by Laozi and Zhuangzi as well as works by the Celestial Masters were not even included in the first Taoist canon. Taoists have never agreed on any common teaching. But they share basic concepts in their understanding of the universe and of all life within.

Like many Asian religions, Taoism conceives the material world as ever-changing. Creation and decline follow cyclical or rhythmic patterns. Beneath this surface, there exists a timeless reality, the source of all being and nonbeing. This concept of reality is also reflected in the Taoist cosmology, which distinguishes two aspects of the Tao. The apparent aspect can be recognized in the order of the universe. The world and all plants and creatures emerge from the timeless Tao only to return to it when their time has come. The second aspect is often called the Absolute Tao. It is the source of all creation, the underlying essence immanent in the whole universe.

All people should try to adapt to the apparent aspect of the Tao, to create harmony and find fulfillment. To live in harmony with the world and be with the Tao, people have to accept the course of events around them, taking effortless action (*wu wei*) only. Wu wei literally translates to "without action" but implies the ability to decide when to act and the insight not to hinder natural developments.

Common people as well as the rulers should try to live in harmony with the Tao, but the failure to do so has by far more severe repercussions for emperors than for commoners. In ancient China the first emperor in each dynasty was believed to be chosen by heaven. Morally upright rulers are issued a mandate of heaven (*tian ming*) to direct the course of earthly events. As the dynasty's history grows longer, later emperors enjoy the luxuries available, starting to neglect their duties. Their government turns corrupt, and the empire sinks into chaos. Floods, diseases, and other calamities devastate the country. Heaven then withdraws its mandate again, thus ending the dynasty. Positive signs would then declare the new choice of heaven, appearing in the vicinity of a morally upright person chosen to be the new ruler.

Underlying this belief in a direct linkage between emperors' deeds or characters and natural disasters is the acceptance of certain features of yin and yang cosmology into Taoism. According to this worldview, the world consists of one cosmic energy called *qi*. This energy manifests itself in the two phases of yin and yang. They are not mutually exclusive but constantly move into each other. The stages of this continuous development are associated with five different elements (wood, fire, earth, metal, water), by which names they have come to be known. As yin and yang move into each other, the elements change into one another in cycles perceived as destructive or productive.

Taoism adopted this cosmology and formulated the basic law of impulse and response, according to which all things in the world are closely connected with each other. Not only do different events occurring in one place over the centuries influence each other, but simultaneous events in different places are also closely interrelated. Therefore, if one manages to adjust to the flow of reality and becomes one with the Tao, because of the close linkage between all living creatures and natural phenomena, this will bring forth greater harmony in the whole world. A corrupt government thus echoes on the natural world, causing earthquakes, floods, and other natural disasters. There is no other way to bring harmony to the world than to aim at inner cultivation. If evil is fought, new evil arises out of the force applied. And even peaceful actions strengthen it again, solely through the attention paid to evil.

Many cultures have brought forth millenarian movements, which believed in a better world to come. Most of them display a lineal understanding of time, waiting for or passionately working toward the realization of a future paradiselike state that is believed to continue until the end of times.

Although there were some millenarian Taoist movements, the belief in the nearing end of this world and the coming of a better one always accepted the possibility of a cyclical decline of the future world and a repeated renewal. The onset of this awaited world would be marked by the decline of the current dynasty. It would be another new beginning with every possibility of decline once the time for change came. Not even the millenarian sects believed in the existence of a paradiselike world that would last forever.

Just as the endurance of a dynasty is decided by Heaven, the human life span also is allotted to every person by celestial forces. Heaven watches over the people, judging them by their righteous or evil deeds. According to these observations, the length of each life is measured. The number of gods Taoists believe in and their powers and characters vary greatly according to the teachings of each sect. But most picture the spirit world as a heavenly version of the Chinese imperial bureaucracy. So the decision to end a life can be viewed as a bureaucratic act, death is its enactment.

Although Taoists of different schools accepted a variety of perspectives on death over the centuries, many tried to prolong life and avoid death. Generally the ancient Chinese philosophers are believed to have accepted death as the natural end to each person's life cycle. But even the famous work of Zhuangzi mentions immortals. Later religious Taoists often devoted their activities to practices promising longevity or even immortality.

The immortals (*xian*) mentioned in the Zhuangzi are spirit beings equipped with magical powers, such as the power to fly, who dwell on mountains in the Eastern Sea. But already in the Han period they were believed to live in a distant paradise (Kunlun, a high mountain in Central Asia, or Penglai, a paradise located in the Eastern Sea), which cannot be accessed by mortals without great difficulties. One way to attain the state of an immortal was to ingest a magical substance from the isle of Penglai. Some emperors sent ambassadors to the east to obtain this substance—thus Japan was discovered. Other Taoists studied alchemy or experimented with meditations, ecstasies, breathing exercises, and other longevity practices.

In Han cosmology the human body was believed to consist of two kinds of qi. Whereas primordial qi connects the body to the Dao, the earthly qi is connected to physical everyday survival. Sickness, healing, longevity, immortality, and death are different stages on a continuum of waning or abundant qi. If all primordial qi is lost, death occurs. But if all qi can be transformed into primordial qi through the practice of longevity techniques, the qi turns to spirit. Then even the end of the body has no impact on the spirit of the deceased, which then will reside in paradise.

Just as the body consists of two kinds of qi, in Chinese antiquity every person was believed to be made up of a spirit soul (*hun*) and a material soul (*po*). The souls of celestial and earthly origin join before birth and separate again when death occurs. For the first years after death, they are in contact with the living world. While the material soul needs proper care to prevent it from returning as a ghost, the spiritual part resides in the ancestral heaven and is worshipped at the family's home. Ultimately both souls will merge back into their original elements. The cycle of creation and decline, of birth and death, goes on. From this background it becomes obvious that the immortality Taoists strive for is not physical immortality but a transformation and strengthening of the spirit soul. The immortal still lives in a secluded part of this world. It is not removed to a completely different dimension but has reached a higher level of existence.

Little importance has been given to ordinary time in Taoism. This becomes obvious in the lack of chronicles and historical events recorded by Taoists. Laozi's work, the *Tao Te Ching,* is exemplary in this respect, as it contains no dates and mentions neither proper names nor anything else to connect it with any historic time or place. This pervading ahistoric attitude is also mirrored in other texts of the Taoist canon. Beneath all worldly events, all creation and decline, lies a timeless reality that remains unchanged. The goal of Taoists is to transcend the flow of these worldly events and to become one with the underlying timelessness. Dimension such as time and space have to be left behind to enter eternity.

Taylor, Frederick W. (1856–1915)

In the field of organization studies, the American engineer Frederick W. Taylor is recognized as a pioneer in scientific management, a set of techniques for analyzing how any given job is performed, devising a more efficient way of performing it, and then training workers in the use of the new, improved method. Taylor's own academic training as an industrial engineer and his practical experience in factories as a machinist, foreman, and plant manager enabled him to develop a methodology that, over the course of a century, has not only directly influenced the way in which most manufacturing operations are performed but also helped to shape the very background of modern thinking about how organized human activities are to be managed and, consequently, about the way in which most people view time.

The cornerstone of Taylor's career was the commonsense recognition that in the performance of any task, certain methods will prove more efficient than others. The worker who, each time after assembling a machine component, must pause to fetch another set of parts from a bin on the other side of the factory will of course produce fewer units per day than will a worker who can simply extend a hand and pick the next set of parts from a moving conveyor belt. The worker who must stop to change the bit in his drill press twice to machine a single workpiece correctly will be less productive than if the component itself were redesigned to eliminate the need to change drill bits.

In serving industrial clients, Taylor and his associates, armed with notebooks and stopwatches, would carefully observe each routine step in a manufacturing process, analyze the task down to its smallest details, and discuss the job with the workers who actually performed it. Next, they would reengineer the task so as to eliminate all wasted time and motion and, finally, assist managers in retraining workers to use the new, more efficient method. In later years, Taylor would use the new technology of motion picture cameras to record on film the way industrial jobs were being performed, the better to analyze each movement and identify instances of wasted time and motion.

Such exercise of managerial control over the smallest aspects of workers' performance has been strongly criticized for removing the chief source of satisfaction from workers' lives, placing workplace knowledge in the hands of management and thereby alienating laborers from their own work. The effect, critics say, has been to devalue the acquisition and practice of traditional craft skills and to replace these with mind-numbing and inhumanly repetitive tasks. Also noted by critics is that from the capitalist's standpoint, an unskilled labor pool has the advantage of being quickly trained, cheaper to employ, and, if necessary, easier to replace. Thus, Taylor's methods would seem ideally suited to the purposes of modern capitalism, in which the desire to maximize profit requires the exercise of strict economic rationalism. As the German economist and sociologist Max Weber (1864–1920), a contemporary of Taylor, noted, the Protestant work ethic historically has understood the striving for profit as divinely ordained and the accumulation of wealth as an end in itself. To waste time is thus to be sinful, whereas the rationalizing of time, together with its increasingly precise quantification, serves as the instrument for increased productivity and the ever greater accumulation of capital.

It would be unfair, of course, to hold Taylor responsible for any abuses to which his methodology has been put since his demise. If he was worldly enough not to see the interests of workers and factory owners as identical, neither did he view them, like Karl Marx, as by definition antagonistic. In his 1911 book *Principles of Scientific Management,* he fully acknowledges the value of workers' capacities for insight and creativity in designing better ways to accomplish the desired end of greater productivity, whose benefits would in turn accrue—albeit with perhaps less than perfect equity—to workers, managers, capitalists, and the marketplace alike.

Technology Assessment

Technology assessment (TA) is the systematic study of the conditions and societal and environmental consequences of predominantly new technologies. One should, of course, keep in mind that there are several very different approaches in the field of TA, ranging from the classic TA model embodied by the Office of Technology Assessment (OTA, U.S. Senate, 1972), which warns against technology-related risks and subsequent political blunders in the form of an early-warning system, to the Constructive Technology Assessment (CTA, Netherlands Organization for Technology Assessment), which attempts to accompany, describe, and assess the technology development process. In contrast to ethics, however, TA is more descriptive than evaluative.

The Temporal Structure of Technology Assessment

TA has a temporal structure. It is future oriented in that it develops various scenarios of a possible future state of the world depending on the implementation or nonimplementation of new technologies. This future orientation has its roots in the experiences of previous decades. The realization of the horrifically destructive potential of atomic energy as seen in World War II by the dropping of two atomic bombs on Hiroshima and Nagasaki and the still imminent danger of the annihilation of the entire planet as the result of a nuclear war has made most people aware of the fact that technical knowledge is more than just theoretical. Technical knowledge put into practice is ambivalent. Like the atomic bomb, it can be used to wipe out hundreds of thousands of people in one fell swoop. Likewise, even if it is used for peaceful purposes, it can get out of control as shown by the example of the Chernobyl nuclear power plant meltdown.

On the other hand, this technology could help reduce carbon dioxide emissions and thereby slow down global warming, which is itself largely the result of technological developments. These technological developments have improved our daily lives in many ways: For example, new technologies in modern medicine have, on the one hand, significantly increased our life expectancy but on the other are also partly responsible for the dramatic growth of the world population. When we consider the modernization of agriculture, we see a similar tension: On the one hand, it has helped prevent countless famines, but on the other, it has caused serious damage to the environment. Looking at modern information technology, the same can be said: It has made daily life much easier, but not without new demands and dangers, for example, to the private sphere. The rapid improvements in transportation from the car to the airplane are no different, because together with the World Wide Web they have given rise to globalization as we know it today with its opportunities and risks.

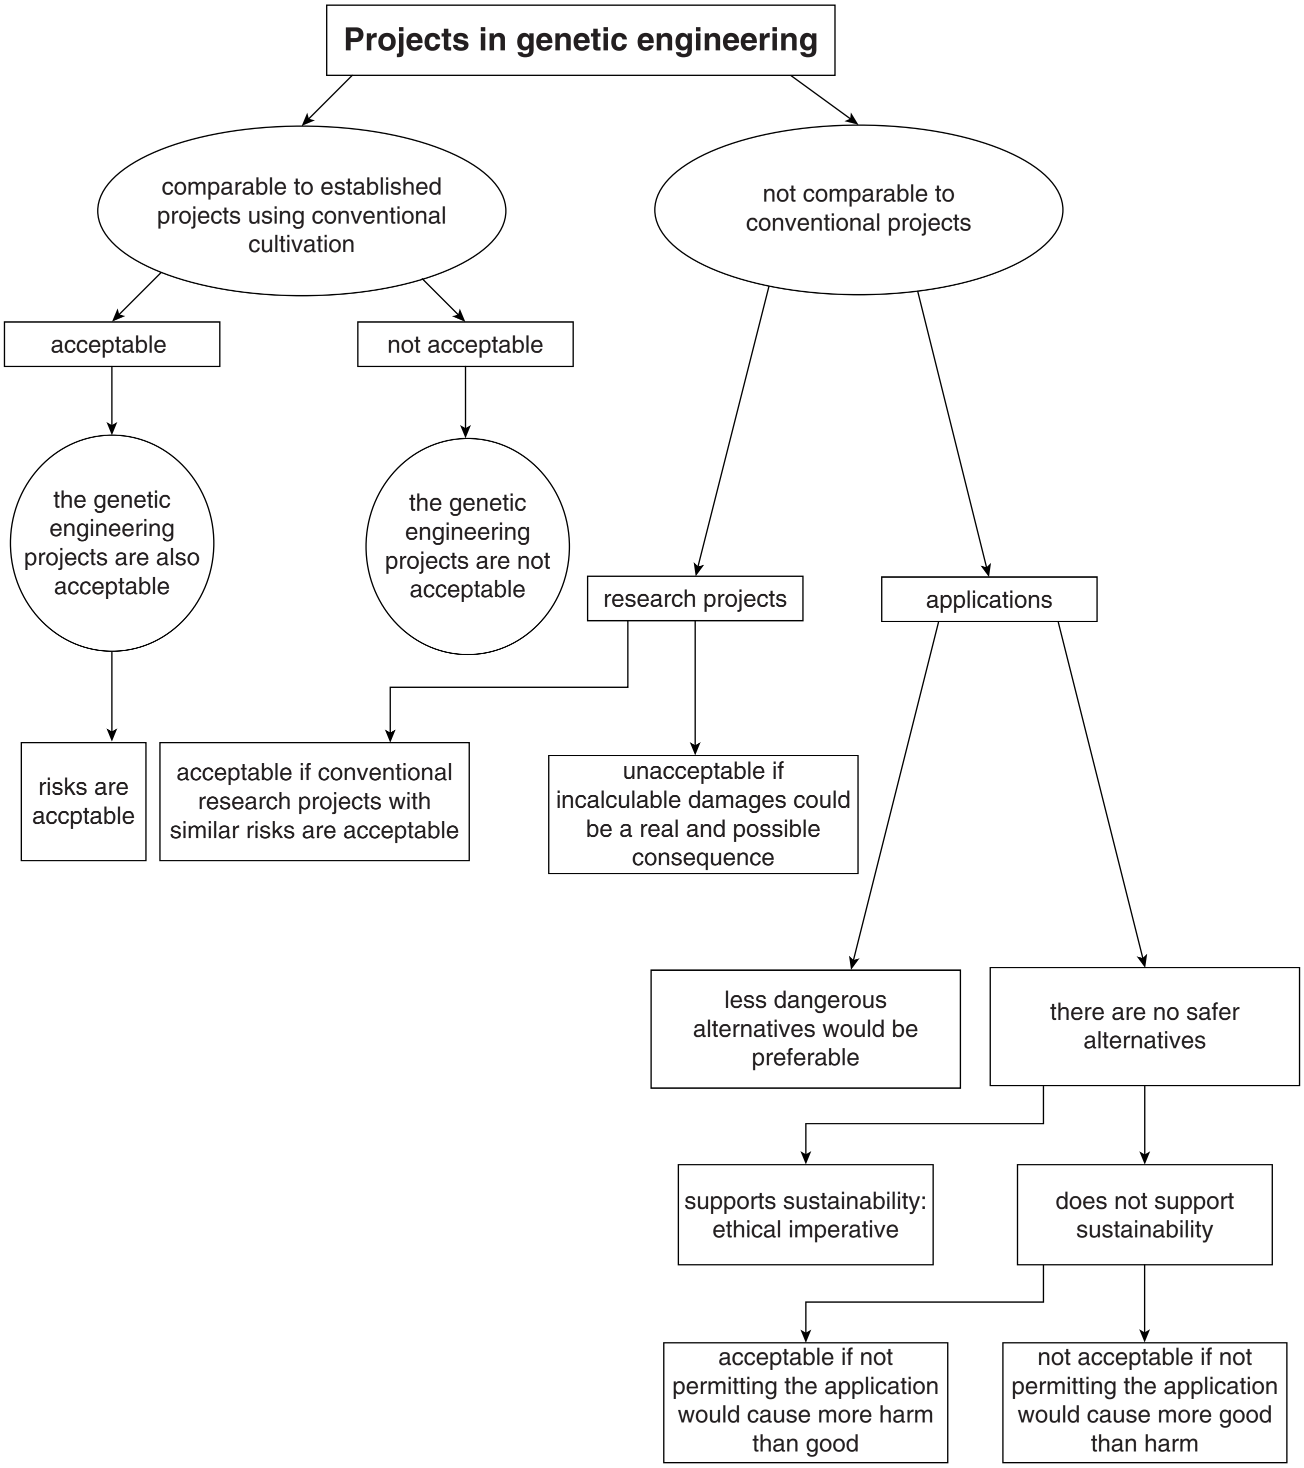
Against this very background, philosophers such as Martin Heidegger have already warned against an ambiguous understanding of technology and have called for a new attitude toward technological possibilities. TA has made it its task to consider prospective technological possibilities as a transdisciplinary collaboration. These considerations are directed at prospective consequences: TA does not want to put all technological possibilities under general suspicion. Instead, it is about trying to make sure that the future is still worth living in for the projected 9 billion people who will inhabit it in 2050 and that global catastrophes that could result from the misuse of technology are avoided.

Important Principles, Their Problematic Nature, and Decision Trees

The so-called precautionary principle and the principle of sustainability are key principles for every future-oriented TA. The philosopher Hans Jonas, inspired by discussions in the Club of Rome in the 1970s as well as by elements of the German legal tradition (*Vorsorgeprinzip*), formulated the central idea of the precautionary principle, with its imperative responsibility. His core belief is that the future of humankind is fundamentally threatened by current technological possibilities. This threat can be successfully faced only when technologies that could cause major and irreversible damage are not realized. The precautionary principle should function here as a kind of maxim principle: Conduct yourself in such a way that the conceivably worst consequences of a possible technology are minimized. It could, of course, turn out that we have to completely do without a given technology. In accordance with Jonas, environmentalists, for example, have called for an end to nuclear power and also a partial ban on genetic engineering in the agriculture sector, or at least a very controlled and cautious implementation of this technology.

With all of this in mind, the fundamental issue at the heart of every TA addresses the fact that because we cannot predict the future and, therefore, have to make decisions bound together with risk or uncertainty, the position of the precautionary principle as a maxim-principle cannot hold water in practice. Theoretically, the speculative risk of any technology, which could in the long run lead to catastrophe, is conceivable. Furthermore, Jonas overlooks a very essential defect of overcautiousness. A cautious person could also inhibit the development and implementation of technologies that could be very useful for humankind. For this reason, we have to work with hypothetical risks and, therefore, develop a decision tree. Using the decision tree, we can decide whether technologies that are in line with the precautionary principle and function under the principle of sustainability—meaning that they at the very least provide ecological, economic, or social advantages without putting one at risk for the sake of the others—should be developed.

The example of genetic intervention in agriculture can serve to illustrate this point: Are there conventional cultivation methods comparable to the new possibilities of genetic intervention? Are we dealing with research purposes or with an application? In the case of the former, how much do we know about the extent of potential damage? In the case of the latter, we need to ask whether harmless alternatives are preferable with regard to application. A decision tree for a TA in the case of green genetic engineering could look like this:



Political and Temporal Dimensions of TA

Recently, the precautionary principle and the principle of sustainability have gained considerable significance on a national and international level (1987 Montreal Protocol; the numerous international treaties and declarations reflected in the 1992 Rio Declaration on Environment and Development, which was signed at the United Nations Conference for Environment and Development; and the Kyoto Protocol). As long as individual countries can ignore international agreements without the threat of sanctions, the political influence based on findings from TA will remain limited. For this reason, one could say that the egoism of some groups of people living today threatens the future of coming generations. When someone ignores the fundamentally temporal structure, namely the consequences for the future caused by current technologies, he or she violates the aforementioned principles. So technology assessment is grounded in a serious concern because of the temporal structure of our changing the world.

Teilhard de Chardin, Pierre (1881–1955)

Since his student years in the Auvergne region of central France, Pierre Teilhard de Chardin was devoted to both science and religion; he specialized in geology and paleontology. After teaching the natural sciences in Egypt, he studied theology in England where he later became a Jesuit priest. As a result of reading Henri Bergson's *Creative Evolution* (1907), Teilhard embraced the sweeping temporal perspective of organic evolution. After becoming ensnared in the infamous Piltdown man fossil discovery (this specimen was later proven to be a hoax), he returned to France to become a stretcher bearer during World War I. He had several mystical experiences in the trenches and would later have a mystical experience of planetary scope while doing research in the Ordos Desert of Inner Mongolia. His ongoing dedication to historical geology more and more convinced him of the necessity to take organic evolution seriously in both his scientific and religious reflections.

Teilhard sought to reconcile evolutionary science with Christian theology. But, as a consequence of now introducing evolution into his own lectures and writings, he was silenced by the Roman Catholic Church. Briefly, his scientific view of time was not compatible with the religious conception of creation. However, with fortunate irony, his Jesuit superiors exiled him to China where he had to limit his academic activities to geological investigations and scientific publications.

While a geologist at the Cenozoic Laboratory of the Peking Union Medical College, Teilhard became involved with the excavations in the western hills near the village of Zhoukoudian. At this site, he participated in the discovery of the fossil remains of Peking man (*Sinanthropus pekinensis*), a hominid form that existed in China about 350,000 years ago. This evidence strengthened Teilhard's commitment to organic evolution in general and human evolution in particular. His numerous articles increased his growing reputation as a prominent geopaleontologist. Likewise, Teilhard became very concerned about the far-reaching consequences of human evolution for understanding and appreciating the true place of our own species within cosmic time and earth history.

Now having ample time to rigorously reflect on his unique experiences as a Jesuit scientist, Teilhard decided to write a book that would present a comprehensive view of the meaning and purpose of evolving humankind within this unfolding universe; he had expanded his vision to encompass the remote past and the distant future. The result was his major systematic work, *The Phenomenon of Man* (first published in 1955 in a French edition). It offered a philosophical worldview that boldly attempted to reconcile science and theology within an evolutionary framework. The Vatican and the Jesuit order were so alarmed by his unorthodox ideas about God, evil, free will, original sin, and personal immortality that Teilhard's book was not published until after his death.

Taking the vastness of evolutionary time seriously, Teilhard saw this universe as a cosmogenesis; creation was not a single event that happened in the past but is an ongoing process of creativity in terms of ever-increasing complexity and ever-centralizing consciousness. He maintained that the unity of this universe is ultimately grounded in units of spiritual energy that have been becoming more and more concentrated throughout cosmic history. Actually, his cosmology is essentially a planetology grounded in a spiraling sequence of global spheres.

Focusing on the finite and spherical earth, Teilhard interpreted our dynamic planet in terms of emergent layers of matter, life, and thought: Geogenesis had produced the geosphere, biogenesis has created the biosphere, and noogenesis is now forming the noosphere. He saw converging and involuting evolution resulting in a future layer of collective consciousness. Guided by a meta-Christianity, this human noosphere will eventually detach itself from the earth, transcend space and time, and become united with a personal God at the Omega point. This end-goal of planetary evolution is a mystical union of human and divine spirit.

Teilhard's bold vision had taken seriously the new perspective that emerged as a result of evolutionary time. Going beyond outmoded ideas and traditional beliefs, and despite his personal conflicts with myopic thinkers, Teilhard's optimistic concern for the survival and fulfillment of humankind still remains an inspiration to enlightened individuals in science, philosophy, and theology.

Teleology

In philosophy, teleology is the attempt to comprehend and explain the universe in terms of ends or final causes. Teleology is based on the proposition that the universe has design and purpose, that its effects are in some manner deliberate, and that in order to understand it completely, one must take into consideration final causes. Teleologists admit that physical causes may be deterministic and agree that the object of scientific research is to discover universal laws of phenomena can be rationally explained when adequate causes are assigned to them—if the conditions of their occurrence are known. Teleology states that this determinism reveals a "direction" in nature; that is, the universe is headed toward a goal or completion. Thus, teleologists feel there is little question regarding whether the cosmos has a final cause; rather, the question should be whether humanity has the ability to see it.

Teleology emphasizes the concept that a final cause or purpose is inherent in all humanity. There are two types of such causes—intrinsic and extrinsic finality. *Extrinsic finality* consists of someone realizing a purpose outside him- or herself, primarily for the welfare of others. *Intrinsic finality* consists of someone realizing that a purpose exists within him- or herself by means of a natural tendency directed toward the perfection of its own nature. For instance, an atom obeys quantum principles that did not evolve but nonetheless are "givens." In addition, one's life is intended to play out in a specific manner, so that one's existence protects itself from death and disease.

When extrinsic finality is overemphasized, a likelihood exists that anthropic principles might be attributed to supernatural intervention or superstition; for example, God was angry at the world so he sent a flood to destroy all terrestrial life. Intrinsic finality provides the basis for the teleological argument that God exists and for the intelligent design debate regarding how human life evolved. Teleologists feel that relying solely on Darwin's principle of natural selection is faulty, because evolution focuses exclusively on the immediate causes and mechanisms of events, never looking for a rationale that explains the synthesis of different facts. Hence, if a clock is dismantled, one discovers nothing but springs, pivots, levers, and gears; on the other hand, if the mechanism causing the watch to work has been correctly formulated, could one not say that the clock was designed for the purpose of keeping time? Moreover, many philosophers state that biology is profoundly concerned with questions concerning causation and how constraint functions have affected the structure of life—Darwin's theories did not upset this thesis. For instance, when Darwin saw the various beaks of Galapagos finches, he thought that due to the area's scarcity of birds, one could surmise that a single species had been modified for different ends. This is a most un-Darwinian statement.

Historically, teleology has been associated with Aristotle, while the rationale of teleology was studied by Immanuel Kant and, again, made central to speculative philosophy by G. W. F. Hegel and the various neo-Hegelian schools, including that of Karl Marx. In Hegel's opinion, individual human consciousness, as it attempts to reach for autonomy and freedom, has little choice but to deal with an obvious fact—humanity's collective identities (the multiplicity of worldviews, ethnic, cultural, and national identities) that separate members of the human race both now and in the past and that always have and always will set different groups of people against each other in violent conflict. Hegel speculated that the "totality" of mutually antagonistic worldviews and life forms in history was best seen as being driven toward the completion of goals. In other words, a time would come at an end point in history when the "objective contradiction" of "subject" and "object" would eventually change into a form of life that has left all violent conflict behind.

Many individuals think that there is only one teleology, but there are many. Following are brief descriptions of each:

- *Philosophical Teleology.* Aristotle felt that the explanation of, or justification for, something was to be found not only in its functions or possible use but also in its final goal; that is, the reason for which the phenomenon was created. Every object in the universe (from subatomic particles to stars) is composed of some type of substance, has an efficient and final cause, and so on. Both Platonic and Neoplatonic theories of creation fit this kind of teleology.
- *Theistic (Dualistic) Teleology.* Monotheistic creationism (Judaism, Christianity, Islam, etc.), which posits the belief in an existence of an all-powerful God that created the world, represents dualistic teleology. According to Christian beliefs, teleology symbolizes a simple argument regarding the Creator's existence—that is, the order and efficiency found in nature is not accidental. If world design indicates order, then by necessity God exists, as there is no way of explaining how human beings (as well as other complex species) could have arisen by chance alone.
- *Natural Teleology.* Science, overall, dismisses teleology, though some scientists are believers in "natural teleology." It has two parts:

  In *bounded* natural teleology, a particular state of being is reached, regardless of the environment.

  In *unbounded* design or contingent teleology, the end of something is unknown; rather, it is the consequence of making a selection when several alternatives are on hand.
- *Process Teleology.* This belief states that the directional development of creation arose neither by chance nor because a beneficent God loved the universe but from the snail-like progress of evolution.

Teleportation

The term *teleportation,* widely used in science fiction literature, may be broadly defined as the act of transferring an object from one location to another without the actual movement of the object through the space separating the two locations. This implies, therefore, that not only is the space required for travel eliminated from the process, but also the time of travel is eliminated, or nearly so. Several theories have been put forward to explain how such movement of persons or inanimate objects would take place. These include movement by psychic means, or through manipulation of the spacetime vacuum or geometry, or even through parallel universes. At present, the reality of teleportation is somewhat different from the definition given above, which arose partly out of decades of science fiction lore. This entry explains why this is so, followed by an outline of the general steps currently being employed in teleportation schemes in the scientific world, along with some of the actual experiments performed in the past decade and a half.

The steps required to facilitate the teleportation of an object may be generalized as follows: The exact composition of the original object is identified, after which the object at that location is disassembled. The details of the object's makeup are then transmitted to the final location and an exact copy of the original object is constructed. Despite what has been portrayed in current and past works of science fiction, teleportation of macroscopic objects is not yet part of the foreseeable future. Teleporting a human, for example, would first involve analyzing approximately 10^{28} atoms that are found within the human body. Storing the information obtained would require vast amounts of space. At present (and even in the foreseeable future), there is no computer technology available to handle that capacity of data, while even with the best possible technology, accessing and transmitting this information would take millions of centuries. In 1982, another problem arose from Dennis Dieks, William Kent Wootters, and Wojciech H. Zurek's no-cloning theorem, which, as its name implies, states that it is impossible to make an exact copy of any quantum particle. The major reason, however, for the impracticability of macroscopic teleportation is the violation of one of the key principles of quantum physics, Heisenberg's uncertainty principle. This principle states that it is impossible to know simultaneously all the properties of a quantum particle. The problem that arises is that in replicating the original object, all the information about each particle in the object must be known. The uncertainty principle makes this impossible.

While teleportation of macroscopic objects is not yet a reality in the scientific world, in 1993 a team of six international scientists (Charles Bennett, Gilles Brassard, Claude Crépeau, Richard Jozsa, Asher Peres, and William Wootters) proposed a mechanism for another type of teleportation (quantum teleportation) that obeyed all the laws of physics. Quantum teleportation may be defined as the transfer of quantum information from one particle to another some distance away; the state of a system, and not the system itself, is transferred. It uses a feature of quantum mechanics known as *entanglement,* along with the transmission of classical information, to transfer an unknown quantum state to some arbitrary location. Entanglement, also known as the Einstein-Podolsky-Rosen effect, is a property exhibited by quantum systems that are correlated with each other in some way, even though they may be separated spatially. States that are entangled are often regarded as one quantum system because of the strong correlations that exist between them. Entanglement is essential to any teleportation protocol, because it allows the state being transferred to remain unknown; there is, therefore, no violation of the Heisenberg uncertainty principle.

The following gives a general idea of the protocol employed in quantum teleportation. Alice, the sender, wishes to teleport the state of a quantum system, particle *c,* to Bob, the receiver. (Alice and Bob are not real people; they are systems that transmit and receive the state teleported.) Because this state is unknown to Alice, the Heisenberg uncertainty principle is obeyed. To facilitate the teleportation scheme, Alice and Bob require two channels, one for the entangled particles *a* and *b* and one for the transmission of the necessary classical information. In this way, Alice can divide the full information that describes the state of particle *c* into a purely classical part and a purely quantum part, and then send them to Bob via the two channels. They begin by sharing a maximally entangled state (this state is one of four possible states known as Bell states) comprising particles *a* and *b;* Alice is given particle *a* and Bob is given particle *b*. This can be done at any time before the teleportation process. For them to remain in a coherent entangled state, however, they must be kept isolated from their environments. At this stage, there is no classical or quantum correlation between particle *c* and the entangled particles *a* and *b*. Particle *c* and the entangled pair therefore exist in what is called a pure product state.

Alice initiates the interaction of particles *a* and *c* and performs a complete measurement on the two particles in the Bell basis. This results in one of four Bell-state possibilities that are equally probable. Because *a* and *b* are initially entangled, there is an immediate change in particle *b* that is based on the interaction of *c* with *a*. Particle *b* is now in one of four possible pure states that depends on the outcome of Alice's particles and is related to the original state of particle *c*. Alice then performs measurements on the joint properties of her pair of particles and transmits this information via the classical channel to Bob. The act of measuring destroys the quantum state of particle *c* such that particle *c*, as it originally was, no longer exists. This is expected, because the no-cloning theorem must be obeyed. Based on the classical information sent to Bob, he is then able to perform the necessary operations on *b* to transform it into an accurate replica of *c*.

Quantum teleportation requires the transfer of both quantum and classical information. However, unlike the transfer of quantum information in the teleportation process, classical information transfer is not instantaneous, because any such communication that is faster than the speed of light would violate the laws of relativity. Therefore, quantum teleportation cannot take place instantaneously.

Theoretically, quantum teleportation allows for the perfect transfer of the state of a system from one location to the next so that the final state of Bob's particle is an exact copy of the state teleported by Alice. However, in reality, imperfections in the initially entangled pair (in Alice's measurements and in Bob's transformations) tend to limit the fidelity of the teleportation process.

Experiments and Future Prospects

Several teleportation experiments have been performed since 1993 and, with exciting breakthroughs over the years, have come a long way from the teleportation of the polarization state of a photon in 1997. These experiments include the teleportation of squeezed states of light (1998), the teleportation of a laser beam (2002), the teleportation of photons over relatively long distances (2003–2004), the teleportation of states of trapped calcium and beryllium ions (2004), and the teleportation of a laser beam, in which information was embedded, into a cloud of atoms (2006).

Quantum teleportation is considered to be one of the most promising applications of quantum entanglement. However, there has also been the proposal of another teleportation protocol (2007) that does not require sharing an entangled state between Alice and Bob. Instead, an optical field is used to transmit the quantum state of the "object" from the sender to the receiver, at which point an exact replica of the object is constructed. Proponents of this scheme claim that it will result in greater teleportation fidelity, because the extent to which particles *a* and *b* (as mentioned before) are entangled is a limiting factor in the teleportation process. They also claim that their method will result in an increase in the distances achieved by current teleportation techniques, because light is used as the medium of transfer.

Quantum teleportation has become an important mechanism in the transfer of quantum information from one place to the next. It is a key resource in long-distance quantum communications and in quantum computation protocols. It is thought to be the quantum wiring for futuristic ultrafast computers and for the execution of operations at points, such as quantum logic gates, that are separated spatially. In nearly a decade and a half, quantum teleportation has developed from a theoretical proposition to experimental reality. With the progression of time, there have been gradual increases in the sizes and in the complexities of "objects" being teleported and in the distances over which teleportation occurs.

How far quantum teleportation or other such schemes will advance the conventional concept of teleportation remains to be seen.

Telescopes

Throughout human history, humankind has longed to reach beyond its physical limits. With the rise of the empirical sciences, people learned to question and expand the range of their senses with the help of optical tools, and telescopes have literally changed our worldview. Telescopes have served in the discovery and cartography of our planet; they have revolutionized the arts of navigation and war; they have taught us about the lifetime of a star, how galaxies looked at an early time of their existence, and how celestial bodies can be applied as chronometers. More than once, telescopes have thus redefined the borderline between science and religion, as illustrated, for example, by the well-known dispute between Galileo and the church.

In order to understand how much telescopes have contributed to our knowledge, it is necessary to follow their advancement through time. The use of telescopes has both benefited from and pushed ahead the development of state-of-the-art optical technology, materials, and fabrication techniques. Leading astronomers were often known as the manufacturers of the best lenses and mirrors of their times. The rise of the telescope was paralleled by the flourishing of optical theory, which gave insight into imaging principles, diffraction phenomena, and aberration, and which is connected to the work of great physicists like Christiaan Huygens, Isaac Newton, Joseph von Fraunhofer, and Ernst Abbe. Today, cutting-edge telescopes contain mirrors 8 meters in diameter and are located on top of isolated mountains, such as the Very Large Telescope in Chile, or even sent into space, like the Hubble Space Telescope. Those instruments collect light from objects of ever increasing distance—light emitted billions of years ago—and hence allow us to literally observe the evolution of the universe through time.

Precursors and Early Optics

The history of the telescope starts long before people began to assemble lenses and mirrors into tubes. Ancient civilizations, including those of the Babylonians, Egyptians, Chinese, and Assyrians carried out systematic observations of the night sky and created their own worldviews as a mixture of physical law, religious belief, and myth. At that time, lenseless observation tubes were used for aiming at particular regions of interest, helping to follow the motion of celestial bodies and to screen off disturbing light sources. The oldest known lenses, presumably used as magnifying glasses and for lighting fires, are dated back to the Assyrians of the 7th century BCE.

A first heyday of astronomy can be located during the Greek era. In his *Optica,* the father of geometry, Euclid (c. 365–c. 300 BCE), was the first to describe the linelike propagation of light. The Greeks (e.g., Hipparchus of Nicaea, 140 BCE) composed star maps of surprising accuracy. Also, the first detailed studies on the properties of reflection and refraction were performed by the Alexandrians Heron and Ptolemy during the 1st and 2nd centuries CE. Ptolemy is known best for his geocentric worldview, which placed the earth at the center of the universe and all other sidereal bodies on circular orbits around it.

During medieval times, much of the precious scientific knowledge of the Greeks was lost again—and the earth regained its disk shape. We can thank the Arabs, who themselves were skilled astronomers with their own observatories and precise star catalogues, that Ptolemy's work was preserved in translation.

In the 13th and 14th centuries, the dissemination of magnifying glasses and spectacles in England and northern Italy were the stimulus for many new experiments. Among others, Leonardo da Vinci mentions in his diaries the idea of "glasses for the eye to see the moon large." It was not until the 17th century that the first real telescopes were constructed; still, even without them, a number of major astronomical works was to announce the arrival of a new scientific era. In 1543, Copernicus released his book *Concerning the Revolution of Celestial Bodies,* which turned out to be a revolution itself, though of the (hitherto very anthropocentric) sciences. The Copernican system could avoid many of the Ptolemaic difficulties, especially the counterintuitive *epicycles,* by identifying the sun as the center of the universe and the earth as just one of the planets orbiting around it. But still not all discrepancies between the calculated and the observed planetary motion were resolved, and it was another 65 years until Kepler, using the outstanding observation records of his former teacher Tycho Brahe, found the solution to be elliptical orbits.

Revolutions: The First Tube Telescopes

The construction of the first telescope is commonly ascribed to the Dutchman Hans Lippershey, who applied for a patent for his invention in 1608. This request was rejected because in the following months, other people with similar instruments and claims appeared. One of the first and best-known people to use telescopes for astronomical observations was Galileo Galilei, who had heard rumors about the Dutch invention in 1609 and immediately started to build his own telescopes. The early Galilean telescopes consisted of a 60-centimeter tube holding a convex objective and a concave ocular (see sidebar). Among the numerous important discoveries by Galileo are the moon's craters, sun spots, the discrimination of the hazy Milky Way into single stars, and the first observation of Jupiter's inner satellites. Encouraged by his findings, he became a great defender of the Copernican worldview: If objects were found to revolve around other planets, then clearly the earth is not the center of everything. His strong stance was answered by the church with an inquisitional trial and verdict.

When Johannes Kepler, arguably the most advanced optician of his time, heard about Galileo's discoveries, he started an excited correspondence with the Italian. Although he had never envisaged a telescope, he published groundbreaking works on the fundamental principles of optics and telescopy, including the geometrical relations of imaging ("paraxial approximation") and the principles of the pinhole camera. He also suggested new types of telescopes (see sidebar) and multiple lens combinations to reduce aberration errors.

Following the Stars: Navigation and Timekeeping

Beyond their purely astronomical use, telescopes always had an earthbound purpose for geodesy and navigation. Especially with the rise of the seafaring age, the reliable determination of one's own coordinates from the stars became imperative. While the latitude could be derived easily by measuring the altitude of the pole star, the longitude required following the position of the stars through time. Because no precise chronometers were available, the relatively swift motion of the moon on the background of the stars was commonly used as a clock, which presupposed very accurate star maps. With the improvements of telescopy at hand, the Royal Observatory in Greenwich was founded under the auspices of Isaac Newton in 1675 to create exact star catalogues for sea navigation.

The different purposes of telescopes resulted in two standard mounting setups, which correspond to different astronomical coordinate systems. The first is the *altazimuth style,* which can be rotated about a vertical axis and a horizontal axis to determine the spherical angular coordinates *altitude* and *azimuth* of the celestial sphere. The second—the *equatorial* or *parallactic setup*—aligns one rotation axis along the earth's rotation axis and thus features observation planes parallel to the equator and thus parallel to the movement of the stars along the sky. In this setup, the tracking of a star is reduced to one rotational degree of freedom, which simplifies matters from an observer's point of view.

The exploration of celestial motions with telescopes also improved human timekeeping abilities. With the sun as the natural basis, the periodic rotation of the earth defines our "solar time," which has led to the demarcation of longitudinal time zones. The arbitrary zero point is set at the longitude of the Royal Observatory at Greenwich, England, the basis for Greenwich Mean Time (GMT). However, due to the ellipticity of earth's orbit around the sun and its nonuniform velocity, the day length varies periodically over the year on a minute scale. Furthermore, as the earth continues on its orbit, the rotation between two consecutive noons (i.e., the sun passing an observer's meridian) is larger than 360°. These effects can be neglected in everyday life; however, for astronomical purposes, more advanced time measures are required.

Most straightforwardly, the fixed position of the stars can be used as a frame of reference for the earth's rotation, defining the *sidereal time.* A related, more complex system is that of a *universal time,* which is calculated from a formula based on the varying position of the earth relative to the sun, as well as the precession of the earth's polar axis. Another measure, *heliocentric time,* takes into account also the difference in propagation time of sunlight to the different positions of the earth throughout the year. Finally, it was discovered that the earth's rotation is intrinsically irregular, and hence a linear time flow cannot in principle be defined accurately with respect to the earth's motion. Therefore, a flexible time measure—the *ephemeris* or *dynamical time*—was introduced, which links the time units to their use in gravitation theory and updates them regularly according to the measured position of the sun, the planets, and the moons.

A Race Toward the Infinite: Refractors Versus Reflectors

As people tried to increase the power of telescopes, they soon encountered physical limits. In order to minimize spherical aberration (see sidebar), the magnification had to be realized by means of lenses with small curvatures. This fact promoted the use of lenses with great focal lengths and diameters, leading to bizarre-looking constructions. Around 1650, Hevelius of Danzig built several lengthy wooden telescopes, the largest of which measured an incredible 45 meters in length.

Christiaan Huygens, father of the wave theory of light and the pendulum clock, also constructed large telescopes, ranging from 3.6 to 38 meters in length, with which he made the first observation of Saturn's rings and its moons.

Newton was one of the first to conceive of correction setups for dispersive effects by combining different optical materials (predecessors of the later *achromates*). However, Newton believed that these chromatic aberration errors (see pp. 1234–1235) were an insurmountable obstacle of refractors, and in 1671 he turned his efforts to a new type of telescope: the reflector. The idea to use mirrors as the primary optical element had been around almost as long as telescopes, but it was thought that mirrors were in principle inferior to the perfection of lenses—a grave mistake. By 1720, the quality of mirrors could compete with good refractors. Also, different layouts for reflectors had appeared, and the *Newton* and *Cassegrain* styles (see pp. 1234–1235) took a leading role. Both are still used in most telescopes today.

The final breakthrough of reflector telescopy is owed to Wilhelm Herschel, a German musician who engaged in astronomy after settling to England in 1757. Herschel's aptitude allowed him to increase the size of his parabolic mirrors gradually to 1.2 meters, bringing him fame and royal honors. He discovered Uranus, some of Saturn's satellites, and a huge number of double stars and star clusters; he resolved details of the Great Orion Nebula and thousands of stars of the Milky Way, whereupon he even correctly guessed the Milky Way's flat profile and our position in it.

Another milestone was a huge and rather unmanageable reflector finished in 1845 by the wealthy Earl of Rosse; it was named "Leviathan" for its gigantic appearance. The 4-ton mirror with a 1.8-meter diameter and a focal length of 16 meters superseded all previous endeavors and revealed, among other things, the shape of spiral galaxies. However, by the time of "Leviathan's" operation, large refractors also had become available and in fact fashionable due to a series of discoveries. In particular, Neptune had been spotted in 1846 with the excellent Fraunhofer 24-centimeter refractor, after its existence was famously mathematically predicted from Uranus's nonideal orbit. The second half of the 19th century can be considered the pinnacle of refractor telescopy; it yielded such great instruments as the Russian Pulkova telescopes, the Potsdam double refractor, and the outstanding 1-meter Yerkes refractor conceived by George Ellery Hale.

This success was made possible by the work of one man—Joseph Fraunhofer, the father of optical technology and quality control. In addition to other scientific abilities (e.g., he worked on far-field diffraction and the analysis of the solar spectrum), Fraunhofer possessed an unrivaled practical knowledge about geometrical-optical properties and glass chemistry. He created accurate charts of the refractive indices of optical materials and suggested how to combine them as achromates. Also, he replaced the *Pröbel* ("trial and error") technique of lens making with reproducible manufacturing procedures. Before his early death in 1826, he constructed a couple of measurement telescopes on equatorial mounting of unprecedented precision; almost-identical copies were made by his successors for many decades. A comparable comprehensive expertise in optical technology was not achieved until 1900, when the lucky constellation of the optician Ernst Abbe, the glass chemist Otto Schott, and the industrialist Carl Zeiss coincided in Jena, Germany.

Nonetheless, by the turn of the 20th century, refractors finally gave way to a new generation of reflectors, which held advantages in terms of color correction, aperture size, mounting stability, and a short tube length. Large-scale reflectors were erected around the world, such as the Crossley reflector at Lick observatory (1904) and the Zeiss telescopes at Hamburg-Bergedorf (1911), Berlin-Babelsberg (1915), and Uccle (1932). The leading telescopes of that time were the 1.5-meter (1908) and the 2.5-meter (1917) reflectors at Mount Wilson observatory, initiated by G. E. Hale. Mount Wilson was home to several decades of cutting-edge observations, including Hubble's discovery of the redshift of distant galaxies.

Modern Telescopy

The modern history of telescopy starts in 1948 with the Mount Palomar observatory in California, which was conceived of by G. E. Hale and later named after him. The observatory is located a height of 1,700 meters and houses a 5-meter Cassegrain reflector. The 15-ton mirror with its 19-ton bearing was encompassed by a clever "horseshoe" mounting, which was actually designed for much smaller amateur telescopes. With the optical power available, astronomical interest was finally shifted to extrasolar research. In 1962, quasi-stellar radio sources, the so-called quasars, were discovered. Other major results achieved at Mount Palomar include the typology of Cepheid stars, which led to a revision of the Hubble constant and hence to a recalculation of interstellar distances, resulting in an increase of the estimated size of the universe by factor of two to three

The Russian telescope at Mount Pastukhov (1976), with its 6-meter mirror, was the first to use altazimuth mounting again. The return to this "simpler" setup was made possible by the recent development of computer steering. The telescope itself is gigantic: It measures 42 meters from the bottom angular bearing to an observer cabin at the top of the tube, and it comprises about 700 tons of movable parts, which are steered with arc-second accuracy. The telescope achieved its full performance only after the installation of a new main mirror.

A significant contribution to telescopy was made by Bernhard Schmidt, who developed a method to use spherical mirrors instead of parabolic ones. Spherical mirrors can be fabricated much more easily but are subject to inadmissible distortions when used as focusing optics, even though the difference between a paraboloid and a sphere for a 5-meter mirror is less than 0.14 millimeter. Schmidt removed certain errors (*coma* and *astigmatism*) by inserting a limiting aperture at the center of the sphere, and he took care of the *spherical aberration* (see sidebar) by augmenting the

aperture with a large, weakly deformed correction lens with a tricky profile. The enormous advantage of a Schmidt telescope is its increased field of view, which makes a real scanning of the sky feasible. This makes the Schmidt telescope a good complement to the high-resolution telescopes. The world's largest Schmidt system (2 meters in diameter) is located at the Karl Schwarzschild Observatory in Jena-Tautenburg, Germany; the next largest is the 1.8-meter "Big Schmidt" at Mount Palomar.

In addition to the mere technical limitations of building ever-larger mirrors for telescopes, the cost to fabricate large scopes rises by a factor roughly proportional to the third power of the diameter. Addressing both of these issues, two new techniques were tried at the construction of the Mount Hopkins observatory in Arizona in 1979. The telescope conjoins the foci of six separate Cassegrain reflectors, realizing the first multiple mirror telescope (MMT). Together, the six 1.8-meter mirrors gathered as much light as a 4.5-meter mirror, but construction costs were less than one third of what they would have been for a telescope with a 4.5-meter mirror. For several reasons, the groundbreaking MMT was later replaced by a telescope with a single 6.5-meter mirror, which was the first to be manufactured with the so-called spin-casting technique: During the cooling process, the hot glass liquid is rotated constantly such that the centrifugal force naturally pushes it into the correct parabolic form. Spin casting is used today for the most advanced telescope mirrors and has helped to reduce the fabrication time, the material effort, and hence the costs of large mirrors.

Since the 1960s, telescopes for nonvisible wavelengths have also been playing an increasing role in the study of astronomy. For example radiotelescopes (suitable for wavelengths of a few meters) have made many important scientific contributions based on the radio signals from quasars, pulsars, and nebulae and are greatly involved in the SETI (Search for Extraterrestrial Intelligence) program. The largest single-reflector radiotelescope—which has become popular through the movie *Golden Eye*—is located at Arecibo, Puerto Rico. It has a diameter of 305 meters, and it contains about 39,000 aluminum tiles. Today, radiotelescopes are often linked together using interferometry, the coherent superposition of waves from different reflectors, to form so-called arrays. From such an artificially increased detection surface, much higher resolutions can be obtained.

An outstanding observatory site is located on top of the 4,200-meter Mauna Kea, Hawai'i where clouds and atmospheric turbulence rarely disturb the view. Mauna Kea has been the home of many telescopes, including the 3.6-meter Canada-French-Hawai'i (CFH) reflector (1977), the 3.8-meter United Kingdom Infrared Telescope (UKIRT, 1979), the James Clerk Maxwell Telescope (JCMT, 1987) with its 15-meter reflector for the submillimeter wavelength regime, and two Keck telescopes (1992, 1996). The Keck telescopes were funded by a $140 million grant from the Keck foundation and were involved in the discovery of the oldest known galaxy. Each carries a 10-meter mosaic mirror composed of 36 hexagonal tiles, each of which is adjustable separately with 4 nanometers accuracy, somewhat reminiscent of the MMT technique.

In the early 1990s, the European Southern Observatory (ESO) erected a large telescope facility on the extremely remote Mount Cerro Paranal

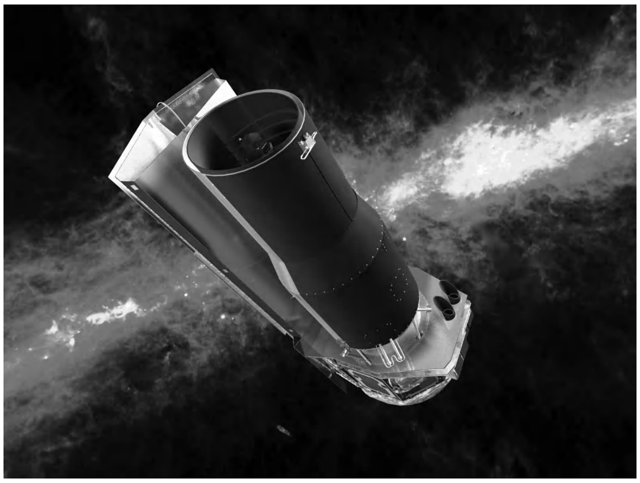
(2,635 meters) in the dry Chilean Atacama Desert. Paranal is home to the famous Very Large Telescope (VLT), which consists of four identical 8.2-meter reflectors that can be combined interferometrically to work as one ultralarge telescope. The four telescopes feature adaptive optical elements in the collimated part of the beam that activate several hundred times per second to counteract the negative effect of atmospheric turbulence on what the observer sees. The adaptive optic is adjusted with the help of an artificial, laser-produced "star" in the upper atmosphere. The VLT was the first telescope to spot an exoplanet.

Ambitious new telescopes—such as the Japanese Subaru telescope on Mauna Kea with its 8.2-meter mirror (1999) and the Large Binocular Telescope (LBT) with a doublet of two 8.4-meter mirrors on Mount Graham, Arizona (2004)—have marked the way into the next millennium, and exciting results can be expected from them.

Space-Based Telescopy

The idea of circumventing the limitations that the atmosphere puts on viewing the heavens by placing a telescope in an orbit around the earth dates back to German rocket science in the 1920s and was greatly promoted by Lyman Spitzer in 1946, after the first successful launching of small spectrometers into the upper atmosphere. The rapid development of space technology and satellites soon proved the unique quality of pictures recorded from space, so that finally in 1977 a project for a space-based observatory was started. The completion of the project took NASA 13 years (in part it was delayed by the *Challenger* catastrophe in 1986), and the projected cost of $450 million tripled to $1.5 billion, part of which was funded by the European Space Agency (ESA). The observatory was named the Hubble Space Telescope (HST) in honor of Edwin Hubble, and it features a 2.4-meter main mirror and several cameras and detectors to identify waves from UV to IR wavelength. It orbits the earth 600 kilometers above the ground at a speed of 27,000 kilometers per hour, taking 1.5 hours for one revolution.

When the HST was first launched in 1990, it turned out that the main mirror was deficient—it deviated from the ideal parabolic shape by



NASA's Spitzer Space Telescope (artist rendering). The Spitzer space telescope was launched into space by a Delta rocket from Cape Canaveral, Florida, on August 25, 2003. During its mission, Spitzer will obtain images and spectra by detecting the infrared energy, or heat, radiated by objects in space between wavelengths of 3 and 180 microns (1 micron is one millionth of a meter). Most of this infrared radiation is blocked by the earth's atmosphere and cannot be observed from the ground.

Source: NASA/JPL-Caltech.

2 micrometers, resulting in major distortions of the image. In an amazing space repair mission, the defect was corrected. The HST data are transmitted via a network of satellites, and many thousands of papers have been published on HST data. By now, the HST has delivered many images of objects that would not be accessible otherwise, like close-up views of other planets and their moons, or evidence of black holes at the center of galaxies. Assuming that no collision occurs, the HST's lifetime may well exceed another 15 years before it decays from its orbit into the atmosphere. The HST is supported by other space telescopes focusing at different wavelengths, like the Infrared Spitzer space telescope and the Chandra X-ray observatory.

Watching the Past Happen

The information obtained through a telescope—for example the position, size, spectrum, and brightness of a star—is derived from the light that this very star emits. This light takes time, of course, to reach us. Light travels at the constant

The Physics of the Telescope

A telescope is an optical instrument designed to create a magnified image of a distant object on a detector (such as the retina of the human eye). Similar to microscopes, telescopes consist of at least two lenses. Figure (a) displays the image formation with two convex lenses, observing an object at a finite distance. The dark gray lines delineate the light path of the image formation in the eye.

The function of a telescope relies on the principles of geometrical optics, where rays that are parallel to the optical axis in front of a convex lens will intersect its focal point after they pass through it, and beams that run through the center of a lens are not deviated. The primary lens, the *objective,* generates a real, inverted image at an intermediate plane. For that purpose, the original object has to be located outside the focal length *f1* of the primary lens. The real image appears within the focal length *f2* of a secondary lens, the eyepiece or *ocular,* which causes the observer to see the object with a certain magnification. Together, the ocular and the pupil of the eye work exactly like a magnifying glass. The resulting apparent object size can be determined from the backward projection of the rays passing through the secondary lens (dashed lines), thereby forming a virtual image.

(f) Chromatic aberration

(g) Spherical aberration

The difference between a microscope and a telescope is that the latter aims at comparably large objects at great distances (e.g., stars) rather than at tiny but very close objects (e.g., cells), which requires the focal length of the primary telescope lens to be much larger. In fact, the distance to the object can typically be considered *infinite* without making any huge error. This means that the angle between the two rays leaving the object in figure (a) can be assumed to be approximately parallel. In this case, the intermediate image appears exactly at the focal plane *f1*. If *f1* furthermore coincides with *f2* (*confocality*), then the rays leave the ocular parallel again, and the eye is fully relaxed (no adaptation needed). In figures (b) and (c), Kepler and Galileo telescopes are shown, respectively; the infinity and confocality assumptions were made with both. Note that because the retina image is flipped once more by the human brain, the Kepler telescope produces an upside-down impression of the object. The Galilean telescope avoids the inverted intermediate image by using a concave ocular, so that one perceives an upright impression of the object.

Today, most telescopes used in astronomy are reflectors. In a reflector telescope, a concave mirror (followed typically by a secondary "catcher" mirror) is substituted for the objective or primary mirror. Nonetheless, the imaging process remains basically the same, involving an intermediate image and a magnified observation through an ocular. Mirrors avoid the difficulties associated with lens errors and can be fabricated with considerably larger dimensions, which allows them to collect much more light and obtain a higher resolution. This advantage compensates for the fact that refractor telescopes typically block a fraction of the incident light with their optics.

Figures (d) and (e) display the layout of Newton and Cassegrain telescopes. The Newton telescope possesses a 45° mirror on the optical axis and a characteristic side viewport, whereas in the Cassegrain setup, the beam is "folded" twice and sent through a hole in the main mirror along its initial direction. Nowadays, the final image is often recorded with sensitive electronic detectors like CCD (charge-coupled device) cameras, which allow for long-time illumination and also cover spectral ranges invisible to the human eye.

Three central entities for the characterization of a telescope are the magnification, the resolution, and the field of view. For all telescopes, the *magnification M* is defined as the ratio between the angle of observation with and without the additional optical aid, $M = \alpha_2/\alpha_1$, as indicated in figure (a). In the case of an infinite object distance and a confocal setup, this is equal to $M \approx f1/f2$, the ratio of the two focal lengths. For example, a Kepler telescope with focal lengths of $f1$ = 2 meters and $f2$ = 2 centimeters attains a magnification of 100x. For large Newtonian reflectors like the Herschel telescopes from the 1780s, where $f1$ = 2.1 meters and $f2$ = 0.5 millimeter, magnifications of 4,000x or larger are achieved. However, it is not desirable to increase the magnification indefinitely: No matter how large the magnification, a natural limit for the *resolution*—which determines the smallest structure that can be seen sharply—is set by the finite diameter of the primary lens or mirror, at the boundary of which the incident light is diffracted. A pointlike light source, for example, a distant star, is thus not imaged as a point, but as a set of concentric rings with a certain intensity distribution. Two stars can be separated only if centers of the corresponding ring structures do not overlap. According to the *Rayleigh criterion,* the minimum resolvable angle $\Delta\alpha_{\min}$ between two light sources is given by $\Delta\alpha_{\min} = 1.2.\ \lambda/D1$, where λ is the wavelength of the emitted light and D1 the diameter of the primary lens or mirror. For example, the Hubble Space Telescope with its 2.4-meter mirror attains $\Delta\alpha_{\min} = 2.5\times10^{-7}$rad at $\lambda = 500$ snm, which corresponds to a spatial resolution of 96 meters on the moon's surface (that is, at 380,000 kilometers distance). Such a resolution cannot be obtained by earth-based telescopes without additional measures of compensation, because fluctuations in the atmosphere limit the angular resolution to about $\Delta\alpha_{\min}^{earth} = 5\times10^{-7}$ rad.

A second, practical restriction for the highest reasonable magnification is the reduced *field of view*—or *solid angle of observation* Ω. The further one looks into the sky, the smaller the observed fraction of the sky becomes, and hence the motion of the stars becomes more difficult to follow. Ω is proportional to the ratio between the diameter and the focal length of the primary optical element squared, $\Omega \sim (D1/f1)^2$. Because the diameter D1 also determines the amount of light collected, a large Ω facilitates the detection of faint or more distant objects, though at the expense of magnification; if one wants to improve the magnification by increasing $f1$, one has to increase D1 accordingly in order to warrant the same illumination.

However, the use of large lenses or mirrors is accompanied by certain problems. In addition to the increasing difficulties of fabrication and mounting, large optics are typically subject to considerable imaging errors. For example, the refractive properties of lenses depend on the wavelength of the transmitted light, so that light rays of different colors will be focused at different positions [figure (f)]. Because stars do not emit at a single wavelength but with a characteristic spectrum, an image produced with a lens microscope will be "smeared out" over several image planes, which is called *chromatic aberration.* But even for monochromatic light, aberration errors occur: Rays refracted or reflected by a circular surface (i.e., by a lens or a spherical mirror) arrive at different foci depending on their incidence distance to the central optical axis [figure (g)]. This effect of *spherical aberration* can be counteracted by using "flat curvatures," that is, by using the central parts of lenses or spherical mirrors only, or by using parabolic mirrors, which avoid spherical aberration altogether. Other imaging errors include *coma, astigmatism,* and *distortion.*

finite speed of 299,792 kilometers per hour, which is the maximum possible velocity in our universe and the upper boundary for the transmission of information, as Albert Einstein posited in his theory of relativity. The distances in the universe are so huge that they are measured with light-years (the distance light travels in one year), or even millions and billions of light-years. This implies that the light from distant stars has traveled a very long time before it reached us, and the information it provides is in fact that of the star at an earlier time. When we use the light to determine the age of a star, this star might even have already ceased to exist.

The more remote an object is, the further we look into the past. Light from the sun takes about 8 minutes to reach the earth. The next star closest to our sun, Proxima Centauri, is already 4.2 light-years away, and the next galaxy is the Andromeda nebula at 2.7 million light-years. Probably the most distant object observed so far is a very faint galaxy behind the massive galaxy cluster Abell 2218. For the observation, Abell 2218 functioned as a magnifying *gravitational lens,* thus allowing observers to collect more light due to the light-bending effects. The faint object was detected with both the Hubble and the Keck telescopes, and it is approximately 13.4 billion light-years away; its light is the oldest light ever recorded. The pictures revealed a tiny galaxy of only 2,000 light-years in diameter, containing about a million stars that are only a few million years old; in contrast, a typical galaxy contains hundreds of billions of stars, and an "average" star like the sun is 4.8 billion years old. The evidence suggests that this galaxy is being observed at a time when star formation has just started, 750 million years after the big bang, which agrees with previous estimations of a 14-billion-year-old universe, as known from the recession velocity of the expanding universe.

By giving us the very possibility of peering at the past, telescopes have enabled us to formulate the central cosmological questions, theories, and models about our universe. Having framed humankind's way through time toward a modern scientific worldview, telescopes continue to teach us a humble perspective against the infinity we are encountering through them.

Terrorism

In the past decade or so, terrorism has become a prominent topic of Western security agendas. Up to the 1970s, terrorism had been regarded as a merely internal problem of nation-states. In the 1980s, the Reagan government suspected the Soviet Union of collaborating with international terrorist organizations. Terrorist organizations were acknowledged as actors in world politics. However, rather than as independent actors, they were seen as puppets of the Communist leadership. In the 1990s, however, after the fall of the Berlin Wall, terrorism gradually came to be acknowledged as an autonomous force in international relations. By now, it is considered one of the most pressing dangers, if not the single most important security problem of the West. An important aspect of the terrorist threat to Western societies lies in the terrorist's "seizure" of time. After a brief general introduction into the concept and history of terrorism, this entry discusses the special time-relatedness of terrorist violence, which can be described as an acceleration of warfare.

War on Terror

Since the terrorist attacks on the United States of September 11, 2001, the place that the Soviet

Union and the "Eastern bloc" had left vacant after the dissolution of the Communist empire in the late 1980s has been taken by international terrorism and its state allies. From today's point of view, the period from 1989 to 2001, which had begun with President George H. W. Bush's optimistic vision of a more peaceful "new world order," appears as a mere interim phase between the era of the Cold War and the current era of the "war on terror."

Opinions diverge on how useful it is to equate the current threat of terrorism with that of former security challenges. Whereas the U.S. government drew a parallel between the 9/11 attacks and the strike on Pearl Harbor, most political scientists have been more cautious about citing historical precedents. Nevertheless, by and large they have joined in the official U.S. assessment that the 9/11 attacks mark the beginning of a new era, in which international terrorist organizations, alongside hostile state actors characterized as "rogue states," form the major threat to state security. The UN Security Council has subscribed to this view in its Security Council Resolution 1373, in which the terrorist aggressions of September 11 are classified as an "armed attack"—a term that has hitherto been reserved for belligerent state conduct. As a consequence, in the light of the new events, the natural right to individual and collective self-defense that the UN Charter has codified in Article 51 is widely considered to extend to cases in which a state is the victim of a terrorist attack that is comparable in size and impact to a regular armed attack.

Although there is a relatively broad consensus among state actors and international security organizations on the strategic and political necessity of responding to the threat of terrorism as a new form of political violence, there is much less agreement on the crucial question of how terrorism can be countered. At the core of the difficulty of reaching common ground in the debate on antiterrorism strategies lies the elusiveness of the term *terrorism*. Because "terrorism" is such a contested and highly ideological subject, the term has to be clarified before the specific relationship between terrorism and time can be addressed.

Historical Origins

It is by no means evident where the origins of modern terrorism can be found in the history of the strategic use of violence. Some historians trace terrorism back to the antique practice of tyrannicide. In ancient Greece, natural right allowed or even demanded the overthrow of an illegitimately usurped regnancy. In the city-state of Athens, for example, to commit tyrannicide and thus help reconstitute a legitimate government was a civic duty. The Roman Republic took over from the Greeks the doctrine of a natural right to resistance against despotism. The most famous politically motivated murder committed with reference to this doctrine was the assassination of Julius Caesar by Marcus Brutus and his associates in 44 BCE. Although the right to resistance was abrogated in the Roman Empire, Christianity reestablished the doctrine of resistance with recourse to the fifth book of the Christian New Testament, Acts of the Apostles, and to their claim that the religious duty to obey God's orders trumps the civic duty to obey the worldly sovereign.

The doctrine of resistance is not confined to Western thought. The Assassins, a radical Shiite sect that fought against the Christian crusaders from 1090 to 1272, serve as an early example of violent resistance in the Muslim world. In light of the recent Islamist terrorism, the Assassins have been considered precursors of the contemporary terrorist fight against the "West." Yet, despite a few similarities concerning the apocalyptic dimension of their ideologies and the idea of martyrdom, the Assassins fundamentally diverge from modern terrorists in that their violence was directed only against the invaders and spared civilians.

Although the justification of the use of violence with reference to God's commands is quite common among present-day fundamentalist terrorists, and despite the fact that ethnic or secessionist atrocities are usually exculpated in the name of a natural right to resistance, one must be careful not to take these self-portrayals at face value. Two things have to be considered. First, while violent resistance against a government may be legitimate if the government is tyrannical and if no other nonviolent means are at hand, terrorism is in principle illegitimate as a means of violent resistance. As will be argued in more detail below, the distinction between other forms of political violence and terrorism cannot be drawn by merely considering the aims of violence (its finality). Acts of resistance that have an unjust cause are not necessarily to be classified as terrorist acts—although the government under attack is likely to do so. Rather, the difference between mere violent resistance and terrorism becomes apparent when one looks at the way in which the violence is carried out and the targets at which it is directed (its modality). Mere violent resistance is directed against political and military leaders and may affect civilians only secondarily, whereas terrorist violence has civilians as its primary target. If terrorism is analyzed in light of the doctrine of resistance, the focus is inevitably on the question of the legitimacy of ends. This question, however, is always open to political debate and blurs the difference between justifiable and unjustifiable modes of violence.

The comparison between terrorism and regicide is misleading for a second reason. It obscures the fact that terrorism as a challenge to the modern territorial state emerged only in the 19th century and must therefore be regarded as a distinctively modern phenomenon.

As opposed to classical accounts of political violence, terrorism does not directly challenge an established order by way of the elimination of its representatives. Rather, it tries to undermine the territorial state's promise of securing the life of its citizens through the monopolization of the legitimate use of physical force. Thus, terrorism presupposes the modern conception of the state as a guarantor for the security of its citizens, which is due to Thomas Hobbes's political philosophy.

The rise of international terrorism is a more recent phenomenon still. Its origins lie in the 1960s and 1970s, when left-wing terrorists attempted to build coalitions across Europe, and when German members of the Red Army faction started to collaborate with Palestinian terrorist groups.

The Concept of Terror

The term *terror* is of Latin origin and means "fear." In Roman criminal law, the threat or execution of torture is meant to cause terror in the convicted. Although the current use of the word *terror* for an extreme form of fright and horror has its etymological roots in early history, the political use of the term dates back only to the French Revolution. In 1793, in order to cope with a state of national emergency, the Jacobins, a radical democratic faction, established a dictatorship that they called "régime de la terreur" (reign of terror). Contrary to contemporary usage, this characterization was meant to have positive connotations. For the Jacobins, terror was a necessary means for making possible the "reign of liberty," which was threatened by domestic opponents and foreign enemies (e.g., counterrevolutionary uprisings, the antirevolutionary coalition of European monarchies). In times of crisis, terror was thought to serve the moral task of educating the people and eliminating its enemies. On the Jacobin account, it was an emanation of political virtue.

Although, in the case of the Jacobin reign of terror, violence was directed against civilians by the state and was thus meant to strengthen and not to weaken the state's power, the Jacobin conception of terror as a distinctively political instrument bears more resemblance to modern terrorism than do the previously cited forms of resistance. Despite the crucial difference between state terror and (antistate) terrorism, three features of the Jacobin terror stand out as characteristics of subsequent forms of political terrorism as opposed to other forms of political resistance.

First, the political aim of terrorism cannot be accomplished by means of physical violence alone. In order to be effective, the terrorist attack has to disseminate fright and terror among the population. What is at stake is not primarily the physical annihilation of enemies but the silencing of opposition. Therefore, the permanence of potential terror has to stand out as an implicit threat to the established societal and political order. Second, the use of violence is justified at the moral rather than at the strategic level. Terror is not understood as a necessary evil but as a political principle that serves some higher ideal. Terror derives its legitimacy directly from the highest ends. Third, terror is not satisfied with replacing the "tyrant" as the embodiment of disorder but aims at reshaping the entire political system and society.

Toward a Definition

If terrorism as a distinctively modern form of political violence is to be distinguished from other forms of political resistance, how then can terrorism be defined? So far, no universally accepted definition of terrorism has been found, despite numerous attempts in the General Assembly of the United Nations. As former U.S. president Ronald Reagan put it with an eye to the war in Nicaragua (1980–1990), "One man's terrorist is another man's freedom fighter." Yet, if the focus is shifted from the (supposed) ends of violence toward its means, a definition of terrorism can be approached. As a first step, it is useful to contrast terrorism with closely related phenomena in order to detect what it is not.

First, terrorism is not war. Unfortunately, in the context of the so-called war on terror, the distinction between terrorism and war has been somewhat blurred. Sir Peter Ustinov's comment that "terrorism is the war of the poor, and war is the terrorism of the rich" reflects the contemporary tendency to conflate these different categories. However, three crucial differences have to be taken into account: (1) War is a conflict between states. Any other use of the term *war* (war on crime, war on terror, etc.) is metaphorical. (2) Because war is a conflict among states, it involves the mutual recognition of the warring parties as sovereigns. To be sovereign, on the classical pre–League of Nations account of international law, is to have a right to go to war. In the famous words of the Prussian historian of war, Carl von Clausewitz, "War is the continuation of politics by other means." Thus, conflicting states need not condemn one another as morally evil. The aim of war proper is the submission of the political adversary, not the annihilation of the enemy. Hence, although war in the technical sense is a violent conflict among states, the two ideologically laden world wars must be seen as departures from the classical concept of war. (3) Because the warring parties usually accept each other as equals, war has been a concept of international law since the formation of the modern international system. Far from being a legally unregulated space, war is governed by international law from its formal opening to its ending. The most important regulation of the laws of war (*ius in bello*) is the distinction between combatants and noncombatants (civilians). It is imperative for military conduct in war that civilians never be targets of attacks.

Second, terrorism is not guerrilla war. Guerrilla warfare, which was established as a paramilitary practice in the Spanish resistance to the Napoleonic occupation and which has been a successful strategy in the anticolonial wars, is directed against a state army by nongovernmental private actors. Guerrilla fighters resemble terrorists in that they fight against an enemy that is superior in size and war machinery. Therefore, they resort to the tactics of ambushing regular troops. But contrary to terrorists they more or less respect the difference between combatants and civilians. They may attack politicians and leading figures of the economic system, but only insofar as they are taken to be representatives of the hostile system. Furthermore, guerrilla war can be seen as a subtype of war, because it entails a military strategy. Terrorism by contrast is characterized by the psychological strategy of terrifying the population. Last, guerrilla war is defensive insofar as it can only be fought on domestic territory and requires the logistic and moral support of the domestic population. Mao Zedong reminded guerrilla fighters that they were "fish in the water, and the water is the people." Terrorism, conversely, is offensive. Terrorist acts of violence can be carried out abroad. Support of the population is not a prerequisite of violence, but its projected consequence.

Third, terrorism is not mere crime. Although it employs criminal means, it is to be distinguished from criminality by its political motivation. The aim of terrorist activity is not primarily personal enrichment, but the good of a political unit. Furthermore, emphasis is put not only on the immediate outcome, but on the long-term consequences of the terrorist's deed. More important than its instrumental use is its symbolic value, which is to be found in the demonstration that the state cannot fully guarantee the security of its citizens.

Having distinguished terrorism from war, guerilla war, and crime, an attempt at a positive definition can be made. Terrorism, then, is a form of irregular, organized, and politically motivated use of violence, not directly motivated as resistance to concrete suppression, that is systematically directed toward civilians and whose desired effects are accomplished not through strategic success but through the psychological consequences of terrifying.

Terrorism and Time

In what follows, the relation of terrorism to time will be considered from five different angles. First, it will be inquired what it means for the terrorists' self-understanding as political actors to be situated in the context of modernity and of modernity's specific conception of historical time. Second, the concept of different "generations" of terrorism will be explored. Third, it will be argued that three types of terrorism can be distinguished according to the account of historical time in which they situate themselves. Fourth, some attention will be given to the importance of time management for the terrorist's mode of action. And fifth, it will be pointed out what this sort of terrorist time management means for the state military and for politics.

1. Whereas in former epochs history was conceived of as a cyclical movement, the modern understanding of history is that of a linear progression that either moves toward an end that can be accomplished in history (teleological conception of history) or aimlessly moves toward an ever receding horizon. Whether aimless or not, the conceptualization of history as a linear process renders society a potential object of directed political planning. In the Middle Ages, feudal society was seen as a reflection of the immutable divine ordering. The enlightenment's philosophy of history, however, conceptualized history as the succession of different types of societies. Since then, the ideas that society is man-made and that the task of politics is not to fulfill some prescribed plan but to bring order to the otherwise disorderly or even anarchical human affairs have become constitutive for the modern self-understanding.

This conception of society as a political project is an integral assumption of early terrorist violence as opposed to more classical forms of violent resistance. Whereas in antiquity and in the Middle Ages resistance was justified as bringing about a return to the natural state of affairs that had been overthrown by the tyrant, the Jacobins resorted to terror in order to create a modern republic of virtuous citizens. Jacobin terrorism is not about the replacement of political personnel but about the creation of something entirely new.

The social-revolutionary terrorists who played an important role from the 1960s to the 1980s inherited the future-directed Jacobin conception of historical time. They sought to bring about a social revolution that was deemed the next step in the historical evolution. By contrast, ethnonationalist terrorists who seek the secession or autonomy of an ethnic group often stick to backward-looking perspectives. Independence and liberty are often portrayed as ideals that have to be regained rather than first achieved. A third category of present-day terrorism can be characterized by its outspoken hostility toward the cultural aspects of modernity and its conception of politics. The terrorism of Muslim fanatics draws on the relatively widespread resentment in the Islamic world that is directed against the modern ideals of secularism and emancipation. The fundamentalist's sense of being oppressed by the West is a reaction to the perceived acceleration of history, in the course of which the Islamic world, which had been culturally preponderant for centuries, seems to have been overtaken and finally left behind by the West. The most threatening form of terrorism that Western civilians and governments currently have to face thus has its roots in the perceived desynchronization of history in the era of globalization.

2. Terrorism scholars usually distinguish three "generations" of terrorism. First-generation terrorism in its early forms dates back to the 19th century. It bears some resemblance to other forms of armed resistance, like guerrilla war, in that it confines its actions to a special territorial conflict. Terrorism of this sort aims at the secession or autonomy of an ethnic group that its adherents deem suppressed. The fight of the Zionist Irgun against the British occupants in the then Ottoman province of Palestine from 1943 to 1948, which resulted in the foundation of the state of Israel, falls into this category, as does the Algerian National Liberation Front's (NLF) fight against French colonial rule from 1954 to 1962. Although first-generation terrorism has been succeeded by second- and third-generation terrorisms, it still exists in the present. The Irish Republican Army (IRA) in Great Britain, which has only recently renounced armed resistance, and the enduring fight of the Basque Euskadi Ta Askatasuna (ETA) in Spain are current examples of first-generation terrorism.

Terrorism of the second generation has a wider range of action. Although focused on a local conflict, it agitates on a regional or even global level. By transcending the boundaries of locality, it aims at drawing regional or global attention to a local conflict. Although attempts at the internationalization of conflicts can be traced back to the militant Zionism of the Irgun and to the Algerian terrorism, the "founding" of second-generation terrorism is usually attributed to the Popular Front for the Liberation of Palestine (PFLP), which in 1968 hijacked a plane of the Israeli airline El-Al on its way from Rome to Tel Aviv. Irrespective of their ethnic backgrounds, passengers were turned into victims of the terrorist attack. The hijackers demanded that Palestinian political detainees be liberated and coerced the state of Israel to start bargaining with the formerly ignored political representation of the Palestinian people, the Palestine Liberation Organisation (PLO). Another example is the taking of Israeli athletes as hostages during the Olympic games in Munich in 1972 by the organization Black September (a splinter group of the Fatah, which is another military arm of the PLO). In internationalizing its group of potential victims and its area of operation, terrorism had achieved a new dimension.

In contrast to second-generation terrorism, terrorist groups of the third generation, of which Al-Qaida is the most well known, do not act on behalf of a specific political group. Unlike the two formerly mentioned Palestinian second-generation terrorist organizations Fatah and PFLP that are affiliated with the PLO as the political representation of the Palestinian people, third-generation terrorist organizations do not have a political representation. Like second-generation terrorist groups, they act on the global scene. Unlike second-generation terrorism, however, they do not have fixed logistic bases. Although they do in fact need the support of so called safe havens (states that support or sponsor terrorists) in order to erect and maintain terrorist camps, their organizational structure is less dependent on that of states than is the case for second-generation terrorist groups. This territorial flexibility is due to a network structure that allows the terrorists to decentralize the preparation and execution of attacks. A terrorist network consists of small units, so-called cells that are autonomous to a large degree and thus capable of planning and carrying out terrorist attacks independently from the other associated terrorist cells.

3. The distinctions among the three generations of terrorism highlight the fact that terrorist strategies have changed over time (although first generation terrorism is still a present phenomenon). But beyond that, different types of terrorism can also be distinguished according to their different time horizons and their construal of the relationship between terrorist action and historical time. If terrorist action is undertaken in the name of an ethnic group (as is always the case in first-generation terrorism and more often than not in second-generation terrorism) terrorists have a near- to medium-term time horizon. Although the struggle for succession, independence, and so forth may take a long time, the aims of ethnonationalist terrorism can in principle be achieved in the here and now. A raising of awareness and a shift in the balance of power must be brought about by the terrorists, but there is no need for a new epoch in history in order for the terrorist aims to be accomplished. The ethnonationalist terrorist acts within a given historical context; he does not act upon history itself.

To act upon history is precisely the mission of the social-revolutionary terrorist, who carries out violence on behalf of a seemingly suppressed social class. Referring to the strategy of modern guerrilla war developed by Mao Zedong and the leader of the Cuban Revolution (1956–1959), Che Guevara, social-revolutionary terrorism took shape in Latin America during the 1960s and was then adopted by the violence-prone part of the extreme left in several European countries. The most prominent social-revolutionary terrorist group was the German Red Army Faction (RAF), which was active in the Federal Republic of Germany from 1968 to 1998.

The social-revolutionary terrorist conceives of his agitation as a trigger to a social revolution, which he sees as the dawning of a new epoch in history. Typically against the background of the Marxist philosophy of history, he is convinced of the necessary collapse of the antagonistic bourgeois society. Marx and Engels had placed their emphasis on the analysis of the self-defeating dynamics of the capitalist economic system and neglected the political question of how the transition from capitalism to socialism and communism might be brought about. Disappointed at the failure of the Marxian prophecy that a social revolution will take place in the most advanced bourgeois societies, social-revolutionary terrorism addresses this crucial question, albeit in a way that must be seen as a departure from classical Marxism. First, while Marx and Engels had been skeptical about the influence of violence on the course of history, social-revolutionary terrorism makes terrorist attacks the primary ingredient of its revolutionary strategy. Violence is meant to force the government to a repressive overreaction, which will in turn heighten the class awareness of the suppressed people. Second, in focusing its strategy around violent attacks, social-revolutionary terrorism favors an elitist conception of social revolution. The overthrow of the capitalist regime will not be the result of popular uprisings alone. Rather, as Che Guevara pointed out in his so-called theory of focus, these uprisings must be instigated by the revolutionary elite in the first place.

The principal idea behind this conception of terrorist agitation is that of an acceleration of historical time. If the time is not yet ripe for a social revolution to happen naturally, it may nevertheless be brought about by terrorist activity.

This idea of the acceleration of history is taken up by a third type of terrorism, which speaks on behalf of neither an ethnic group nor a social class, but of a religious sect. Central to most forms of religiously motivated terrorism is an apocalyptic dimension that culminates in the idea that the world is destined to fall. Because the fundamental ills of human existence cannot be healed, the best a religiously motivated terrorist can do is accelerate the decline of the world. The aim of terrorism, then, is not to enter the final staircase of the teleological historical development, as in social-revolutionary terrorism, but to terminate world history as such. The end of time is what has to be accomplished through terrorist activity.

The apocalyptic dimension of the terrorism of religious sects is clearly apparent in the Japanese sect Aum Shinrikyo (1987–1995), which in 1995 released deadly sarin nerve gas into the Tokyo subway system and thus committed the first successful terrorist attack ever with weapons of mass destruction. Initially the group sought to prevent an apocalypse, but after the failure of its political agitation—which the leader of the sect, Shoko Ashara, had professed would save the world—the sect prepared for the inevitable Armageddon. In light of the obscure ideology of Aum, which is based on the predictions of the French astrologer Nostradamus (1503–1566), the nerve gas attacks appeared as the cult's way of hastening the advent of apocalypse.

4. If one abandons the long-term historical perspective and takes a closer look at the practice of terrorism, a threefold time-relatedness of terrorism becomes apparent. First, the tactics of ambush and sudden retreat, which account for the elusiveness of terrorism, accelerate and fracture the combat at the same time. In turn, these tactics of acceleration and fracturing lead to the slowing down of war on the part of the state that engages in antiterrorism. Mao Zedong has characterized guerrilla war by the extension of war in time and space. This characterization holds true for the war on terror, too. Like guerrilla fighters, terrorists cannot be defeated in a decisive battle (*Entscheidungsschlacht*). Similarly, terrorists cannot be defeated all at once if terror cells are organized in a network-like fashion. The very term *war on terror,* therefore, raises the specter of an endless war.

Second, modern terrorists are masters of timely synchronization. The shocking and terrifying effect of the 9/11 attacks is due in part to the terrorists' symbolic take on time. Beyond the sheer number of victims, it was the perfect synchronization of the assaults on the Pentagon and the World Trade Center that made the 9/11 attacks an unprecedented event in the history of terrorism.

Third, the terrorists' tactics of time management extend to the reception of the attack. They take into consideration the worldwide simultaneity of mass-media reporting. Had the attacks of September 11 not been broadcast live throughout the world, they would not have shaken the global public to the same degree. It is a commonly known phrase among terrorism scholars that terrorists do not necessarily want many people dead; they want many people watching. Terrorism, as has been pointed out above, is primarily a strategy of communication and only secondarily a military strategy. As such, its effectiveness is a matter of mass-media reporting that nowadays extends to the farthest corners of the world instantaneously.

5. Terrorists' tactics of accelerating and fracturing combat and their symbolic seizure of power through careful time management and simultaneity pose a serious threat to contemporary states. The French urban planner and philosopher Paul Virilio, who has dedicated his life's work to exploring the connections between speed, military strategy, and politics, points out that every military and political confrontation is fundamentally a struggle for the power of movement. It can be discerned throughout history that the party that turns out to be quicker and more flexible is destined to prevail over

its slower and more static opponent. Yet, whereas in former times the tendency toward acceleration was regulated by inert physical and moral forces (like ramparts or moral bans), which moderated the speeding up of warfare, the Industrial Revolution of the 19th century was followed by a dromocratic (*dromos* = "run") revolution that gave birth to an age of unrestricted acceleration, or so Virilio's argument goes. Since then, according to Virilio, chronopolitics has taken the place of geopolitics. In line of this argument, the struggle for military and political power is primarily a struggle for speed.

Sociologists of time like Hartmut Rosa distinguish two waves of acceleration. The first significant speeding up of nearly all spheres of life took place around 1900. As a consequence of the technical innovations in the aftermath of the Industrial Revolution, such as the development of the telephone and the automobile, daily life accelerated, as likewise did military strategy (introduction of airborne strikes, etc.). A second push of acceleration can be perceived since the 1970s with the path-breaking developments in microelectronics and the digital revolution, which have been accelerating the speed of our communication and transport systems enormously.

Modern terrorists, who are highly dependent upon modern accelerating technologies like the Internet, are themselves part of the acceleration in the military sphere. Against the background of this brief outline of the history of acceleration, one major threat of modern terrorism can be identified in its capacity to speed up strategic and political processes.

The terrorist tactics of acceleration and fracturing challenge not only the military. Worse than that, they put pressure on the democratic political system. As Virilio and Rosa emphasize, democratic politics cannot be accelerated boundlessly. Deliberation as the foundation of democracy necessarily requires time. In order for a general law to be considered just, it has to be the outcome of rational discussion. Therefore it is not surprising that the measures that the U.S. government (and to a lesser degree the European governments as well) has taken in order to prevent further terrorist attacks—the set of regulations that have become known as the Patriot Act—have been criticized for putting the democratic rule of law at risk.

Generally, the executive branch is strengthened and seizes power in times of crisis. The classical necessity clause—the understanding and use of implied powers to solve political crises and emergency situations—has been a constituent feature of the politics of the constitutional state since its beginning. In the state of emergency, the powers have to fulfill their functions; otherwise there is no time left to deal with the pressing dangers. Because the parliamentary process of legislation is by its nature time-consuming, the executive branch is strengthened in times of turmoil.

However, the critics of the current war on terror maintain that the extraordinary measures that were taken after September 11 cannot be justified as emanating from the necessity clause. The degree to which ad hoc measures have taken the place of general laws in post-9/11 antiterrorism legislation indeed seems alarming. Liberal critics argue that by limiting civil rights in order to enhance the information-gathering capacity of the government so that it can react quickly in case of emergency, politics undermines the very basis of the constitutional state. Whichever position one takes, it is striking that the attempt to keep up with the terrorist logic of acceleration brings politics into conflict with the law.

The conflict that arises between law and politics in situations of crisis can be discerned in international law as well. In reaction to the 9/11 attacks, the *National Security Strategy* (NSS) has put forward the doctrine of preemptive strikes (the so-called Bush doctrine). According to this strategy paper, the harboring of terrorists by states should be categorized as an imminent threat that is a sufficient ground for legitimate preemption. According to international law, in order to allow for preemption, a threat must be imminent and overwhelming, leaving room for no other means and no time for deliberation. However, faced with an enemy that does not have to mobilize in order to strike and can thus attack unexpectedly, the NSS argues that a preemptive strike can be legitimate even if the traditional criteria are not met. The latest war against Iraq (2003) has been justified by reference to this doctrine of preemption. The international community, however, has not subscribed to this view. Again, one is confronted with a split between the law and a policy that tries to keep pace with the terrorist logic of acceleration.

It is an open question whether the Bush doctrine of preemptive strikes will prevail. The answer depends in part on the future of terrorism itself. If terrorist organizations manage to acquire weapons of mass destruction, seize hold of global information networks, or simply continue to threaten the civic life in Western societies, it is likely that politicians will be willing to give up existing standards of international law and civic liberties in order to keep pace with the terrorist logic of acceleration. Therefore, inquiries as to how terrorism can be fought within the boundaries of law are of primary importance. One crucial aspect of such theorizing is the analysis of the relationship between terrorism and time.

Thales (c. 624–c. 548 BCE)

Thales is the person often credited with being the world's first philosopher, a claim first made by Aristotle. He belongs to the Presocratic group of philosophers, a grouping of people who had little in common except having lived before Socrates was born. His dates of birth and death are unknown, but the least unreliable estimates place him between 624 and 548 BCE. Little is known about the life of Thales, except that he was a native of the Ionian city of Miletus and that he traveled widely in the eastern Mediterranean. He is customarily associated with, and thought to have been the tutor of, Anaximander and Anaximines. These Milesian philosophers are the earliest of the Presocratics. Nothing written by Thales has survived; his thoughts are known only from later writers who paraphrased them. In addition to his work in philosophy, Thales was credited with significant work in mathematics, astronomy, politics, and economics. A theorem in geometry still bears his name. Whatever the truth about his actual contribution, he was clearly thought to be outstanding. Aristotle's pupil Theophrastus credited Thales with being the first "to reveal the investigations of nature to the Greeks." Thales was regularly counted among the seven sages of classical Greece.

The contribution of Milesian philosophers like Thales was their seeing the need for finding a single source that could serve as a general explanation for the natural world. Their world abounded with supernaturalist explanations and explanations we would now describe as mythological. But these were insufficient for the thinkers of Miletus. Where Homer attributed the origin of all things to the god Oceanus, Thales taught that water was the prime element in all things. Aristotle—our source for this information—speculated on some reasons for this teaching, including the primacy of water on the earth, its core nutritive function, and the moist nature of most things when reduced to their core elements. This is not to say that Thales had no role for the gods at all. Aristotle alluded to Thales's conviction that all things are full of gods, which he gave as an explanation for the ability of a magnet to move iron. Most commentators interpret Thales at this point to mean some variation of a vital principle when he speaks of the gods.

Another important anecdote about Thales comes from Herodotus, who reports him predicting a solar eclipse. It took place during a battle between the Medes and the Lydians, who promptly abandoned the contest and fled in disorder. The eclipse has been traced to May 28, 585 BCE, a date the American physicist Victor Stenger has given as the day science was born. As Stenger argued it, Thales got the date right because his mathematics and his science were right, not because he divined the gods or conferred with oracles. Others have expressed some skepticism that Thales made anything more than an inspired guess.

Other information about Thales comes in the form of anecdotes. Plato tells of Thales tumbling down a well while engrossed in study of the stars, much to the amusement of a Thracian maidservant. And Aristotle tells of Thales buying up all the olive presses in winter, when they were cheap and unused. This occasioned much scorn among the locals and confirmed them in their suspicion that philosophers were an unpractical lot. But his knowledge of the stars and the seasons meant he knew the spring promised a bumper olive crop. When this duly transpired, the people had to come to Thales and hire the equipment from him at whatever rate he asked. This showed, Aristotle wrote, "that philosophers can easily be rich if they like, but that their ambition is of another sort."

Thanatochemistry

Thanatochemistry (from the Greek *θάνατος,* Thanatos, the personification of death in Greek mythology) is broadly defined as the chemistry and chemical aspects of those sciences related to mortuary practice. In particular, modern thanatochemistry encompasses *embalming,* the temporary preservation of human remains that enables them to be presented intact at a funeral ceremony. Thus, the objective is to overcome the effects of decay, a natural consequence of time.

One of the earliest manifestations of embalming was mummification, developed by the ancient Egyptians several thousand years before the common era. The Egyptians were motivated by spiritual or superstitious notions that after death, preservation empowered the soul of the deceased, which would then return to the corpse. The abdomen was opened and all the organs removed. The emptied body was then coated in natron (hydrated sodium carbonate), which facilitated drying. When in contact with moisture, it gives alkaline solutions, which provide a hostile environment to putrefying bacteria. The treated corpse was then wrapped in linen and canvas, and put to rest inside a tomb.

Mummification of a corpse need not necessarily involve any deliberate intervention. Naturally occurring, albeit extreme, environmental conditions have resulted in similar preservation, as evidenced by recent discoveries of naturally mummified remains; for example, the colloquially named Ötzi the Iceman, discovered in a glacier of the Ötztal Alps, 1991, and the Tollund man found buried in a peat bog on the Jutland Peninsula in Denmark in 1950 were both found in remarkable sates of preservation due to anaerobic and very cold and acidic conditions, respectively.

Shortly after the conclusive identification of the chemical formaldehyde by German chemist August Wilhelm von Hofmann in 1867, its preserving properties were discovered, and it is now the basis of contemporary methods of embalming. Aqueous solutions of formaldehyde (with trade names such as Formalin or Formol) kill living cells, both tissue and bacterial, by dehydration of cytoplasmic fluids and coagulation of the constituent proteins by their reaction with the primary amine groups of peptides in the formaldehyde. Aesthetically, color changes produced during this reaction can give the appearance of blood flowing under the skin. The moisture within the cell is replaced with a rigid gel-like material, which allows the embalmed tissue to retain its structural integrity. Moreover, the tissue can resist any subsequent bacterial attack.

Embalming fluids are injected directly into the arteries of the deceased. A concentrate of *arterial chemical* (based on a mixture of formaldehyde, glutaraldehyde, or in some cases phenol) is diluted and mixed with nonpreservative ingredients to give a case-dependent solution of *embalming/arterial fluid,* which is administered. The proportion of arterial chemical is dependent on the required longevity of preservation. Some additional *coinjectants* include water modifiers to maintain optimum alkalinity of the solution; dyes; humectants, which give dead tissue a hydrated and natural appearance; and cell conditioners to prepare for fluid absorption and to remove blood clots.

Despite its success as a preservative, formaldehyde has been shown to be a potent carcinogen. With many other ingredients of embalming fluids also known to be toxic, the search for safer arterial chemicals is ongoing.

THEODICY

The problem of evil arises in most religions in some form or other, although it is most acute (and therefore most discussed) in the Abrahamic religions. It consists of the problem of reconciling the nature of God (or of the gods) with the nature of the world; in particular, a creator's goodness, power, and knowledge are held to be in conflict with the evil that is found in the world. One of the main sorts of approach to the problem is theodicy: the attempt to reconcile the existence and nature of God with the nature of the world. Time plays a part both in the way that the problem is understood and in some of the approaches to it.

The notion of evil varies from tradition to tradition, generally falling into one of a number of categories—two concerning the source and two the nature of evil:

- *Suffering*—physical and psychological pain
- *Metaphysical Evil*—contingency; that is, matters such as death and the shortness of life.
- *Natural Evil*—the result of the way that the world is (the laws of nature, through natural disasters)
- *Moral Evil*—the result of the actions of intentional beings

Time is involved primarily with metaphysical evil, though what is at issue is more what happens within time than the nature of time itself. That is, the process of aging, the shortness of life, and so on. In the Buddhist tradition, for example, Prince Siddhartha gave up his life of luxury (the Great Renunciation) when for the first time in his life he encountered old age, sickness, and death, and found that suffering (*dukkha*), founded in impermanence (*anicca*), is the universal human condition. This notion of evil is highlighted by recent discussions of what is known as "evolutionary theodicy," which focuses on the fact that pain, suffering, and extinction are an essential part of the evolutionary process.

Time also plays a role in the discussion of defenses against the problem of evil, with regard to God's nature. If God is eternal—that is, a nontemporal being, outside time—then God must create the world "all at once"; its beginning, middle, and end exist, all equally known to God, though from within the world the future (and much of the past) is unknown. There seems on this account to be no room for free will, or even for contingency: God, being essentially benevolent, omnipotent, and omniscient, creates the best; therefore this world is the best of all possible worlds (however odd that may seem to the creatures who live in it), and it is logically impossible that things should have been otherwise. That I might have been a politician or a serial killer rather than a philosopher might seem to be a genuine possibility, but in fact God necessarily created this world, in which I am a philosopher. Thus the free-will defense is challenged.

If God exists temporally, and if the world has not always existed, then God created it at a particular time; the world's future development is thus open (especially if genuine contracausal free will exists). This account allows for the freedom of the will, and if we take the future to be unreal, it allows us to say that God created the world without knowing what we would make of our free will. (For if the future does not exist to be known, then it is logically impossible to know it.) This raises, however, problems about the timing of Creation. It also raises the specter of ways the world might have turned out that are much worse than the actuality; although God created the world without knowing what the consequences would actually be, God knew that they might be horrendous, and this can be argued to conflict with divine benevolence.

Theology, Process

Process theology (PT) posits the idea that God has two natures (is bipolar) and that he is an inherent part of the countless processes taking place throughout the universe. God's nature is primordial or transcendent (he is perfect, thus, he never changes), as well as immanent. (He is part of the cosmic process itself and hence cannot be separated from the cosmos.) This process is called *epochal;* that is, it does not occur due to quantum mechanics or any other branch of science, but by creative experience, which continually influences itself in temporal sequence.

The method of PT is more philosophical, rather than biblically or confessionally based, though many feel that it is a better method for understanding, and expressing, Christian traditions. Moreover, the PT method stresses the significance of science in understanding God. Thus, PT is akin to natural theology and is associated with the American, empirical theology tradition whose adherents include Shailer Mathews, D. C. Macintosh, and Henry Nelson Wieman, all of whom felt that using inductive reasoning and the scientific method should be the primary tools for theology. PT shares many ideas with the evolutionary thinking of Henri Bergson, Samuel Alexander, C. Lloyd Morgan, and Pierre Teilhard de Chardin. Without doubt, the most important influence was Alfred North Whitehead, the originator of process theology.

Alfred North Whitehead

Whitehead (1861–1947), renowned for his mathematical/philosophical ability, wanted to find a set of philosophical concepts that was capable of explaining all beings, from God down to the smallest bacterium. Combining philosophical speculation with science, he created a construct he called the "actual occasion" or "actual entity," that is, the basic unit of all reality. Whitehead felt that all things could be explained as being the result of actual occasions, all related with different degrees of depth. An actual occasion is nothing more than a brief occurrence that is created by one's self and is influenced, in part, by other actual occasions.

Whitehead thought that every actual occasion or entity has two natures—one physical and the other mental. In terms of physicality, the actual entity experiences or "prehends" the corporal reality of other actual entities, whereas in terms of mental phenomena, it prehends objects through which actual entities possess intangible definition. These objects are usually defined as theoretical or conceptual possibilities of the universe, and the actual entities disconnect themselves from each other whether or not they recognize these possibilities. The term *prehend* refers to a touching or clutching of the material and/or theoretical data of actual entities. Prehending allows actual entities to be interconnected (not externally, however, as is the scenario in several other philosophical schools). In essence, this means that the entities are not inaccessible or autonomous beings, but are present in other actual entities as interconnected moments of an ongoing process. This quality of prehension or sensation is not a conscious or intellectual act except with higher forms of life but the dipolar formation and the prehensive role are present in some sense in every actual entity, regardless of its intricacies.

Whitehead felt that creativity was another universal concept and that each actual entity possessed a modicum of freedom that was articulated in one's "subjective aim." The self-creative process is a method for attaining one's subjective aims and includes the unification of its historical prehensions, accomplished through the addition of something new—which may be likened to the entity's exceptional gift to the world. Once the entity has realized its subjective aim, it attains "satisfaction" and then shuts down, no longer experiencing anything. It now becomes a focal point for the prehensions of any ensuing actual entities. The actual entity's life is brief, and each individual process that takes place in the world must be viewed as the development of organically related occasions or momentary experiences.

What traditional philosophers would call an everlasting substance, Whitehead called a succession or "route" of actual occasions with a common trait. Change is explained by the creative input of each occasion in the series, while endurance is clarified by common, everyday qualities that are inherited from antecedent occasions. How all things maintain stability is explained in this way, whether they are electrons, stars, plants, mammals, or human beings. Man is the center of all incidents involving remembrance, imagination, and discriminating intangible emotions. On the other hand, it is God who is the ultimate, actual entity; hence, he projects (in a perfect manner) each function of the supreme actual entity. Whitehead felt that metaphysical logic cannot be attained if one sees God as an exception to the rules; rather, God is the primary example from which all metaphysical principles are to be explained. This allows God to prehend absolutely by each entity found throughout the cosmos; likewise, he is prehended by everyone else, though only in a partial fashion. As the creator, he has power over everything and places boundaries regarding the use of imagination. He influences goals by making sure each individual has a perfect "initial aim." Whitehead felt that God did this with a "primordial nature," meaning that the Creator envisioned each unending thing and its relative worth in the "real" or "concrete" world.

Whitehead thought that without eternal objects, humanity would have no concrete possibilities, nor would there exist any values to be actualized, and yet only something that is "real" influences actual entities. This shows that God knows and comprehends each never-ending object; likewise, he has the wherewithal to function as the basic fount for universal order and values. For Whitehead, if there were no Creator, the cosmic process would be chaotic, not creative. God, in his infinite wisdom, enables the cosmos to become concrete by allowing specific principles to exist within certain divine parameters.

God, as bipolar, has a physical side, also called a "consequent nature," which may be defined as God experiencing the completed actuality for each individual circumstance. He brings the finished entities into heaven in order to exist with him as receivers of his perfect prehension—giving them "objective immortality" as a consequence of their achievements. (It should be noted that Whitehead stated that no actual entity has subjective immortality except God; humans live subjectively, due only to an ongoing chain of actual occasions.) In addition, the Creator gives the universe its information regarding any entities God prehended, so humanity will be knowledgeable and richer for its past.

God, through the process of prehension, is in continual contact with each subatomic particle found within our universe, within every nanosecond constituting the life of that being. This allows God to be immanent in the world process itself, while leading it on toward greater value and aesthetic intensity—however, it is not coercion, but gentle and loving persuasion that allows him to accomplish this. Although he transcends the world, God, as the actual entity, keeps the world consequently within himself, while suffering and growing along with it through the creativity that he and the world possess.

Charles Hartshorne

Although process theology, under Whitehead, had reached maturity in 1929 (when he published *Process and Reality*), few theologians cited him before the 1950s. During this period, theologians were preoccupied with neo-orthodoxy, a movement that rejected natural theology and compartmentalized theology and science. One notable exception was Charles Hartshorne, who developed Whitehead's thought and became its chief proponent during the 1960s and 1970s. Like Whitehead, Hartshorne looked at metaphysics as the study of general principles by which all particulars of experience are to be explained. Hartshorne was more rationalistic because, for him, metaphysics dealt with what was outwardly required, or with "a priori statements about existence," or true statements regarding any state of affairs regardless of the circumstances. He took up Whitehead's metaphysical system, defending it as the most lucid and feasible argument concerning philosophy. He agreed with Whitehead on the predominance of "becoming" (which is comprehensive of being, unlike that found in classical philosophy), as well as *panpsychism,* the grouping of sensation as a common feature of every entity.

Hartshorne agreed with the law of polarity, but his view regarding the dipolarity of God was slightly different from Whitehead's. He rejected Whitehead's beliefs about eternal objects and felt God's consequent nature was better termed "concrete nature," which translates into God living within an authentic existence, regardless of the condition, with all the wealth of accumulated values of the world up to that present state. God's intangible personality is composed of certain traits and characteristics that are everlastingly and essentially true of God, at all times. On the other hand, the traits regarding God's concrete nature are those specifics that he has gained by interacting with the cosmos in accordance with the circumstances. God in his tangible actuality is a "living person," in process; his existence is composed of an eternal retinue of holy occurrences or happenstances. This is different from Whitehead, who envisioned God as being a distinct, never-ending, actual entity.

The contradictions found in God's personality means he is absolutely essential (according to his intangible nature), but conditional according to his concrete nature. This does not mean, however, that he is independent in his intangible nature but dependent in his concrete nature; on the contrary, God is independent because nothing in the cosmos possesses the power to intimidate him, nor could anything induce him to act in a manner diametrically opposed to his loving-kindness. God is affected, however, by human responses to his will. Hartshorne did not think God should be seen wholly in terms of his goodness, nor in contrast to weakness of his creation.

Hartshorne thought that the single greatest mistake in classical theism was to think otherwise. For instance, denial of God's indispensable comprehension of the dependent world, or God's ageless act of constructing a world that is sequential, or the Creator's great and abiding love for humanity, which supposedly involves God in history—none make him relative to or dependent upon anyone or anything. Hartshorne contended that if chronological development and creativeness ultimately exist, then God, in some unknown manner, must have also been progressing. Likewise, he is reliant upon humanity's free will.

This set Hartshorne as an opponent to classical theology, and thus, he developed what has been called a neoclassical theism, which states that God can never be surpassed in either perfection or social relatedness. If God is perfect love, then he possesses a complete sympathetic comprehension of every creature and responds appropriately and lovingly in every situation in every event. In plain language, while the Creator is supremely boundless in his conceptual character, he is relative in his tangible nature. No one and/or no thing could exceed him in his supremacy regarding connectedness with every living being. On the other hand, the Creator can improve himself. He can and does progress, not becoming more moral or perfect, but growing in the joyousness and feeling of the world, in knowledge of actual events, and in the experience of the values created by the world. It should be noted that Hartshorne did not think God had the foreknowledge of future events; hence, while God's knowledge is complete regarding that which can be known, he nonetheless continues to grow with the process of the world.

God possesses a unique, transcendent personality, which means he is immeasurably more than the earth in its entirety (contra pantheism). Contraclassical theism states that God takes the universe solely within his being, in both his perfect comprehension and his love. This could be viewed as nothing more than his own, unique prehension, or God's understanding of the myriad innovative events taking place continually throughout the cosmos. This is a pantheistic image of God, making Hartshorne the chief protagonist for this argument in the 20th century. In Hartshorne's opinion, St. Anselm realized several, essential components regarding theistic beliefs, primarily "perfection" and its exclusivity among other notions. Anselm's argument lacked cogency, because it relied on a classical theistic view of perfection. The neoclassical view of perfection, Hartshorne felt, overcame the many objections modern philosophers had about the term—primarily that perfection cannot be consistently defined. In Hartshorne's opinion, perfection either exists or is required not to. This, in turn, leads to the conclusion that only the self-contradictory does not exist and that the Creator—if he is self-consistent—is in reality necessarily existent.

Teilhard de Chardin and After

Neo-orthodoxy waned after 1960, leading many theologians to study Whitehead and Hartshorne as philosophical sources for a modern-day expression of Christian faith. Beginning with the doctrine of God, theologians John Cobb, Schubert Ogden, Daniel D. Williams, and Norman Pittenger wanted to show that the process view of God is actually more in harmony with the biblical view of God (as dynamically related to human history) than is the time-honored Christian view of traditional theology. They felt that the monopolar conception of God as changeless, incontrovertible, impassible, and in every sense independent was a belief originating with the Greeks, not the Bible. Williams studied the Christian notion of love, arguing that Whitehead's philosophy aids theologians in clarifying God's boundless love in a manner completely divorced from the orthodox opinions of God.

Other writers of Christian theology using a process perspective are Bernard Meland, Ian Barbour, Peter Hamilton, Eugene Peters, Delwin Brown, William Beardslee, Walter Stokes, Ewert Cousins, Eulalio Baltazar, and Bernard Lee. Though process theology is encountered mainly within Protestantism, Roman Catholic thinkers now feel its influence as well (the last four theologians listed above are Catholic). Roman Catholic theologians are slowly accepting Whitehead. In addition, they ponder the writings of Teilhard de Chardin, whose ideas are traditionally split from Catholicism but share a philosophical kinship with the Whiteheadian tradition.

Pierre Teilhard de Chardin, the famous French priest-philosopher, viewed the universe as evolving toward a perfect state of being, or the end goal for humanity. His philosophy melded a scientific grasp of the reality of evolution as a force of nature within the universe (cosmogenesis) with metaphysics. In essence, Teilhard's beliefs regarding evolution centered on the idea that the earth is slowly becoming a collective brain due to a layer of human consciousness surrounding the globe. At some point in humanity's future, this stratum of consciousness will separate from the planet and will join with God and thus will become one with him. Teilhard called this the Omega point, as this uniting was, in his conception, our final goal as a species. His interpretations concerning humanity's future allowed process theology to be viewed as panentheistic; that is, while God is immanent, he is also transcendent.

THUCYDIDES (C. 460–C. 399 BCE)

Thucydides was one of the great chroniclers of ancient history. Renowned for recording the history of the Peloponnesian War, Thucydides not only provided future generations knowledge of a war for which few other data exist, he also developed an influential methodology for observing and documenting historical events. Ironically, few records of Thucydides' life survive from which we might better know and understand the man himself.

Thucydides' great work was to chronicle the Peloponnesian War, the decades-long conflict between Athens and Sparta (and their respective allies), which began in 431 BCE. Like few previous historians, Thucydides went beyond compiling a cursory accounting of major events in his day. Throughout the conflicts of the time, Thucydides documented naval engagements, cavalry maneuvering, troop type and strength, and speeches of individuals commanding the war's course. Likewise, Thucydides documented the spread of plague throughout Athens and its devastating effect on both populations and society. All the while, Thucydides employed methods of data collection that included the verification of stories he heard secondhand, the investigation of contemporary texts, and the inscribing of speeches he witnessed. Additionally, Thucydides sought to view the onset of war from multiple perspectives, seeking an understanding of the causes of a conflict and people's reaction to it.

Although Thucydides, an Athenian, provided future generations with documentation of the Peloponnesian War, his own life remains a mystery. Thucydides is believed to have lived from approximately 460 to 399 BCE, dates based primarily on positions he held in the military rather than on actual documentation of his birth and death. At one time an Athenian general tasked with saving the colony of Amphipolis, Thucydides was exiled from Athens after failing to arrive in time to prevent the colony's capture. A final distinctive note regarding Thucydides' life is that he experienced firsthand the plague as it swept through Athens toward the beginning of the war, killing a significant number of Athenians in the process. Of the rest of his life, including the circumstances of his birth, his rise to the rank of general, and details of his exile, little more is known.

TIDES

Tides are the cyclic rising and falling of the earth's seas and oceans caused by the concerted gravitational pull of the sun, moon, and earth itself. On a geologic timescale, there has never been a more profound factor in the shaping of the world's coastlines than the everlasting ebb and flow of the tides. Even powerful tsunamis and hurricanes are no match for this primordial rhythmic cycle.

Classic tides tend to be semidiurnal, with two high and two low tides occurring each day. As the earth spins in its orbit, it creates a centrifugal force that is equal to the gravitational attraction of the moon, keeping the moon in place. As the moon rises in the night sky, the water will bulge toward its strong gravitational pull, forming a high tide. On the other side of the earth, the centrifugal motion of the earth is much stronger than the gravitational pull of the moon, creating another bulge away from the moon and another high tide. The low tides occur between these two periods, when the centrifugal force and the gravitational pull of the moon cancel each other. Areas at the poles often experience seasonal diurnal tides, with only one high tide and one low tide a day. This is due to a divergence of the two daily times when the moon shifts with the season to its maximum declination of 28º. Most areas experience a combination of semidiurnal and diurnal tides, which is referred to as mixed tides.

The sun also has a significant effect on the overall cyclical nature of these tides. During new and full moons, when the sun is in line with the moon, the combined gravitational pull of the sun and moon create higher than usual tide, known as a spring tide. Conversely, when the sun and moon are at right angles during the first and last quarter, their combined gravitational pulls offset each other, creating very low neap tides. Seasons also play a large role in tidal cycles. In the spring, the moon is closest to the earth, and its gravitational pull is even more profound on the tides, creating a perigean tide.

One common misuse of the word *tide* is in the term *tidal wave*. Tidal waves in a vernacular sense have no correlation with the gravitational pull of the moon and sun but rather are created by underwater earthquakes from the shifting of tectonic plates. These shifts cause shock waves of energy, creating enormous waves known as *tsunami* that race outward toward land. True tidal waves are actually called *bore waves;* in these, the tide produces a wave that travels upstream in a river that runs into the ocean.

The study of the tides has fascinated people since ancient times. Until science was able to explain the daily rise and fall of the tides, many cultures developed stories and myths to explain this daily phenomenon. The ancient Japanese believed that a giant fish lived in the ocean and would drink the water, only to spit it right back out later, causing the rise and fall of the tides. Many ancient cultures noticed the correlation between the moon and the tides. For example, Polynesians believed that the sea god Tangaroa married the moon goddess Hina, and that the two controlled the tides together. The ancient Scandinavians believed that the moon god Mani captured two children, Hjuki and Bil, who were filling a bucket of water from a well. He sent them to the moon, bringing the bucket with them, and it was believed that the emptying and filling of this bucket controlled the tides.

The study of the tides has many practical applications in daily life, including contributions to understanding of coastal states, barrier migration, sea-level changes, and morphological change in geology. Scientists use an instantaneous timescale to determine a real-time picture of the current state of coastal regions. This can be used to study sediment flow, bedform laminae, and intertidal ecology. Many boat captains use an instantaneous timescale to avoid running their ships aground on shallow rocks and reefs.

The event timescale is used to study the cyclic sequences of the tides, as well as extreme disturbances including earthquakes and hurricanes. This is often determined by averaging data from an instantaneous timescale. The event timescale can help to demonstrate how future events can impact morphological changes in the coastline, from the deposition of sediments over long time periods to the formation of completely new islands. The cumulative effect of the long-term mechanical force of the tides is often the driving force behind these overall morphological changes. However, extreme events like volcanic eruptions and major storms can drastically reshape the coastline in a very short time span. For example, a nor'easter off the mid-Atlantic coast of the United States that lasted from March 5th to March 8th, 1962—the notorious Ash Wednesday Storm—caused waves over 30 feet high to crash down on over 1,000 miles of coastline. The storm struck when the tide was at its seasonal highest, a spring perigean. This single event destroyed the landmark Steel Pier in Atlantic City, New Jersey, as well as the Ocean City Boardwalk in Maryland, causing over $500 million in damages along the eastern coastline as well as dramatic geological changes, including the destruction of many reefs and beaches.

A historical timescale is used to sum up several events, often spanning many generations. This is to give engineers an idea of the trends of the tides along a coastline that is to be manipulated for human use. For example, trends in sea level have been recorded since as early as 1682 with tidal-gauge records. These gauges can be analyzed to determine not only proper coastal use but also general environmental trends worldwide. However, because the historical timescale spans many generations, past generalizations of events are causing problems in creating an accurate picture on a historical timescale. Many engineers are turning to computer simulations of large-scale coastal behavior systems to get a more exact idea of coastal erosion and geomorphological changes on this scale.

The geological timescale covers a significantly longer time than the historical timescale, and it is used mostly to reconstruct the past through geological and paleoenvironmental evidence. This is much more difficult to determine, as much of geological history is limited to hypotheses and inferences due to limitations in science. Advances in dating techniques have made more accurate depictions of the past possible. Nevertheless, the consistent mechanical forces of the tides have swept much of the geological history of the coastline out to sea.

Tillich, Paul (1886–1965)

Educated in German universities and having earned a Ph.D. from Breslau University (1911) and a licentiate in theology from Halle University (1912), Paul Tillich was ordained in the Evangelical Lutheran Church (1912) and served as a chaplain during World War I. Tillich taught theology at the University of Berlin (1919–1924), and this was followed by other teaching positions at the universities of Marburg, Dresden, Leipzig, and Frankfurt am Main (1929–1933). After he criticized the Nazi regime, the government barred him from teaching at any German university. Tillich's experiences during World War I and under the Nazi regime gave impetus to his awareness of the tragic nature of historical time. He emigrated to the United States at the invitation of the distinguished theologian Reinhold Niebuhr, and he taught on the faculty of Union Theological Seminary with Niebuhr until 1955, when Tillich moved to a position at Harvard University (1955–1962) before finishing his career at the University of Chicago (1962–1965).

Tillich's theology is governed by his method of correlation, which enables him to have an answering theology in which philosophy raises certain existential questions, and theology tries to provide the answers in the context of time. This method, which is also dialectic in the sense that every positive implies a negative, suggests that philosophical questions and theological answers are in mutual interdependence. In short, Tillich uses his method to analyze the human situation and its temporal nature; this analysis gives rise to certain questions, and the Christian message provides the answers to such questions. In response to the philosophical analysis of being and human finitude, the theological answer is, for instance, God, whereas the questions of existence and life are answered respectively by Christ and Spirit, demonstrating the central nature of the doctrine of the Trinity in Tillich's theology.

Tillich develops his thinking about time within the context of his philosophical ontology and especially the ontological categories that include time, space, causality, and substance. These ontological categories constitute the structure of experience itself and are thus present whenever something is experienced. Not only does the mind comprehend and form reality by philosophical categories, rational thinking is inexpressible without using some category. A category, such as time, is a way that finite beings participate in a mixture of being and nonbeing. Time possesses both positive and negative aspects, as do the other categories. Time is, for instance, creative, direct, and irreversible, and it symbolizes movement and life. From a negative perspective, time represents a moment from a past that is no more and a future that is not yet, whereas the present is a moving boundary line between past and future.

Becoming aware that time is moving one toward death, a person becomes anxious about the transitory nature of human existence. In response to such a threat, a person affirms the present and the threat of nonbeing through an innate, ontological courage that is based in God. Therefore, time is central to human finitude, and the anxiety associated with death reveals the ontological character of time. Moreover, human courage affirms temporality, whereas one would surrender to the annihilating character of time without courage.

Time moves ahead toward something new, unique, and novel, and the creative nature of time is evident with historical time, which appears as time running toward fulfillment, because it is united with the dimension of spirit. The fulfillment of historical time (*kairos*) is for Tillich the event of God's action in Jesus as the Christ, which is repetitively experienced. The fulfillment and aim of the end of history is answered, according to Tillich, by eternal life in the kingdom of God, which is the final meaning of history, because individuals are fulfilled in all areas of their lives.

Time, Absolute

The concept of absolute time is a hypothetical model from the laws of classical physics postulated by Isaac Newton in the *Principia* in 1687. Although the Newtonian model of absolute time has since been opposed and rejected in light of more recent scholarship, it still provides a way to study science with reference to time and understand the phenomena of time within the scientific tradition.

According to this model, it is assumed that time runs at the same rate for all the observers in the universe, or in other words, the rate of time of each observer can be scaled to the absolute time by multiplying the rate by a constant. This concept of absolute time suggests absolute simultaneity by the coincidence of two or more events at different points in space for all observers in the universe. So, absolute time has been discussed in two senses of absoluteness. In first sense, absoluteness means independent of events, while in second sense, it means independent of observer or frame of reference.

Newton's theory was a dominant paradigm throughout the 18th and 19th centuries. Newton regarded time as something absolute, true, and mathematical, of itself and by its own nature, that flows uniformly without relation to anything external, and by another name it is called duration. He explained that the motion of a particle has to be described relative to an inertial frame in which the particle will move at a constant velocity in a straight line unless some external force is applied to it; time among different frames differs by a constant, and all times can be described relative to an absolute time.

This theory encountered strong opposition from many philosophers and some religious thinkers who considered time an illusion. Leibniz, a contemporary of Newton, criticized that Newton's concepts of time and space are identical by their definitions and also opposed him using religious reasoning: that if there were no way to distinguish one time from another, God was faced with an impossible choice to decide rationally on the moment of creation. Many critics do not accept this logic and considered it nonscientific; they would see time created at the instant of Creation.

The concept of absolute time became outdated in early 20th-century scientific dialogue, when electrical and magnetic phenomena were studied theoretically, and Albert Einstein challenged the existence of time and space as separate absolute concepts by introducing a model of spacetime in his special relativity theory. According to this theory, there may always be observers for whom simultaneity is always relative, while there is no such thing as absolute simultaneity and hence no existence of absolute time.

Time, Arrow of

Nothing in common experience would seem to be more assured than the one-way flow of time from past to future. Many everyday events seem to be irreversible. Air rushes out of a punctured tire, never back into the tire to reinflate it. Heat flows from higher-temperature bodies to those of lower temperature, never from lower to higher, cooling a room for free. Heat engines use up energy, never producing useful energy for free. People age and die, never rising from the dead and growing younger.

The empirical fact that many physical events occur in only one time direction is codified in physics as the *second law of thermodynamics,* which requires that the *entropy* of a system, a measure of disorder, must always increase or, at best, remain constant when that system is isolated from the rest its environment.

However, the second law does not represent an infallible universal principle. Consider a closed room full of people. The air in the room is composed of individual molecules that move around pretty much randomly. Suppose someone opens a window at just that instant when all the air molecules just happen, by chance, to be moving in the direction of the window. The air then rushes out of the room and everyone inside explodes and dies.

No known principle of the mechanics of particle motion forbids this tragic event from happening. Although possible, it is very unlikely. The probability that all the molecules are moving in the direction of the window when it is opened is minuscule, and therefore not likely to occur even once on earth during the planet's entire existence.

If we were watching a film showing all the air in a room escaping through a window, leaving behind a vacuum, we could reasonably surmise that the film is being run backward through the projector. But suppose we have a room with just three molecules, as illustrated in Figure 1. The chance that the molecules randomly fly out the window is not at all small. Watching a film showing this event, we cannot judge for sure that the film is playing in reverse.

So, in one case we can determine the direction of time. In the second case we have no basis for even assuming that there is a direction of time. Irreversibility seems to hold true when there are many particles, while it is absent when there are only a few.

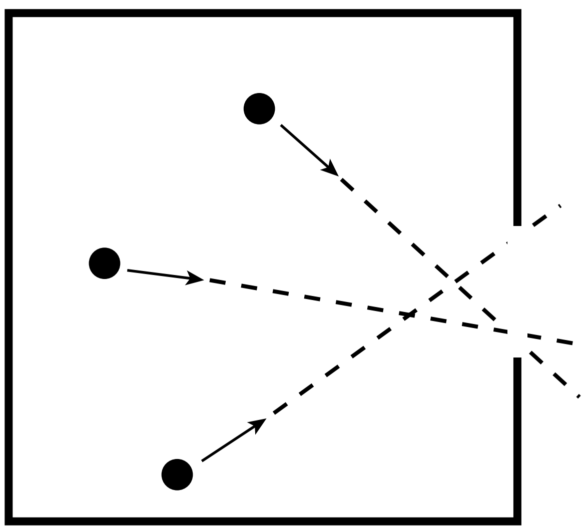

Figure 1 A chamber with three molecules

Notes: The probability of all three molecules escaping through an opening, leaving behind a vacuum, is not small. No direction of time can be defined with this observation.

Clearly, it cannot be a fundamental law of physics that processes involving *N* particles or fewer are reversible, while those with greater than *N* particles are irreversible. What is *N?* 100? 10,000? 3,486,756,493? For irreversibility to be fundamental, it would have to apply for any value of *N*. As far as we can tell, it does not.

The second law of thermodynamics is simply a convention that, as Ludwig Boltzmann showed in the late 19th century, defines the commonsense direction or *arrow of time*. It amounts to little more than a definition of the arrow of time as the direction of increasing entropy of the universe. Open systems, that is, systems that exchange energy with other systems or their environment, can gain or lose entropy. Organization is viewed as a lowering of the entropy of a system. It requires outside energy to do the ordering and a corresponding increase in entropy of the outside system that is providing that energy. So, as the sun provides energy for ordering processes on earth, the entropy of the universe as a whole gains the entropy that earth and the sun lose.

The arrow of time is thus a statistical asymmetry that is not built into the fundamental nature of the universe. The air in a room is not forbidden from emptying out when a window is opened, killing everyone inside. A broken glass can reassemble and a dead man can spring to life, if randomly moving molecules just happen to be moving in the right direction. However, these events are extremely unlikely, because our macroworld is composed of huge numbers of particles that move around more or less randomly.

Other Arrows of Time

The fundamental principles of physics do not distinguish between forward and backward time. Some rare processes exhibit a small (0.1%) asymmetry in the probabilities for both time directions, but these do not forbid events from happening in either time direction.

The expansion of the universe would seem to single out a particular time direction, thus defining what is called the *cosmological arrow of time*. But that direction is just the direction of increasing entropy of the universe, and so is identical to the thermodynamic arrow. Cosmological models can account for the low entropy at the beginning of the big bang, and an overall time symmetry is possible if one considers the time before the big bang as containing a mirror universe expanding in the time direction opposite to ours. While we cannot observe this universe, nothing in the known principles of physics or cosmology rules it out and, indeed, they seem to suggest the possibility.

A time asymmetry appears to occur with electromagnetic radiation, where sources are usually seen to emit radiation and not absorb it. This suggests a *radiation arrow of time*. However, the basic equations of electromagnetism, Maxwell's equations, are time symmetric and allow for radiation in both time directions. The observed directionality is the result of the boundary conditions that are set up in most problems, where the source and detector are specified by the way the experiment is conducted.

Finally, the measurement process involving so-called wave-function collapse in quantum mechanics has been suggested as a fundamental source of an arrow of time. However, it has been proven that quantum mechanics is perfectly time-symmetrical. Furthermore, quantum experiments seem to exhibit a backward causality that suggests that time is reversible at the quantum level. Many of the so-called paradoxes of quantum mechanics, such as particles appearing simultaneously at different points in space (*nonlocality*) can be understood with time reversibility without the need to invoke superluminal motion.

Time, Asymmetry of

The directionality of time is a common, everyday experience. However, that direction, called the *arrow of time,* is simply a convention. Nothing in the principles of physics prevents processes from occurring in either time direction. In the human macroworld, however, many events have a much higher probability for occurring in one time direction than the reverse. That is, for all practical purposes, they are irreversible.

Air never flows back into a punctured tire to reinflate it. Heat never flows from lower temperature to higher temperature. People never grow younger. These events are never observed—yet they are not in principle impossible. The bodies of our normal experience are composed of a vast number of particles that move around randomly. The probability that particles of outside air just happen to move in the direction of a hole in a flat tire to inflate it is not zero; it's just so low that we are not likely to ever see it happen. A dead person could even come back to life spontaneously, but don't count on it.

An apparent asymmetry in time exists, but it is a statistical effect that is not present in the processes involving few particles, such as the processes observed in chemical, nuclear, and elementary particle reactions. These reactions all occur in either time direction. For example, hydrogen and oxygen can combine to form water, with some heat given off:

$$H_2 + O \rightarrow H_2O + \text{heat}$$

The reverse process also occurs when heat added to water produces hydrogen and oxygen:

$$H_2O + \text{heat} \rightarrow H_2 + O$$

While the rate for a reverse process will not always equal that of the original process because of various statistical factors, the basic probabilities are exactly equal. At least that is the case for all chemical and nuclear reactions and for most elementary particle reactions.

The operation that reverses the time direction of a process is referred to as *T* for *time reversal.* Two additional related operations are also defined. In one, designated *C* for *charge conjugation,* the particles in a reaction are all changed to their antiparticles. In the other, designated *P* for *parity,* the *handedness* of the process is changed—as if the process is viewed in a mirror. From very basic axioms in physics, it can be proved that all physical processes are *invariant* (unchanged) under the combined operation *CPT.* This is called the *CPT theorem.*

Indeed, all chemical and most nuclear and elementary particle reactions are invariant under the operations *C, P,* and *T* when each is performed separately. However, in 1956, C. S. Wu and her collaborators showed that parity invariance was violated in the beta-decay of radioactive cobalt-60. In general, the *weak force,* one of the four basic forces in the universe, violates parity invariance.

In 1964, Val Fitch and James Cronin discovered that the decays of neutral K-mesons were not invariant to the combined operation *CP.* Assuming that the *CPT* theorem is correct, this provided indirect evidence that time reversal invariance is also violated in these reactions.

Since then, direct evidence for *T*-violation has been found in the decays of neutral K-mesons. *CP*-violation has also been confirmed in the decay of B-mesons.

It is important to understand that the empirical fact of time asymmetry does not imply time irreversibility. The reactions violating *T*-invariance still happen in both time directions. However their basic probabilities are not exactly equal, differing by small amounts, typically 0.1%. Hence, it appears unlikely that this time asymmetry is the fundamental source of an arrow of time in the universe. Time reversal with equal probabilities can be maintained for all fundamental processes by making sure to also operate with *C* and *P,* that is, change all the particles in a reaction to their antiparticles and view the process in a mirror.

Invariance principles provide the foundation of much of physics, reflecting as they do fundamental symmetries of the universe. For example, applying a theorem proved by Emmy Noether in the early 20th century, it can be shown that any physical models that are invariant under translation and rotation of the spacetime coordinate system will contain as fundamental "laws of nature" conservation of energy, linear momentum, and angular momentum as well as Einstein's *special theory of relativity.* Einstein's *general theory of relativity* follows from similar considerations. Generalizing Noether's theorem to more abstract spaces, one finds that almost all of the rest of physics follows from a generalized principle called *gauge symmetry.*

The violation of any of these invariance principles shows that the corresponding symmetry is broken. Without broken symmetries, much of the complexity that is found in nature would not exist. For example, *CP* violation is believed to have played a role in the early universe to produce the large difference between matter and antimatter that now exists. Currently particles outnumber antiparticles by a billion to one. Cosmological models suggest that the universe was born in a state of complete chaos and thus in complete symmetry (*see also* Universe, Origin of). When the first particles appeared, there were equal numbers of particles and antiparticles. If this had remained the case, the universe today would be pure radiation, as all the protons would have been annihilated with antiprotons and electrons annihilated with positrons (antielectrons), with none left over to make atoms.

Original symmetries such as *CP* were spontaneously broken, making possible the complexity of stars, planets, and life. Complexity thus arises naturally out of simplicity, somewhat analogous to the way the spherical symmetry of a region of water vapor is broken as it freezes into a snowflake.

Time, Cosmic

Cosmic time is a measure of time on a scale of billions of years, during which the universe is cooling and expanding from its initial hot, dense state, and stars and galaxies are evolving. The universe had its beginning about 14 billion years ago in the big bang. By contrast, the earliest signs of life on earth only date back to about 3.7 billion years ago, and cosmic time is vast in comparison with the scale of a human lifetime. An even shorter timescale marks the life of quantum particles, the smallest forms of matter and energy that wink in and out of existence so quickly that some cannot be detected directly.

Time itself did not exist until the birth of the universe in the big bang. Albert Einstein showed that it is the fourth dimension of spacetime (the other three being the conventional dimensions of space) and that any directional movement is also a movement through time. Throughout cosmic time, stars and galaxies evolve. This is evident in the birth, growth, and death of stars and in the formation and changes in galaxies. Change is a key factor in the slow-moving cycle of cosmic time, and a more narrow definition states that a single unit of cosmic time is the span of time through which the universe has changed fundamentally.

The fundamental change involves the shifting balance between matter and another, as yet poorly understood, form of energy. Recent observations indicate a change in the Hubble constant, a measure of the rate of expansion of the universe since just after the big bang. This evidence that the rate of expansion is accelerating was an unexpected finding, because calculations indicated that the amount of normal matter and energy present in the universe would lead to a gradual slowing down of expansion. However, scientists have discovered a previously unrecognized form of repulsive substance, a dark energy, that acts like negative gravity, pushing matter apart, and this may account for the acceleration. With the passage of time, matter will become more dilute, carried along, like raisins in a loaf of rising bread. Dark energy appears in minute amounts within this expanding space and, acting as a repulsive factor, will eventually overtake matter as the dominant factor in the universe. The fundamental change wherein dark energy overtakes matter is calculated to be about 10 billion years—a single unit of cosmic time.

Time, Cyclical

Fundamental to human existence has been an attempt to understand, interpret, and influence the world in which we live. Various peoples have developed their own unique approaches to these issues in the form of systems of beliefs, values, and behaviors. It is within the context of these systems, collectively referred to as *culture,* that the interpretations of time have taken shape, which are thus rooted in raw human experiences and responses to life and to the natural world. On a daily level, the lives of most individuals seem to possess a one-directional aspect in that they consistently and ceaselessly move forward, from moment to moment and event to event, each day bringing new experiences, growth, and decay. Life does not appear to stop or move backward. A linear concept of time, then, reflects the common perception and experience of most people today and has been integral to various peoples' understanding throughout history. Logically speaking, whatever has a beginning will have an end: a line, a life, a universe, a history, and so forth. Because linear time typically posits a beginning, it implies that there will be an end as well.

In many traditional cultures and belief systems, the linear aspect of time is important, for it explains distinctions, growth, and change. At the same time, however, it is seen as simply a part of a greater dimension, a circular or cyclical one, that is far more encompassing and that can be seen in the daily rotation of the earth, the lunar cycle, the seasons of the year, the migrations of animals, and so forth. From early childhood and continuing throughout life, humans witness and live with the cycles of time both in nature and in human existence. In order to survive, early humans had to adapt themselves to these cycles and came to see themselves as a part of this natural process. The greatest amount of adaptation can be seen with the more rural peoples, for whom working with and depending on nature and its cycles are integral to daily life. As a consequence, the cyclical view of time has been a predominant view throughout history, especially in traditional cultures and belief systems. Cyclical time, or circular time, does not require either a beginning or an end. Thus, those who think of time cyclically need not conceptualize an ending of time, of humanity, or of existence. Instead, they tend to envision a reality that simply has always been and will always continue. This does not mean that creations do not occur, but that, generally speaking, they are also a part of a cycle, just as are all aspects of reality.

Ancient Cultures and Concepts

Although we cannot know for certain the various preliterate understandings of time and the human relationship to it, we have long had to pattern our lives in accordance with the cycles of the natural world. Hunters developed their methods and practices in conjunction with prevalent animals and migration cycles. Agriculturalists and food gatherers learned to function in conformity with seasons and weather cycles, which have also determined the types of shelters constructed and clothing worn. Because humans and nature share common space in the world, it is therefore natural that traditions and beliefs in many cultures reflect this fact. In the ancient beliefs of both India and China, for example, there developed a circular understanding of the relationship and even a dependency between humans, nature, and the spirit world.

Early Greek philosophers and poets, especially Hesiod and Pythagoras, conceived time cyclically. Pythagoras proposed that, at the end of the present universe, everything will return to its previous state and begin again exactly as it did before. In his *Works and Days,* Hesiod (8th century BCE) divides existence into five stages, starting with an age of wisdom and peace and gradually degrading to the final stage in which there is hatred, violence, and warfare. Ultimately, however, he posited a return and a new beginning. The ancient Hindu writings describe existence somewhat similarly, although in four stages. Both Mayan and Aztec cultures understood time in a great cycle, as can be understood in the latter's calendar.

Because ancient cultures have typically viewed humans within the broader natural order and cycle, they sought to live in some manner of harmony with and within it. Because the entire natural world has existed in a seemingly endless cycle, it is natural, then, that humans have not only lived in accordance with these cycles but have also seen their own existence as part of an endless cycle. In some of the earliest human burial sites to be uncovered, items such as foodstuffs, animals, and tools have been found. These point to a belief in an afterlife, a belief that humans will return to a material existence in some place and in some form where such items may well be useful and necessary. Thus, in many cultures, death has long been understood as a type of transitional sleep and transference state, from which one will awaken in a new place. Death precludes rebirth and a new life. In the myths of some religious cultures, even a god or deity will die, only to be reborn again, the death serving some important function. This does not mean that there has been a denial of the linear aspect of time. Instead, the linear progression of life has typically been viewed as ultimately leading to a return to a previous state. In some cases, this has been back to an original state, back to the beginning of time. To some, their "mythical past" is actually an ever-present reality. Tyson Yunkaporta, an Aboriginal writer and scholar from Australia, notes in relation to a popular Aboriginal creation myth: *The rainbow snake is still pushing up the mountains.*

Agrarian peoples have long lived in accordance with the natural cycles of the earth. In those cultures where technology has not changed life appreciably from generation to generation, the concept of time in the form of a cyclical constancy is easy to understand. Each generation is, in many ways, a reenactment of the previous one, albeit with new players. Values, traditions, beliefs, and practices remain the same; there is little reason to change. There is a security in this way of thinking and this approach to life. Within development of various advanced forms of technology, many farmers and others have been able, to a certain extent, to free themselves from those cycles, but not completely. Irrespective of technological advancements, the natural rhythms of the earth continue to exert great influence over the lives of humans and nature. As long as this is the case, the cyclical view of time will play an important role in the lives of many people.

Time, Emergence of

"Time is inseparably connected with history. Everything that exists in time has its history. Time and history are almost synonymous: History is measured by time, and time flows together with historical processes." These are commonsense views, and there certainly is a grain of truth in them, but they also need to be revised in the light of contemporary physics. This entry reviews the findings of recent physical theory and research, discusses linear and cyclic models of time, and links the temporality of the world to change and the creative process.

History is doubtlessly rooted in the physical world, and the laws of physics that shape the physical world provide constraints for possible histories. The laws of classical physics seem to corroborate the aforementioned commonsense view regarding the connection between time and history. However, classical physics is valid only as a limiting case of some more fundamental theories, and the real roots of time and history should be looked for in these more fundamental strata of the world's structure.

In the theory of relativity, of which classical mechanics is a limiting case, it is not space and time taken separately that form a stage for physical processes, but their combination into a single geometric entity, called *spacetime*. Any particular decomposition of spacetime into space and time depends on the choice of a local reference frame; that is, on the state of motion of the observer connected with this reference frame. Only spacetime itself, and not space and time taken separately, has the invariant meaning—in other words, the meaning independent of the choice of a reference frame. Consequently, if history is measured by time, history is also dependent on the state of motion of a given observer. A typical example is provided by the process of a gravitational collapse. If it is viewed by an observer collapsing together with a dying massive star, its history will end up catastrophically in a finite time, but when it is viewed by an observer regarding the process "from outside," that is, from a safe distance, the history of the collapsing observer will last forever only asymptotically approaching the "nonreturn" surface. Human history is notoriously accused of lacking objectivity: No two accounts of the same event coincide. But the present case is much more dramatic: Physically, the history of a process is not constituted by this process alone, but rather by a relationship between this process and a particular reference frame.

As for cosmic history, the history of the universe, local time (time within a cosmologically small neighborhood of a given observer) is usually identified with the first coordinate of a local coordinate system. But, in general, there is no unique coordinate system that would cover all of spacetime, nor is there any guarantee that if we cover spacetime by many coordinate systems, all local times determined by them could be smoothly joined together to form a single cosmic time. This could be done only if certain conditions were satisfied. And what is extremely interesting—these conditions seem to be very exceptional in the collection of all possible universes.

Time and Causality

Is there any possibility to make the history of an observer or a particle more independent of the choice of a reference frame? There is such a possibility if we look at the concept of history from the geometric point of view. Geometrically, the history of an observer or a particle can be described by a curve in spacetime followed by a given observer or a particle. Curves, as geometric entities, are independent of the choice of a reference frame. In the theory of relativity such histories are classified into three classes. Curves traced by observers and by nonzero rest-mass particles are called *timelike* curves. Photons are distinguished from all other particles because as light particles they have a distinguished status in the theory of relativity—they move with the limiting velocity in nature, the velocity of light. Curves followed by photons (zero rest-mass particles) are called *light* curves or *null* curves. There are also the so-called spacelike curves that do not represent histories of any known physical objects. Such objects would move faster than light. Timelike and null curves together are called *causal curves,* because only along these curves can causal influences propagate.

Every point p in spacetime has a *normal neighborhood* in which timelike curves passing through p form the interior of a cone, the "surface" of which is formed by null curves passing through p. This cone is called the *light cone* of p. Two events can be causally connected (i.e., one of them can be the cause of another) only if one of them is situated on or within the light cone of the other. Spacelike curves, which transmit no causal influences, lie outside the light cone. Having all this in mind, one often speaks, like Stephen Hawking and George F. R. Ellis, of the *causal structure of spacetime.*

The causal structure of spacetime within the normal neighborhood is relatively simple (it is essentially the same as in the special theory of relativity), but things get complicated outside of it. For instance, spacetime can contain closed causal curves. In such a case the causality principle is endangered. In a world model in which this happens, the global history is replaced by the continuous recurrence. In 1949 Kurt Gödel discovered the first solution to Einstein's field equations with closed causal curves; now, many such solutions are known. The existence of these solutions testifies to the fact that the idea of "temporal loops" does not involve contradictions (at least within the conceptual framework of general relativity), but if we add some external factors to the causal structure of spacetime, serious problems can arise. For instance, if we put a killer into such a spacetime, he could be able to kill his father before his own birth! This seems silly, but if we replace the killer with suitable differential equations and the problem of initial conditions for them, difficulties can appear in matching suitable initial conditions with their corresponding solutions (the so-called Cauchy problem), and the paradox remains in its full force. Therefore, it seems reasonable to exclude such pathologies. We are doing so by imposing the *causality condition* on all "physically admissible" spacetimes. It forbids the existence of closed timelike curves in such a spacetime. But we must exclude also "almost-closed" causal curves that are on the verge of violating causality. Spacetime, in which this requirement is satisfied, is said to be *strongly causal.* (It satisfies the *strong causality condition.*)

Spacetime is a subtle mathematical structure, and its various substructures must cooperate accordingly. The *Lorentz metric structure* (or *Lorentz metric* for short) plays the crucial role in the spacetime architecture. It coordinates all other spacetime substructures by determining which curves are timelike, spacelike, and null. Another function of the Lorentz metric is that it makes meaningful space and time measurements, and there are space and time measurements that allow us to experimentally determine the Lorentz metric. But in every space and time measurement, unavoidable measurement errors are inherent (even if we do not take into account quantum effects). This implies that the Lorentz metric can be experimentally determined only with a finite accuracy. We can express this by saying that infinitely many "nearby" Lorentz metrics are compatible with given space and time measurements. Consequently, if we require that spacetime should be strongly causal, we must extend this postulate to all "nearby" metrics. Otherwise, within the "safety margin" (determined by the finite measurement accuracy) we could have causality violating spacetimes. Therefore, we must exclude the situation in which a slight perturbation of a Lorentz metric (on a strongly causal spacetime) produces closed timelike curves. As noted by Hawking and Ellis, spacetime that satisfies this condition is said to be *stably causal.*

It turns out that this causality property is strictly connected with the existence of a global time in a given spacetime. This means that every observer in this spacetime can be equipped with a clock measuring a smooth flow of time. Let us represent the history of such an observer by a timelike curve. A clock carried by this observer associates to every point of this curve a real number (an "hour" shown by this clock). In other words, a monotonically increasing function is determined along this curve. ("Monotonically increasing" means "increasing and never decreasing.") We see that from the mathematical point of view the global time idea is implemented by the existence of a smooth monotonically increasing function defined along every timelike curve representing the history of an observer. In 1968 Stephen Hawking proved the theorem stating that the global time (in the above sense) exists in spacetime if and only if this spacetime is stably causal.

We meet here a beautiful example of a subtle interaction of mathematical structures when they are incorporated into a physical theory. Three apparently very different things—the possibility of making space and time measurements (consequently the very possibility of doing physics), causal interactions (stable causality), and the existence of global time—turn out to be but some aspects of the same properties of the metric structure. The universe is a much more organized whole than standard textbooks of physics and astronomy allow us to suspect.

However, a relativistic world model satisfying the stable causality condition still does not resemble the Newtonian universe in which simultaneous events are well determined independent of how far from each other they are situated. In a stably causal relativistic universe, clocks carried by all observers need not be synchronized (they should only indicate a continuous time flow) and, in general, there is no way to determine simultaneity of distant events. To guarantee such a possibility we must impose a yet stronger condition on spacetime. This stronger condition is connected with deterministic properties of spacetime. A spacetime is deterministic if each event in it can be predicted from suitable initial data. These data must be given on an initial surface, called a *Cauchy surface.* In general, the geometric structure of spacetime does not admit the existence of such a surface (or it admits only a *partial* Cauchy surface, such that only the events situated in some region of spacetime can be predicted from the initial data on this surface). Spacetimes in which there exists a (global) Cauchy surface are said to be *globally hyperbolic.* Strong symmetry properties of globally hyperbolic spacetimes ensure that the concept of absolute simultaneity can be made meaningful in them. And only now we have our "familiar stranger" (from the title of J. T. Fraser's 1987 book), the cosmic time of our world.

The question arises: How restrictive are the above global time-admitting conditions? The answer is that they are very restrictive. In the collection of all possible relativistic world models (i.e., in the collection of all possible solutions to Einstein's field equations) the world models admitting the existence of a global time form the zero-measure subset. This means that if we had to choose a world model at random, the chances to pick up a model admitting a global time would be negligibly small. The same is true if we would like to pick up at random a world model with absolute simultaneity from among all world models that admit global time. All achievements of contemporary cosmology that so successfully reconstruct the history of our universe bear witness to the fact that the world we inhabit belongs to this selected family of universes that admit a global time. How to explain this fact remains so far an unanswered question.

Arrows of Time

In the preceding sections, we were able to establish conditions for the existence of the global time in a given world model. They are connected with causal properties of spacetime, and are—as we have seen—severely restrictive. We should notice that these conditions say nothing about the direction of the time flow (the arrow of time). Two such directions are possible, and neither of them is distinguished in any way within the geometric framework of general relativity. To determine the arrow of time we need an additional criterion. It is commonly believed that such a criterion is provided by the second law of thermodynamics: the law of the entropy increase. *Entropy* is a mathematical function that measures the degree of disorder—or, equivalently, the degree of energy dissipation—in a given physical system. The second law of thermodynamics asserts that the entropy of an isolated system (in which no reversible processes occur) always increases until it reaches its maximum value. The state with the maximum entropy is called the *equilibrium state.* The second law of thermodynamics, as applied to the universe as a whole, says that the entropy of the universe increases and goes to its maximum. It is this increase of entropy that determines the arrow of time.

There is no doubt that the present universe exhibits the thermodynamic arrow of time, but this fact poses several questions of a cosmological significance. The thermodynamic arrow of time implies that the present entropy of the universe is lower than its future entropy and higher than its entropy in the past. In fact, the very meanings of the terms *past* and *future* are defined by the entropy increase. According to theoretical physicist Paul Davies, we should also keep in mind that the law of entropy increase is a statistical law and should be understood in the probabilistic sense. This means that the increase of entropy is more probable than its decrease provided that a physical system under consideration consists of a sufficiently great number of individual entities (particles, molecules, and so on). When this condition is not satisfied, the thermodynamic arrow of time is not well determined or not determined at all.

The law of entropy increase, when extrapolated to the past, leads us to the *initial state* (near the big bang), when the entropy of the universe had to be extremely low. But the standard cosmological model tells us that "in the beginning" matter was evenly distributed throughout space and was at a uniform temperature. In the usual conditions (when only short-range forces are taken into account) such characteristics are typical for a system in the state of maximal entropy. However, in the cosmological environment, gravity (which is a long-range force) is acting, and conditions for the equilibrium state change radically. A large-scale self-gravitating system becomes more and more clumpy, and black holes will eventually be formed in it. Although the concept of gravitational entropy is not yet well elaborated, the thermodynamics of black holes (a subject rather well known) gives us a clear hint that in the cosmological setting the clumpiness of matter and the formation of black holes lead to a large entropy increase. Taking this into account, it is clear that the universe in its initial state could have a very low entropy in spite of a smooth distribution of matter. In this case, the contribution from the gravitational entropy would dominate over the contribution from the entropy of ordinary matter. According to Penrose, this is connected with the origin of the arrow of time on the cosmic scale. However, we should keep in mind that the relativistic statistic thermodynamics is so far not well elaborated and, in particular, there is no commonly accepted definition of gravitational entropy. And without these ingredients our understanding of the arrow of time remains partial and fuzzy.

Eternal Return

The discovery by Gödel of the solution of Einstein's equations with closed timelike curves has revived the old idea of a cyclic universe. In the context of general relativity, this idea can assume a stronger version or a weaker version. The stronger version is suggested by Gödel's solution. In this version, the history of the universe forms a closed "time loop"—the same event occurring somewhere in the universe has already occurred infinitely many times, and it will be occurring in the future infinitely many times. As we have seen above, such an idea—philosophically attractive as it might be (at least for some philosophers)—faces rather serious difficulties related to the problem of causality, and it is nowadays not popular among philosophizing cosmologists. But from time to time it attracts attention of some of them. For instance, in 1998 J. Richard Gott and Li-Xin Li speculated that in the very early universe there could exist a region with closed timelike curves. This would eliminate the troublesome concept of the beginning of the universe. However, to make this idea physically more plausible, these authors had to assume that the region of spacetime with closed timelike curves is separated from us by *causal horizons*. Otherwise, causal pathologies could infect our present physics.

According to the weaker version of the eternal return idea, the history of the universe is open (i.e., the same events are never repeated), but it consists of an infinite sequence of oscillations: each contraction phase is followed by an expansion phase that in turn initiates another contraction phase, and so on to infinity. This scenario meets the very serious difficulty with the singularity separating every expanding phase from the preceding contracting phase. When one approaches the separating point, some physical quantities (such as matter density) tend to infinity, and the classical singularity theorems (proved by Stephen Hawking, Roger Penrose, and others in the 1960s) tell us that the singularities cannot be avoided without violating very realistic physical conditions. These conditions could eventually be violated by quantum gravity effects, but no commonly accepted quantum gravity theory is now existing.

The *eternal return* issue is clearly connected with the Poincaré recurrence theorem. Let us consider a classical system of material points acted upon by forces that depend only on positions of these points. Let us also assume that both the coordinates of the points and their velocities remain bounded. The Poincaré theorem asserts that the trajectories of these points will return, in fact infinitely many times, arbitrarily close to the positions already occupied by them. The theorem, when put into the cosmological setting, can be interpreted as saying that the history of a spatially finite universe will be "almost closed"; that is, the universe will come back arbitrarily close to the state already occupied by it, and this scenario will be repeated infinitely many times.

It was mathematician Ernst Zermelo who noticed that in the system satisfying conditions of the Poincaré theorem, the law of the entropy increase cannot be valid, because the increase of entropy leads the universe to the equilibrium and not to the states it previously occupied. Austrian physicist Ludwig Boltzmann responded to this difficulty by remarking that the objection does not stand if the law of the entropy increase is understood statistically. In such a case, a decrease of entropy is only less probable than its increase, but it is not excluded. Even if the universe reaches the equilibrium state, there is always a probability that it will deviate from it. Boltzmann speculated that the present universe can be fluctuating around its equilibrium state, and only its region of our astronomical vicinity finds itself in a fluctuation in which entropy actually increases.

The Poincaré recurrence theorem was formulated within the conceptual framework of classical mechanics, and it was Frank J. Tipler who proved its relativistic counterpart. Tipler's theorem asserts that if a cosmological model satisfies the following conditions: (1) It is spatially closed, (2) gravity in it is always attractive, (3) Laplacian determinism holds true in it, and (4) every curve in its spacetime, being the history of a particle or the history of a photon, at least once experiences tidal forces, then this cosmological model cannot be "time periodic"; that is, it cannot return to the state once occupied by it.

As we can see, neither the Poincaré theorem nor the Tipler theorem say anything about "open" world models, but for "closed" universes, the relativistic version of the theorem points in the opposite direction from the classical version.

Physical Clocks and Creative Processes

Independent of all discussions around the idea of eternal return, modern cosmology displays the universe in the state of a long evolutionary process: from the big bang and nucleogenesis to the formation of galaxies, clusters of galaxies, stars, and planets. Moreover, biological evolution, regarded as a fiber of cosmic evolution, is deeply rooted in all the above processes. There are strong reasons to believe that a long evolutionary history of the cosmos was indispensable to produce a living cell, not to mention an intelligent observer.

In our previous discussion we have indicated that, from the geometric point of view, a clock should be interpreted as a monotonically increasing function along a timelike curve in spacetime, but to have a truly evolutionary process, a physical clock is needed; that is, a physical device measuring real processes. Such a clock could be described as a subsystem of the world, itself a process, the changes of which could be compared with changes of its environment. Not in any conceivable world can such a subsystem exist. Without enough order, no sufficiently regular subprocesses are possible. This is why in the equilibrium state, admitting only chaotic motions, there could not exist a subsystem that could be identified as a physical clock. Our organisms are the sort of physical clocks that can exist only in far-from-equilibrium states. There is no doubt that truly creative processes had to be at work in our genesis and, as we know today, no creative processes can operate without the intervention of some chaotic phenomena. We are, therefore, creatures from the boundary region between order and chaos. The temporality of our existence is but an aspect of the temporal structure of the world.

Time, End of

The concepts of the "end of time" or the "end of the world" can be viewed from both religious and scientific perspectives. The terms can encompass the extinction of the earth, the universe, humanity, and even the extinction of time itself. "End-time" is an example of a term associated more specifically with religious beliefs.

Religious Aspects

From the beginnings of civilization to the present, people of many cultures and religious backgrounds have accepted beliefs that offer some kind of reassurance about life after death. Such beliefs have been characterized by the association of specific cycles of time with the supernatural.

The term *eschatology* is associated with last things, specifically including the end of time. The earliest known example of an eschatological faith is Zoroastrianism, founded in the 6th century BCE by the Iranian prophet Zoroaster.

Mythical eschatology has generally offered a cyclic view of history in which order is created out of chaos at both the beginning and the end of time. Historical eschatology includes the concepts of messianism, apocalypticism, and millennialism. *Messianism* is characterized by the presence of a single person who will lead others to redemption. *Apocalypticism* anticipates a dramatic intervention by God, who will recognize the faithful majority. *Millennialism* is named for the concept of an ideal 1,000-year kingdom that would be formed before the world's end. In that kingdom, Christ and his saints will reign and the forces of evil will be destroyed.

An example of the persistence of an ancient belief into the present can be seen in the interest shown in an ancient Mayan calendar's identification of the year 2012 as the end of a world cycle. Some believers definitely anticipate it as an end time.

Scientific Aspects

History offers many examples of attempts to identify end times that did not materialize, but that fact is not likely to stop future speculation. Meanwhile, modern physicists have proposed a number of alternative theories about whether the universe is likely to have an end and how that might occur.

About 1920, Sir James Jeans proposed the "steady-state theory," where the universe has no beginning or end and continues to expand while maintaining a consistent average density. An important first step toward an alternate theory was Edwin Hubble's law, proposed in 1929. Hubble's law led to the concept of an expanding universe, which further led to the idea that the universe had a beginning and possibly an end. The end, or "big crunch," would occur when the universe stops expanding, its matter having enough density to cause it to collapse into itself.

Since the 1950s, several observations have supported the big bang theory of the origin of the universe. Physicist Stephen Hawking particularly points to explorations of the Cosmic Background Explorer satellite, COBE, in 1992, as providing support for the big bang. Hawking proposed that, though the universe is finite, it has no boundaries in imaginary time, which runs at right angles to ordinary time. The no-boundary theory does imply that the universe will eventually recollapse, but the collapse will take much longer than the 15 billion years that the universe will have taken to expand. He speculates further that the contracting phase will not take an opposite "arrow of time" from the expanding phase, and time will not go backward.

More recently, cosmologists Paul J. Steinhardt and Neil Turok have introduced the cyclic model of the universe as an alternative to the big bang theory. The model still includes a big bang and a big crunch. But since the universe in the model has no beginning and no end, these occurrences would represent transitions from contracting to expanding phases in endlessly repeating cycles. In the model, dark energy plays a role in regulating the way in which the cycles occur.

An alternative to the positive view of dark energy in the cyclic model has been proposed by a team led by physicist Robert R. Caldwell. The "big rip" theory speculates that dark energy, or another unknown force, might speed up the expansion of the universe to the point where all matter would essentially be ripped apart. Yet another theory, first proposed by the 19th-century Scottish physicist William Thomson, was "heat death"—a condition where energy would be evenly distributed uniformly throughout all matter, and the temperature of the universe would drop to nearly absolute zero.

Modern cosmologist Frank Tipler has moved in a less common direction, combining his scientific research with his religious beliefs to develop a theory that attempts to prove the existence of God and an afterlife by using the laws of physics. He refers to the end of time as the Omega point, a phrase used earlier by Catholic evolutionist Teilhard de Chardin. Tipler predicts that this point will occur about 100 billion years in the future. He distinguishes between proper time, by which the finite age of the universe is measured, and subjective time, which allows for infinite amounts of life and thought as well as the processing of information. He envisions a closed universe in which the gravitational energy from the collapse of the universe will increase faster than the universe's movement toward zero, allowing our descendants to have an unlimited knowledge of the system.

Instead of concentrating on speculations about the past, present, and future, British physicist Julian Barbour speculates that time itself does not really exist and is defined only by our perception of changes that occur. Others before him have made the case that time is an illusion invented to try to make sense of the universe. Following this logic, time would no longer exist if either life or the universe itself disappeared. Many have shared similar theories, recorded back as far as the writings of the Greek philosopher Parmenides (c. 515–c. 445 BCE).

Speculation about the future of the earth and the universe is of obvious interest to scientists, theologians, and philosophers, as well as to the average person. Whereas certain theories about the end of time have received more general acceptance than others, even the most advanced scientific and theological explanations will remain subjects of study and debate into the foreseeable future.

Time, Galactic

Galactic time is the process of tracking time relative to the age of our galaxy. The center of the Milky Way galaxy is located in the terrestrial night sky in the constellation of Sagittarius, at a location with a strong radio source called Sagittarius-A. It is optically invisible due to the concentration of dust and debris that is gravitationally influenced by a suspected galactic black hole; however, it is found by utilizing radiotelescopes that receive radio frequencies that penetrate stellar obstructions.

A galactic year is one complete revolution of the sun around the galactic center. The sun takes approximately 240 to 250 million years to orbit the galaxy, and if the assumption of the age of the sun is assumed to be 4,500 million years, then the sun is approximately 18 galactic years old. Much of the information about the exterior of the Milky Way is difficult to discern given that observations are taken from within. This is the same effect that kept most of humanity puzzled over how objects in the solar system behaved before Nicolaus Copernicus revolutionized astronomy with the heliocentric solar system model in 1543. Now that technology and instrumentation are improving to more precise levels, it is easier to detect and determine the small-scale changes occurring in the "fixed" stellar background. The same technological improvement occurred in 1609 when Galileo was able to observe the night sky in more detail with the advent of the telescope.

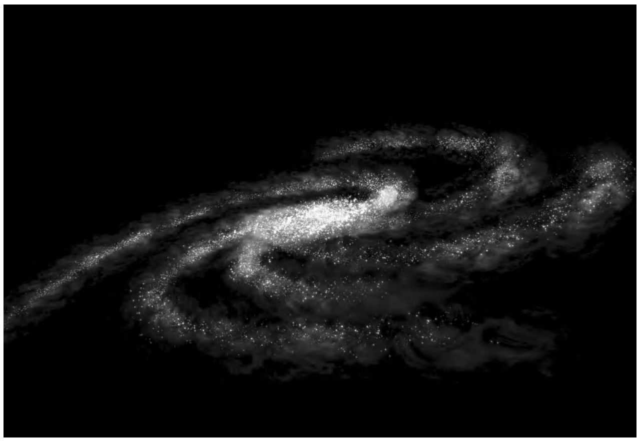
The Milky Way

Debates among astronomers regarding the rotational periods of galaxies create many questions. For example, we are able to surmise the rotational period of our own galaxy, but assumptions made in calculating other galactic rotation rates create unrealistic results. Edwin Hubble determined a range of age for the universe. When calculating the rotational period of Andromeda, the resulting value is greater than the Hubble range for the age of the universe. This discrepancy is based on assumptions made in calculating distances to galaxies, particularly in the mean distance of those stars known as Cepheid variables. Distances to Cepheids are estimates as well, and are used as "markers" to determine galactic separation because of their rotational periods. When the distance factor changes, all other related measurements change with it.

The local group of galaxies are assumed to be the same age as the universe, and, based on spectroscopy calculations, are mostly moving apart from one another at varying rates. There are also galaxies that are moving toward each other, such as ours and Andromeda, which are predicted to merge in another 6 billion years. Our sun is estimated to exist for only another 4.5 billion.

Stellar Evolution

To determine stellar evolution, astronomers use the Hertzsprung-Russell diagram (H-R diagram) developed by Ejnar Hertzsprung and Henry Norris Russell in 1910. The H-R diagram provides a way to age stars and reasonably predict their future behavior. The age scale relates the size, luminosity,



An artist's impression of our home galaxy—the Milky Way. Our solar system is one of billions in the galaxy, and the galaxy is one of billions in the universe.

and color of a star to calculate its relative age. Most stars spend their lives on an area known as the Main Sequence, evolving from high-temperature, high-luminosity stars to low-temperature, low-luminosity stars. The diagram also takes into account events that may occur to the star through its life cycle that change its classification from a Main Sequence star.

Our sun, for example, is in the average yellow range on the Main Sequence. Based on the H-R diagram, our sun is 4,500 million years old and at the midpoint of its existence. Eventually, it is expected to become a red giant, encompass part of the solar system including Mars, then recede to a white dwarf. However, the sun does not have enough mass to collapse upon itself and create a black hole.

Since its inception, other diagrams have been based upon the H-R diagram. The H-R diagram is also a tool useful in calculating distances to other galaxies and star clusters.

Time, Historic

History (as opposed to prehistory) refers to a written record of the human past, so historic time is the period in which we have had such records. The line between prehistory and history is not distinct, and there has been much debate among historians and archaeologists about where the former ends and the latter begins.

The distinction between history and prehistory is fairly recent, with the word *prehistory* first being used in the 1860s. At this time, anthropology underwent a shift known as the "time revolution" or the "revolution in ethnological time." Prior to this revolution, the history of humankind was believed to extend back only a few thousand years, in keeping with beliefs about the timeframe of events in the Bible. The paradigm shift was spurred by the discovery of human tools near the remains of extinct species, and it also occurred around the same time that Darwin's *On the Origin of Species* (1859) was published. Humankind's existence was now lengthened by hundreds of thousands of years. It was during this time period that the field of anthropology emerged.

Because changes in the human way of life were gradual, no single date can be pinpointed as the start of history. The year 3500 BCE is often cited as the (approximate) date when recorded history began. This was contemporary with the beginnings of Sumerian society, located in Mesopotamia. The Sumerians developed cuneiform, one of the earliest known systems of writing. It began as a series of pictographs, in which different concepts and objects were represented by pictures, used chiefly for tallying and recording inventories of goods.

Another school of thought states that history began later, around 750 BCE, in Greece. It was during this period that writing began to involve analysis, instead of lists and simple records, as in prior times. For this reason, the period prior to these more detailed written records is sometimes referred to as "proto-history," a period between prehistory and history.

Herodotus, who lived in Greece in the 5th century BCE, is sometimes referred to as the "father of history." His account of the Greco-Persian war, known simply by the title *History,* is considered the first historical narrative of the ancient world. While other historical records had previously been written, his was the first to appear as a narrative whole. In addition to his narrative of the events of the war, Herodotus also described the political climate and social customs of the time, providing a rich source of information on Greece during the 5th and 6th centuries BCE.

While written records can provide information about a time period, historic sites, with their tangible artifacts, can provide even more information. Using both types of resources provides the most detailed information about a time period or culture. An example is the pyramids built in ancient Egypt, used as tombs and settings for funeral rituals. Inscribed on the walls of pyramids from the 5th and 6th dynasties (2465–2150 BCE) are *pyramid texts,* the oldest religious literature in Egypt. These hieroglyphic texts contain myths, spells, and incantations meant to protect the dead king or queen buried there. It is thanks to these writings that we understand the pyramids' purpose and Egyptian views of the afterlife. According to the pyramid texts, the tapered shape of the pyramids was meant to resemble a ramp or stairway for the soul to ascend to the afterlife.

These inscriptions were later augmented by *coffin texts* placed directly on the inside of the sarcophagi containing the bodies. These also contained spells and rituals, but they were used for all Egyptians, not just royalty. One of the coffin texts, later named *The Book of Two Ways,* gives a detailed picture of the journey to the afterlife, including maps and spells to help the deceased.

The Parthenon, a structure built in Athens, Greece, in the 5th century BCE, is another historical site whose history has been illuminated by the survival of written texts. Built as a temple for the goddess Athena, it was also used as a treasury building. Thanks to records describing its construction, we know that each column was built separately, under the direction of a different master mason. The records also state that a variety of methods were used to put the stones in place, including ropes and machinery.

Historical records have also enhanced our understanding of the Taj Mahal, built in India during the 17th century. The building acted as a tomb for Mumtaz Mahal, wife of Mughal emperor Shah Jahan. Official records from the emperor's court, as well as other Mughal historical records during that time period, describe the building of the tomb, its architectural features, and the cost of construction. A letter from the emperor's son also indicates that maintenance issues developed during the building's long construction. Without such records, our knowledge and understanding of this structure would be more limited.

Time, Illusion of

Perceptual illusion has been defined as "a perception of a thing which misrepresents it, or gives it qualities not present in reality" and as "distortions or incongruities between percept and reality." Such definitions are often considered as aspects of the psychology of time, as there are states during which time perception does not faithfully represent what is regarded as objective time. This is especially the case for the dimension of event duration.

Time illusions associated with the duration of events reflect the nature of the cognitive processes underlying time perception. Because these processes are strongly context dependent and are affected by factors such as the duration measurement paradigm (prospective or retrospective), duration measurement method, and nontemporal information load required during a target interval whose duration is being estimated, situations will occur when, as a result of change in one or more of these factors, the duration of an event or a target interval will be perceived as different from that of another event or target interval although the clock time of these two instances may be identical. Hence, most time illusions that are related to duration are relative: That is, we can argue that the illusion appears only when two situations or two intervals are compared. For example: Present someone with two commands (e.g., "start" and "stop"), with a 10-second interval between them. Then ask him or her to judge the duration of the interval. Present another person with a similar task, but this time read a list of words during the interval and ask this person to memorize the list. Most likely the second person's duration judgment will be longer than that of the first person. The reason is that in the first case, the person was presented with an "empty" time interval, whereas in the second case the interval was "filled" with words to be remembered. The emerging illusion is called the "filled interval illusion," according to which "filled" time is estimated as longer than "empty" time. However, this direction of the illusion occurs only when durations are estimated retrospectively. The direction will be reversed if the duration is estimated prospectively; that is, when the person is told in advance and before the start of the target interval that he or she will be required to estimate its duration.

The filled time illusion—with its two aspects—occurs because retrospective and prospective time estimations rely on different courses of information processing. In the retrospective condition, duration judgment is based on information retrieval processes from memory, while in the prospective condition the perceived duration is a function of the quantity of attentional resources, which are directly apportioned to temporal information processing.

The difference in information processing between the retrospective and the prospective conditions causes another relative time illusion that results from the influence of the load required for nontemporal information processing during the target interval to be estimated. In the retrospective condition, when the required load is high, duration will be judged longer than when the required load is low. The prospective condition yields the mirror image of its retrospective counterpart.

Another time illusion is summed up by the saying: "A watched pot never boils." In an experiment bearing out this illusion, a person is asked to watch a transparent container full of water that is placed on a flame; the person is asked to wait until the water boils. The participant is told at the outset that she will have to estimate the time interval from the start of the experiment until she receives a certain instruction. In the second condition, the participant is asked to do the same, but this time, some transparent solution has been added to the water, which causes the fluid's boiling point to rise—as a result, the waiting time before boiling increases. When stopping the experiment under Condition 2 after a time interval that was exactly identical to the boiling time in Condition 1, and asking the participant to estimate the time interval, the estimation will be longer in Condition 2 than in Condition 1. The explanation for this is that when a person is asked to wait for water to boil and this does not happen at the expected point in time, increasingly more attentional resources will be invested in temporal information processing. Since this is a prospective condition in which the sense of duration is a function of the resources directly apportioned to temporal information processing, the sensation is extended under Condition 2. In principle, as long as a person is waiting for a certain event to occur (say, a friend's arrival) the sense of time will be extended relative to a situation in which he is not waiting.

Waiting in a line also constitutes a good illustration of the influence of a person's expectations concerning the end of a target interval on her sense of that interval's duration.

When an event comes to an end before its time, its duration will be experienced as shorter than that of an event with an identical objective duration whose end was perceived as taking longer than expected.

Our expectations regarding the end of an event are even more pronounced in the case of an unpleasant event, as, for instance, in the case of pain. When we put our hand in a container filled with water near the freezing point and are asked to estimate the duration of our holding our hand there, the estimation will be longer than in the case of holding our hand in a container with pleasantly lukewarm water for an identical interval. The reason for this difference is that our wish to end this aversive event increases the amount of attentional resources available to temporal information processing. Similarly, individuals were found to have an exaggerated estimation of the duration of earthquakes. The wish for an event to come to an end, depending on the event's degree of pleasantness, affects the sense of that event's duration. This is reflected in the saying: "Time flies when you are having fun."

Another time illusion is exclusive to the retrospective condition. If we ask a person to estimate retrospectively the duration of a reading of a list of words—say, a list of food-related words—the estimated duration will be longer as a function of the amount of unrelated words included—for example, names of countries. The unrelated words divide the list, and thus have a segmentation effect. This effect is apparently caused by the influence of information retrieval from the memory on which retrospective time estimation is based. Similarly, the larger the amount of contextual changes (e.g., change of light conditions in the room), the longer will be the perception of the event's duration in that room, compared with an identical event in a room whose lighting is not changed.

A well-known time illusion, which Gustav Fechner described as early as 1869, is the "time-order error," which is manifested in the influence of the temporal sequence of events' appearance on the estimation of their relative duration. Thus it can happen that an interval that occurred first will be perceived as longer than an interval of an identical duration that occurred second in time ("positive time order error"). The reverse, too, can happen, when the first interval is perceived as the shorter one ("negative time order error"). The direction of such order-related errors is determined by a number of factors, the most prominent of which is the objective duration of the intervals. The phenomenon has a number of explanations, as researchers have not reached agreement on one single valid one.

Another type of time illusion is connected with the complex interrelations between our perceptions of movement, time, and distance. One such illusion is called the Tau effect. For example: If we stimulate three points that create an equal-sided triangle on a person's forearm, and the objective time interval between stimulating the first and second point is longer than that between the second and the third, then the distance between the initial two points will be perceived as longer than that between the second and the third. The same phenomenon occurs for the visual and auditory senses (e.g., distance between light points or sound sources). The reverse effect—the perception of the time interval elapsing between the lighting up of two light points is influenced by the physical distance between them—is called the Kappa effect.

Similar illusions resulting from an intuitive perception of the connection between distance, time, and speed occur among children who are at a stage of cognitive development characterized by intuitive thinking. Thus, experiments conducted by Swiss psychologist Jean Piaget have borne out that if a kindergartner or first grader is shown two toy cars that are both made to start moving at the same point, but with one of them moving faster, and therefore completing, in a given time interval, a greater distance than the other, the child will estimate that the faster toy car has moved for a longer period of time than the slower toy car. This happens because a child at this developmental stage is unable to take the influence of speed into account and will judge duration as a function of distance only.

Time, Imaginary

Imaginary time is a concept most popularly known because of its use by physicist Stephen Hawking in his research on the origin of the universe and the relationship between time and space. The simplest definition of imaginary time is time measured by the use of imaginary numbers. The mathematical concept of imaginary numbers was developed in the 16th century in order to define the square root of a negative number. Just as imaginary numbers should be seen as positioned at right angles to ordinary real numbers, so imaginary time can be described as existing at right angles to real time.

It seems to be unclear when and where the precise use of the term *imaginary time* first came into being, though a number of sources have been identified in which the essence of imaginary time was described. An early example is a 1908 paper presented by German mathematician Hermann Minkowski, proposing the concept of time as a fourth dimension. Another is a 1927 book, *An Experiment With Time,* by J. W. Dunne, exploring the idea that the past, present, and future exist concurrently.

In modern mathematical and theoretical physics, imaginary time has been considered to be a necessary element in research involving various particle and field theories. It also has practical applications in such fields as engineering.

A fundamental aspect of Hawking's research has been an attempt to develop a quantum theory of gravity. General relativity does not work well on small distances and does not take the uncertainly principle of quantum mechanics into account. That principle states that the more accurately a position can be measured, the less accurately speed can be measured. The reverse is also true. As part of this research, Hawking has made use of imaginary time—a theoretical concept arising from quantum theory.

Hawking points out that imaginary time is well defined mathematically. And, though it sounds like a creation straight out of science fiction, he makes a case for it being just as real in its own way as is the real time within which we normally operate—perhaps more real in describing the actual axis of the universe.

Starting from the concept that the validity of any mathematical formula applied to our universe must describe it accurately, Hawking asserts that the use of imaginary time does produce results that we have already observed about the universe and that it is also supported by other observations, even though those may need further study and proof. This approach has been labeled top-down cosmology.

Hawking and physicist James B. Hartle have applied the concept of imaginary time in their research on the origin of the universe, including their efforts to develop a unified theory derived from Einstein's theory of relativity and from Richard Feynman's concept of multiple possible histories of the universe. In his sum-over-histories theory, Feynman considered time to be a dimension in space that could move both backward and forward, allowing for variant pasts and futures. Hawking later stated that the idea of multiple histories of the universe is now accepted as fact.

The big bang, now generally thought to have created the universe about 15 billion years ago, has been described as a singularity in ordinary time, or a point at which the spacetime curvature and the density of matter were infinite. But in imaginary time, it can be envisioned merely as a single point, such as the earth's north pole, with no beginning or end. Knowledge of the state of the universe in imaginary time can allow for the calculation of its state in real time, and, since the latter is dependent on the former, the universe can be described as a self-contained system.

In one model, the universe could be envisioned as a sphere with four dimensions, but with a slightly flattened south pole. Had the universe remained a perfect sphere in imaginary time, it would have continued to expand forever. Instead, there was an initial burst of expansion, followed by a decrease that allowed for the development of galaxies and life.

In another model, the universe would resemble a nutshell, or a membrane, with four dimensions. It would still be a sphere, but with some irregularities. The interior of the membrane might represent a fifth dimension where no time exists.

In real time, the occurrence of the big bang would have indicated that the laws of physics had broken down. But, since imaginary time does not necessitate that the universe have a beginning or an end or any boundaries, the laws of physics would still have been in operation. On a BBC radio broadcast, Hawking clarified that determining that the universe followed the laws of physics when it began would neither prove nor disprove that God exists—but it does indicate that there was nothing arbitrary about the process.

Hawking points out that the classical laws of physics work for large systems because the many changes that occur can be averaged for predictability. But when the big bang occurred, the universe was very small, making the uncertainly principle important at that early time. Hawking adds that changes in microwaves coming from space have allowed us to observe the probable small changes occurring in the history of the universe. In 1992, NASA's COBE (Cosmic Background Explorer satellite) detected such irregularities and provided evidence supporting the big bang theory.

Hawking and most other physicists make it clear that many of the concepts they have proposed are theories yet to be proven. As with any scientific effort, it is important that physicists build on the work of others. But it is also inevitable that they will not always be in agreement on the specifics. Yet Hawking and other physicists have expressed optimism that combined research efforts will produce a unified theory of the universe in the near future. When that occurs, Hawking anticipates that such a theory would be available to people in all walks of life, enabling enlightened discussion on the reason for the existence of the universe and its inhabitants.

Time, Linear

Time is commonly conceived as being linear, in constant motion, moving from past through present to the future. The past is behind us and exists only as memory; we can live and experience only the present; we have to accept the inevitability of the future. This represents the way most people in the world today understand time and is predicated on the belief that all events happen in a linear sequence and that the direction is only one way: forward. This view has long predominated in Western thinking, and any alternate view is discounted as ill-informed and without substance. It is fundamental to nearly all Western worldviews, including those found in the contemporary physical and social sciences. It is integral to concepts as basic as growth, evolution, and cause and effect. The value of such a view is that it makes rational empirical sense, aids in organizing our lives and our societies, reflects our common understanding of everyday phenomena, and fits into our common approach to and conception of reality. Integral to this has been the belief that time exists independent of all other forces, and there is nothing that can be done to alter it.

In the latter half of the second millennium CE, several European thinkers sought to elaborate their own philosophy of time using existing Western models. These include Sir Isaac Newton, Immanuel Kant, and Martin Heidegger. Although they differ in their understandings and interpretations (Kant, e.g., denies an origin to the universe), they all essentially elaborate a linear concept. As a consequence, it is the European view that predominates in the West, and increasingly in the rest of the world as well. A competing model of time, the circular view, has also been important in the way humans have understood time. It has long been integral to indigenous cultures and Asian traditions and is addressed in a separate section.

Thinking in a linear fashion, we can reflect upon the past as well as make plans for the future. In actuality, however, it is this preparation for the future that tends to consume the bulk of most people's lives, whether it be in the form of work, study, exercise, or even eating and sleeping. The vast majority of human activities are undertaken, for the most part, to help make our futures better, rather than as ends in themselves. Concepts such as time wasting and time management, hourly wage, multitasking, deadlines, bank accounts, financial investments, and retirement planning all become important in one's thinking and functioning, and all are predicated on a linear understanding of time. While there are clear benefits to thinking of time in a strictly linear manner, many of our problems, especially in modern times, can also be traced to such an approach. The more one focuses on the passing of time, the more one thinks of the past with either longing or regret, and the more one also becomes concerned for the future and seeks to utilize more of one's present time in preparation for the future. If one is not able to adequately fulfill one's plans and hopes for the future, emotions such as stress, anxiety, and unfulfilled expectations are experienced. For many, then, the present is consumed by and becomes little more than planning for the future, which, in reality, never exists.

In addition, those who think about human existence with a strictly linear fashion tend to see humans as separate from nature, for the latter is viewed as functioning cyclically (rotation of seasons, migration of animals, etc.). This bifurcated view places humans apart from nature rather than a part of nature, and this separation allows humans to treat nature differently from the way that humans are treated. From this comes the view that while humans are believed to have souls, nothing in nature is seen to possess a soul. All of nature is viewed collectively as a process or as something for humans to use that has little or no independent value in itself.

However, not all Western understandings of time reflect the common linear understanding and independent nature of time. Christian mystics have posited a reality beyond these boundaries. William Blake's poem "Auguries of Innocence" expresses a similar vision. In the latter half of the 20th century, Albert Einstein and various theoretical physicists challenged traditional views of linear time and postulated a far more contextual approach in conjunction with space, human involvement, and other factors. The experiments of Alain Aspect and the theories of David Bohm and Karl Pribram have been fundamental in questioning long-held Western views of time and have led to many rethinking the supposed absolute nature and reality of linear time.

Time, Logics of

Logic can be understood as the study of principles of valid inference and demonstration. Inspired by a thorough analysis of arguments in natural language, formal logics investigate the structure of statements and arguments through the analysis of formal systems of inference. Formal inference systems represent symbolic models of reality or a certain application domain. Because of their very mathematical nature these models are predestined to draw safe conclusions about this reality in a quasimechanical manner. Logics of time (also temporal logics or tense logics) focus on the characterization of temporal phenomena of the domain being modeled. They constitute the subfield of philosophical logics where relationships like "earlier," "later," or "at the same time" are investigated.

The most prominent family of temporal logics traces back to Arthur Prior, one of the pioneers of temporal logics. Prior was convinced that the apparatus of formal logic could not only be used to characterize eternal and unchanging truths, but also would be suitable for a rigorous study of aspects of reality that change over time. In the middle of the last century he showed that certain canonical extensions of the well-known classical logics could be used for this purpose. As a consequence, there is now a system of temporal logics in the style of Prior's, giving interesting insights into the possible structures of time.

All temporal logics are extensions of classical propositional logics. We will therefore start our brief journey through the world of temporal logics with a short introduction to the calculus of propositional logics and will then sketch several simple but representative temporal extensions of this calculus.

Propositional Logics

A formal system of inference consists of three components: (1) a syntactically well-defined language adequate to formulate assertions about the application domain, (2) a set of distinguished assertions—so-called axioms—whose validity in the application domain is taken for granted, and (3) a set of inference rules used for the derivation of new valid propositions from existing ones.

The syntax of the language of a logical calculus is defined with respect to a symbol set specific to this calculus. In the case of propositional logic, this set contains three types of symbols: (1) connectives like $\neg$ ("not") or $\rightarrow$ ("if . . . then . . .") that can be used to form complex sentences from simpler ones, (2) punctuation symbols like that allow formulating nested sentences, and (3) an unlimited repertoire p, q, . . . of so-called propositional variables that represent the atomic parts of sentences.

Like mathematical variables, propositional variables can be assigned values. In the case of logic, possible values are "true" or "false": A certain propositional variable is set to "true" if one believes that the respective proposition holds in the application domain. Otherwise this proposition variable is set to "false."

Propositional variables are the basic (atomic) building blocks of the sentences of propositional logics. The following syntactical rules recursively describe how complex sentences, so-called well-formed formulas, can be systematically built using the available connectives:

1. Every propositional variable is a well-formed formula.
2. If ϕ is a well-formed formula, then so is $\neg\phi$ ("not ϕ").
3. If ϕ and ψ are well-formed formulas, then so is $\phi \rightarrow \psi$ ("if ϕ then ψ").

With the help of compound formulas, complex propositions can be expressed: Let us, for example, assume that the propositional variables p and q represent the elementary propositions "Abraxas is a raven" and "Abraxas can fly." The formula $(p \rightarrow q)$ then expresses the proposition "If Abraxas is a raven then Abraxas can fly," and the formula $\neg p$ represents the proposition "Abraxas is not a raven."

In order to improve the readability of complex logical formulas, propositional calculus offers additional logical connectives mirroring how humans form complex sentences from more primitive ones. Two of these connectives, the logical connectives $\vee$ ("or") and $\wedge$ ("and"), can be defined in propositional logics from the basic connectives $\neg$ and $\rightarrow$:

1. $(\phi \vee \psi)$ ("ϕ or ψ") as a shorthand for $(\neg\phi) \rightarrow \psi$, and
2. $(\phi \wedge \psi)$ ("ϕ and ψ") as an abbreviation for $\neg(\phi \rightarrow \neg\psi)$.

Hence, if the propositional variable r represents the statement "Abraxas is black," then the compound formula $(p \wedge r)$ can be used to say "Abraxas is a black raven" and the formula $(p \vee r)$ to express "Abraxas is either just a raven, just a black thing, or a black raven."

Once the interpretation of the propositional variables is fixed, the truth-values of arbitrary complex formulas made from these propositional variables can be determined. For this purpose, the truth-values of their subformulas have to be combined according to the meaning of the connectives gluing these subformulas together. If, for example, we assume that Abraxas is a regular raven, which therefore can fly, that is, p = *true* and q = *true*, then the meaning of the connective $\rightarrow$ forces the value of the formula $(p \rightarrow q)$ to "true"; but if we know that Abraxas had a fight with a cat that injured one of his wings and left him as a bird that no longer can fly, that is, p = *true* and q = *false*, then $(p \rightarrow q)$ will evaluate to "false."

A well-formed formula is called logically true (valid) if it evaluates to "true" for any possible combination of truth-value assignments to the propositional variables contained in it. Valid formulas form the basis of logical arguments because they are indisputable by definition. The formula $(p \vee \neg q)$, for example, evaluates to "true" whether the propositional variable p is interpreted as "The moon is made from green cheddar cheese," and therefore set to "false," or whether it is interpreted as "√2 is an irrational number," and therefore set to "true." The formula $(p \rightarrow q)$ on the other hand is not a valid one, because the meaning of $\rightarrow$ forces it to yield the value "false" if p is set to "true" and q is set to "false."

The classical propositional calculus is designed to characterize just those sentences that are valid. The key to this characterization is axiom schemata. Axiom schemata look like regular logical formulas but contain schema variables ϕ, ψ, . . . instead of propositional variables as basic building blocks. If each occurrence of a schema variable in an axiom schema is replaced by the same formula, an axiom results. Axiom schemata therefore serve as compact representations of big collections of axioms.

The logician Lukasievicz has shown that the following three axiom schemata suffice for a separation of the valid formulas of propositional logic from the nonvalid ones:

L1: $(\phi \rightarrow \psi) \rightarrow ((\psi \rightarrow \theta) \rightarrow (\phi \rightarrow \theta))$.

L2: $(\neg \phi \rightarrow \phi) \rightarrow \phi$.

L3: $\phi \rightarrow (\neg \phi \rightarrow \psi)$.

Schema L1 states that "if . . . then . . ." relationships are transitive. Schema L2 evinces that a proposition ϕ will hold if this proposition is a consequence of its negation $\phi \neg$ (*consequentia mirabilis*). In addition, schema L3 specifies that from a contradiction, as it is evident when both ϕ and $\neg\phi$ are given, anything (ψ) can be concluded (*ex falso quod libet*). Any instantiation of each of these schemata yields a formula that is valid in propositional logics. For example, one such instance is the axiom

$$(p \vee q) \rightarrow (\neg (p \vee q) \rightarrow \neg r)$$

which results from L3 by substituting ϕ with $(p \rightarrow q)$ and ψ with $\neg r$. This axiom evaluates to true whatever truth-values are assigned to the propositional variables p, q, and r.

From the logical axioms corresponding to L1–L3 and additional formulas, which the user of the calculus may have set as given for the application domain, new formulas—so-called theorems—can be derived by the following inference rule:

> If formulas ϕ and $(\phi \rightarrow \psi)$ have been derived in an earlier stage of the argument, then the formula ψ has the status of being derived as well.

This rule is called Modus Ponens. It is a safe inference rule: Any truth valuation of propositional variables that renders both ϕ and $(\phi \rightarrow \psi)$ true forces ψ to be true as well. Modus Ponens therefore allows reasoning with propositional formulas independently of their interpretation. It reduces reasoning to an act of symbol manipulation where new valid formulas are mechanically constructed from other valid formulas.

If, for example, the propositional variables $p1$ and q represent the statements "It is raining" and "The streets become wet," respectively, then one is justified to claim q as soon as both P and $(p \rightarrow q)$ ("If it is raining then the streets become wet") have been concluded. One can safely do so even if one does not have the slightest idea of what rain actually is and why streets in the real world are made wet by it.

Extending Propositional Logic to Temporal Logics

One way to introduce temporal specifications from natural language into formal logics amounts to extending formal logics by temporal modalities like "It was the case that" and "It will be the case that." Prior used the symbols p ("past") and F ("future") for this purpose. In order to simplify the expression of temporal statements he also introduced the following two derived modalities: H ("It always was the case that") for $\neg P \neg$ ("It was not the case that not") and G ("It will always be the case that") for $\neg F \neg$ ("It will not be the case that not"). The temporal modalities modify the proposition they are subjected to: The sentence $p\phi$ represents the temporal statement "ϕ was true in the past" and the sentence $F\phi$ the statement "ϕ will be true in the future."

Since temporal statements can be further modified by temporal modalities, complex temporal specifications expressed in natural language can be formulated in the language of temporal logic as well. If, for example, one wants to express that the event q, "It is raining," had happened in the past and before the event r, "The streets become wet," one can do so with the temporal formula $P(Pq \wedge r)$. Or, if one wants to assert that "It always rains (ever since, now, and forever)" then one can do so with the formula $(Hq \wedge q \wedge Gq)$.

According to Prior, the meaning of the temporal modalities has to be drawn from natural language. Natural language refers to the present with the help of *tempora verbi* and expressions like "yesterday" or "the day after tomorrow." Prior therefore states that even temporally unmodified sentences of temporal logic always have a relationship to the present. A temporally unmodified propositional formula ϕ in a temporal logic therefore always is supposed to mean, "ϕ holds right now." The point in time that represents the present and with respect to which a temporal formula is evaluated is also called the index of evaluation of this formula. Temporal operators like P or F shift the evaluation index to a point in the past or the future, respectively.

Depending on the specific conception of time one wants to formalize, the logical axiom schemata L1–L3 have to be augmented by a set of temporal axiom schemata that regulate how to draw temporal conclusions correctly. Any axiom setup of this kind implicitly defines a logic with its own temporal characteristics. All temporal logics by Prior set minimal temporal requirements by postulating the following three temporal axiom schemata:

T1: $H(\phi \to \psi) \to (H\,\phi \to H\,\psi)$ as well as $G(\phi \to \psi) \to (G\,\phi \to G\,\psi)$.

T2: $(PG\phi \to \phi)$ as well as $(FH\phi \to \phi)$.

T3: If ϕ is an axiom, then $H\phi$ and $G\phi$ are axioms as well.

Schema T1 describes how temporal and logical reasoning interact: If ϕ did always follow from ψ in the past $(H(\phi \to \psi))$, then, if ϕ was always true in the past, then ψ was also always true in the past $(H\,\phi \to H\,\psi)$; and, if it always will be the case that ψ follows from ϕ $(G(\phi \to \psi))$, then, if ϕ will always be the case, so will be ψ $(G\phi \to G\,\psi)$. T2 controls the interaction between the temporal operators: If at some time in the past, ϕ was clear to be always the case in the future $(PG\phi)$, then ϕ must also hold at present (ϕ); and if at some time in the future, it will be clear that ϕ was the case ever since $(FH\phi)$, then ϕ must hold now as well (ϕ). The precondition in T3, that ϕ is an axiom, is essential for schema T3 to produce only valid formulas.

According to Edward Lemmon, the temporal logic K_t (t for "time") resulting from the logical axioms L1–L3, the temporal axioms T1–T3, and the inference rule Modus Ponens is called minimal temporal logic. Minimal temporal logic, for example, allows the mechanical derivation of

$$F(\phi \wedge \psi) \to (F\phi \wedge F\psi).$$

This formula states that, if one knows that at some time in the future both ϕ and ψ hold $(F(\phi \wedge \psi)$, then there must be times in the future where ϕ and ψ hold $(F\phi \wedge F\psi)$. The converse statement $(F\phi \wedge F\psi) \to F(\phi \wedge \psi)$, in accordance with intuition, is not mechanically derivable in K_t: Just knowing that two events ϕ and ψ will take place at some time in the future $(F\phi \wedge F\psi)$ does not justify the claim that they will take place simultaneously at the same time in the future $(F(\phi \wedge \psi)$.

An interesting meta property of the minimal temporal logic K_t is directly visible in schema T1, T2, and T3: The mirror image of a formula ϕ is always derivable in K_t if ϕ itself is derivable in K_t.

If ϕ is a temporal formula, then its mirror image is the formula obtained by simultaneously replacing each occurrence of the modality F by P and vice versa. The formula $F(\phi \rightarrow P\psi)$, for example, is the mirror image of the formula $P(\phi \rightarrow F\psi)$, and $GP\phi$ is the mirror image of $HF\phi$ due to the definitions of the temporal modalities G and H. The mirror image of the mirror image of a formula ϕ, of course, is ϕ again.

Branching Structure of Time

The minimal temporal logic K_t already sets the necessary preconditions for mechanized temporal reasoning. However, it does not make any specific commitments with respect to possible structures of time. In order to formalize these structures, Nicholas Rescher and Alasdair Urquhart invented what they called branching (tense) structures.

A branching structure is a precedence relation < on events where $e_1 < e_2$ means that the event e_1 is temporally located before event e_2. Branching structures have to fulfill two conditions: transitivity and backward linearity. They are transitive if for any three events e_1,e_2, and e_3, $e_1 < e_3$ whenever I and $e_2 < e_3$. They are backward linear if for any two events e_1 and e_2 both preceding a third event e_3 (i.e., $e_1 < e_3$ and $e_2 < e_3$), the following holds: Either $e_1 < e_2$, or $e_2 < e_1$, or e_1 and e_2 occur at the same time.

In a branching tense structure, many different paths leading from an event into its futures may exist, but the past of this event, that is, the set of events preceding it, is always uniquely determined. Any path in a branching structure, that is, leading from earlier to later events and cannot be extended into the past or the future, describes a possible course of events (a temporal branch) allowed by the given branching structure. Temporal branches may be of infinite length. They may even contain temporal cycles: sequences of temporally ordered events where the last event coincides with the first. A branching tense structure that (1) does contain an earliest event e_0 (representing the origin of time), (2) does not exhibit branches with temporal cycles, (3) does not fall apart into completely separated temporal substructures, and (4) has the property that any event has a uniquely determined event immediately preceding it, can be imagined as a tree. All branches of this tree are labeled with events: The root of this tree is labeled with e_0 and the other branches with those events that immediately precede the events at the branches they directly lead to. Backward linearity ensures for treelike branching structures that there is exactly one uniquely determined path from any event back to the origin of time.

An event that has more than one immediate successor in a branching tense structure is called a branching event. An event e_2 is called determined with respect to another event e_1 of a branching structure, if this structure does not contain a branch that starts at e_1 but does not eventually lead to e_2. In this case, either e_2 has to lie in the past of e_1, or e_2 lies in the future of e_1 and the branch connecting e_1 and e_2 does not contain any branching event (e_1 included).

If e_3 is not determined with respect to e_1, then e_1 is said to lie in the open future of e_1. Depending on what happens at the branching nodes on the path connecting e_1 and e_1, e_3, may eventually occur or not. In a completely determined branching tense structure any event is determined with respect to any other event and the branching structure degenerates into a linear order of events where no event has an open future.

Branching Time Logics

Branching time logics assume that time has a branching tense structure with open futures. The simplest branching time logic Kb (b for "branching") results from augmenting minimal time logic Kt by the following two axiom schemata:

T4: $H(\phi \rightarrow HH\phi)$ as well as $(G\phi \rightarrow GG\phi)$.

T5: $(P\phi \wedge P\psi) \rightarrow (P(\phi \wedge \psi) \wedge \psi) \vee P(\phi \wedge P\psi) \vee P(P \vee \psi)$.

Axiom schema T4 characterizes time as exhibiting a transitive branching structure: If ϕ was always true in the past ($H\phi$), then it was always true in the past that ϕ had been always true in the past ($HH\phi$); and (according to the corresponding mirror image schema): If ϕ will always hold in the future ($G\phi$), then at any future time, we can be sure that ϕ will hold in the future ($GG\phi$).

Axiom schema T5 commits time with respect to its past as a backward linear structure: If ϕ and ψ were true at two (maybe different) times t and t' in the past ($P\phi \wedge P\psi$), then either $t = t'$ and therefore $P(\phi \wedge \psi)$, or t' precedes t forcing $P(\phi \wedge P\psi)$, or t precedes t' entailing $P(P\,\phi \wedge P\psi)$.

As in the minimal temporal logic K_t, only the Modus Ponens rule is needed for deriving theorems like, for example,

$$(H\phi \wedge \phi \wedge G\phi) \rightarrow GH\phi$$

from the axioms specified by L1–L3 and T1–T5. This formula states: What was always true ($H\phi$), is true now (ϕ), and will be true forever ($G\phi$), has the property that at any future time it will be true that it was always true in the past ($GH\phi$).

Branching time logic K_b, in accordance with intuition, gives time a treelike forward branching structure leaving open alternative futures while excluding an ambiguous past.

Linear Time Logics

Linear time logics make even stronger commitments on the structure of time. The simplest linear time logic K_l (l for "linear") augments the branching time axiom schemata T1–T5 by axiom schema

T6: $(PF\phi) \rightarrow (P\phi \vee \phi \vee F\phi)$.

This schema requires that any proposition ϕ, for which at some time in the past it was true that ϕ would be true at some later time ($PF\phi$), either must have been true in the past ($P\phi$), hold at present (ϕ), or will be true at some time in the future ($F\phi$).

K_l forces a linear structure upon time and therefore uniquely determines both its past and its future. With $\phi = \neg\, q$, T6, for example, excludes a temporal structure, which declares a proposition q true at some time in the past while leaving a chance that its status today is false ($\neg\, q$) and not true (q) until today and beyond. Such a temporal structure would make ($PF \neg\, q$) true without making at least one of ($P \neg\, q$), $\neg\, q$, or ($F \neg\, q$) true at the same time and therefore contradicts the temporal postulate T6.

Linear time logic K_t, for example, allows the derivation of proposition ($\phi \rightarrow HF\phi$): Of anything true at present (ϕ) it always was clear that it would hold at some time in the future ($HF\phi$).

There exist, of course, many more ways to specify the structure of time consistently and in even finer detail than the simple temporal logics we have sketched so far. It is, for example, possible to force a dense structure on linear time via the axiom schema

T7: $(F\phi \rightarrow FF\phi)$ as well as $(P\phi \rightarrow PP\phi)$.

If an application demands this axiom schema to hold, then it assumes that between any two points in time there is at least one more point in time where an event can happen. Another axiomatic extension of linear logic ensures the opposite by underlying time as a discrete structure. Using appropriate axiom schemata, time can also be given a start or an end: Adding

T8a: $G\phi \vee FG\phi$

to Kl forces time sooner or later to come to an end, and adding

T8b: $H\phi \vee PH\phi$

results in time not extending infinitely into the past. If, on the other hand, one wants to make sure that time does not have an end, one can do so by postulating the axiom schema

T9a: $F\,(\neg\,\phi) \vee F\phi$,

while a commitment on

T9b: $P(\neg\,\phi) \vee P\phi$

expresses the assumption that time has no beginning. T8a and T9a as well as T8b and T9b, of course, are axiom schemata that are pairwise incompatible with each other—an attempt to add them simultaneously to K_l would result in an inconsistent and therefore useless logical theory from which anything could be concluded.

Spacetime Logics

Branching structures are not restricted to purely temporal relationships between events. A complex interaction of temporal and spatial aspects, for example, occurs in Nuel Belnap's theory of branching spacetimes. This theory generalizes

Rescher and Urquhart's theory of branching time by allowing histories (complete courses of events) to be not just linearly ordered sets, but spacetimes with a relativistic causal ordering: The interior of the forward light cone in Minkowski space contains the possible futures of a spacetime point—those locations that can still be reached from and affected by it by sending a signal at a speed slower than light. The theory of spacetime also addresses questions of causality because in spacetime structures the ordering relation "e_1 precedes e_2" can be understood as "e_1 could cause e_2."

Until recent work by Thomas Müller it was not evident that a tense-logical language can adequately work in the context of special relativity: Special relativity rigorously defines which events are simultaneous for any observer and any given point on his world line. Depending on the respective frames of reference used by observers, and their relative movement, they may or may not agree upon the presentness of an event. A simple tense logic like K_b therefore cannot consistently model relativistic affairs. What is needed instead is a generalization of simple tense logic of the type that Müller calls a "logic of points of view," that is, a logic where (1) the index of evaluation includes an inertial frame of reference and (2) there are (modal) operators available to shift that index. In the simplest case such a logic would provide a propositional modal language, where the propositions refer to what is true or false at "moments" that are given by spacetime points in the sense of Belnap and not just time points as in nonrelativistic logics of time.

Applications of Temporal Logic

Not any arbitrary axiomatic commitment to the structure of time is intuitively plausible or even useful for practical applications or philosophical considerations. In order to be appropriate for the application of logical methods, potential application domains should profit not only from being describable in its relevant spatiotemporal aspects. The corresponding descriptions should also allow for drawing valuable conclusions about the respective domains.

Typical application domains for temporal logics therefore are fields like the philosophy of language, the field of linguistics (especially the subfield of computational linguistics, which studies computer models of language), the field of computer science (especially the subfields studying the specification and verification of dynamic technical systems), the field of artificial intelligence (especially the subfield studying automated planning of actions that intelligent agents perform in order to achieve certain goals), or the field of systems biology (especially the subfield studying the dynamics of biomodels). All these fields, like philosophical logic in general, utilize formal tools and methods of symbolic logic in order to approach questions of foundational relevance for their theoretical and practical advancement.

Time, Measurements of

Time is commonly defined as a measured or measurable period during which an action, process, or condition exists or continues. Throughout history, time has been measured by various cultures in standard natural units of days and years, and in hours, minutes, and seconds or their equivalents. Weeks and months were culturally selected for civic preference.

Time is measured in discernible units, all related to solar and lunar motion across the terrestrial sky. From an observational perspective, it is easy to understand the reasoning behind the geocentric model holding influence over culture for so many centuries. The most basic measurement of time is the length of the day, or the time it takes for the sun to complete an apparent circle in the sky beginning at the local meridian. The true motion is the earth rotating on its axis; however, time measurements were developed from a geocentric perspective.

Origin of the Day

The length of day was assigned the closest number of periods that fit between solar meridian transits. Mathematicians and archaeologists credit the origins of the time divisions back to the Sumerians, who employed a base-12 counting system. Various theories state that, excluding thumbs, there are 24 segments on the remaining eight human fingers, which Sumerians are believed to have used as a basis for counting. At night, time was measured by the appearance of given stars crossing a certain sky point to mark the time passage. For tracking time during the day, the sundial was invented.

The Babylonians improved this division by segmenting the day into 12 hours (each twice the modern length). Furthermore, the hour was subdivided into 60 units (another base-12 factor), and then divided again by 60 to define the smallest unit. Using factors of 12 kept things simple, and archaeologists know that Babylonians utilized a base-60 (sexagesimal) counting system. The sexagesimal concept has been retained for many centuries because it is simple and reliable. It is no surprise, then, that measurements of geometrical shapes are also in a sexagesimal (extended base-12) system of 360°.

Origins of the Hour, Minute, and Second

When the ancient Greeks required a standard for measuring time, they asked the philosopher Hipparchus to devise a system for planning events. As a result, Hipparchus applied the concept of divisions based on an equinoctial system (equal day and night). This occurred at the equinoxes, and was called *Hora,* the Greek word from which we derive "hour." Hipparchus, however, considered only the daylight hours when making these divisions. Ptolemy later defined geometrical divisions of the circle into 60 (*minuta*) and in turn divided *minuta* again by 60 (*secunda minuta*). To this day, clocks are still circular with 60 divisions. Eventually, the geometric system was copied to the measuring of time, and the minute and the second were applied.

The Calendar

Calendars were developed to track the passage of days. The first calendars date back to the time of Mesopotamia, but the Greeks are credited with being the first to attempt to use a standard form of measurement based on the motion of the moon around the earth. The Romans created a separate solar calendar, which became the basis for our modern calendar. Several revisions were made, including adding months to synchronize the lunar and solar cycles, rearranging month lengths, and rearranging monthly delineation. Over time, political issues throughout the empire resulted in an unreliable calendar, and Julius Caesar reorganized the calendar into a standard measurement. The Julian calendar was adopted circa 46 BCE. The lengths of the months in the 12-month Julian calendar remained centered on the lunar cycle, and alternated 30- and 31-day lengths. The only exception was February, which contained only 29 days in order to maintain calendar reliability. Originally, January and February occurred at the end of the calendar year, but eventually the Julian adaptation moved them to the start of the year instead. The result was a misalignment of the names of months with their position in the year: For example, the 7th month, prefixed *septem,* Latin for "seven," became the 9th month.

The Week

Grouping days into a week was done mostly as a matter of civil convenience. Many civilizations have had varying numbers of days in the week, usually based around civic events. The Babylonians began the practice of the 7-day week due to their belief that the number 7 was sacred. In addition, other religions give importance to the number 7, particularly Judaism and Christianity. The most apparent characteristic of choosing a 7-day week, however, is the equivalency of the lunar phase points and the lunar cycle. The names assigned to the days of the week were those of the Roman gods related to the seven known nonstar objects (see Table 1).

The Month

The month was based on the lunar cycle. The lunar synodic cycle, or the time it takes the moon to complete a meridian cycle, is 29.5 days. As a result, most calendars reflect this in an average 30-day cycle. Each cycle consists of a full set of lunar phases measured between each new moon phase. Additional days are appended to certain months in order to round out the earth's orbital period and reach to the return of the summer solstice, or the point at which the sun is highest in the sky. The names of the months are also taken from cultural gods of interest, as well as some notable historical figures (see Table 2).

The Year

The measurement of the time between the summer solstices marks one complete orbit of the earth around the sun and became known as the year. The year is the basis for most historical measurement, including how humans measure age. The concept of the year and the four seasons has been constant for more than 4,000 years. Regardless of whether a culture employed a solar or a lunar calendar, most had a concept of marking the earth's revolution around the sun (although for most of this time people believed it to be the sun's motion around the earth).

Time Zones

When dividing the earth's angular sum of 360° by 24, the result is 15°. For each hour, then, there is 15° of the earth's sphere that can see the sun in a relatively common position. It is common practice now to use these lines of longitude on a globe, where each line of longitude represents one official time zone. Therefore, there is a 1-hour lag in solar position at the time zone extremes, so sunrise and sunset times will vary within a given zone. For example, sunrise and sunset between Boston and Detroit (both in the Eastern Time Zone) differ by nearly one hour; sunrise in Madison, Wisconsin, at the eastern edge of the Central Time Zone is similar to the Boston sunrise, but time tables in Pierre, South Dakota, on the western edge of that time zone, are similar to time tables in Detroit.

Celestial Time

Astronomically, time is measured from one standard location in order to keep stars at a constant sky position. This system, called the equatorial coordinate system, measures locations in right

Table 1 Origins of weekday names

Day	*Original Meaning*	*Culture*	*Roman Deity*	*Other Deity*	*Celestial Object*
Saturday	Saturn's Day	Roman	Saturn	N/A	Saturn
Sunday	Sun's Day	Old English	N/A	N/A	Sun
Monday	Moon's Day	Old English	N/A	N/A	Moon
Tuesday	Tyr's Day	Nordic	Mars	Tyr	Jupiter
Wednesday	Wodan's Day	Nordic	Mercury	Wodan	Mercury
Thursday	Thor's Day	Nordic	Jupiter	Thor	Jupiter
Friday	Freya's Day	Nordic	Venus	Freya/Frigg	Venus

Table 2 Names of the Julian and Gregorian months

Month	*Culture*	*Deity*	*Deity Function*
January	Roman	Janus	Beginnings/Endings
February	Etruscan	Februus	Keeper of the Underworld
March	Roman	Mars	God of War
April	Roman	N/A	Named for the word *aperire*; to open or bloom
May	Roman	Maiesta	Goddess of Honor
June	Roman	Juno	Queen of the Gods
July	Roman	N/A	Julius Caesar
August	Roman	N/A	Augustus Caesar
September	Roman	N/A	Latin; Septem, or seven
October	Roman	N/A	Latin; Octo, or eight
November	Roman	N/A	Latin; Novem, or nine
December	Roman	N/A	Latin; Decem, or ten

ascension and declination, allowing astronomers to pinpoint exact celestial locations for observational accuracy. The right ascension divides the 360° of the sky into 15° segments synonymous with the earth's longitudinal system; each line of right ascension marks 1 hour of clock time. Declination is the height above or below the celestial equator. This type of coordinate system allows astronomical time to be constant for every star. Due to sidereal variation, the coordinates on the equatorial system will shift progressively from night to night.

Time, Nonexistence of

Time's movement is apparent to us in the rising and setting sun, the seasons, birth, growth, and death. Throughout history these changes have been seen as a flow from the past into the future. That flow exists alongside another aspect of time—the present. The present is where I am writing this article and though it is obvious time moves from the present into the future, philosophers have often debated that fact and some even claim that time does not exist.

Before deciding about the existence or nonexistence of time, a definition is needed, which is where the problems begin. Time is defined as a duration; possessing past, present, and future; every moment that has been or will be; the entire period of existence of the known universe; a system of measuring duration; a precise instant; and a measured interval, to name just a few. With so many different definitions it is difficult even to discuss the subject.

Physical time, however, is the subject of this entry. As to its definition, there may be no better authority than Albert Einstein, who succinctly stated that time is *what the clock measures.* This time is represented by the *t* variable found in physical formulas that we use to put satellites into orbit, calculate the speeds of falling bodies, measure the motions of planets, and many other things.

Physical time as we know it didn't always exist. Long ago there were no clocks and no formulas that possessed a *t.* Time was not measured in seconds or minutes or hours. It was defined by sunrise, sunset, mid-morning, noon, afternoon, and early evening.

Time: A Standard Motion

This relaxed view of time began to change when ships began sailing on the open seas. For sailors, transportable mechanical instruments—clocks—that matched exactly the spin of the earth became a matter of life and death. Knowing an exact time, combined with sky charts, allowed navigators to calculate a ship's distance from ports and shoals. Clocks started out as imprecise timekeepers, which led in turn to imprecise charts, incorrect locations of shoals, and shipwrecks. Of course clocks didn't improve instantaneously. It was an evolutionary process with a huge selective pressure for perfection.

The gut of a mechanical clock is called its movement. That movement is a miniature earth whose hours, minutes, and seconds, respectively, represent smaller portions of that spin.

Time is not usually thought of as distance, but a second, or 1/86,400 of a mean solar day, represents about 30 meters of the spin of the earth. As clocks became more precise, they were in the race to be the official standard of measurement. Each swing of a pendulum has a period of motion determined by its length. The definition of the meter was once the length of a pendulum having a half-period of one second. The earth's motion, the clock's motion, and distance were all elements of time.

But since the period of a pendulum is determined by the force of gravity, and gravity varies slightly over the surface of the earth, this produced clock error. So motion was removed from the definition of the meter and replaced by: one 1/10,000,000 of the length of the earth's meridian that passes from the pole to the equator through Paris. Just when a distance seemed secure as a standard for the meter stick, it was deposed again by time and the movement of a clock. Today that clock does not track the earth's spin but is defined as "the time interval equal to 9,192,631,770 periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the cesium-133 atom." That movement also defines the meter: the length of the path traveled by light in vacuum during a time interval of 1/299,792,458 of a second.

This brings us closer to understanding the nature of physical time. It is a uniform and unvarying motion that we use to measure other motions, and distances. When your boss says, "Come to a meeting at eleven or get fired," what he is saying is that his motion and your motion should cross paths simultaneously with a certain position on the clock face, whose hands are a standard motion. People are examples of nearly random motion since they regularly stop, start, and change their speeds and directions. A standard reference motion such as a clock helps us gauge our activities so that we can arrive at places on time.

If no regular motions existed—for example, if the earth didn't spin and the sun were always at high noon—the question "What time is it?" would have no meaning. The time would be the same time it always was, high noon. So the answer to the question, "How fast does time flow?" is *time moves exactly as the earth spins.*

In a broader view, time represents a class of motion, call it a subset of motion. Which is to say that as far as can be determined, physical time is a useful uniform motion.

Time Dilation and Biological Clocks

Until the beginning of the 20th century, scientists had the sense that time was a steady, unchanging flow. The invariant flow of time came to an end in 1905, when Albert Einstein formulated the special theory of relativity. He showed that motion affected how clocks kept time. A fast-moving clock, really fast moving, keeps slower time. This has since been shown to be true with atomic clocks. That helped end the notion that a clock in one part of the world would keep precisely the same time as a clock elsewhere. Studies of high-speed subatomic particles show that their rate of decay slows down in relation to their speed of travel, according to the predictions of special relativity. Known as time dilation, this slowing of clocks established that time can flow at different rates in moving frames of reference.

The effect of time dilation has been expressed in the "twins story." Imagine one twin becomes a space traveler while the other stays on earth. The traveler takes a one-year journey into space at nearly the speed of light and discovers on returning home that his twin has aged 50 years. Time for the traveler had slowed down.

Relativity predicts that this slowing is even more dramatic the closer one travels to the speed of light. At light speed, all clocks come to a dead stop. A traveler with a relativistically stopped clock would not experience time, or anything at all. For him, travel across the universe would be instantaneous; indeed, infinite time would pass by instantaneously. Of course, earthbound clocks would measure the duration of a trip across the universe in the billions of years.

What is the meaning of Now in radically different speeding frames of reference? At the speed of light, the Now of a stopped clock is a frozen instant of time that contains the whole time span of the universe. Clearly, if living observers could travel close to that speed they would have deep differences of opinion about the flow of time and the meaning of the present. For this reason, philosophers tell us the Now has no meaning in our universe.

Bio-Relativistic Speed Limit

However, philosophical speculations about the existence of the Now seldom take into account biological laws. It is widely assumed in writings about relativistic travel that life can exist at high speeds. Yet to date no one (to my knowledge) has examined how the laws of relativity will affect biological clocks.

For a century it has been hypothetically assumed that a biological clock moving at high speeds will slow down similarly to a mechanical clock. The operative word is hypothetical. In physics, observers are not real live actors in experiments. They are ghosts looking at what takes place. Somewhere, storytelling by physicists dropped the "hypothetical" and replaced it with real live observers. Live observers, however, are multicellular organisms whose cells are packages of chemical soups. The clocks within each cell are not gears, they are baths of molecules, ions, and atoms that are in constant motion. Called "Brownian motion," this is high-speed random molecular motion to and fro, up and down, that assists in biochemical reactions.

Biological clocks, therefore, can be reduced to particles in motion that must follow exactly the same rules examined by physicists in particle accelerators. Those studies confirm that molecules that approach the speed of light will require geometrically larger amounts of energy for each incremental increase in speed. How would this affect the rapidly ricocheting molecules within the cells of a speeding observer? Unlike at slow speeds, near the speed of light Brownian motion in the direction of travel would be restricted and shortened. This is because the forward direction of motion requires substantially more energy than any other direction. This effect becomes pronounced near the speed of light, where it would take energy approaching infinity to accelerate a molecule faster in the direction of travel.

What would happen inside the cell? Imagine being a tiny observer who could throw a ball in the direction of motion toward a cell wall. As you started to throw, your arm would feel a strange force. This would be caused by the increased energy needed to accelerate your arm in the direction of motion. If the ship was moving fast enough, you would barely be able to move your arm in the forward direction. And when you let the ball fly, it would move very slowly. Even more perplexing, if you threw the ball in the opposite direction, your arm wouldn't feel that force. The ball would fly quickly toward the cell wall. But when the ball rebounded off the wall it would immediately slow.

This asymmetric movement of particles would lead directly to strange activities within the cell. Each molecule, especially those freer to move, would move more distance toward the cell wall opposite the direction of travel. Over time the more mobile molecules would accumulate in that region. The same thing would be happening to all the motions of particles within the cell. Molecules in the electron transport chain would end up in the wrong locations. Electrons would not be transported. Cellular systems would be disrupted.

Since life itself depends upon the isotropy of Brownian motion, it seems no theoretical possibility exists that we can move at high relativistic speeds. Relativity, contrary to what has been written, establishes that high-speed motion will extinguish life. Why the relativistic effects of Brownian motion have remained unexplored until now is because biologists seldom or never study physics, and physicists seem desperately to want to travel to the stars someday.

As yet we do not know what that biorelativistic speed limit is. Can cellular systems tolerate a 0.1%, 1.0%, or a 10% increase in relativistic mass? We don't know. Even small changes in the energy needed to accelerate particles faster could accumulate into a statistical and fatal disruption of biological engines. It seems likely that a 1.0% increase in relativistic mass, which corresponds to travel at 14% the speed of light, may be a maximum upper speed limit for life, though the speed limit is most probably at an even slower speed.

A quirky discovery about where we live supports the existence of a biorelativistic speed limit. Radio telescopes have found background radiation that appears left over from the event marking the origin of the universe, known as the big bang. This radiation can be used as a benchmark of speed and shows that our planet is moving through space at about 380 kilometers per second, a little faster than one-thousandth the speed of light, or about 800,000 miles per hour. This is really fast by vehicular standards but very slow by cosmological standards.

We are moving so slowly that it poses a pivotal philosophical question. We could claim we are unique, but when arguing about humanity's relationship to the universe it is widely agreed that the proper argument is to assume we are not unique. From a statistical point of view it makes sense that it is more likely we are average than a rare example of life. Similarly, it is more likely that the conditions of our evolution represent the standard conditions for the evolution of life elsewhere. It follows then that life elsewhere is likely to exist at the slow end of the speed spectrum too. And, like us, it probably can't travel at relativistic speeds either.

Why would life be concentrated at the slow end of the speed spectrum? One possibility is that the statistics of evolution requires low not high relativistic speeds. An object moving at near the speed of light experiences the birth and death of the universe in an instant. At such speeds the moving object has a stopped clock where no or little physical change is taking place. In contrast, evolutionary change requires the high clock speed characteristic of slow-moving matter.

The origin of intelligent life is built upon a long chain of chance chemical interactions beginning with the big bang that took place around 15 billion years ago. The first stage of life formation was the making of heavy atoms such as carbon in the nuclear furnaces of stars. How long this took is uncertain, but it would likely have been billions of years. Next this material was ejected back into space as a result of supernova explosions. This material then became part of new star formation. The solar system appeared about 5 billion years ago. Biological laws of evolution require that a planet possess proper conditions, and a vast number of chemicals and molecules that can interact. Evolution may even depend upon the regular cycle of night and day. So after about 12 billion years of chance chemical and nuclear reactions, and then 3–1/2 billion years more of chance biological evolution, we finally appeared. All of this took a high clock speed.

Observation of the background radiation shows that biological clocks are running at about the highest clock speed possible. It is hard to know if we are at the leading edge of the evolution of intelligent life, but we certainly are not at the tail end. Taking the above into account, our speed through the universe does not seem unique; it is the speed at which life would be expected to evolve.

This has theoretical implications. Physicists tells us that "time is relative," but the laws of evolution, the biorelativistic speed limit, and star formation suggest that slow speeds are good for the evolution of life. Time becomes significantly relative only at high speeds where intelligent life probably has not yet had time to evolve and may never evolve. That being the case, intelligent life in the universe is likely to share a similar time frame, which would mean that for life, *time is not relative.*

Frozen Motion

The arrival of the general theory of relativity raised new problems concerning the nature of time. Almost anyone could understand Newtonian physics, but few understood the full implications of Einstein's general theory, as it is called. His gravitational field equations were a mathematical laboratory for experimenting with the nature of time and space.

Enter Kurt Gödel, who had gained fame for his solution to a vexing problem concerning the logical foundation of mathematics known as the incompleteness theorem. Both Gödel and Einstein had escaped Nazi Europe to live near Princeton University in the state of New Jersey. There they became good friends.

Gödel surprised Einstein with calculations concerning time based on the formulas of general relativity. He played with the variables to create a universe where the distribution and motion of matter caused the axis of time to bend around and connect with itself to form a time loop or circle. This result is known as a closed timelike curve (ctlc). If one were caught in this time loop, every year forward would represent a year closer to the past. This is strange, because in our universe time moves only from the present to the future. The past is gone completely.

Interpreting the nature of the universe from gravitational field equations is tricky. Those equations do not include important laws such as the second law of thermodynamics, which shows that the direction of time is toward the future, not the past.

Assuming Gödel's universe behaved like ours quickly leads to paradoxes and inexplicable physics. In Gödel's universe, all matter must ultimately return exactly to an earlier physical and temporal state. On a trip into that universe you would find that light behaved strangely. After leaving the sun it would someday converge back onto the sun and unite with the same electron from which it came. Think of it as a wind-up toy. When the toy quits moving in Gödel's universe, the hand of a mysterious force must reach down and push the toy backward to rewind it so that it can run down again. The Gödel universe was a cyclic winding and unwinding of the universe. There the fusion of hydrogen to make helium within the sun would have to reverse each time the toy ran down. The heat and light that left billions of years ago would have to be sucked back from intergalactic space. That also means that all the molecules in existence, all the photons, subatomic particles, and the solar wind would ultimately reverse directions and return to their place in the sun.

But such physical activity is contrary to known laws. For example, hydrogen fusion, a reaction in the solar furnace, is caused by gravitational forces that squeeze atoms together so that the reaction can take place. To reverse that action would require the reversal of gravity. The result, of course, would not be a return to a prior condition. Gravity is not a time-symmetric force like other forces of nature. Its reversal would not return matter to prior positions. Reversal would result in a phenomenal explosion as matter repelled itself violently throughout the universe. So bringing the sun back to its original condition cannot be achieved by reversal of the laws of physics.

Gödel sidestepped these grave physical problems by designing a simplified universe that was an unchanging cloud of homogeneous dust that rotated rigidly through spacetime. In his universe there are no stars to produce light, and all matter moves in the same relative positions. Gödel's universe can be viewed as a huge plane upon which balls are resting. The whole thing is spinning like the earth, but nothing is moving. If one sat a video camera on that plane and watched for an eternity, no motion, not even the spinning, would be detected. Basically it was a static universe where an unchanging eternity was the principal feature of time. It was a cosmological spacetime clock that ticked but did not keep time. Gödel reasoned that if a future time became a past time, then neither past nor future really existed. The logical paradox is obvious. The flow of time had lost its meaning. In his universe, time no longer existed. Given that the properties of time in his universe were based upon general relativity, he concluded that time had the same properties here, too, so time must not exist for us either.

A major difference exists between our universe and the Gödel universe. Gödel assumed a living being could travel in a speeding rocket to the future and arrive at the past. But if that were possible, an examination of Gödel's mathematics should reveal a point when a person's body would begin reversing its biological growth and aging patterns. No such mathematical turning point exists. The math would also show when a trip into the future would cause a person to shrink in size and mysteriously return into the womb. It should also show how a cremated person's dispersed ashes could be collected and reconstituted, like a can of condensed milk, by adding water or some miraculous substance. The absence of a mathematical reversal point, where matter begins to reconstitute itself into a prior state, is a glaring deficiency that points theoretically to something other than common interpretations.

Growth and development are fundamental biological laws that are as absolute as the constancy of the speed of light. The laws of physics were not designed to govern issues about life, and Einstein's formulas wisely make no statements about life. In our universe biological laws govern the growth and development of life and those laws are clear. Adults don't grow younger and trees don't reverse their growth to become seeds.

A hint to a resolution of the time travel problem was given by Gödel himself. Closed timelike curves (ctlcs) that appear in some solutions of the formulas of the general theory might be a direct result of peculiar (*frozen*) motion of matter. Though this was not his preferred explanation, Gödelian-like ctlcs appear in formulas where there are high gravitational fields associated with rapidly spinning matter, such as near black holes, wormholes, spinning-solid-cylindrical universes, and superstrings. In all of these, matter has become compressed and perhaps frozen in time. Examining the conditions of matter in all those locations is beyond the scope of this article, but another example, a spinning-solid-infinitely-long-cylinder of matter that has ctlcs helps to confirm a causal link between spinning, frozen matter, and time warps.

The idea that the motion of matter is related to time has ancient philosophical origins. The flow of time and relative motion have been viewed as the same. For example, if all motion stopped, in our homes, on the streets, and in the world around us, we would intuitively see this as stopped time. Time starts again when motion begins again. This is also captured by special relativity. At the speed of light, clocks come to a stop. From that speeding vantage point, motion has stopped too. There the flow of time and existence itself comes to an end. The reason time did not exist in the Gödel universe was because relative motion didn't exist. It was a frozen universe.

Incomplete and Inconsistent

The view that other life in the universe may not experience the same Now that we do is based in part upon the fact that observers moving in relation to one another will have different clock speeds. But there is another Now, known as the present, that is not connected to clock speeds. This is a "universal Now" that is under philosophical attack. We know the Nows experienced by observers having greatly different clock speeds are not identical, but we know too that they both exist in the present. This is confirmed by cosmic rays with very slow clock speeds that collide with relatively stationary atoms that have high clock speeds.

The debate about the nature of time is in part a struggle over competing definitions of its flow and of the Now. At the turn of the 19th century, light had conflicting definitions. It was first considered a particle, then a wave, and finally Einstein won a Nobel Prize for describing light as both a particle and a wave. His quantum of energy, or photon, helped kick off quantum mechanics. Given that light has multiple properties, and that philosophers over the centuries have frequently seen time as an eternal present, or as motion, then this suggests that time may exist at least as a duality: an eternal present or Now, where the flow of time depends on matter in motion. Rather than competing descriptions, these are complementary explanations of time—just as a wave and a particle are complementary descriptions of light.

Gödel's incompleteness theorem is a life raft for those who may not agree with the metaphysics of time commonly derived from the laws of physics. This theorem states that mathematical systems ultimately are inconsistent and/or incomplete. Physical laws are mathematical systems that are known to be incomplete. Most notably, quantum mechanics, the description of the microcosm, has yet to be unified with Einstein's theory of gravitation.

A disturbing feature of many of the laws of physics is that they lack an arrow for the flow of time from the present to the future. This is interpreted as implying that such an arrow does not exist, yet no observation of nature is more solidly established than that time flows from the present to the future. Therefore the absence of an arrow of time is another instance where the laws of physics are incomplete.

Further, if ctlcs indicate matter can go back in time, this requires a duplication of mass, which violates the law of the conservation of mass and energy. That law was basic to the gravitational equations that produce ctlcs, so either the general theory of relativity is being misinterpreted or the theory is inconsistent. The former is the most likely.

The incompleteness theorem allows us to look hard at metaphysical statements like "time doesn't exist" or "the Now doesn't exist" or "time forms a block where past and future exist." Because the mathematics upon which those statements are based is incomplete and/or inconsistent, some consider such metaphysics to be suspect. The readings below include a selection of views on these and related topics.

Time, Objective Flux of

The concept of an objective flux of time, time that flows equally in all places, has existed for thousands of years. Humans have thought about time—its beginning, its end, and its characteristics in between—since before the advent of written history. Every culture had a creation myth, which inevitably included the idea of time itself. The incipient science that emerged in ancient Greece looked at time more objectively, searching for its nature. Aristotle, in the 4th century BCE, dissected the everyday term *time* into a mere number used for measurement. Although the number *of* something (in Aristotle's argument, movement) may be changed by adding or taking away an amount of the thing being measured, the number *itself* could not be changed. A concept like speed does not apply to a number, so time must flow continuously everywhere. Two centuries earlier, the Greek metaphysicist Heraclitus outlined his explanation of time's movement. His famous concept of flux, the constant change that everything in the world experiences at each moment, was in a way that of time itself. Time and change were inextricable, although not explicitly the same. Furthermore, since every event changes, time must be one of the main characteristics of all events. So Heraclitus defined time and events by each other, making each necessary for the other's existence. This agreed with his theory of the inherent unity of all objects. However, Heraclitus did not at any point deviate from the common idea that time passes at the same rate for all observers.

Time as a universal constant maintained its place in common belief with very few dissenting voices until modern times. In the 18th century, though, a renewal of interest in philosophy and discoveries in natural science gave birth to new schools of thought regarding the most basic ideas of all: time and matter. Bishop George Berkeley, in developing his philosophical theories, utterly rejected matter and time as real phenomena. The minds of humans and the ultimate mind of God were the only things he believed truly existed, and all other items that are usually considered concrete Berkeley reasoned to be thoughts in discrete people's minds. This included time, which became the procession of these thoughts through the mental landscape.

Another philosopher of the era, Immanuel Kant, also attempted to elucidate the elusive flow of time. He also labeled it a construct of the intellect, what humans use to order experiences into a useful form. It was one of the first substantially subjective views of time, since logically if time was a pattern coming from an individual's mind, it could and probably would be different for each person. Still, neither Berkeley nor Kant managed to change the Newtonian outlook on time.

Isaac Newton stated unequivocally the objective and unchanging nature of time and space in his 17th-century masterpiece, the *Philosophiae Naturalis Principia Mathematica.* Time itself never changed, although Newton acknowledged that the common means of measuring time may be inaccurate. Especially, he connected the idea of the inexorable flow of time with the amount of time that things exist, claiming that nothing could change the duration of existence of an object. Technology was not sufficiently developed until the 20th century to prove Newton wrong.

Theory of Relativity

Albert Einstein's theory of relativity finally destroyed the concept of an objective flux of time. His work was spurred by one of the few problems known at the time that Newtonian physics could not solve. No matter how many experiments were carried out, no one could show that light's speed appeared greater when the earth was moving toward its source than when our planet was receding from it; in other words, light speed did not vary with relative motion as all other speeds did. Einstein solved the problem simply by taking the experimental evidence for the truth. If one considered the speed of light to be absolute, then space and time must be relative universal components, not speed. Einstein then investigated the other effects this relativity of our four everyday dimensions had on the universe.

The Unity of Space and Time

The unity of space and time can be derived from a simple, classic thought experiment. If one person arranges to meet another person for lunch in a building, four coordinates are used. The place chosen for the meeting must be described using three of the coordinates; two for the building's street intersection, and one for the floor the meeting room occupies. However, this is not enough information. The time of the meeting must also be specified. This need for this set of coordinates can be generalized to any event in the universe. All four coordinates are necessary to describe one point. Therefore, they and the objects they describe—namely space and time—are linked.

Hermann Minkowski took Einstein's original connection of space and time and developed it further, claiming that time and space were actually one thing, which he labeled *spacetime.* Points in space and events in spacetime are analogous, since each point in space also exists for some duration of time. Einstein used Minkowski's four-dimensional spacetime continuum for various later facets of relativity.

Objective Spacetime

If a room with no windows is floating in any given direction at a constant speed in empty space, there is no method to determine from inside the room whether or not the room is moving. This circumstance is a cornerstone of relativity; it's commonly known as an inertial reference frame. Within a reference frame, all the laws of physics apply and sets of measurements agree with each other. Moreover, due to the theory of relativity, every inertial reference frame has the right to consider itself stationary. The corollary of this claim is that everything else in the universe is in relative motion compared to the specified frame. When two frames are moving relative to each other, their measurements will differ. The size of the discrepancy depends upon the relative speeds of the two reference frames; the closer to the speed of light, the greater the discrepancy. When this mechanism applies to measurements of time, it is called *time dilation,* and when the mechanism affects measurements of distance, *length contraction* is the term. There is an absolute interval between two points in spacetime, however, and it can be deduced from the measurements taken in any inertial reference frame. This interval remains the same regardless of the reference frame measuring it. Therefore, spacetime is objective, although there is no absolute reference frame.

There is a single exception to the relativity rule: the speed of light. Regardless of any reference frame's velocity, light is always perceived as moving at the same speed. Relative movement at substantial percentages of the speed of light can lead to contradictions concerning simultaneity. For instance, two flashlights are shone on a person in the middle seat of a minivan going three quarters of light speed, one by someone in the front seat and one by someone in the back seat. Another passenger would say that both light beams hit the person simultaneously, provided the distances between the seats were equal. However, a person standing on the curb would claim, with equal validity, that the beam from the front seat hit the passenger first, since the minivan was moving toward the light and thus the light had less distance to cover. The two witnesses disagree on the simultaneity of the lights hitting the passenger. Such disagreements on simultaneity occur only for independent events, however. Dependent events, like the birth and death of a person, are always seen as occurring in the proper order.

The final result of Einstein's theory was the destruction of the concept of unchanging, rigid time. Time does not flow the same way for all observers; a universal objective flux of time is a fallacy. This is obvious in extreme situations still being researched, like the area near a black hole's surface. Gravity there warps spacetime so greatly that time stops at the event horizon, and disappears completely beyond it.

Supporting Experiments

Einstein's theory of the spacetime continuum has been tested multiple times since its conception over a century ago. All experiments, both mental and physical, have supported his original hypothesis.

In addition to the argument listed above concerning the use of four coordinates to identify a point in spacetime, several other thought experiments were instrumental in elucidating Einstein's more difficult ideas. The light-clock, made of one mirror fixed above another and a single photon bouncing between them, elegantly describes time dilation. If one light-clock, with a photon labeled A, is stationary on a table and another one, with a photon labeled B, moves along the table at a constant velocity, the moving light-clock slows down in comparison to the stationary one. This is because the photon cannot change its speed, but it must add a horizontal component to its motion (as seen from the reference frame of the stationary clock) to keep bouncing off the horizontally moving mirrors. Therefore, photon B must make one complete bounce in more time compared to photon A, since it has farther to travel.

Many scientific experiments have been carried out as well. Even earlier than Einstein's work, Albert Michelson conducted experiments in 1881, and again with Edward Morley in 1887, that showed that light always traveled at the same rate. The first experimental vindication after Einstein's controversial papers were published occurred in 1919, when astronomers showed that stars' light was bent by the mass of the sun by precisely the amount Einstein had predicted. More recently, researchers working with the elementary particles called muons have found that these subatomic particles go through time dilation in nature. When created in the laboratory and moving at earthbound speeds, these particles decay in several millionths of one second. In nature, when muons leave the sun traveling at nearly light speed, they live for at least 8 minutes. In 2007, a NASA probe conducted a space experiment to test the magnitude of spacetime warpage caused by the earth. The data supported Einstein's theory of relativity to within 1%.

Beginning and End of Time

Although the very concept of time having a beginning or an end requires a measurement of time outside of and encompassing this universe's time, it is still a highly researched topic by scientists and laymen alike. Stephen Hawking has created a mathematical trick to be able to visualize the beginning and end of time fairly simply without assuming an ultimate, beyond-universal measure of time. He labeled it imaginary time, and defined it conceptually as the dimension at right angles to time. This turns the beginning and end of time into ordinary points in spacetime, different from any others only because no time exists before the first point or after the last point. The current physical consensus is that time began at the big bang, as spacetime expanded along with all the matter constituting the modern universe. Time's end is a slightly more difficult matter, as it depends upon a measurement that has not yet been completed. The density ratio of matter throughout the universe determines whether the universe—spacetime itself—will expand forever or collapse back in on itself. If the universe expands indefinitely, time will never end; if the universe follows the big crunch scenario, time will end when the entire universe returns to a primordial singularity. Scientists are still calculating this crucial number, so the ultimate fate of the universe is still unknown.

Time, Observations of

Time, as an object to be observed, is a human concept. In order for time to be observed, this concept needed to be converted to a measurable entity. These measurable, or observable, separations of time can be divided into various groupings.

Observations of time can first be categorized as either temporal or fixed. The temporal, or relative, observations of time constantly change in their lengths. Based, for example, on the apparent motions of the sun or moon, these temporal segments vary from day to day, and even from latitude to latitude in a single day. Whether it is local time, based on the hour of "high noon" when the sun is at the zenith, or the length of sunlight to be divided into equal components (traditionally 12), these would not recur at identical intervals from day to day or place to place (or both). While these observations were only relative, such as measured in the length and/or direction of a shadow on a sundial, they did provide reference points—useful in Jewish and Muslim societies, for example, in determining the daily prayer times in relation to the sun's position in the sky. Fixed observations, on the other hand, occurred regularly and at specific intervals—even if the intervals were not of equal size from day to day, they were equal in parts each day, such as the Catholic prayers being at specific hours of the day—whether they were temporal or fixed hours.

The cyclical nature of the universe was realized as a way to observe time was found useful by the nomadic societies who needed to know when to move their herds or the agrarian societies who needed to know when to plant seeds. It was noted the seasons changed regularly, and observable phenomena such as stars reappeared in the same spot in the sky on a regular basis—what we consider to be a solar year. This led to fixed separations of equal lengths of time that occur regularly, such as months and years.

Both temporal and fixed observations of time can be separated as well into two types of observations—naturally occurring and human made. Natural time is based on the regularly occurring events in nature, such as solar noon, or the reappearance of a star at a particular point in the sky, such as the Egyptians identified. Natural time observations can be based on the rotation of the earth on its axis—the 24-hour day, as we know it; or the revolution of the earth around the sun on its orbit—the solar year, as we know it. Even the recurrence of the full moon—the lunar month—is a naturally occurring event that indicates regular passage of time. These events occur naturally, and whether or not the passage of time between these events' recurrences is measured, they still recur regularly. It is only when humans decided to sort these times into observable components of equal lengths that the concept of a fixed-length passage of time, such as clock time (hour, minute, second, etc.), the 7-day week, or varying month lengths, for example, was instituted.

The Industrial Revolution created a greater need for a constant, consistent observation by which to measure time at work from day to day. This was still temporal in part, since it was based on latitude, with each location on the globe having its own starting and ending point of the day—varying even from town to town. In the 18th century and on into the 19th, many did not own clocks, and wristwatches had not been invented, so there was a reliance on factory whistles or bells to announce the start and end of the workday.

The growth of railways and the importance of accurate timetables, both to ensure against accidents and to enable passengers to schedule travel by rail, necessitated an even more standardized measurement of time. This did not occur all at once; it took the additional effects, in part, of instantaneous telegraphic communication requiring a need to know what was sent and received when and in what order, and, later, the First World War, to demonstrate a critical need for standardized time measurements and observations worldwide so that the starting and ending times of events could be shared across locations without confusion. Uniform observations would enable everyone to know of distant events, which would often affect local events as well.

The solar year is based on the observation of the earth's cyclical path around the sun, causing seasons and the changing ratio of sunlight to darkness at each sunrise. This is one type of year, the one that is truly cyclical. Before this type of year was regularly observed, the lunar calendar was in common use, based on the temporal cycles of the moon's revolution about the earth that created what became to be known as months; and the appearance of the moon, which changed regularly. Muslim calendars still follow the moon's cycles exactly, using a temporal, natural calendar for their year. A problem with this is that the time between the start of one year and the next is not aligned with the earth's revolution around the sun, causing a misalignment with the seasons and therefore resulting in a gradual shift in the months as time passes. The traditional Jewish calendar, for example, follows the lunar cycle but adds a leap month regularly to keep the observations of time close to equivalent between the solar year and lunar cycles. The Catholic calendar is the solar calendar, following the divisions that keep events occurring at the same point on the earth's orbit around the sun each year.

The increasing complexity of society created a need for more precise divisions of time and eventually resulted in the standardization of units to ease observations of time across great distances. Similarly, the need to share observations of larger periods of time—years, decades, centuries, millenniums—led to standardization. Rather than saying, for example, "five big snows after John's barn burned," which of course would be meaningless to outsiders, one could now observe the passage of time as 5 years.

Observations involving estimations of the age of artifacts from the remote past are now based on the rate of decay of radioactive isotopes. These measurements are especially useful in such disciplines as archaeology and geology that deal with prehistoric events that occurred thousands and even millions of years ago.

Time, Operational Definition of

All the quantities physicists call "observables" are operationally defined; that is, they are specified in terms of measurements performed by well-prescribed measuring procedures. Temperature is what we measure with a thermometer. Voltage is what we measure with a voltmeter. Following Einstein, time is operationally defined by what is measured on a clock. Whatever its construction, a clock will provide a series of ticks and a counter of those ticks.

Almost any series of repetitive events, such as your own heartbeats, can be used as a clock. However, defining time by your heartbeats would result in physics equations that would have to be written in such a way as to take into account your daily activity. The time it takes an object to fall from a given height would be less on a day that you sat around at the computer than on a day when you ran a marathon. Obviously, for the sake of simplicity and the desire to describe reality in an objective way, we should use some more universal measure of time.

Throughout history, time has been measured by highly repeatable, nonsubjective events such as day and night, the phases of the moon, and other observations in the heavens. While astronomical calendars, divided into days and hours, suffice for the timing of familiar events, science has required a finer scale that does not have to be constantly recalibrated because of the irregularity of earth's movements. Galileo introduced the pendulum as a timing device for experiments, and even today mechanical clocks and watches rely on the pendulum to provide uniformity and accuracy. However, science has greatly improved the methods for standardizing time, and the mechanical clock has become obsolete except as an attractive piece of antique jewelry or furniture.

Today the standard of time is set by atomic clocks. The second is defined as the duration of 9,192,631,770 periods of the radiation corresponding to the transition between the two hyperfine energy levels of the ground state of the cesium-133 atom at rest at absolute zero. Since observing such an atom is impossible, this requires a theoretical extrapolation to get the above value. The National Institute of Standards and Technology (NIST) and the United States Naval Observatory now provide a time source stable to 100 picoseconds (10^{-10} second) per day as a satellite signal. However, the primary time and frequency standard is now provided by averaging a set of *Cesium Fountain* atomic clocks at the NIST laboratory in Boulder, Colorado, which at this writing will not gain or lose a second in more than 60 million years.

All of the observables in physics are now calibrated against the time measured on the standard clock. In particular, the distance between two points in space was defined by international agreement in 1983 to be proportional to the time measured on a standard clock for light to travel between the two points in a vacuum. Specifically, the international standard unit of length, the meter, is the distance traveled by light in 1/299,792,458 of a second in a vacuum.

In developing his special theory of relativity in 1905, Einstein postulated that the speed of light in a vacuum is a constant—the same in all reference frames. Since then, special relativity has proved enormously successful in describing observations. As a result, Einstein's postulate is now built into the structure of physics by the very definition of distance.

The current definition of distance has a profound consequence that is rarely emphasized in the textbooks. Since 1983, distance in science is no longer treated as a quantity that is independent of time. In fact, distance is now officially defined in terms of time, that is, as a measurement fundamentally made not with a meter stick but with a clock: the time it takes light to travel between two points in a vacuum. Of course, in practice we still use meter sticks and other means to measure distance, but in principle these must be calibrated against an atomic clock.

So, as it now stands by international agreement, all physics measurements reduce to measurements made on clocks. The table below shows the fundamental units of various physical quantities shown as a power of a second, s^n.

time, distance	s^1
velocity, angular momentum, electric charge	s^0
acceleration, mass, energy, momentum, temperature	s^{-1}
force, electric and magnetic fields	s^{-2}
Newton's constant G	s^2
pressure, mass density, energy density	s^{-4}

Since the process of measuring time involves counting ticks, observables should be represented by rational numbers—integers or ratios of integers. The smallest time interval that can be measured is 5.4×10^{-44} seconds, the *Planck time*. In Planck units, any value of time is an integer.

Time, Origin Of

See Time, Emergence of

Time, Perspectives of

The 18th-century philosopher Immanuel Kant wrote that time has no real existence outside the human mind. It is of course true that time itself is not a tangible object and therefore can be considered an abstraction or a human construct. Humans have been organizing and making meaning out of time for millennia, with different cultures developing their own models, which have influenced their perspective of time. Although differing viewpoints on time can seem strange to outsiders, it is consensus within a given group that is important. As long as the people holding a given perspective agree on it, they can then measure the duration of events or synchronize activities.

An example of different cultural perspectives of time was demonstrated by a study at California State University, Fresno, where college students in California and in Brazil were asked about their concepts of "early" and "late." When asked how much time would pass before one would be considered late for an appointment, the Brazilian students' average was almost twice as long as that of the California students.

One way of looking at perspectives of time is by seeing time as relative or as absolute. *Absolute time* is measured quantitatively, using numbers and units. These units may be arbitrary (such as seconds, minutes, or weeks) or may be based on natural events (such as planetary motions). The units used will differ from culture to culture. The Mayans, for example, based days on the rotation of the earth. However, they used multiple calendars based on different numbers of days, and even one calendar based on the cycles of Venus.

Relative time is not measured with numbers. Instead, two or more events are compared, either in duration or in order of occurrence. The geologic timescale shows relative time. Using this system, scientists can describe the timing of an event (or the relationship of two events) in the earth's history according to a sequence of eras, eons, and smaller units. While the system divides time into more and more specific units, the units are not measured numerically. All of the eras (and all of the eons, etc.) are unequal in length, since the beginning or ending of a unit is usually determined by major geological events.

Time can also be seen as either circular or linear. Western culture tends to see time from a linear perspective, which is believed to have grown out of Judeo-Christian beliefs that the universe has a beginning (creation by God) and will have an ending. In the 17th century, Isaac Newton represented time mathematically with a line, and wrote that time "flows equably without relation to anything external." Although Newton is credited with introducing the idea of linear time to the Western world, ancient Hebrew writings also refer to this viewpoint. In this perspective, time consists of an orderly sequence of events, progressing continuously. The flow of time is constant, and we do not have control over its passage. (An example of this viewpoint would be the phrase, "Time marches on.") In this way, time can be understood as an arrow or a conveyor belt, always moving forward.

An example of a linear measurement of time is the Mesoamerican Long Count Calendar (also known as the Mayan Long Count Calendar). Dates are identified by the number of days that have elapsed since a particular starting point (calculated to be August 11, 3114 BCE, in the Gregorian calendar). A single day was known as a *K'in.* Additional units were used to describe periods of 20 days, 360 days, and even longer periods.

Many ancient Greek and Roman philosophers saw time as *circular,* a perception that is still found in Buddhism, Taoism, and neo-pagan religions. This perspective is based on observations of natural recurring phenomena, such as the rising and setting sun. In circular time, time is not "lost" to the past—events are just moved to another place in the cycle. Although new events continue to happen after older events, things always return to a previous state. An example would be reincarnation, in which a new life begins after one ends. In this case, the word *circular* does not mean that literally the exact same things happen over and over again.

Time can also be seen as monochronic or polychronic. In *monochronic* time, time is broken down into precise units, which allows events to be scheduled and organized. Tasks are performed individually within a fixed period. In this perspective, time is a finite resource that is not to be wasted, as embodied in the expression, "Time is money." Time is also sometimes treated as if it were a tangible object, as people often speak of saving or spending it. Punctuality is culturally important, and being late for an appointment is often taken as a sign of rudeness or a lack of respect. The monochronic viewpoint of time is also found in cultures that see time as linear, such as North American and northern European. To someone not used to this viewpoint, monochromic time may seem overly scheduled and rigid.

In *polychronic* time, time is seen as more fluid and not as rigid or precise as in Western cultures, allowing plans to be changed more easily. Schedules are not as important, and lateness is more acceptable. Many actions are performed at the same time, and completion of tasks is more important than preset schedules. Polychronic time is characteristically used in Latin American, Native American, and Middle Eastern cultures, as well as other cultures that view time as circular. A person accustomed to monochronic time may feel psychologically stressed when placed in a culture that follows polychronic time, as it may seem more chaotic and less organized.

Monochronic and polychronic time perspectives are not mutually exclusive. Specific environments within a culture (such as a home or a place of work) may operate in a more monochronic or polychronic way than the rest of society at large.

Time, Phenomenology of

Philosophers since the early Greeks have speculated on the nature of time, often with diverging views. Aristotle gave a clear and detailed definition of time, saying it represented a numerical measure of change between the past and the present. Plotinus later disagreed and saw time as more than counting and as related to eternity and the soul. Since then, philosophers such as Baruch de Spinoza, Immanuel Kant, and G. W. F. Hegel have proposed a variety of approaches to understanding the nature of time.

The phenomenological attempt to understand time began early in the 20th century when Edmund Husserl developed the major precepts of phenomenology. Husserl believed one should study specific phenomena—love, death, time, and the like—divorced from the traditional scientific method of gathering and analyzing data. Because phenomena are perceived by the senses, it is inevitable that there will be confusion and a dilution of the true description of each phenomenon because of ingrained presuppositions and attitudes. To understand a phenomenon fully, it must be reduced to its essence, removing any natural attitudes about it, relying instead on a subjective approach. In the case of time, this requires discarding any preexisting ideas concerning time as well as any scientific beliefs about the physicality of time. Any objective evidence of time at all has to be reduced to a relationship to consciousness, which in turn is defined by intentionality, a flow from the now to the new now. In a converse relationship, this also means that intentionality is basically time-consciousness, which originates with perception.

The first step on the way to understanding is to ask how a nonmaterial object such as time, viewed as a subjective phenomenon, can be made evident by a philosophical approach that opposes naturalism or objectivism, which our current technology and science embrace and have done so for more than 500 years.

Phenomenologists might respond that only by relying on a priori descriptions can one apprehend an explanation of the causes or purposes of elements. What then, is an a priori description of time? It is a concept of the living present, which implies another and more fundamental level of consciousness: the absolute flow of time-constituting consciousness, or the consciousness of immanent temporal objects. To study time from a phenomenological point of view is to attempt to understand time not in terms of physics or mathematics, but solely to describe it in nonempirical, philosophical terms.

A simple way to introduce the phenomenology of time is to think of time as a fountain—not the physical construct that creates the fountain, but the beingness of the fountain that exists only while it is running and throwing water up in an arc. The water changes, but the fountain remains as a fountain because the water, in its successive iterations, *retains* the form of the fountain. This idea of *retention* is integral to the phenomenological understanding of time consciousness. Retention, for Husserl, is a deeper concept than simply keeping something in memory. Rather, it implies intentionality; not simply an echo, but a consciousness of the past. In this sense, the common metaphor for time as a river leads to some confusion about how we perceive time. If the metaphor is extended, then the river begins with a glacier or melting snow, which proceeds from mountain to valley to the sea and then ends in a different entity—the ocean. Yet time, in a phenomenological sense, cannot be said to have a beginning or end. Time simply *is,* as the fountain *is.*

A phenomenological approach to understanding time implies that time is an essence that can be made evident, described, and "encountered." In other words, it should be possible, through this branch of philosophy, to apprehend the essence of time. In his lectures on the subject of time, Husserl distinguished among several types of time: objective, experiential within the inner self, and a deeper consciousness of inner time. He referred to the latter as the *deep living present,* which was the basis of the ego. Husserl also discussed the "now-point" as the source-point of individuality. Seen in these aspects, the ego, or self, has a temporal existence that can be understood.

Using an example from music as a temporal experience, consider a melody as it is played. A listener hears a note, then another note, and another, and so on, continuing to the end of the selection. At any one moment, the ear can hear only one note of the melody. How then can the fullness of the musical work be appreciated or understood? The mind puts all the notes together, but the experience of the musical work is not a totality of a temporally unitary action. If it were, we would hear a cacophonous mélange of incomprehensible sounds. Nor can the mind extend the apprehension of the notes over time—a note is played and then is gone.

Using a phenomenological approach, however, each individual note not only may be experienced in the present and recalled from the past, but there also may be retention of recent past notes, that is, a presence in the present of the past. In these terms there is a melding between the past and the present, reducing the distinct line between the two. Husserl referred to this as the living horizon of the now. Furthermore, there is a recessive parabolic effect to what is happening, in that as notes get farther into the past, the farther away they are, the less clear, although they can still be recalled. Instead of the objective view of time, which sees it as a sequential occurrence of individual events, time is viewed as wavelike phenomena where consciousness of time depends on a flow where events emerge and fade in intensity. Rather than a static, moment-by-moment view of discrete instants of time going by as visualized in everyday terms, the past and the present and even the future are simply part of the flow of experience corresponding to the clarity of their impressions.

TIME, PLANETARY

There are two ways to conceive of planetary time. The first is the length of each planetary axial rotation and corresponding revolution, each of which is measured in standard notation. This is practical for short-term measurements, yet quite involved when considering the age of the solar system. The second perspective of planetary time deals with describing the planet's time relative to the processes and events it has undergone throughout its evolution.

Short-Term Measurements

Planets orbit the sun due to the immense effect of gravity that the sun is placing on space. Each orbits at a different rate, directly proportional to its distance from the sun. A common misconception is that the smaller a planet is, the faster it rotates on its axis. However, the opposite is true. Jupiter takes nearly 12 Earth years to complete one orbit of the sun, but only 9.5 hours for the sun to rise and set. Timekeeping would be performed very differently from one planet to the next.

Long-Term Measurements

On a long-term scale, planetary time is vastly different from time measured in human terms. From the planetary perspective, centuries are the equivalent of nanoseconds in magnitude. On Earth, we measure planetary time by using the geologic timescale. The largest measurement is the super-eon. Super-eons divide the geologic timescale into eons. In turn, each division consists of eras, periods, and epochs. After epochs, millions of years become a realistic measurement. The divisions are denoted in terms of cataclysmic events, rather than as a specific continuum of time.

Since the planets in the solar system formed together, a similar scale measures the passage of time on each. Therefore, a similar scale of time is applied. Research continues on the moon, Venus, and Mars, and clues to their histories are developing rapidly. While each eon, era, period, and epoch may occur at different moments in time, all of these histories will use a similar scale of measurement to determine divisional boundaries. For instance, probes such as Magellan (Venus) in 1990, Clementine (Moon) in 1994, and the Mars Global Surveyor in 1997, have gatherer much data and contributed to increased knowledge of planetary geology. Mapping of surface features yields relative rock formation ages and past events. NASA plans to launch many more vessels to study aspects of all the major and minor planets in the solar system.

Study of events on the solid surfaces of the terrestrial planets provides an easy method of observation. The Jovian planets lack a solid core and contain no rocky surfaces. As a result, it is impossible to apply a timescale based on present surface features. Instead, researchers employ a climatologic or atmospheric timescale to measure the passage of events on the Jovian planets. For example, the deviations of Jupiterian radio emissions, changes in Saturnian density, variations in Uranian cloud concentrations, or differences in Neptunian atmospheric spectroscopy all measure the events that shape each Jovian planet's history.

Whereas all of the planets are the same age, each planet's timescale is its relative history broken down into smaller periods between major events. Although humans measure their own history in periods of years, planetary time is on much too large a scale to measure in years, although each event is unique to a planet's timescale; therefore the actual time between events is not a consistent block of time.

Time, Prehistoric

Prehistory is the time prior to written records. It includes not only human existence prior to written records, but also that of other forms of life. Since there are no written records, most of the information gathered about these earlier life forms is acquired through interpretation of fossils and artifacts left behind. These fossils may include human-made tools, whether stone or metal; animal bones; and coprolite, or fossilized excrement. Coprolite offers an insight into the dietary practices of animals and early humans. The study and interpretation of these fossils and artifacts is done by prehistoric archaeologists, and 99% of what is known today about human prehistory is through prehistoric archaeology. The earliest written records appeared around 5,000 years ago in Mesopotamia; 4,000 years ago in Greece; and 3,000 years ago in China. Prehistory ends differently for different cultures, since it is based on the advent of written records.

A number of methods are used in dating materials from prehistoric sites. Dendrochronology, or the study and use of tree rings as a method for dating events, is good for measuring changes in climate, beginnings of agrarian culture, and volcanic activity. Another way of dating fossils is through means of biostratigraphy: the study of fossil records and the surrounding strata in which they appear compared to those of other fossils. Although this method does not suggest a definite date, it does allow scientists to group fossils of the same time period together.

Carbon dating is also a commonly used method. All living things have carbon in them at the same ratio as the carbon in the atmosphere. Plants obtain carbon from the atmosphere through photosynthesis, whereas animals obtain carbon from the atmosphere by eating plants or animals that eat plants. Radiocarbon will cease to be created when an animal dies, at which point carbon-14 will begin breaking down at a constant rate. By measuring the amount of carbon-14 remaining in a corpse against the amount of carbon-12 in it, scientists can give an approximate age of a corpse. Due to outside influences and possible discrepancies in dating techniques, scientists will synchronize their findings with tree rings when possible. This is very important because the margin of error for carbon-14 dating can be as great as 2,000 years.

Beginnings of the Earth

As currently understood, the universe began with the big bang roughly 18 billion years ago. Gases compressed and rotated to form our sun more than 4.8 billion years ago. The debris surrounding the sun started to collect and eventually formed the planets. Earth formed 200,000 million years later, starting as volcanically active molten rock and hardening as it cooled. The steam from the cooling of the lava created the oceans. The earliest forms of life appeared 3.4 billion years ago as blue-green algae, followed by eukaryotes 1.4 billion years later. The first 4 billion years of the earth's history is known as the Precambrian era. Due to plate tectonics and the subduction of older oceanic crust by younger oceanic crust, few Precambrian fossils remain. The last 540 million years are broken down further due in part to the abundance of fossils and the law of superposition, or the observed rule that rock layers follow a chronological sequence that can be observed clearly in current continental crusts.

Age of Invertebrates

The age of invertebrates occurred during the Cambrian and Ordovician periods on the geological timescale, spanning a million years. Multicellular life forms first appeared at the end of the Precambrian. These early life forms included soft-bodied creatures such as jellyfish and other coelenterates. As the earth continued to change, life forms also slowly began to evolve and adapt to these changes. An increase of life forms appeared during the 50 million years after the end of the Precambrian. Some creatures developed external skeletons as a form of protection, and marine life forms grew larger. Most of the modern phyla can be traced back to animals of this time.

Trilobites are an abundant life form of this period, and numerous fossils of these creatures are still in existence today. Other invertebrates, including corals and brachiopods, are abundant as well. The jawless fishes are known to be the first vertebrates to form during this time, nearly 500 million years ago.

Age of Fishes

Marine life expanded and various types of fishes roamed the waters. The first plants found on land begin to grow and multiply. Wingless insects made an appearance here and skitter on land. Jawed fishes arise and dominate the waters, while trilobites begin to decline in number. Toward the end of this period, some fish leave the water and walk on land, comfortable with either habitat. These were the early amphibians. After 90 million years of fishes evolving and dominating, came the rise of amphibians.

Age of Amphibians

Amphibians were abundant from 320 million to 260 million years ago. Large, coal-forming coastal swamps existed. The first reptiles appeared during this time. These early reptiles were small insect-eating creatures. Most amphibians at this time lived most of their life in the water, whereas these new reptiles spent their lives entirely on land.

Age of Reptiles

Two hundred fifty million years ago reptiles dominated the land, and would do so for the next 160 million years. Other reptiles appeared in the waters and in the skies. During these periods, mammals and birds first appear. Based on fossil records, the oldest known bird is *Archaeopteryx,* which appeared 150 million years ago. The dinosaurs died out rather suddenly, relative to the time spans of the geological timescale. Their extinction marks the end of the Cretaceous and the beginning of a new period, the Tertiary. Exactly why the dinosaurs died off is not known, but many scientists believe it was due to a meteor that hit the earth, kicking up lots of dust and debris, trapping sunlight and warming the earth's surface. A thin layer of debris can be found in bedrock strata separating the Cretaceous and Tertiary periods. This separation is known as the K-T boundary.

Age of Mammals

With the mass extinction of 70% of the earth's population, the mammals that survived grew in size and numbers to repopulate the earth. Primates first appeared during the beginning of the Tertiary period and soon evolved several characteristics still in existence today, such as grasping limbs, short snouts, and enlarged brains. Early hominids, or the first humanlike mammals, evolved away from the primate family and are believed to have spent much of their lives in trees.

It is only in the last 5 million years that humanlike creatures have roamed the planet. Our species, *Homo sapiens,* has existed for only the last 100,000 years, a small fraction of life's 600-million-year history of existence.

Hominids

Hominids first appeared in Africa 5 million years ago, south of the Sahara Desert. These early hominids may have used basic tools, such as sticks to poke at food sources. As hominids evolved, their jaws and teeth became smaller and their skulls rounded. The famous Lucy fossil is of this species of hominid. This species evolved into *Homo habilis,* the first hominids to be called humans. *Homo habilis* created specialized tools using harder rocks to create a sharpened edge on softer materials, such as other rocks and bones. These sharpened materials were later fitted with wooden handles, and early axes and knives were soon formed.

Homo erectus were the first hominids to use fire, improving their lifestyle. Fire offered warmth during cold nights, protected the hominids from wild animals, and also provided a means of cooking meat. The fire would become a focal point for hominid dwellings. *Homo erectus* migrated from Africa into Europe and Asia. *Homo neanderthalensis* appeared in Europe nearly 200,000 years ago and were accustomed to living in the colder northern lands. These are the first hominids known to bury their dead.

The first humans to venture to the Americas did so from Siberia via the frozen Bering Strait. From here, some groups settled in North America while other groups continued to migrate south and settle throughout South America. The two prominent cultures created by these nomads are known as the Clovis and the Folsom cultures. There is debate as to whether the Clovis people were the first Americans, or if there was another group on the continent prior to them. The majority of the sites cited as arguments for a pre-Clovis group are located in South America. The Clovis created an early arrowhead used as a projectile tip for hunting mammoths; some believe that the Clovis peoples hunted mammoths to extinction. The Folsom made the Clovis arrowhead as a smaller projectile tip for hunting smaller mammals.

The first humans to journey to Australia are thought to have done so by ocean voyage. The most logical route would have been from Southeast Asia and the Philippines to the New Guinea and Australia land masses. The journey to Australia would have required seafaring vessels, despite the lack of physical evidence confirming such an adventure. Fossil records indicate that early humans did exist in Australia; the questions that remain are when and how they first arrived. The Australian Aborigines are the descendants of these first Australians. Some of them, upon reaching Australia, settled on the Tasmanian peninsula, which, after the rise of ocean levels, became an island. As in the Americas, the first humans on the Australian continent led to the extinction of larger mammals and marsupials.

A hundred thousand years after *Homo neanderthalis* appeared, *Homo sapiens* migrated from Africa. Roughly 70,000 years later, the Neanderthals became extinct, leaving *Homo sapiens* as the only hominids left on earth. Not only were improved tool crafting skills evident, but fossils from this time reveal the artistic interests of these early humans. The oldest musical instrument, with the exception of primal percussion instruments, is a primordial flute that has been dated as 40,500 years old. Other artistic creations followed. Cave paintings were created 30 thousand years ago. These started as images of animals, such as mammoths, horses, and bison; much later abstract humans were added. The meaning of these cave paintings is unknown, but they are believed to be ceremonial in origin. The Lascaux caves in France and the Altamira cave in Spain are among the best-known sites featuring such paintings. After the discovery of Lascaux, several other cave paintings were discovered throughout Spain and France.

Figurines were another artistic creation of this time. Many of these were of animals, although some were human and others a hybrid. The most popular human figurines are the Paleolithic Venuses, or figurines of female entities. With the advent of ceremonial rituals of these hominids, such as cave paintings and human burials, it is strongly suggested that there was a religion of sorts. Since many of the burial sites from this period contain material belongings, it is inferred that these hominids believed that they lived on after death and could benefit from these possessions.

It has not been determined when language arose in prehistory, yet there had to have been some form of communication, verbal or physical, to organize groups for hunting animals and gathering fruits and seeds, to barter, and to share tool-making crafts.

Ancient Civilizations

Around 10,000 BCE, many hunter–gatherer groups began cultivating plants and domesticating animals, leading to settlements of villages and towns. The global transition from hunter–gatherer society and agrarian society took less than 10,000 years. This rapid transition is somewhat of an enigma. There have been a few theories proposed to explain this phenomenon, including that of a massive drought or a large world population boom; however, there is a lack of evidence to confirm either of these theories. Other theories include the competition for farm land and, in some areas such as the Americas, the extinction of larger animals as food supplies.

Early nomadic groups would settle in a valley-like region, near a water source. The valley would act as a natural pen for the extra live animals caught as a future food supply. These animals adapted to their new life, becoming domesticated. Domesticated dogs were used to help herd these animals, whether sheep, goats, or similar species. Seeds from plants gathered were also soon planted and harvested and there was no longer a need to roam. Soon settlements cropped up in similar geographical locations. Communities that were built around these settlements worked together to farm. Over the years, the settlements would grow in size to become villages and towns, and eventually cities, allowing many workers to leave farming to become tradesmen, building tools and making ceramics. The earliest wheel may well have been a potter's wheel for creating ceramic pottery. The creation of pottery becomes prevalent around the same time settlements were formed, since ceramics were heavy, susceptible to breaking, and not suitable for a nomadic lifestyle.

With the discovery of metals came advancement in tools and utilities. Some tools were designed for agricultural use. Sumer, one of the first early settlements, was in the lower Mesopotamian region, between the Euphrates and Tigris rivers. Around 5000 BCE, Mesopotamian farmers implemented irrigation systems to assist with watering their crops. Artifacts found today reveal a knowledge of metalwork and smelting of bronze as early as 3800 BCE. The population of Sumer boomed in 3300 BCE, with small towns evolving into larger cities. This increase in population could have been the result of merchants immigrating to the towns, workers in search of employment, or a combination of these and other possibilities. Because of this growth, there were a number of changes in the Sumerian culture, including city temples being the center of the town. Priests trained scribes to record ongoing town activities and historical events, the beginnings of written history. Other cultures followed with their own written records; for example, the Egyptians and their system of hieroglyphics.

Time, Problems of

There have always been problems with time. Just its three forms and their mode of existence/nonexistence were sufficient to provide material for reflection for about 10 of the most significant philosophers (and philosophizing natural scientists) in history. These thinkers filled hundreds of pages with their ideas on this topic, yet they have almost always, in various forms, repeated one and the same thesis: Time is being that does not exist or it constantly escapes us. Yes, time has the status of being, time is, and our everyday experience or our imprisonment in the flow of time, from which we are not able to escape, proves this. Could we actually deny the existence of something that restricts and determines us so considerably? No, time *is not,* of course. The very definition of its three forms—past, present, and future—is based on the fact that *what we talk about is not.* We cannot explain *it* and yet, we understand *that.* The very expressions used here—"is," "was," "history," "previous"—in some way express the individual modes of time, which we understand but do not know how. Somewhere within these limits all the reflections on the way we perceive and experience time are situated from Aristotle to Jean-Paul Sartre or Maurice Merleau-Ponty.

Being and Becoming

The very problem of time thus becomes an excellent example of how useful it is to abandon the reflections based on the category of being. It is in its essence conceived as being able to resist time and form its opposite in order to guarantee the certainty of knowing in a changeable world. The revision of such reflections by means of the notions of *becoming* and *events* gives us a chance to resolve some dualisms that result simply from metaphysical speculations on *being*. And, of course, this replacement is not only a question of a simple exchange of two words or notions. It is the indication of a different view of reality, the emphasis of its dynamic character and the restoration of its variability, which for centuries has been understood only as an accidental matter of the constantly searched-for substance.

Science, Experience, and the Traditional Oppositions

Physics presents a second and significantly different line of thought on time. The differences are apparently so vital that the first question to ask in relation to time might concern just this double-line character of our reflections on time. It should be pointed out that these two lines of thought represent traditional contradictory views of time: Is time a subjective or an objective matter? Is the time we perceive different from physical time? Are there two times, two different characteristics of our world, or two different views of a single characteristic? To answer these questions is yet more difficult because these two approaches were outlined at almost the very beginning of European thought. Aristotle introduces the obstacles he meets when trying to define time on the basis of movement (which later gives rise to the physical branch of reflections on time), and in an effort to grasp the moment in the sense of *now* (from which later reflections of a rather psychological—and even later of a phenomenological—character arise). In the case of Augustine of Hippo this division is already quite obvious. On the one hand, there are reflections on the creation of the world and the beginning of time; that is, the concept of cosmological time. On the other hand, there are mostly introspective analyses dealing with the question of the form of existence of the three modes of time—the past, the present, and the future—in relation to our perception of time. These two approaches diverge even more with the introduction of modern science, which, particularly in mechanics, transforms time into an abstract entity, and the flow of time itself is always reconstructed by means of differential equations on the basis of the initial conditions. Time becomes part of geometry in the form of the trajectory of moving bodies. The whole of history is thus concentrated in one abstract moment; the past and the future differ only by whether the mathematical sign is positive or negative. Time itself is a neutral background entity with no relationship to what is happening in the world.

Everyday human experience is confronted with all this, which tells us that we cannot exclude time from our considerations, plans, or ideas, that time is one of the decisive or limiting quantities that we have to take into account. The ceaseless awareness of different conceptions of time—physical, everyday, and philosophical—repeatedly raises the question of its essence, or more precisely raises it more or less urgently depending on the various events in human life and changes within society.

While a sense of time has never been absent from the human experience, it returns to physics very slowly and with difficulties, as a precaution, in several forms. The first is related to thermodynamics and *irreversible processes;* the second is conditioned by the limiting speed of signal transmission and causality; and the third is the expression of the whole universe, or *cosmological time*.

It certainly will not be redundant to explore more closely what the common understanding of time is in these areas. Thermodynamics is the study of processes whose main characteristic is a one-way flow of energy. These are also called irreversible processes, expressing the conviction that this one-way flow is a given and cannot be replaced with its opposite.

The final speed of the transmission of any of the signals and the principle of causality lead us to the conclusion that it is not possible to reverse processes so that the consequence precedes the cause, or—put differently—it is not possible to progress physically from the consequence to the cause against the direction shown by the arrow of the causal activity.

Cosmological time is in compliance with the recognized standard model of the universe connected to its expansion, which also seems to define unambiguously the direction against which it is not possible to go. It is probable that irreversible processes are typical not only of thermodynamics, but of all the given modes of expressing time, and we presume that it is important to emphasize this fact. Briefly, this emphasis would be as follows: *The real name of time is irreversibility.* Systems in which only impeccably reversible processes occur would in fact be timeless, that is, without memory, because we could not differentiate the separate and repeating states of the system and they would not have any one-way changing background (an increase in entropy, expansion, etc.).

In some areas of life we connect or even identify time with irreversibility quite intuitively and naturally; in others the connection is less evident but is gradually discovered.

Folk wisdom teaches us that we can never be wise before the event. We seldom understand this knowledge, proved by generations, as real information; more often it is just a sign concerning the irreversibility of our deeds. If we are interested in the theoretical basis for the futility of trying to be wise before the event, we will have to go through a considerable part of the history of physics and we will not be able to avoid a confrontation with existentialism in order to end up with physics again; this time, however, with its most modern, actually still developing, theories.

The conviction about the irrevocable and unchangeable character of our past deeds does not arise out of physics but out of experience (which has not been theoretically defined for a long time) of the one-way flow of events, which take us from the past and our birth to the future and the inevitable end. This experience is in sharp conflict with classical physics, which is based on formulas drawn from natural laws, which are perfectly symmetrical in relation to time. The invariable characterization of physical laws concerning time transformations is nevertheless (in classical science) also quite evident, and one could say it is self-evident. Would there be any sense in formulating laws that would apply differently on Mondays and on Sundays? Classical physics does not recognize a difference between the past and the future, and if it wants to calculate the state of the system, what it was like or what it will be like, it is sufficient to adjust the sign next to the quantity defining time.

Consequently, the description handed down through classical physics may be viewed as timeless. If it is possible to achieve through such simple adjustment a free manipulation of the past and the future, the term *irreversibility* disappears from our vocabulary and with it, in fact, the possibility to decide unambiguously what was first and what was next. And since for classical physics (intruded into the formulations of physical laws that are invariable concerning time transformations) there does not exist any "late"; the saying about being wise after the event thus loses its meaning and one easily can be wise before the event. Or, to put it more simply: It is not a problem for classical physics to change the values of the entry data and to discover the state of the system for a new input no matter whether the result is a state in the past or the future.

The evident discrepancy of such a description and common experience with irreversible events led to an alternative understanding of time that was found primarily in existentialism-oriented branches of philosophy. Here, irreversibility became one of the basic features of this concept of time, and the discrepancy between the physical and philosophical approaches seemed to be crucially important and unsolvable. Yet both sides offered arguments that could not be easily ignored. Physics has an array of successful explanations and even technical applications that are based on them; philosophy, on the other hand, emphasized the indisputable transitory nature of our being. It appeared that each concept dealt with something different, that there existed two different times, which also was reflected in the result of the discussion between Albert Einstein and Henri Bergson.

Despite the dissimilarities of all three approaches—the folk understanding of time as irreversibility; the philosophical approach to the existential experiences of finality, freedom, and responsibility of human beings; and finally the physical description of the world—they share one illusion, which is their opinion of the deterministic character of our world. "To be wise after the event" in the folk interpretation expresses nothing other than our regrets for the initial conditions we chose in the past and suggests that if we had chosen otherwise, we would arrive at clearly predictable consequences in the end. The futility of the hunt for these “woulds” (if I had . . . , I would now . . .) consists precisely in the fact that it is impossible to change a decision made in the past. But if it were possible, the folk saying would dissolve in the physical approach, for which the pursuit of “woulds,” that is, the counting of states of the system toward the past as well as toward the future, is the common experience. The existential approach also succumbs to the deterministic illusion, but the “would” present here is oriented rather to the future and in this sense the hunt for it is not futile. The existential philosopher asks how to decide now and here (i.e., what would/should I do?) to be able to bear the responsibility of the consequences, which are certain to appear in the future in the chain of causal relations. In a paradoxical way, determinism (i.e., in this interpretation of the certainty that it is possible to gain a good understanding of the consequences of one’s deeds—and to be responsible for them) on the one hand, and human freedom and responsibility on the other, are connected here. How could one be responsible for one’s deeds if it were in principle impossible to assess their consequences, because their appearance would be entirely accidental, without following any rules? Or, to put it in a different, perhaps more precise, way—the world must correspond to deterministic ideas so that responsibility is possible, and at the same time determinism must be violated so that freedom is possible.

The questions of irreversibility and determinism thus prove to be closely connected with the conception of time, and the development of physics since the end of the 19th century has shown such a connection more and more distinctly. Thermodynamics, quantum mechanics, and the theories of chaos represent in this development—one by one in the order given—the main theories that compel the changes in our understanding of time.

The laws of thermodynamics and the introduction of the notion of entropy are among the historically earliest forms of what is called the arrow of time—the physical process that embodies the irreversibility of time and, through that, the split with the existing concept related to classical mechanics. The idea of the irreversible growth of one physical quantity and the adoption of irreversibility into human thought constituted the first steps of physics toward the concept of time, which was somewhat closer to the existential or even just commonplace idea of the impossibility of going back in time and redeeming the mistakes of the past. The significance of such a step consisted, however, in the fact that the classical notion was seriously questioned rather than in the offer of the new conception. Because if we had remained at the fact that the essence of time was fully expressed only by entropy, the folk saying of “being wise after the event” would be a mere caution that most probably one can never be wise before the event. No matter how small the probability is, it is not an impossibility. It is the consequence of the fact that the growth of entropy is not a physical law of the same nature as Newton’s laws of mechanics, which are dynamic (i.e., their predictions are utterly unambiguous), but the result of a statistical count, therefore it belongs to laws of the statistical kind. Even time would then become just a statistical matter and it would be only probable that we will die once, that we cannot return to the past, but the opposite would not be physically impossible. The more people hunted for “woulds” and the longer they did so, the greater would be the hope that one of them would succeed. Thus there arise more complicated and complex conceptions and the search for irreversibility (which physics has accepted as its problem) is spreading to other areas of modern physics.

Quantum Mechanics and Time

Quantum mechanics in this respect brings one good and one bad piece of news. The bad news is that the conclusions of a number of experiments the result of which is the twofold possible interpretation of quantum processes allowing us to think of the movement of particles against the direction of time, of the violation of causality, and of the border behind which irreversibility is an unknown word again. Those who find these results unacceptable can reject the application of our conception of time in the microworld and ascribe to each level of the organization of material structures as well as to each system their own temporal characteristics. The better news (from the point of view of the supporter of folk wisdom) is brought by Hugh Everett’s concept of *many worlds,* which arises in the second half of the twentieth century as an alternative, or in a certain sense, broadening conception of the Copenhagen interpretation of the basic experiment of quantum mechanics. The principle of uncertainty, the principle of complementarities of some characteristics of the elementary particles and their probabilistic description lies in the foundations of what is called the Copenhagen interpretation of the experiment, during which the observer does (not) observe the transit of the particle through two holes, and alternatively discovers its particle and wave character. The Copenhagen interpretation discusses what is termed the collapse of the wave function, which occurs as a result of the observer's measurements. In other words—observers, through their observations, cause the quantum system to pass from one of the many probable states to one, the real one, which is also discovered by observations. The observations thus take part in the realization, and other possibilities from the probabilistic field are not fulfilled. Everett's conception of many worlds offers a different view. All the possibilities of the quantum system are not reduced by observations to one real state, but they are fulfilled in such a way that at the moment of choice the universe divides into various branches, where each of them is the continuation of one of the possibilities. The observers find themselves in one of these worlds, depending on the result of their observations. The universe thus splits in each quantum choice and there exist many more or less similar branches of its development. All possibilities are fulfilled. Even if it seems that in such a universe, where everything occurs, it would not be difficult to be wise before the event just because everything is real, things are by no means as simple as that. The folk saying ends in the impossibility of returning to the past and redeeming our previous decisions there. Even if we found the means for traveling through time and managed to get to the point of making a decision, even though we caught the "woulds" in this way, we would not achieve anything. The change of decision would not mean a change in reality, from which we got to the past. The only thing achieved would be that we would have set out on a different branch of development of the world; certainly without the possibility that the one we came from would cease to be real.

Chaos Theory

Significantly less fantastic, though not less strange and interesting grounds for our hunt for "woulds" are offered by theories of chaos. If we take into consideration these theories that have arisen since the 1960s, the hunt for "woulds" seems not only futile, but also dangerous even where we might, by some miracle, catch the "would." Let us leave aside for the time being irreversibility itself; what remains from the folk saying is the conviction (shared even by some theoretical conceptions) of the fully deterministic character of our world. If we wanted to change slightly the consequences of some of our deeds in such a world (supposing that we could return to the past in such a world), it would be sufficient to change slightly our initial conditions as well; if we wanted to achieve significantly different results, we would be able to change the power or the intensity of our decision. The difference in causes is directly proportional to the difference in consequences. The theories of chaos, of which the so-called butterfly effect is the most popular, show that it is not so in the macroscopic world controlled by dynamic laws. It shows that even in the case of much simpler systems, compared with the field of human decision making, it is often impossible to predict eventual consequences unambiguously, not because we do not know the initial conditions but for reasons concerning the principle itself, one of which is also the impossibility (not inability) of discovering the initial state of the system (appearing in the role of the cause) with arbitrary preciseness. In chaotic systems even a slight deviation in initial states can lead to very different results in final states. The field of human behavior definitely does not belong to simple systems, which means that it is even less possible to define with sufficient exactitude all the causes that contribute to the resulting state. For us it thus means that even if we found a way of being wise before the event, even if we coped with irreversibility, it would be very dangerous to perform only the slightest adjustments, because the consequences could not be unambiguously defined.

Irreversibility

Therefore we might merely complement the folk saying. It is never possible to be wise before the event, and even if we could be and were wise before the event, it would not change our reality, and if it could change it, we would never know what the change might be. Nothing essential has thus changed the folk saying, which is understood rather as a caution, at least in terms of its relation to the past. As far as the future is concerned (how to be wise enough now so that in the future I would . . .), it certainly still is a desirable activity, but it becomes the saying about looking before leaping. As far as the conception of time is concerned, much has changed. As has been shown, a meaningful discussion of time is possible only where we find irreversibility; that is, irreversible events and processes. A system with perfectly reversible processes is an eternal system, not a system of time; a fully reversible time is not time but eternity. And irreversible time is in fact a pleonasm: Time and irreversibility are the same. If time exists, it exists as the irreversibility of events. The replacement of time with irreversibility moreover provides us with the ability to understand much better, or even more vividly, some relativistic games with the temporal-spatial continuum, in which exchanges of the temporal and spatial coordinates occur—for example with the description of the fall of a material body into a black hole. If we understand space as part of a continuum where we can move freely in all directions, that is, we can return to places where we have been, and time as the part that allows movement in just one direction, thus preventing a return, then their exchange is evident precisely through (ir)reversibility. As soon as it is not possible to go back in space (and this is precisely the case of the body that falls into a black hole and has gone beyond what is called Schwarzschild's radius), this dimension has the same characteristics as the temporal one, which, on the contrary, can gain the character of reversibility and thus become the spatial one.

Nevertheless, the extreme area of black holes is not the world of folk wisdom. In our macroworld, where we clearly distinguish between temporal and spatial characteristics, it is still true that (as Michel Serres reminds us), as far as (ir)reversibility is concerned, we are the masters of space but the slaves of time.

The very name of time is irreversibility and irreversibility is embodied in concrete events. Time understood as flow is the result of the human effort to keep being in the world and have the chance to talk about events.

Three Basic Themes

The persistence of the discussion concerning time in 20th-century science thus has three basic themes: (1) Beginning of time, (2) Direction and irreversibility of time, and (3) Ontic basis of our considerations of time.

The question of origin, birth, and creation—simply the beginning of anything—has always been attractive thanks to its search for one of the basic secrets of nature: *Where does the new come from?* The question becomes more intensive when we realize its reverse aspect concerning annihilation and death: *Where does the old go?* The question seems difficult in the case of objects becoming and finishing; it is even more difficult in respect to the birth and death of human beings. Once we examine the origin of time itself, the question becomes cosmological. Despite the intensity of cosmological and other research, the most frequent answer is to wait for a better theory to appear.

We can state positively that it is proven without any doubt that the question cannot be answered if we consider time as an independent quantity, in both the physical and metaphysical senses. The next question might examine the conception of time as a real quantity.

The second sphere of problems completes this inquiry by adding an existential dimension. Is it really impossible to reverse the flow of time? What physical or other process determines the direction of the flow of time? If there are more processes, why does one of them become dominant? Is there a time flow whose physical basis could be discovered?

These formulations are, however, related to the third theme—the research of the ontic basis of our considerations on time. Is the differentiation between the past and the future anything but a psychological dimension of beings endowed with consciousness? If space is not a perpetual repetition of the same, which process, or whatever it is, decides about the course of history?

Direction of Time

One of the undeniable consequences of the fact that the considerations about time are deduced from such processes (origin–end) is the included conception of direction of time, its one-way flow and irreversibility. The picture of time flow seemed appropriate to describe the time dimension of phenomena and processes observed at the macroscopic level. The one-way flow and irreversibility of time was thus considered an obvious fact from the beginning, similar to a river flowing from its source to the estuary, or the sun moving from east to west. The thought of reverse direction of such processes meant transferring considerations into the sphere of miracles, myths, and fairy tales.

Psychological Arrow of Time

The psychological arrow of time explicitly expresses the state of the human mind. On the one hand, the mind is able to reconstruct out of apprehended pictures the succession of particular states of some events—in other words, to remember. On the other hand, the mind is capable of developing the succession and of continuing it by adding events that have not yet happened—that is, to anticipate. This arrow of time is thus constituted by the direction that stems from the remembered (the past) to the anticipated (the future). There is, however, nothing in the background of the psychological arrow but pure human experience without any deeper theoretical argumentation.

The first, so far the only arrow of time based on the pairs of concepts (past–future, memory–anticipation) is completed by an explanation more scientifically based, thanks to the development of the natural sciences and the disciplines mentioned above.

Thermodynamic Arrow of Time

In all closed systems, entropy is continuously increasing and its growth is irreversible, which would correspond with our conception of time flow. It is, however, problematic that the growth of entropy is a statistical phenomenon. That means that time and its flow are only questions of probability or our incapacity to register all data needed to evaluate the processes in progress.

Ilya Prigogine refuses to accept entropy as an obvious physicalization of time and draws attention to the larger context of the problem. Prigogine even talks about the rediscovery of time. Up to now, physics—the physics of Einstein and, for example, the physics and cosmology of Stephen Hawking—describes the world that is. That means the world of being that is considered static by physical laws, despite all changes observed by human eyes. Prigogine emphasizes that such physical theories are not able to describe the creation of the new. If we want to talk about evolution and emergence, we have to stop discussing the world of *being* and start to discover the world of *becoming*. The theory of being is no longer sufficient; we need a theory of becoming. Time in the universe that is becoming is not a simple scale or a physical quantity; according to Prigogine, it becomes a *constitutive element of the universe*. In the universe with history, even particular objects can exist only by becoming—they originate, develop, and perish—time is thus considered as the fundamental element of the universe, not as an a priori form or a number in equations, or even as our mistake in describing our world. Prigogine's attitude nevertheless conceals a certain danger: the hypostasis of time. The debate about the constitutive role of time necessarily evokes an idea of something, an independent entity gifted with creative capacity.

Wave Arrow of Time

By studying elementary interactions, some physicists show the indefiniteness of time and the problematic character of physical processes described by quantum mechanics. It turns out that the very process could be described by various means that would differentiate only according to their orientation in time. The electron–photon interaction can be illustrated by a diagram that corresponds with time orientation of other (even macroscopic) processes; the positron–photon interaction could be described by the same diagram, only with an opposite time orientation. In other words, the electron of the preceding interaction seems to move against the (generally accepted) orientation of time.

The possibility of several readings of the diagram thus means nothing less than a full symmetry of the mentioned processes in respect to the orientation of time.

Cosmological Arrow of Time

The universe has been evolving from a specific starting point (whose more specified determination is subject to intensive interest of cosmologists), via the emergence of recently observed structures to the future that is subject to many hypotheses and philosophical speculations. One of the basic features of the universe is its expansion; it is a physical process identified with the cosmological time and has the same orientation as the growth of entropy in the whole universe, at least in the contemporary phase of the evolution of the universe and according to the suppositions up to now.

It seems then that everything is perfectly related and shows the pertinence of our ideas on the direction of time. Up to now, we have considered only the processes that are finally interpreted on the macroscopic level; that is, on the level compared with ordinary human experience. But these waters, calm until now, seem to have been disturbed by the development of quantum mechanics.

It appears that the cosmological arrow is orientated from the singularity to the recent, richly structured universe that is still evolving. The adequacy of this consideration will be examined later. Nevertheless, another problem has emerged: How can we be sure that all past states of the universe are well measured by time units deduced from movements that emerged much later? To what extent could seconds be considered as a meaningful description of the state when there are no atoms whose oscillations could be defined (not to mention planets)? We might, perhaps, consider time units in which *seconds* would be replaced by *temperature degrees* of the universe, which would create a thermodynamic arrow.

The Problem Restated

At the expense of some simplification, it would be possible to formulate the problem in more precarious terms. The question of time is, to a certain extent, a problem created by human beings. The idea of time was deduced in early human history from relatively simple movements and started to live its own life—a life so independent and unique that it became difficult to find a physically real basis to serve as a criterion for decisions in more and more complicated situations that appeared during the evolution of human knowledge. The need for this criterion finally led to the fact that the anthropocentric character of the idea was fully demonstrated in the way human beings imposed on the universe (their description of it) their own image of the flow of time and based upon it the whole cosmological explanation of cosmogenesis.

If any effort to find the ontic basis of time leads to the difficulties mentioned above, let us accept the conclusion that we have looked for the basis of something that does not exist. Time does not exist. This does not mean that we should throw away our watches and timetables; time remains a fairly good tool for communication. We have to remember, however, that anywhere we talk about time, there is a hidden movement included. Time measurements are therefore nothing but a comparison of two or more movements, one of them considered the etalon. A question remains whether the comparison of movements in various orders (e.g., biological and physical) is always informative and whether it is even possible to conduct the comparison (e.g., the changes in the early states of the universe and the later movements).

If we accept this hypothesis, the evolution of the universe and its history will not be constrained. They are not determined by an ideal time axis, they are determined by events, their succession and sequence, causal relations and concrete processes.

Time does not exist, only events do. The number of years we count in our lives is not important; it is crucial what we experience during our becoming.

TIME, REAL

There is no commonly agreed-upon definition of *real time*. Indeed, the definition of "real time" is dependent on its application and context. Some trace the origins of the term to the missile age in the early 1950s where it was used in the simulations of intercepts of ballistic missiles by analog computers. One can distinguish between the time of the simulation (where events of milliseconds, days, or years could be represented in minutes or hours) and the actual time or real-world "real time" of an event.

In fact, depending on the application, three different meanings can be ascribed to the term real time. As mentioned above, the first meaning is actual time as opposed to simulated or other non–real-world time. For example, a distinction can be made in a live theatrical production between the actual time that transpires during the production (the real time) and the elapsed time of the fictional event (illusory time). In 15 minutes of real or actual time, a period of years may have passed in the story portrayed on stage.

The second meaning of real time is that it occurs immediately, or without delay; that is, it happens almost instantaneously or at the same time. Technological advances, particularly the advent of the Internet and modern information and communication technologies (ICT), have made this type of real time achievable. For example, it was as early as 1988 that Internet relay chat (IRC), a forerunner of instant messaging, was developed by Finnish student Jarkko Oikarinen, enabling people to communicate via the Internet in "real time"; that is, appearing to communicate without any appreciable delay, almost synchronously.

Thus, with the coming of the Internet and other ICTs that allow users to access information from anywhere in the world seemingly instantly, real time as instantaneous access has become generally equated to "online"; for example, online gaming, online communication. The immediacy of the online environment can be contrasted to the batch processing of earlier computer systems where data were collected over time "in batches," and then submitted all at one time for processing. This resulted in a sizable delay between the collection of data or the query/event and the receipt of results or computer response.

Videoconferencing uses real-time systems that transmit video across networks, displaying it at the other end seemingly instantaneously. Court reporters now routinely use technology called computer-aided transcription (CAT) to make available words spoken in the courtroom as text on computer screens, with just a few seconds' delay; this is, in real time. Live satellite broadcasts allow viewers, for example, in the United States to see events in Iraq in real time. Improvised musical or other artistic works are created at the same time that these are being performed and so are real-time works. With the use of technology and skilled captioners it is now possible to convert the audio portion of a live program or event almost instantaneously into captioned text (real-time captioning).

The third meaning of real time is in its use in computer-controlled systems. Computers are now frequently incorporated or embedded into aircraft, cars, cell phones, home appliances, manufacturing assembly lines, traffic lights, video game consoles, and many other applications that control real-life processes. Computers must therefore be able to respond to the external environment or real-life conditions fast enough to satisfy some requirement (e.g., to deploy an airbag when a car accident occurs). Computers used in space flight must respond quickly to changing conditions to keep the rocket on its course. Robots in factories must respond within a certain time to keep the assembly line moving at optimum speed. To ensure that all operations in the assembly line run smoothly, the robots must respond neither too quickly nor too slowly. Thus, real time in these systems does not necessarily mean fast but rather as fast as required by the external conditions or particular system. So it is possible for a real-time system to be relatively slow, but it must be guaranteed to respond within a specified time. Therefore, the main characteristic of a real-time computer system is not that it is fast but that it has to meet explicit, strict deadlines. If it fails to meet the deadline, negative consequences result, with their severity depending on the particular system. For example, antilock brakes must respond to changing road conditions immediately in order to avoid serious damage to driver and vehicle. Real-time computer systems in which a catastrophic failure occurs if the "deadline" is missed are called hard real-time systems. In systems known as soft real-time systems, no major catastrophe occurs if the system is slightly delayed. There may just be degradation in service; for example, computer control of an audio and/or video signal that fails to meet its deadline simply results in poor or reduced quality audio or video.

In conclusion, the term real time is sometimes used in contrast to simulated or other non-real-world time or illusory time, as the *actual* time. In other contexts, real time is synonymous with fast, immediate, or instantaneous. At other times it is used to describe those systems for which response *must* be within a specified time. Thus for some applications real time means actual time; for others it means practically instantaneous; and for others real time can be in microseconds, minutes, hours, or even days, depending on external conditions or the function to be performed.

Real time may also be referred to as real-time or realtime.

Time, Relativity of

That the nature of time corresponds to common human experience was an opinion expressed in the introductory passages of Newton's *Principia*. According to him, time is just as *absolute* as space. In more modern wording, the *spacetime continuum,* a four-dimensional set of point-like *events,* is "fixed" in a unique way by the sytsem of parallel straight lines, which are world lines of reference points at rest with respect to the absolute space, and, in this way, deremine what happened (or will happen) in the same place. Similarly, the spacetime continuum is "cut" in a unique way through the system of parallel three-dimensional planes orthogonal to he world lines of reference points, determining what happened (or will happen) *simultaneously.* In these planes (three-dimensional spaces in a given moment) Euclidean geometry is valid, with the laws most simply expressed in terms of Cartesian coordinates. Similarly, one time coordinate exists whose differences determine the time interval between separate simultaneities. This interval is common for all *ideal clocks* and objects, so that the interval of the *coordinate time* is also the interval of the *proper time* of an ideal clock. The laws of Newtonian mechanics also indicate how to construct instruments that measure time by their periods or motions.

Of course, belief in the absoluteness of space and time was based on experience, which absolutized temporally conditioned human knowledge. At first, absolute rest was considered as rest with respect to the earth's surface; after recognition of the planet's motion, absolute space could be related to the heaven of fixed stars, but later the mutual motion of these stars was also recognized. Thus the Newtonian concept of absolute space began to be rivaled by the (special) *relativity principle,* which insisted on the validity of Galileo's description of happenings inside cabins on a stationary and a moving ship. It seemed that although it is possible to determine experimentally an *inertial system of reference* where the law of inertia is valid, it is impossible to indicate a rectilinear and uniform motion with respect to such a system. Therefore, different frames of spacetime are equally valid and, consequently, absolute space does not exist.

The Newtonian concept was seemingly supported by optics, indicating that the speed of light is independent of direction only in the system connected with absolute space. After the inclusion of optics in Maxwell's electromagnetic theory, experiments were proposed with the goal of proving motion with respect to absolute space. The most famous was the Michelson–Morley experiment near the end of the 19th century. The negative results of these experiments would provide support for the principle of relativity and seemed to argue against the Maxwell theory. But according to Einstein in 1905, it is possible to combine the relativity principle with Maxwell's theory and so build a promising basis for the development of physics. It is only necessary to abandon—together with the concept of absolute space—the old concept of absolute time.

This old concept sprang from the feeling that *simultaneous* means "seen in the same time." The determination of finiteness of the speed of light undermined the background of this concept. A natural synchronization of distant clocks can be based on the exchange of light signals: If a light signal is emitted at time t_i from point A, reflected at point B, and received back at A in the time t_f, then the moment of the reflection in B corresponds with the synchronized time $t = (t_i + t_f)/2$. Of course, this definition of simultaneity depends on the system of reference, where clock A is at rest, and thus it is *relative*.

It is possible to understand the principal features of this new concept of space and time by watching a course of events in one-dimensional space (e.g., on a street with the movements of pedestrians, cars, and traffic lights). Let us denote t and x as the time and space coordinates with respect to the street, t' and x' these coordinates with respect to a car moving at velocity v. Then the speed c will retain its value in both directions, if the coordinates in both systems are connected by the *Lorentz transformation*

$$x' = \gamma\,(x - vt),\ t' = \gamma\,(t - \beta x/c) \qquad (1)$$

where $\beta = v/c$, $\gamma = 1/\sqrt{(1 - \beta^2)}$. According to the *special theory of relativity* (STR), the laws of physics are not changed by the Lorentz transformation. The Lorentz transformation gives a new presentation of the principle of relativity. It means that simultaneity is relative—the same t in different places does not mean the same t'! Putting the speed of light equal to infinity in (1), we obtain the *Galilei transformation* with absolute simultaneity.

Let us consider two events in the same places from the point of view of the car, that is, $x'_2 = x'_1$. The clock in the car will measure the interval of *proper time* $\Delta\tau = t'_2 - t'_1$ between them. As can be easily obtained from the Lorentz transformation, the time interval

$$\Delta t = t_2 - t_1 = \gamma\Delta\tau \qquad (2)$$

will be measured by clocks placed along the road and synchronized with respect to the rest of the clocks on the road. Thus the interval of proper time is the shortest of all the time intervals between events. We speak about the *dilation of time:* A clock moving with respect to some system of reference slows down with respect to this system. (Note that this delay is not immediately visible to a distant observer, because the finite speed of light also plays a role.)

The dilation of time was reliably confirmed above all by observation of the half-life of unstable elementary particles in cosmic space and in laboratories on earth. Let us stress its *relativity:* A specific clock of the system S´ delays with respect to the synchronized set of clocks of the system S, but this assertion also remains valid after the exchange of S and S´.

A deeper insight into the nature of simultaneity is offered by the four-dimensional formulation of the STR created by Henri Poincaré and Hermann Minkowski. According to this, the spacetime *interval* Δs between two events in spacetime exists independent of the choice of reference system, whose square is expressed in the *Minkowskian coordinates* as follows:

$$\Delta s^2 = c^2\,\Delta t^2 - (\Delta x^2 + \Delta y^2 + \Delta z^2). \qquad (3)$$

Confining ourselves to one-dimensional space (two-dimensional spacetime), we obtain the *Minkowski diagram* (see Figure 1) allowing one-dimensional motions to be represented graphically. Let us use *ct,* time multiplied by the speed of light, as the vertical coordinate, and x as the horizontal coordinate. The right-angled lines halving the quadrants depict events connected with the origin (the *now-here* event) by means of the light signal. These events form a *light cone* in four-dimensional spacetime. The spacetime interval, the light cone, and the speed of light are *absolute* according to relativity theory, whereas the space and time interval between events are *relative* with respect to the choice of the reference system. The upper half of the interior of the light cone (including the boundary) represents the events reachable in principle from the initial event by a velocity not exceeding the speed of light and thus causally influenceable. They form the *absolute future* of the initial event. Similarly, the events in the lower half of the interior of the light cone form the *absolute past* of the given event. The events outside of the light cone can always become simultaneous with the initial event with the proper choice of the system of reference. This fact does not create trouble, because the events outside the light cone are not causally connected with the initial event. Arthur Eddington proposed calling this set of events the *absolute elsewhere*.

Spacetime in the definite system of reference is therefore again fixed by parallel lines and cut by the three-dimensional surfaces orthogonal to them. But whereas this fixing and cutting results in a unique "net" according to Newton, every inertial system of reference defines its own net according to Einstein and Minkowski. (Remember that the Minkowski diagram in the Euclidean plane does not allow an illustration of orthogonality in the Minkowski sense, where the axes ct' and x' are orthogonal to each other, just as the axes ct and x are).

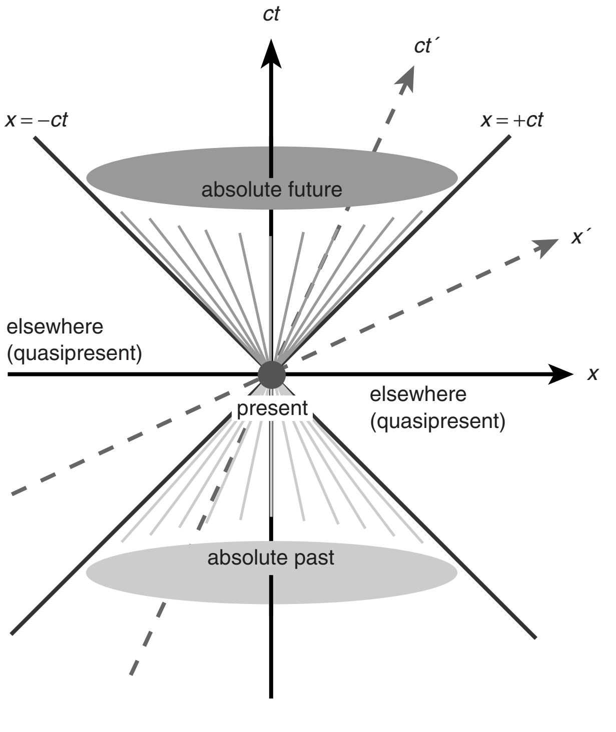

Figure 1 Minkowski diagram

The relativity of simultaneity in Einsteinian physics naturally aroused the interest of philosophers. In Newtonian theory, it was admissible to consider absolute simultaneity as something like a rising curtain at whose edge events are realized as they transit from a future "not yet" nonexistence into a past "already" nonexistence. The impossibility of clearly understanding such a curtain according to the special theory of relativity created doubts about the objectivity of time's *flow.* The natural reaction of a number of outstanding relativists (e.g., Einstein, Gödel) was to consider spacetime as "given" and the flow of time as an illusion of consciousness.

Einstein's general theory of relativity (GR) of 1915 meant a further advance. According to it, spacetime is curved by its matter content. The square of the infinitesimal interval has the general form

$$ds^2 = g_{ik}\,(x^j)\,dx^i dx^k \tag{4}$$

where x^i represents four spacetime coordinates and g_{ik} the components of the *metric field* dependent on them. It is possible to introduce a *locally geodesic system* in an arbitrary point (event). In this system, the interval takes the form of equation (1) with the diagonal matrix

$$g_{ik} = \mathrm{diag}\,(+1,-1,-1,-1) \tag{5}$$

but the first derivatives of the metric components with respect to spacetime coordinates vanish, which also means that gravity's forces in the given system disappear (weightless state).

In this way, STR and its concept of the relativity of time is locally valid. It is possible to retain the idea of fixing spacetime by the world lines of "reference points" and cutting it by the surfaces of "simultaneity." But the world lines are no longer parallel right lines, and surfaces are no longer parallel planes. In general, surfaces of equal amounts of time are not even orthogonal to the world lines of reference points, which means that coordinate "clocks" are not synchronized. It is possible (at least theoretically) to construct spacetimes without a globally defined reference system and without global time coordinates. (The latter is especially interesting in the case of spacetimes with "time loops" allowing the world lines to intersect each other and thus correspond with Gödel's universe, in which a return to the past is possible.)

Thus, GR deepened the difference between proper time and coordinate time. Whereas proper time is an absolute quantity independent of the choice of reference system, coordinate time is in general only an orienting tool for describing spacetime and loses real metrical and physical meaning.

On the other hand, there are realistic solutions for the Einstein gravitational equations that allow for the privileging of specific coordinates of time. In the gravitational field surrounding stationary bodies (e.g., the earth or the sun), it is suitable to choose the time coordinate in such a way that the gravitational field remains unchanged (i.e., the metrical coefficients are independent of time). This time has a different rate at different distances from the body, as can be demonstrated by the red shift of spectral lines in the case of sending the signal "upward." Similarly, in cosmology, the proper time of objects participating in the expansion of the universe is privileged, synchronized in such a way that its value corresponds with an equal level of evolution of the universe. Supposing the homogeneity and isotropy of the universe on large scale, cosmology thereby introduces time exhibiting some similarity with Newtonian absolute time.

The history of physics includes theories refuting the uniqueness of proper time. The Weyl unified theory from 1917 supposed that clocks moving along different paths do not retain their calibration after meeting, but Einstein showed that this contradicts the identity of atoms in the same quantum states. The theory of kinematic relativity, proposed in 1948 by Edward A. Milne, worked with two different measures of time, electromagnetic and mechanical, with the rate changed in the course of cosmological evolution. Similar ideas could be revitalized by the discovery of time variabilities of physical constants, but at present there exists no evidence for this.

Time, Reversal of

Our perceptions of the irreversibility of time seem obvious. We remember the past, we experience the present, and wonder about the future. Organisms are born, live, and die. Entropy, the gradual loss of energy by a body, increases. Nothing in our experience runs backward. There is even a popular phrase for this awareness—the arrow of time. Arthur Stanley Eddington, a physicist, popularized this phrase in the 1920s.

This belief in the forward motion of time is relatively new in our cultural history. Primitive peoples thought time was cyclic. They watched the recurring cycles of time in terms of the movement of the heavens and the seasons and drew a logical, if unstated, conclusion that the past and the future were constantly revolving and repeating. In Western culture, this was true until Judeo-Christian beliefs posited the concept of the irreversibility of time.

However, whether approached from the standpoint of Newtonian physics, Einstein's special theory of relativity, or the quantum mechanics formulated by Heisenberg and Schrödinger, there is a problem with our perception of the arrow of time. Equations from each of these fields work just as well whether time is running forward or backward. Another physicist, Eugene Paul Wigner (1902–1995), formulated the consequences of time reversal invariance for the solutions of the equations of quantum mechanics. Invariance, in mathematics, describes quantities that are unchangeable in mathematical operations. Wigner established the general notion of the time reversal transformation of quantum states. As it turns out, there is a resolution to this apparent paradox. Statements in quantum terms about the reversibility of time deal with equations relating to motion and not about actual motions that we experience empirically.

When physicists or mathematicians talk about time, they generally use the symbol T to represent the time variable. As such, T is an additive variable; that is, time intervals are physically measurable and can have associated algebraic signs (plus or minus). One can add two intervals together to make a longer one, or subtract intervals to create shorter time intervals. The neutrality of mathematical equations, particularly in physics, would imply that negative T can exist, and this possibility makes it easier to solve some equations as well as to deal with equations formulated in the mid-19th century describing the behavior of electromagnetic waves.

James Clerk Maxwell (1831–1879) was responsible, among other important discoveries, for developing equations that expanded from Michael Faraday's theories about electricity. Maxwell's research ended with four mathematical equations (known as Maxwell's equations) that described how electrical and magnetic fields performed. Maxwell's most important achievement was his extension and mathematical formulation of Michael Faraday's (1791–1867) theories of electricity and magnetic lines of force. In his research, conducted between 1864 and 1873, Maxwell showed that a few relatively simple mathematical equations could express the behavior of electric and magnetic fields and their interrelated nature; that is, an oscillating electric charge produces an electromagnetic field.

Maxwell's equations applied to radio waves imply that these waves travel at the speed of light, yet the equations are invariant regarding the past and future. In other words, the equations work equally well whether radio waves travel into the future or the past.

Two physicists, John Archibald Wheeler (1911–) and Richard Phillips Feynman (1918–1988), studying the mathematics and physics of electromagnetic waves in the 1940s and Maxwell's equations, advanced the idea that radio waves could be received both after and before transmission from the source. Waves that arrived after transmission are called retarded, and waves that arrive before transmission are advanced. Wheeler and Feynman hypothesized that advanced and retarded electromagnetic waves are produced in equal measure. Perhaps a radio transmitter sends out 50% of its power into the future and 50% into the past. Why then, do we not hear the advanced (past) radio broadcasts?

Wheeler and Feynman theorized that the advanced waves from a radio transmitter are absorbed by matter and disappear. However, the absorption itself produces secondary radiation in the form of new electrical charges, again with one half advanced and one half retarded. Eventually, the advanced waves return to their original source. Wheeler and Feynman were able to prove mathematically that the advanced secondary radiation could double the original transmission, which eventually would cancel the advanced wave of the original source through interference. This scenario could explain why we do not hear radio broadcasts from the 1920s.

The theory rests on an assumption that all of those radiated waves are eventually (no matter how long it takes) absorbed, as they reach farther and farther into the universe. If not, then at some point enough might return to the earth in the form of advanced (past) radiation. Perhaps this does happen, but our equipment is not sensitive enough to detect something like Franklin Delano Roosevelt's inauguration speech in 1932 where he said, "The only thing we have to fear is fear itself."

Several experiments have attempted to test whether or not any radio waves go into the past. Bruce Partridge tried beaming more or less continuous beams alternately between the universe and into a local absorber. His theory was that if any radio pulses were transmitted into the past as well as the future, then the waves that reached the past would have an effect on the power consumption of the transmitter. Even his most sensitive instruments did not find any such diminishment of power. An experiment by Paul L. Csonka suggested a different way to test this, but equipment sensitive enough to complete such a test was not available. In 1980, another physicist, Riley Newman, used a dipole-transmitting antenna fed with periodic microwave pulses of very short duration. A receiving dipole antenna 10 meters away searched for power above background noise level at fractions of time before transmission of each pulse. However, he concluded that if there were an incoming wave from the past, it would miss the detector antenna and arrive at a very different time. Therefore, none of these experiments established physical evidence of advanced waves.

As more particles such as antimatter and various subatomic particles such as the kaon are discovered and studied, there may at some point be a definitive way to determine whether, as there is with spatial asymmetry, time itself is asymmetric or symmetric.

Time, Sacred

Sacred time is, in the strictest sense of the term *sacred,* time set apart. It is time that is separated from profane, everyday time, distinguished by its connection with the deeper, holy, extraordinary experience of life. Sometimes described as "the breaking forth of the eternal in time," the experience of sacred time has been conceived variously as a presence in which the past and future collapse into an "Eternal Now," or the complete conflation of past, present, and future into something that might be referred to as timelessness or the collapse of time. It includes notions of a sense of time "bending" or "stretching," particularly during private or public rituals; accompanying psychological or physical trauma; or resulting from deep encounters with an extraordinary event, object, or being. The experience of sacred time neither necessarily suspends nor eradicates "common" time. There are, however, instances where cultic beliefs regarding either a cosmic or individual end-time include an enlightenment that takes place outside of time, or where the ritual or spontaneous experience of the eternal includes an experience of the transcendence of time. An iconic experience of this transcendence of common time is represented, for example, where Buddhist iconography depicts the Buddha as sitting under a bo tree just before his enlightenment, then as having disappeared from under the bo tree upon his enlightenment, and finally as sitting under the bo tree again upon his decision to return to work toward the enlightenment of the world.

For the nonbeliever, the concept of sacred time is as a study in religious anthropology. For the believer, it is a study in piety. Whereas none are exempt from the biases of their own concepts of time to render a purely scientific assessment of sacred time, rigorous studies of sacred time do seek to avoid either religious or secular doctrinarism.

Whether grounded in philosophical or religious commitments, the main aspects of sacred time broadly include "cosmic sacred time" or the understanding of sacred time as it relates to the origins and ends of the universe, and "human sacred time" or the historical experience of human communities with their calendars of ritual time including feast, fast, and worship.

Cosmic Sacred Time

Basic to cosmic sacred time are the two ends of the cosmological spectrum: the cosmogon and the eschaton, the universe's beginning and its end. Cosmic sacred time presents sacred time on a cosmic scale calculated, so to speak, on the timepiece of the gods. Concepts of cosmic sacred time reflect what is arguably the primary directive of the religious enterprise: to explain the beginning of things and to speculate or give reassurances about the end of things. Various cultic systems provide sometimes vague, sometimes detailed speculation on the timeline that separates the cosmogon from the eschaton. For those cultic systems, this span reveals the ultimate sacred history.

Perhaps the greatest divide between broadly categorized concepts of sacred cosmic time lies between linear cosmic sacred time and cyclical cosmic sacred time. These two concepts are often referred to, in an imprecise way, as Western and Eastern concepts of time, respectively. But the more religious concepts anthropology and archaeology uncover, the less precise this geographic distinction seems. The history of Western, Greco-Roman-based philosophy is scattered with the ideas of an "eternal return." Many if not most European and American indigenous religions testify to the cyclicality of the world. And for their part, nominally cyclical concepts of time often appear to reflect cyclical experiences that are nevertheless experienced within a context of clearly linear time: cycles of birth, death, and rebirth—whether of a soul or of a universe—do not necessarily require or even imply the birth, death, and rebirth of exactly the same soul or the same universe.

The classical Mayans possessed perhaps the most well-known time-obsessed religious system. With a system of calculation that precisely calculated astronomical events spanning millions of years, the Mayan calendar appears to have calculated the beginning of time starting on the order of billions of years before the present. Some have proposed that the end of the Mayan calendar, though not, apparently, the end of time itself, can be calculated as coming late in either 2011 or 2012 CE. Although popular eschatological and apocalyptic speculation may well accompany the approach to this proposed end, scholars suggest that the classical Mayans themselves expected a "great change" rather than a proper universal eschaton. Not surprising for a belief system that placed such enormous emphasis on time, an end of time itself does not seem to have been part of the Mayan concept of cosmic sacred time.

The structure and timescale in the concepts of Hindu cosmic sacred time have been recognized as similar to those of modern scientific theories, speculating as they do on a potentially infinite succession of universes each with their beginning, middle, and end. Hindu concepts of cosmological time have included the establishment of each cosmogon in the flowering of a lotus from Brahma or in the Golden Womb. After a succession of phases called *yugas* that are perhaps billions of solar years long, a final and corrupt yuga would follow and, at its end, the closing of the universe that would be just as intimately connected to the divine as its opening. The big bang eventually is followed by the big crunch. According to most Hindu systems, the current universe is in its final yuga. Although the end of the current and final yuga is most commonly conceived as being millions of years after the present, imprecision has afforded sufficient interpretive room to allow for the occasional speculation on, and anticipation of an imminent eschaton.

Possibly due to their wealth of written scripture, Buddhist cosmologies are perhaps even more diverse than those of Hinduism, from which Buddhism inherited many of its cosmological and eschatological concepts. As for the end of time, Buddhist schools speculate that in a long succession of enlightened ones (or Buddhas), the coming Maitreya Buddha would be the final one. As with Hinduism, which declares the last age to be the most corrupt, Buddhist eschatology anticipates that the return of the final Maitreya Buddha would be preceded by great human corruption, the most telling aspect of which would be the complete forgetting of the Buddha's teaching. It was originally thought that the Buddha Shakyamuni had declared that his teachings would disappear close to 500 years after his death. But when that time came and went, this date was clarified by some of his followers as being not 500 but 5,000 years. Some time after these 5,000 years, the Maitreya Buddha would bring all beings to an enlightenment that would occasion a blissful human earthly experience or, alternatively, a Nirvanic collapse of time.

In Judaism and its inheritor Christian and Muslim systems, circumstances surrounding the birth of the universe are less clear than those connected to the creation of the world, which has been dated at a little more than 5,700 years before the present. Cosmological themes similar to other sacred systems already mentioned include formlessness and chaos preceding the activity of a creator God. Eschatological speculations within Judaism and among Judaism and its offspring, however, vary widely.

Late BCE and early CE Judaism was rife with messianic fervor during Greek and Roman dominance in the Eastern Mediterranean from at least the time of the Maccabee Revolt (165–67 BCE) and increasingly around the time of the fall of the second temple in Jerusalem (70 CE). Beliefs varied among different Jewish sects as to whether the arrival of a messiah would result in a divine reign in time or a collapse of time into a Platonic eternal present. In addition to better-known Jesus and

Dead Sea sects, there were various Jewish communities that gathered outside a Jerusalem laid ritually waste by occupation forces and their—from the perspective of these sects—apostate Jewish collaborators. One end-time scenario possibly produced by just such a sect is the Jewish Book of Daniel (mid-2nd century BCE) and its later imitators, including most famously the Christian Book of Revelation (mid- or late-1st century CE). In both of these texts, the essential message was articulate and succinct: The eschaton was near. Since the timeline of the Jewish canonical Book of Daniel came and went without the expected apocalypse, Messianic Judaism has made few claims of a sacred timeline for the eschaton, though speculation about possible messiahs continues.

In the sweep of Christian cosmic sacred time, various Christian sects have maintained the nearness of the eschaton ever since. There have been a variety of interpretations of cosmic time within both orthodox and heterodox Christianity that have included eschatological expectations around the year 500 CE, then before and after the turn of the 1st millennium CE, then around the turn of the 2nd millennium CE, and at various points in time in between.

Islam inherited both Messianic Jewish and Apocalyptic Christian expectations when the belief system accepted the books of Judaism and Christianity as divinely inspired, albeit not as authoritative as the direct words from the divine found in the Qu'ran. The Muslim eschatological concept focuses on the *Qiyamah* or Last Judgment. There are hadithic references to the expectation that this Last Judgment would be inaugurated by the return of the Prophet Jesus; but perhaps having learned from their Christian cousins, Muslims have tended to avoid any reference to the nearness or distance in time of the eventual eschaton.

Human Sacred Time

Human sacred time consists of time that is intentionally set aside for the purposes of at least acknowledging and anticipating, if not necessarily experiencing, "the breaking forth of the eternal in time." Observed throughout the world and throughout history, human sacred time results in calendars that regulate feasts, fasts, and ritual worship. Experiences that are considered to have been personal sacred moments (e.g., Saul of Tarsus's enlightening experience falling off his donkey), although certainly significant for the individual involved, are not times that have been intentionally set aside. As such, these are not included in this concept of human sacred time.

Ancient civic cultic life intentionally integrated political and sacred calendars or, perhaps more accurately, recognized no such distinction between the religious and the civic. Cultic practices of ancient Greek, Roman, and Asian civic cults grew up as virtually indistinguishable from their mythological cults, arguably rendering both civic and mythological cults "religious." More modern civic religious or quasi-religious cults such as Soviet, Nazi, or nationalistic cults, however, appear either to layer an intentionally and transparently fabricated mythology onto their civic cult or, alternatively, to adapt a preexisting mythological cult to meet their civic needs. As such, although modern civic cultic practices produce structures that function like human sacred time, they are at least nominally secular.

Sacred feasts celebrate the preferred god or saint or some divine or holy event. Feast time has often suspended distinctions, particularly social and economic distinctions. Kings might be lampooned or even come to bodily harm; servants might become "masters" for a time; or, in its diluted modern echo, secretaries might demean their superiors by cutting off their bosses' neckties. Such contrived and time-limited equality is reflected most clearly in the many cults where sacred feasts have been communal ritual meals. Whether this represents a theological position that the gods treat all humans equally or, on the contrary, reflects a reprieve from divinely established inequality, feast time provides an outlet for social pressure from below that might otherwise boil over—and do so under much less circumscribed circumstances.

Sacred fasts, which are at a minimum the sustained, nonnecessary suspension of solid nutrition, are closely connected to ritualized mortification or sacrifice. In the fast, the participants are usually encouraged to contemplate, just as in the feast they are usually encouraged to, celebrate. Somewhat more dramatically than in the feasts, the fasts often provide for, or contribute to a cultic path toward the sacred encounter. As such, fasting can encourage a personal, individual breaking forth of the eternal. More often, the fast serves to remind the participant of mortality, dependency on the cult's sacred source, or both.

Whereas feast and fast times are in a sense extraordinary, ritual sacred time is regular and includes scheduled worship. Scheduled worship sets aside a regular time to celebrate, contemplate, venerate the divine, or to abase oneself with perhaps less intensity and therefore perhaps somewhat diminished expectation than feast or fast time. Although ritual sacred time does not always necessarily include the breaking forth of the eternal in time, it does attempt to create an environment in which such a breaking forth is made possible in the worshipping moment. At minimum, ritual sets aside time for reflection on, and celebration of, an experience of the eternal in the past; or a time to focus on the hope in, and anticipation of the arrival or return of the eternal in the future. This experience of sacred time can result from the visitation of a god, gods, or deputy of the divine such as an angel or familiar of the god; the arrival of a divine person or avatar; simply "feeling the presence" of the divine or the eternal; or otherwise having the experience of transcending or existing out of time or physical space.

In addition to connecting a community to the important events in the lives of a cult's heroes and martyrs, human sacred time also connects a community to important astrological events. The most obvious of these are the events connected to the cycles of the earth and its sun. The solar year appears to be a nearly universal unit of time, the often invisible and unquestioned context in which sacred calendars are set. Seasonal events based on the earth's solar cycles have provided the context for the vast majority of sacred feasts and fasts. Closely associated with these seasons are the plant-focused events of gathering or farming cultures. Here, feasts and fasts reflect social or individual needs that coincide with the economic realities of seed time and harvest. Analogously, many hunting cultures integrate animal migration, mating patterns, and spawning seasons in their sacred calendars. The other main astronomical body that focuses human sacred time is of course the earth's moon. Lunar cycles have been closely attended to, even among cults that otherwise hold little or no particular reverence for the moon itself. Judaism and its descendant cults provide well-known examples of lunisolar calendars, human sacred time that follows the movements of both the sun and the moon. Other heavenly bodies that have influenced sacred calendars include, for example, Venus, Mars, and particular constellations of stars.

Conclusion

Both religious and secular sources have provided explanations for the apparently universal cultural experience of human sacred time. On the pious side, reasons for the intentional setting aside of time can include the necessity of sacred time to ensure the continuation of the individual's or the community's divine favor, or even the continuation of the universe itself. On the secular side, psychology, sociology, and anthropology describe sacred time as an essential tool for community coherence, or simply a means to make life more enjoyable or even bearable.

Persistent questions that continue about sacred time include debates about whether sacred time reflects an escape from life or a deeper experience of life; and whether the source of sacred time exists outside of or is somehow transcendent of time, or is best explained by natural human social or psychological needs. The basics, however, are well established. When fully understood, sacred time on both the human and the cosmological scale have been present in all cultures at all times, including the most secular of cultures and times. Observing and investigating the phenomena of sacred time provides important insights into particular cultures, revealing much about concepts of the sacred, the cosmos, the human, and time itself.

Time, Sidereal

The precise definition of a sidereal day is the time it takes for the vernal equinox to return to the local meridian. The local meridian is simply an imaginary circle that connects the celestial north with the celestial south and passes through the zenith (the most overhead point) and nadir (the most underfoot point) relative to the observational location. The celestial sphere is an imaginary shell encompassing the earth on which all other objects are placed without taking into account stellar distances (see Figure 1). On the celestial sphere, the vernal equinox is the zero point for the equatorial coordinate system. The vernal and autumnal equinoxes are the points where the celestial equator intersects with the earth's orbital path. The length of a sidereal day is 23 hours, 56 minutes, 4.1 seconds. It is slightly shorter than the solar day, which causes stars to appear to rise and set earlier each night.

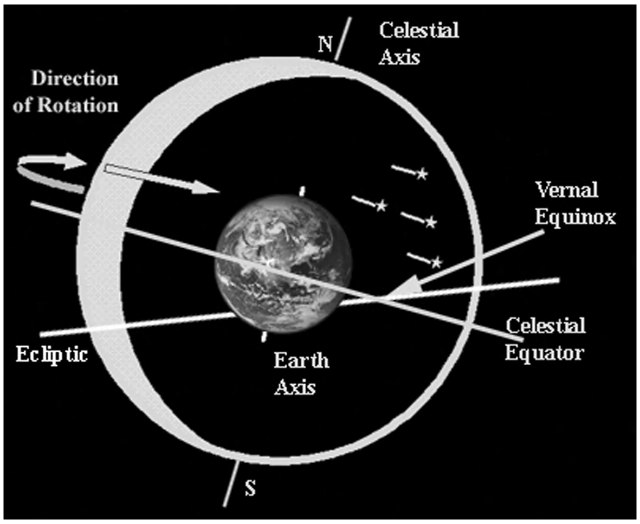

Figure 1 External view of the celestial sphere

Observational Effects

A less stringent method can be applied to any object on the celestial sphere, for example an arbitrary star such as Antares (Figure 2a). Any star appearing against the stellar background will need one complete sidereal day to return to its starting point (Figure 2b), as Antares has below. This includes not only stars near the earth's equator, but also stars and objects that appear at both polar regions and all points between. Since the sun is comparatively close to the earth, and the distant star is relatively "fixed" to the stellar background, the sun will take an additional 3 minutes, 56 seconds of the earth's rotational time to return to the local meridian than does the star. While the earth's axis is currently directed toward the region of Polaris, it is not fixed, and Polaris on a daily basis exhibits a small circular path that takes one sidereal day to complete. Stars near the poles tend to circle the polar regions visibly night to night, and are called circumpolar stars. These stars neither rise nor set because the earth's axis of rotation is directed toward those regions.

Precession of the Poles

The earth's northern polar axis will not always remain constantly aimed at Polaris, however (and the southern axis will change accordingly). The earth is acted upon by external gravitational forces such as the sun, moon, and other planets. This effect causes the earth to wobble and not spin vertically, but rather obliquely, like a gyroscope. This effect is called precession, and influences where the earth's axis will celestially point in a somewhat large area of space. The cycle, or Precession of the Poles, takes approximately 25,800 years to complete. In approximately 12,000 years from now, the star Vega will be the object of direction for the earth's northern axis. The South Star is currently Sigma Octans, and is quite faint. However, in 2,200 years, the star Gamma Chameleon will mark the southern pole with a bit more luminescence.

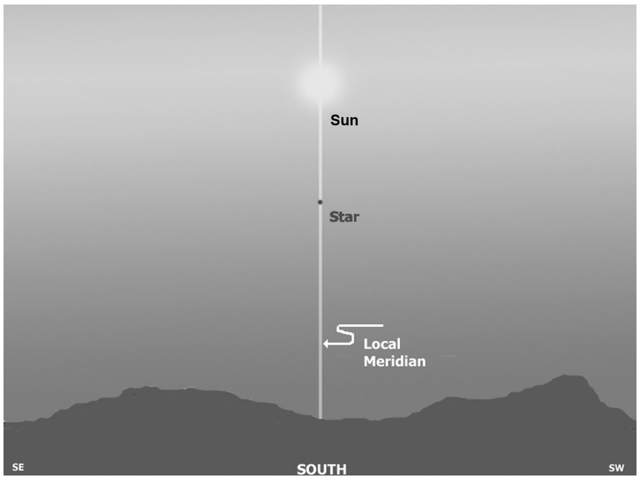

Figure 2a View of the sky at local noon on Day 1. Both the sun and the star are on the local meridian

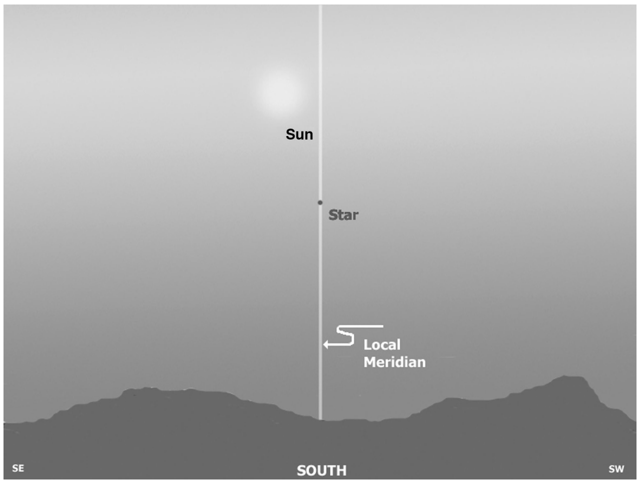

Figure 2b The star has returned to the local meridian before 24 hours has elapsed

Seasonal Variations

Throughout the year, the rotation of the earth and its orbit around the sun cause a seasonal shift in constellations. In addition, the axis of the earth is inclined at 23.5 degrees. This causes an additional change in the relative positioning of the objects on the celestial sphere. Following the vernal equinox, the sun and the stellar background objects seem to take a northerly change with respect to the ecliptic until the summer solstice, then a southerly decline past the autumnal equinox to the winter solstice. A northerly apparent shift resumes between the winter solstice and the vernal equinox, and the cycle repeats. On the vernal equinox, sidereal time and solar time are at their peak coincidence. Likewise, they are at 12 hours' difference on the autumnal equinox.

In the northern hemisphere, for example, the star Sirius makes a visible appearance in the summer dawn sky. After one sidereal day, Sirius returns to the exact same location; the sun, however, does not return for an additional 3 minutes and 56 seconds. After 6 months, this effect of the earth's revolution will lead to Sirius becoming visible almost 12 hours later.

Sidereal Variation

Measuring precise daily transits of the sun across the meridian uncovers discrepancies in the length of a sidereal day. These inconsistencies are due to the eccentricity of the earth's orbit as defined by Johannes Kepler. In addition, the sun's apparent annual motion varies along the ecliptic as it returns to the vernal equinox. These motions occur as the earth approaches the sun leading to its orbital perihelion, thus shortening the length of its sidereal day. As an object in orbit approaches the parent body, gravity accelerates the object and causes an apparent shortened time as the object has moved further and subsequently its parent object reaches the meridian faster. The reverse is true at orbital aphelion; the orbiting object is at its slowest, and therefore takes longer for the parent body to reach the local meridian, slightly lengthening the sidereal transit.

Sidereal Calendars

The ancient Egyptians employed a sidereal calendar in conjunction with a lunar calendar; it was the first to incorporate a fixed length of days to measure one year. The Julian calendar did not exist until the last century BCE (by some accounts, 46 BCE). The Egyptian new year occurred when Sirius was first visible in the morning sky, which in modern times corresponds to July 19. Akin to a lunar calendar, a sidereal calendar causes too much variation with respect to solar positioning.

Time, Subjective Flow of

The subjective flow of time changes continuously. This variation is part of our everyday experience. When we are waiting, bored, or feeling blue, the subjective passage of time slows down. Time drags. When, however, we are involved in a fascinating discussion or absorbed in a skillful performance, we can become unaware of time and later feel that time has passed very quickly. As these examples show, attention and mood states play a fundamental role in the subjective passage of time. As explained below, our experience of the flow of time is based on our cognitive and emotional states.

In a phenomenological analysis of time experience, Edmund Husserl and Maurice Merleau-Ponty discern two complementary aspects of temporality: (1) the feeling of a present or "nowness" and (2) the flow of time. William James pointed out the paradox of this dual experience of time. We perceive the unity of the present. A fundamental temporal window of consciousness spanning a few seconds defines our sense of now. We simultaneously experience the passage of time, best described by a stream or flow. Events that have a certain duration constantly slip into the past. The flow constitutes itself into an event that might be anticipated, then actually experienced, and later remembered. This very phenomenon constitutes our experience of temporality.

The speed with which time flows can vary considerably. The allocation of attention to time or to events constitutes the first of two basic factors which influence whether the flow of time "speeds up" or "slows down." When we focus our attention on time, time slows down. When we are distracted from the passage of time, it speeds up. The upper portion of Figure 1 depicts this relationship graphically. The more we attend to the passage of time (left portion of the upper triangle), the slower the subjective passage of time and the longer the duration of experienced time. The more we pay attention to events around us (right portion of the upper triangle), the faster the subjective passage of time and the shorter the duration of experienced time. Thus, Figure 1 applies to the situation in which we attempt to achieve a sense of the flow of time, that is, we are "prospectively" (at present) attending to time (we are interested in how fast time goes by). When absorbed in entertaining activities, like watching a dramatic play or working on something exciting, we do not pay as much attention to time, and time "flies by." Attentional models of time perception have been formulated to account for these phenomena by assuming an internal "clock," similar to a stopwatch with a pacemaker and an accumulator, which emits and stores temporal units, respectively, and represents subjective time.

Emotional processes have an influence on whether attention is *directed to* or *distracted from* time. A subjective slowing of the flow of time is often experienced when we are bored, anxious, or depressed because when we are suffering from psychological distress, we have fewer meaningful thoughts and engage less in entertaining activities. Consequently, time becomes the focus of attention and is perceived as slowing down. Impulsive individuals often experience time as passing too slowly. As they easily become impatient in everyday waiting situations or when few distracting events are happening, these individuals pay more attention to time and subsequently experience an intensive deceleration of time. In contrast, when we are in good spirits, we usually are not focused on the passage of time. We may be absorbed in our activities and "forget" about time. When we finally get around to checking the time, it appears to have passed very quickly, and we are astonished.

A second factor also influences the subjective flow of time. This factor has yet not been accounted for here, but has often been reported in dangerous or life-threatening situations. In road accidents or encountered violence, attention is not directed to time, but focused solely on the sudden, unexpected situation. Nevertheless, people afterward report that time was slowed down, individual moments appeared prolonged, or everything even seemed to occur in slow motion. During a life-threatening event, a person experiences strong emotional

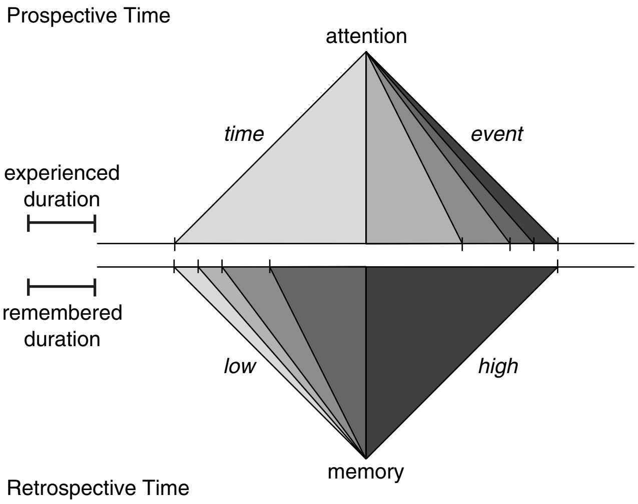

Figure 1 The paradoxical experience of the flow of time

Source: Illustration by Virginie van Wassenhove.

Notes: The upper triangle shows how paying more attention to time leads to a subjective slower passage of time and longer time intervals. In retrospect, however, the passage of time seems slower and time intervals appear to be longer when initially (prospectively) more attention was paid to a time period containing a lot of events that we stored in memory.

distress, needs to react as quickly as possible, and, for this reason, must direct all bodily resources to "fight or flight." Attention is focused on survival skills. Increased mental processing speed enabled by heightened arousal levels is fundamental to coping quickly with the threatening situation. If mental processing speeds up considerably, external events slow down in relation. As the world subjectively slows down, the person suddenly feels she or he has more time to choose adequate responses. In movies depicting battles, the scenes are often shown in slow motion to portray what a person in combat subjectively experiences.

Cognitive and emotional modulations in the flow of time have hitherto been discussed in the context of the present moment, that is, when an observer is presently experiencing a variation of seconds or minutes in the passage of time. However, the flow of time refers to past time intervals, and these time intervals can span years or decades of someone's life. Looking back, memory constructs the feeling of duration or the flow of time (too often leading to the surprised response of "how fast time passes"). Another time paradox unfolds: The time intervals that prospectively were perceived as passing so slowly (while we were directing more attention to time) are in retrospect perceived as if they had lasted a very short time only. Similarly, when we were not paying attention to the passage of time because we were involved in a lot of activities, the retrospective time interval seems to have lasted much longer. Figure 1 depicts this time paradox where an interval that lasted a long time prospectively (upper triangle), appears to have lasted a much shorter time in our memory (the segment with the same shade of gray in the lower triangle)—and vice versa. Time intervals prospectively last so long because nothing exciting is happening, but later on, after this time span has passed, nothing remarkable has been stored in memory. When, however, the flow of time was fast, a lot of interesting events happened, and these experiences, thoughts, and feelings were stored in memory. Memories form the building blocks for our conception of how fast time has passed or how long a duration has lasted in retrospect. Time intervals filled with exciting memories of changing events are regarded as having lasted longer. The flow of time is then retrospectively much slower compared to periods when, for example, during everyday routine, nothing extraordinary happened.

When looking back at periods of our life, we often feel that time passes too quickly. Inferring from the factors which influence the retrospective experience of time, it becomes quite clear that we can change the speed of the subjective flow of time. However, we can only modulate how fast time seems to pass. Time still goes by.

Time, Symmetry of

Although everyday experience leads us to believe that time "flows" in one direction, the equations of both classical and modern physics work equally well in either time direction. Since these equations accurately describe all observations of physical phenomena, from those made with the human eye to those made with the finest scientific instruments, the implication is that time can flow either way.

The *arrow of time* of human experience results from the fact that macroscopic objects contain many particles and these, to a great extent, move about randomly. The probability for a phenomenon happening in one time direction, such as air escaping from a punctured tire, is often much greater than the probability for the phenomenon happening in the opposite time direction, such as outside air reinflating a punctured tire. The reverse time event is not impossible, just highly unlikely. The arrow of time is defined as the direction of most probable occurrences.

At the level of chemical, nuclear, and elementary particle interactions, however, reactions occur in either time direction. Statistical differences between initial and final states can result in different reaction rates for the two directions, but at the basic interaction level the two directions are equally likely.

One exception occurs in certain elementary particle reactions that are mediated by the weak nuclear force. There a slight asymmetry of 1 part in a 1,000 exists. However, reactions can still proceed in either direction with only a slight difference in probabilities.

In 1949 Richard Feynman showed that an antiparticle, such as the anti-electron or *positron,* may be viewed as a particle going backward in time. This symmetry is built into the visual aids called *Feynman diagrams* used by physicists to calculate the rates of various reactions between elementary particles.

Despite the basic time symmetry of physics, most physicists continue to assume directed time in their models. This generally makes no difference, since a particle going backward in time is empirically indistinguishable from its antiparticle going forward in time, where "forward" is defined by everyday experience.

It has been known for decades, however, that quantum mechanics predicts certain phenomena that seem paradoxical. For example, electrons and other particles behave as if they can be in two or more places at the same time. Experiments have been performed that suggest "backward causality," where the changing of the parameters of a detector

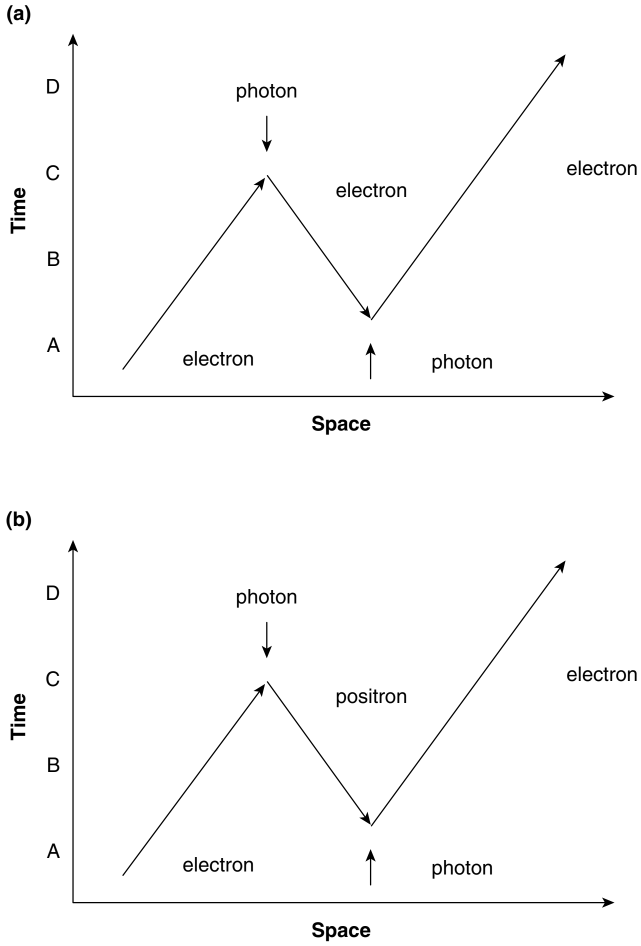

Figure 1 The "Feynman spacetime zigzag"

Notes: In (a), an electron goes forward in time, scatters off a photon, moves backward in time, scatters again, and goes forward. Note that the electron appears simultaneously in three different places at time B. In (b), the conventional time-directed view is shown in which an electron–positron pair is produced at time A, with the positron annihilating with the other electron at time C. The advantage of view (a) is parsimony, with no need to introduce antiparticles. It also offers an explanation for the indistinguishability of electrons.

after the particles to be detected are already in flight affects the behavior of those particles, even though they cannot be reached without sending a *superluminal* signal (signal traveling faster than the speed of light, violating Einstein's theory of special relativity). This is taken as evidence for *nonlocality* in quantum mechanics, in which two events separated in space are still connected despite the fact that no signal can pass between them without going faster than the speed of light.

Time-reversibility offers a possible explanation for these observations. For example, an electron can be seen to appear at two places at the same time when one uses the picture introduced by Feynman, as illustrated in Figure 1. An electron moving through space can be turned back in time by a collision with a photon. Normally this is viewed as simply the production of an electron–positron pair.

We can, however, view the positron as an electron going backward in time. If, in the "past," it is reversed again by a collision with a photon, it can proceed forward in time again, thus appearing in two places at once.

If we insist on a single time direction, an electron appearing two places at once implies superluminal motion (motion faster than the speed of light), which is forbidden by Einstein's theory of relativity. Indeed, in this case infinite speed is needed. While relativity does in principle allow for superluminal motion, it is restricted to particles called *tachyons* that must always travel faster than the speed of light. Particles, such as electrons, that normally travel at less than the speed of light cannot be accelerated beyond that speed. In any case, no tachyons have ever been observed.

In short, time reversibility is not forbidden and indeed is suggested by the basic principles of physics. Furthermore, time reversibility can help to explain the so-called paradoxes of quantum mechanics, what Einstein called "spooky action at a distance," without involving superluminal motion.

Still, one problem remains to be resolved: the *time travel* or *grandfather's paradox*. Simply stated, if you could go back in time, you would be able to kill your grandfather before he met your grandmother, in which case you would never have been born!

The answer to this paradox is rather subtle and has to do with the definition of the arrow of time. Time's arrow is determined by the direction in which the entropy of the universe increases. Entropy is a measure of disorder. Negative entropy is thus a measure of order or information. Thus time's arrow is the direction in which information decreases.

Now, if you were to go "backward" with respect to the conventional direction of time to kill your grandfather, you would be using information from the future that was not available in the past. This implies that the future has more information—*lower entropy*—than the past, a contradiction. That is, it would not be the future but the past by definition. If you traveled back without any information, as if you had amnesia and did not even know your own name, there would be no contradiction, but you would have no way of identifying your grandfather.

Time, Teaching

Because of the time-structured nature of modern society, learning about time is an important element in the socialization of children. Despite its importance, teaching about time is difficult, because it requires developing the most complex mathematical ideas and skills that a child will learn up to about age 12. Understanding time requires the perception that events take place in sequence and are proportionally spaced relative to each other; for example, that breakfast is in the morning, always before lunch, and that that interval is shorter than the lunch–dinner interval. This perception is difficult for young children to develop. Cultivating this perception, building time vocabulary, linking "time sense" to the socially constructed system for measuring time, and operating mathematically within that system must be done by creating physical and social experiences for children as their abilities to comprehend abstract ideas increase with age.

In addition to developing the personal ideas that a child must know to use time effectively, instruction must be linked to other social structures and mathematical thinking, as well as to science concepts defining *day* and *year.* Day and year are the elements of time defined by the reality of nature; all other concepts and units are socially constructed. Teaching time must also develop language and incorporate generalized reasoning and problem solving. A teacher creates activities appropriate to the learner's age, cognitive development, and background experience that challenge the child while creating success. To develop the ideas and skills concerning time, we engage the learner in social interactions to understand physical experiences in order to create active learning that builds deep understanding. Over several years, teaching time must refine the child's understanding of time and develop the language to use it in communication.

Time is difficult to teach meaningfully to children in that the basic ideas are all *constructs,* that is, concepts that have no physical referents. Any concept is a mental construction of the rule that makes all members of a class alike but different from nonmembers. A concept such as *mammal* can best be developed by having children encounter different mammals and through discussion drawing their attention to what makes these examples alike. The concept is further refined by showing how the examples differ from nonexamples, for instance, how mammals differ from reptiles or fish. Alternately, a *construct* is an idea that is built up from other ideas, such as *fairness.* Fairness means free from bias, dishonesty, and injustice, that is, not possessing qualities expressed in other ideas belonging to different constructs. Time constructs explain events in the physical world, but a child cannot hold time, smell it, or feel it. It is an idea that is created by a mental awareness of the pattern of day and year, which are characteristics of the world in which we live.

The basic paradigm for teaching abstract ideas, with the complexity identified above, is to develop the foundational ideas intellectually and build mental relationships among them. The physical component of instruction is to involve the learners in a physical/sensory event and draw their attention to the germane aspects of the experience. The social component requires the use of oral and written language to refine the concepts. Preparation for this social component means developing language, including vague terms such as *soon, later, in a little while, evening,* or *twilight,* as well as precise terms like *noon, night, tomorrow,* or *10 o'clock.* The social component of naming, discussing, and comparing experiences with others gives the learner practice in mentally relating, organizing, and reorganizing the concepts being learned.

Learner-Appropriate Activities

Learning about time begins informally, as is true of other number-related concepts. Still very concrete in their thinking, preschool children begin to use numbers 1 through 10 and usually up to 20. Time vocabulary is developing related to experiences, for example, "*Time* to play!" "*Tomorrow* is your birthday." "We will do that *later.*" "How many *years* old are you?" At this age, it is easier to think about the future than the past, which may get confused with the present; all of *today* is equated to *the present.*

Young children's time sense can be developed by drawing their attention to the passage of time. *Time sense* is the ability to gauge the passage of time mentally and is needed both to grasp time units and to estimate. Funnels with sand can be used in a useful game of seeing which funnel allows the sand to come through *faster.* Preschool children can learn to compare two events that start together and recognize that the one that finishes first is "faster."

By kindergarten, children will know numbers up to about 70 and have a better grasp of what numbers represent. They should have experience with regrouping: the idea that one of one thing may be converted into several of something else, such as 1 dozen eggs is the same as 12 individual eggs. Instruction should develop a sense of *seconds* at this age, as the concept of second is easier to grasp than minute or hour; the child can hold a second's worth of experience in memory and think about it. Rhythmic counting accompanied by clapping helps develop this sense of a second. One child may count rhythmically while another child performs a task, so that the last number named represents the *duration,* just as the last number named when counting a set represents the value of the set. Events can now be compared even if they do not begin together: the one that requires the highest number of counts is "longer." The sense of seconds can also be refined by helping children find five things that take one second, five things that take 10 seconds, and so forth. These benchmarks allow a child to compare personal references to events encountered in other contexts. Telling time to the hour is more important than telling time to the minute, however, because hours are the key time markers of the day—we awake at 8:00, lunch is at 12:00, and we go home from school at 2:00.

By this age, home and school experiences have begun to develop concepts involving *measurement* of time. Measurement serves as an interface between physical experience and mental ideas that adds precision to communication and aids problem solving. Measurement compares a property of the environment against a standard, assigning a number to the property. To use any measurement system fluently in problem solving or social situations, one must have the previously described *personal references* for the socially agreed-upon units. The user must know how the standardized units compare to understood benchmarks and also be able to use the units to estimate values. Refining the previously mentioned *time sense* needed to understand the time measurement system is difficult for children, since the experience of passing time is affected by perception. To tell time, the student must understand personal event markers (lunch is at 12:00) and have a feel for the passage of time. Yet children, being concrete thinkers, think that the week before a birthday *seems* longer because it *is* longer than other weeks. An hour in the doctor's waiting room is longer than the hour of playtime in the afternoon.

Understanding the time-measurement system allows discourse with others incorporating time concepts, and this social interaction furthers the understanding of time. Activities and conversations draw children's attention to the concepts of age, years, and *birthday,* as well as the names of the days, months, and holidays. These discussions refine the child's understanding of *day* and *night* as defined by the presence or absence of light, and related terms including *yesterday, today, tomorrow, morning, noon, afternoon,* and *evening.* Continued attention to noticing "time" to wake up, eat meals, watch favorite television shows, and go to bed strengthens the child's sense of time.

Continued development of the sense of time passing can be enhanced by the presence of chiming clocks in the classroom (although after a period of acclimation, the teacher will have to draw students' attention to the chiming as they will stop noticing it). At this age, children can hold a longer experience in their memories and begin to grasp larger blocks of time. These children should make lists of five activities that take a quarter hour, a half hour, and up to an hour.

A major tool in developing time concepts and mathematical thinking in the primary years is the use of calendar activities every day. Children come to learn that today's date is signified by a name and number, and that a "month" is made up of days. Questions based on calendar activities can help children learn to count, add, and subtract while improving their sense of time passing. At this age children can name the days of the week and know such vocabulary as *weekday* and *weekend.* They should be able to name the months, classify them by season, and connect them to holidays and other events.

It is appropriate at this age to provide instruction on telling time to the hour. However, to do so effectively means accounting for the abstruseness of the digital clock versus the complexity of the analog clock. The digital clock is easier to use to learn to state the name of the present time, so much so that it is possible to name the time without relating this answer to its meaning. For example, it is easy for a 6-year-old child to use a digital clock to state that the present time is 5:56, but he may not understand at all that 5:56 is closer to 6:00 than to 5:00. The digital clock becomes a tool for the child to complete a defined task superficially without having the underlying conceptual understanding.

The digital clock does not convey the passage of time as well as an analog clock. In teaching time at this age is still trying to refine time sense, watching the second hand sweep around an analog clock dial is more sensory than watching a digital clock advance once a minute. Even if the digital clock has a second display, the child has to relate the numeral changes intellectually to the sweep of time. The analog clock also visually displays the idea that the time cycle restarts at 12:00, and it has other advantages.

Nevertheless, the analog clock also has its drawbacks. A typical "regular" clock is three timepieces in one housing. The face usually has a numbered set of indicators for hours (12) and may or may not have an unnumbered 60-part number line for minutes and seconds (60). The minutes/seconds are determined by determining a number of groups of five using the hour-indicating numbers (a mathematical process of skip counting that can be used as preparation for multiplication) and adding remaining units, for example, the minute hand is two marks past the 4, therefore 20 + 2 or 22 minutes. This is a complicated, multistep mathematical process at this age. After learning to use a fully articulated analog clock face, children can learn to interpolate on a clock face that has fewer, or possibly no, hour- or minute-indicating marks.

For starting to learn to tell time to the hour, a good instructional tool is a one-handed analog clock. Instruction should lead to conversations such as, "When the big hand is here (e.g., 8:00) at night, what might we be doing?" (Going to bed). Commercially available teaching clocks can be obtained for such activities. Another appropriate activity is to have a child roll a die, add that number of hours to 12:00 (Midnight), name the new time, and state something that might happen at that time (5:00 a.m.—I am sleeping.). Then a partner rolls the die, does the same thing, and the children continue taking turns.

By second grade, the learner has a more well-developed sense of time and a better grasp of the meaning of numbers (up to about 200). The goal at this age is to refine time-telling to the half hour, quarter hour, and nearest 5 minutes. With an analog clock, if the children have a sense of the meaning of the hour hand, then they may be shown a clock with the hour hand positioned and asked to predict where the minute hand would be; first practicing with hours and half hours and progressing to quarter hours. The clock face also becomes a tool for relating to other mathematics; for example, as a model for unit on fractions. The digital clock can be used more easily to link time benchmarks to the child's daily schedule, for instance, We go to lunch at 11:20, We check the outside temperature every day at 9:10.

In the upper elementary grades (3–5), the *Standards* of the National Council for Teachers of Mathematics call for students to be able to "select and apply appropriate standard units and tools to measure" time. By the third grade, instruction further refines time-telling with analog clocks to the minute. Now children can practice going back and forth between the two time systems, as they can use both systems with equal precision. Given a digital time, children are asked to draw what the analog face would look like or to write the digital time based on a picture of an analog face. The analog clock scale may also be "unwound" to a line and related to a 0–60 number line for other mathematics instruction. The clock scale can also be used as a model for negative numbers, as in "five minutes to lunch," or countdowns to events. Third grade is generally when fraction concepts are used more, and the 60-part analog clock face easily represents halves, fourths, thirds, fifths, sixths, and tenths.

In Grade 4 and above, more complex skills are introduced. Converting weeks into days and vice versa gives practice with a 7:1 conversion process, while day/hour is 1:24, hour/minute and minute/second are 1:60. Converting months to weeks and/or days requires conditional thinking, as months come in 28-, 29-, 30-, and 31-day varieties. Time lines, variants of number lines, can help visually scale historical events relative to each other.

Calculating elapsed time is good practice in a multistep mathematical task for which multiple algorithms (including those invented by the children) can be used to arrive at the answer. Computing elapsed clock time is usually introduced in Grade 4 and refined over a couple of grades. The three skills in elapsed clock time include: determine the duration given the start time and end time, find the end time given the start time and duration, or find the start time given the end time and duration. This instruction starts with finding durations in hours and half hours not crossing noon or midnight, and is eventually refined to finding durations in hours and minutes for events passing a.m./p.m.

By age 14 or so, students are much less limited by concrete thinking. An appropriate skill at this level is to estimate time requirements from a map or scale drawing. Given a map, the student should be able to determine how long it would take to get from one point to another. While a concrete-thinking child could not relate to the representation of a street on a paper map, the older and more abstract-thinking student can. This skill can also serve as a basis for simple, formal algebraic thinking, such as the development of the symbolic representation $D = rt$.

At this age, students can effectively discuss other social constructs such as time zones, the International Dateline, various calendar systems, and daylight saving time. Lessons in science will demonstrate the impact on physics and astronomy of the increased precision with measuring time through history. Internet resources provide intriguing options for various calendars and clocks, based on decimal or base-2 number systems, which can be incorporated into mathematics. Historically, some of the oldest human artifacts indicate records of time reckoning processes that imply our ancestors' first rudimentary observations of nature. This can lead into social studies discussions of prehistoric cultures' efforts at making calendars and keeping time.

Time, Units of

The units of time that we find in all cultures are the obvious ones based on observable natural cycles, particularly the global or astronomical events that seem to occur with regularity. The day is the interval between appearances of the sun in the sky at dawn; the month is the time for the moon to repeat one of its cycles; and the year is marked by when the cycles of the seasons repeat.

The 7-day week arose in Babylonian astronomy, the days representing the sun, the moon, and the five visible planets, which were regarded as deities.

The hour was used in a number of ancient civilizations, defined as 1/12 the time from sunrise to sunset, that is, 24 hours in a day. This probably reflected the widespread use of the base-12 or duodecimal number system in ancient times.

The definitions of the minute as 1/60 of an hour and the second as 1/60 of a minute probably arose from the Babylonian use of a base-60 counting system. There were 86,400 seconds in the 24-hour day.

Many cultures used the moon as the clock by which they scheduled various important rituals. It remains today the basis of the Jewish and Islamic calendars. However, the cycles of the moon are not closely linked to the seasons, with the result that these rituals drift though the seasons as the years go by.

As civilized life became more complex, these measures were refined. The Egyptians needed an accurate way to predict the rise of the Nile and found that counting the moon's cycles was inadequate. Around 4200 BCE they discovered that the "Dog Star" (now called Sirius) in Canis Major rose near the sun about every 365 days, around the time of the annual Nile flood. This led to the 365-day year, which is still in use.

However, the time between seasons is not quite 365 days and even the 365-day year drifts through the seasons. In order to better synchronize Roman festivals, in 46 BCE Julius Caesar introduced the Julian calendar, which included a leap day every 4 years. That is, the year was redefined as 365.25 days. This was corrected further by 11 minutes per year in 1582 with the Gregorian calendar. The Gregorian year is defined as 365.2425 days. The Julian year is still used in astronomy to specify the number of days for a long time interval. Astronomers, however, more commonly use the *sidereal year,* the time it takes the earth to complete one revolution in its orbit, as a fixed frame of reference.

As science developed, so did our units of time. The second was originally defined as 1/86,400 of a mean solar day. In 1956 this was changed by international agreement to 1/31,556,925.9747 of the tropical year for 1900 January 0 at 12 hours ephemeris time. (Since this is an obsolete definition, we need not bother explaining the meanings of *tropical year, January 0,* and *ephemeris time*.)

Defining time in terms of astronomical observations, no matter how precise the measurements, eventually proved inadequate. A clock was needed that could, in principle, sit by itself in a laboratory and not have to be constantly recalibrated against Earth's irregular motion around the sun.

In 1967, again by international agreement, the second was redefined as the duration of 9,192,631,770 periods of the radiation corresponding to the transition between the two hyperfine energy levels of the ground state of the cesium-133 atom. In 1997 this was further refined to specify that the second so-defined referred to a cesium atom at rest at absolute zero. Since observing such an atom is impossible, this requires a theoretical extrapolation to get the above value.

With the second defined as the primary unit of time, the minute remains 60 seconds, the hour remains 60 minutes, the day remains 24 hours, and the year is still taken to be 365 days, as in ancient Babylonia. Our calendars still need to be corrected occasionally to keep them in harmony with the seasons because of the lack of complete synchronization in the motions of astronomical bodies.

Time is inextricably connected with space. Once we have a measure of time, we next need a measure of space or distance. The international standard unit of distance is the *meter.* In 1793 the meter was introduced as 1/10,000,000 of the distance from the pole to the equator. In 1889 the standard meter became the length of a certain platinum–iridium bar stored under carefully controlled conditions in Paris. In 1906 the meter was redefined as 1,000,000/0.64384696 wavelengths in air of the red line of the cadmium spectrum. In 1960 it became 1,650,763.73 wavelengths in a vacuum of the electromagnetic radiation that results from the transition between two specific energy levels (2p10 and 5d5) of the krypton-86 atom.

In 1905, Albert Einstein introduced his *special theory of relativity,* profoundly revising our notions of space and time. The primary postulate of relativity is that the speed of light in a vacuum, a quantity conventionally referred to as *c,* is a constant that does not depend on the motion of the source of light or its observer. Thousands of scientific observations in the century since have confirmed the validity of Einstein's postulate.

In 1983, by international agreement, Einstein's postulate was incorporated into the definition of the meter, which was then defined to be the distance traveled by light in a vacuum during 1/299,792,458 of a second.

This latest definition of the meter, which is still in effect, has a profound consequence that is not widely recognized. Since 1983, distance is no longer treated as a quantity that is independent of time. In fact, as we see from the above definition of the meter, distance is now officially defined in terms of time. Distance is the time it takes light to travel between two points in a vacuum. Of course, in practice we still use meter sticks and other means to measure distance, but in principle these must be calibrated against an atomic clock. The primary time and frequency standard is provided by averaging a set of *Cesium Fountain* atomic clocks at the NIST laboratory in Boulder, Colorado, which at this writing will not gain or lose a second in more than 60 million years.

A further implication of the definition of the second and the meter is that the quantity c is simply an arbitrary conversion factor. If you measure time in seconds and distance in meters, then c is *by definition* 299,792,458 meters per second. If you measure time in years and distance in light-years, $c = 1$, since the light-year is defined as the distance traveled by light in one year. The photon, the particle of light, is believed to be massless and indeed is measured to be so with enormous precision. This implies that photons and thus light travel at the speed c in a vacuum. When light travels through a medium, however, its speed is given by $v = c/n$, where n is the index of refraction of the medium.

Since no perfect vacuum exists in the universe, light can generally be found moving at a speed other than *c*, although the difference is very small in outer space.

Finally, let us list some of the commonly used units of time smaller than the second.

one millisecond = 10^{-3} second

one microsecond = 10^{-6} second

one nanosecond = 10^{-9} second

one picosecond = 10^{-12} second

one femtosecond = 10^{-15} second

Time, Universal

Universal time is the international time standard common to every geographical area in the world. Coordinated Universal Time (UTC) is the number of hours, minutes, and seconds that have elapsed since midnight at the prime meridian. This time is kept on 24-hour clocks and is carefully monitored by international organizations, coordinated by the International Bureau of Weights and Measures in France. Coordinated Universal Time is transmitted by radio signals so people around the world can set their clocks to the exact time, adjusting for their individual time zones.

There are actually several different Universal times, which have varying degrees of control by astronomical forces. These are UT0, UT1, UT2, and UTC. Currently the UTC commonly used by the world is calculated by more than 260 cesium atomic clocks on the earth and 24 above the earth in satellites. Because the earth's orbit around the sun and rotation on its axis is not consistent, adjustments need to be made so that UTC remains close to the actual solar day.

Universal time replaced Greenwich mean time (GMT) in 1928 when the International Astronomical Union defined it as the mean solar time on the Greenwich meridian (zero degrees longitude), with the day beginning at midnight and each day composed of 86,400 seconds. Not all countries made this change in time standard at the same time. As late as 1997, the United Kingdom was unable to change its legal time standard in Parliament away from GMT, although they use UTC.

History

Universal time is the result of a developing history of the human need for timekeeping accuracy. Before the 19th century, local areas adjusted their clocks at noon when the official sundial showed the sun had reached its highest position for that day. In 1878, the needs of railway travel across long distances without accidents led to a system of standardized time zones. In 1880, Great Britain decided to have the same time throughout the country, GMT, which started a new day when the sun was at the highest point above the Royal Greenwich Observatory. In 1884, an international convention was held in Washington, D.C., where it was agreed that Greenwich, England, would be the home of world time, known as GMT or Zulu time and the world would be divided into 24 time zones.

The 20th century began with astronomers in charge of timekeeping and ended with physicists in charge and astronomers in supporting roles. In 1912, the French Bureau des Longitudes conference called for an international organization to oversee world timekeeping, and the following year the Bureau International de l'Heure was set up. In 1920 this group was incorporated into the International Astronomical Union (IAU). Through years of astronomical observation, variations led to the conclusion that some days are longer and some days are shorter due to a variety of factors such as latitude location, earthquakes, continental plate movements, and severe storms. GMT became the mean solar time on the prime meridian at the equator, thus an average of statistical data. In 1928, the IAU replaced GMT with the new designation Universal time.

The year 1955 marked several important events in the development of Coordinated Universal Time. The astronomers and the United States Naval Observatory under the leadership of William Markowitz had been working to define time more precisely through detailed charts of observations of the rotation of the stars through the earth's sky. This became ephemeris time (ET), a timescale based on the movement of bodies in the solar system. In 1955, the General Assembly of the International Astronomical Union, meeting in Dublin, adopted ephemeris time as the international standard. In an attempt to come to terms with the fluctuations of the earth's rotation, they decided there would be three different forms of Universal time. UT0 is measured directly by observation of star transits derived from sidereal time. UT1 is UT0, but corrected for polar wobble and so is a measure of the earth's orientation in space; it is the same everywhere on the earth and was to be used for navigation. UT2 was UT1, but corrected for seasonal variation in rotation speed and tidal friction. These versions of Universal time have specific astronomical uses.

Physicists at the National Physical Laboratory, the United Kingdom's standards laboratory, under the leadership of Louis Essen, had been developing the first successful atomic clock based on the predictable vibrations of the cesium atom. In June 1955 this clock was able to run at a steadier rate than the earth's rotation and to describe the second more accurately. Markowitz and Essen began a project to determine the length of the ephemeris time second in terms of the cesium frequency.

January 1, 1960, marked the beginning of UTC's adoption adjusting seconds each year in order to remain close to the mean solar seconds and the system of radio time signals broadcasting this time. In 1967, a second became officially defined as the time taken for 9,192,631,770 vibrations of the cesium-133 atom inside an atomic clock.

A compromise timescale was devised and on January 1, 1972, UTC became the basis for legal timekeeping in all countries. Civil timekeeping around the world is based on UTC emanating from one of the 49 national timing centers.

Standards Maintained

The International Bureau of Weights and Measures (BIPM) in France is responsible for international standards of measurement, and its time section administers the formula for UTC. Their officials send out two timescales: International Atomic Time (TAI) and UTC. They monitor the accuracy of the more than 260 atomic time clocks around the world that are used for this purpose. In 1972, these two time standards were combined for use with international radio time signals.

GPS, the U.S. Defense Department's Global Positioning System satellites, broadcasts time signals from its own internal atomic clock. These signals are compared with the atomic clocks used to determine UTC. The BIPM coordinates all this timing data as well as adjustments that need to be made for rotational variations. Whenever changes in the length of a solar day threaten UTC to be more than 0.9 seconds from UT1 (which includes the earth's wobble), a leap second may be introduced to bring it back in line. By the year 2000, 22 of these leap seconds had been added due to the slight slowing of the earth's rotation. Radio-controlled clocks adjust themselves automatically from satellite radio signals.

The official source of time used in the United States is the Time Service Department of the U.S. Naval Observatory. Three radio stations of the National Institute of Standards and Technology provide around-the-clock broadcasts that can also be accessed by telephone. Ham radio operators around the world all use the same time, UTC, without the time zone adjustments, so they are always on the same time no matter where in the world they are on the air.

As mobile phone networks, satellites, and computers rely on the coordination of the same accurate time, the latest generation of atomic clocks with laser-cooled atoms and newer technologies will be used to refine that accuracy. The inconvenience and unpredictability of the leap seconds used to match UTC to actual earth rotation of UT1 will need to be worked out as computer systems currently need to be reset to account for these leap seconds. The GPS atomic clock is becoming more dominant as navigation more often uses satellite signals rather than stars. The quick travel and communication of an increasingly complex world demand precision timekeeping of Coordinated Universal Time in order to synchronize human actions.

Time and Computers

The digital computer is the most important invention in the area of information technology since Johann Gutenberg began, around 1450, to use movable type in the art of printing. A computer can be programmed to process, as specified by its user, any information that is translatable into series of 0s and 1s (bits). Even the first fully operative program-controlled digital computers of the 1940s could perform numerical calculations much faster than a human being. Since then, they have succeeded in enormously speeding up all activities that are dependent on real-time information processing (like stock trading) or the efficient handling of huge databases (such as biological research). This is, however, just the most obvious relationship between time and computers. Considering the computer as a highly complex artifact that should be described at different levels of organization, it shows many more connections with time.

The famous computer scientist and pioneer of artificial intelligence, Allen Newell, described a general hierarchical organization of digital computers whose levels become, on the one hand, more and more abstract and, on the other hand, more and more specialized. At the basic level, any computer consists of electronic devices (like transistors). To explain their structure and behavior, knowledge of quantum physics is needed. This implies that on this level the microphysical understanding of time is most relevant.

The next level of computer organization is reached when electronic devices are put together. The behavior of the resultant electrical circuits depends on the current that flows through them. To predict its change over time, the theory of electromagnetism must be applied to circuits of electronic devices (Ohm's and Kirchhoff's laws). It is, in respect to time, even more interesting to look at electrical circuits from a particular functional point of view. This brings us to the third level of computer organization: the level of logic circuits—that is, of electrical circuits whose behavior over time fulfills a function that can be described in terms of logic-based information processing (or Boolean algebra). For example, the logic circuit called OR-gate calculates an output that is the logical sum of two input bits. If the input consists of a single 0 at the most, the output is 1; otherwise it is 0. By abstracting from the physical substrate of the OR-gate and describing its behavior in terms of information processing, irreversibility emerges—a quality that is of utmost importance to our ordinary experience of time. Irreversibility arises from loss of information, which occurs, for example, by calculating the logical sum of two bits. If the logical sum of two bits is equal to 1, the two input bits could have been two 1s, or one 0 and one 1. Knowing just the output makes it impossible to reconstruct the input exactly, so without storing the input the calculation of the logical sum cannot be reversed.

On the next organizational level of computers, integrated circuits are incredibly complex networks of logic circuits. Their designers must know how many bits these networks can process in parallel in a unit of time. Yet most computer users are not interested in hardware engineering. The computer-literate ones begin to work at the fifth level, on which programs written in a wide variety of artificial languages transform data structures. It is a very important question how the time a program maximally needs to perform its task depends on the minimal amount of information that is required to describe this task.

At the top of Newell's general hierarchy of computer organization is the knowledge level on which the behavior of computers (and of computer-controlled artifacts like robots) is described in terms of rationality. Computers are thus considered artificial rational systems that try to realize goals they want to attain, have knowledge about actions as a means of attaining these goals, and choose actions that most probably realize the preferred goals in the best possible way. The subfield of computer science that tries to construct such rational agents, artificial intelligence, has to deal with many fundamental problems concerning time. Rational agents, natural and artificial, have only limited resources at their disposal to solve problems. Their speed of information processing, for example, is finite. They must also make decisions under time pressure since the environments with which they interact are constantly changing. So rational agents must update knowledge of their environment efficiently and make predictions about how a change in some part of the environment will affect all other parts. If, for example, a woman changes her shoes, she does not usually change the color of her hair to go with them. This seems to be a trivial fact, but if there were no general rules by which rational agents reason about changes over time, the computer must be told myriads of such facts explicitly.

Newell's hierarchical picture of computer organization shows that, from the different perspectives of physicists, engineers, information theorists, and programmers of computers, time does indeed play a very important role in the construction and use of computers. This confirms the highly complex nature of these artifacts as physical systems that process information. Going beyond Newell's hierarchy, networks of computers (or groups of robots) that communicate with each other involve a functional equivalent of intersubjectively shared time as an important factor in social cooperation and conflict.

Time and Universes

Our perception of physical existence is measured on four dimensions. The first three are spatial: length, width, and depth, to give a location of an event or object in the universe. The fourth and most complex is time, which gives that event or object a classification of "when." *Our* measurement of time is based on the earth's planetary motions; one revolution on its axis being one day, and one revolution around the sun being one year. This type of measurement offers insight into time's being understood as cyclical, but this could merely be an interpretation based on what was most evident when observations were first being made.

Historically, different civilizations have had differing viewpoints regarding the structure of time flow as either cyclical or linear. The notion of cyclical time has been given primacy by many civilizations including the Hindu, Greek, Babylonian, Chinese, Aztec, Mayan, and Norse. The cyclical flow of time is sometimes symbolized by the *Uroboros,* the snake wrapped in a circle bringing its tail to its mouth. Another manifestation is the circular-shaped calendar, of which the Chinese version is among the most widely recognized. Current cyclical measurements of time include not only how we still use the earth's motions for recognition of the passing of days and years, but also how we divide these measurements into smaller portions. We repetitively use the same names for labeling the 12 months of the year, and use the same number of hours in a day, minutes in an hour, and seconds in a minute.

Although measurements of seconds, minutes, and hours are used in cyclical time measurement, they can also be recognized in linear time measurement. For example, if timing how fast athletes can run the 40-yard dash, their time would be recorded with a linear measurement in seconds. However, the athletes' time could also be broken down into milliseconds, offering either a linear measurement of many milliseconds, or for every thousand milliseconds a cyclical recognition could be made as the equivalent to one second. Among the first to promote the concept of time being linear as opposed to cyclical was Saint Augustine of Hippo (354–430 CE). When he became deeply religious in his 30s, he noted that major events occurred only once in the Bible. The Bible also offers a definitive beginning of existence, with God's creation of the world and everything within it and surrounding it. However, the recurrence of the four seasons passing each year also offers insight as to why cyclical time would have been a natural first perception of time's structure in earlier civilizations.

The modern world uses a combination of cyclical and linear time measurement. This includes the cyclical recurrence of the earth year and the breakdown of its parts (months, days, etc.), and the linear measurements used to keep track of the passing years. Yet if time is actually linear and there is no actual beginning, then following with the second law of thermodynamics (which states that as working systems move forward in time, they move increasingly into a state of entropy), why hasn't the universe completely "run down" on itself? One explanation, discussed later, is the cyclical universe theory.

Two factors that affect time in our universe are gravity and speed. In places where gravitational pull is stronger, time is slower, and vice versa. On a microscale, this effect has been recorded on special, precise clocks on airplanes (which travel at about one millionth the speed of light). The conclusion drawn from these observations predicts that you theoretically could extend your life by about one millisecond (or travel one millisecond into the future) by spending your life flying on a plane around the world from west to east. Speed can also affect time. Mathematically, as an object accelerates, approaching the speed of light, time slows down.

Time Travel

Some cosmologists have proposed so-called wormholes as offering, theoretically, a mode of time travel. It has been conjectured that when a wormhole forms, part of a given plane in the universe is bent in half, with the wormhole acting as the bridge between the two ends. Or, put differently, imagine an empty hard-shell taco with an hourglass-shaped tube—the wormhole—connecting the sides. This theoretically offers a route that is a fraction of the distance than if you were to travel, for example, the 54 trillion miles from earth to the star Sirius.

This theoretical route is so far the closest science has come to an explanation for possible time travel. Unfortunately, no technologies yet exist that would be capable of surviving such a trip, so where or when one would go, and whether one would go forward or backward through time remains unknown. The only other way to theoretically traverse the time continuum is to create a tear in the fourth dimension. To do this would require controlling more than exorbitant amounts of energy, which today we have no way of generating or containing. But for discussion's sake, let's say that we do have the capabilities to travel at will throughout the fourth dimension, and particularly to travel backward. Could we then alter the world by affecting events in the past? This question opens another door: Would you be affecting the events of *your* timeline, or would you be traveling back and changing the events of an alternative spacetime, thus not affecting *your* spacetime at all? For this to be the case, multiple time continuums would have to exist, which would immediately raise the question of whether the traveler to different times would be in turn traversing simultaneously existent but separate universes? And if this is true, since there are literally infinite positions in time in between, for example, this instant and one year ago, would this imply that there are actually *infinite* universes? Clearly our ability to capitalize some day on the possibilities of time travel will require a far greater understanding of time than humanity can be said to possess at present, as illustrated by certain paradoxes and conundrums.

First, we have what is called the *Grandfather paradox*. It poses the question of what exactly would happen if you traveled backward through time and killed your grandmother before your mother was born. Obviously your mother would no longer come into existence, thus negating the event of your eventual birth. So if you were never to be born as a consequence of this murder, then how would it be possible for you to travel back in time to kill your grandmother? Perhaps, at the point of death of your grandmother, you could instantly be "blinked" back to the point in time before you traveled backward on the fourth dimension. A second depiction of using time travel to alter past spacetime is in the popular 1985 movie *Back to the Future,* in which Marty, the protagonist, travels back 30 years and accidentally hinders the courtship of his parents. As events play out in the movie to the point where his parents would no longer fall in love, Marty pulls out a picture of himself and his older siblings in which they start disappearing from the picture, and eventually his hand starts to dissolve into nonexistence until his father makes a move and kisses his mother, at which point Marty's hand and his siblings in the picture reappear. This example also offers a paradox that, if his parents never fell in love to give birth to him, then he never would have been in existence in the first place to travel back in time to interfere with their courtship from the beginning.

Black Holes

Time is recognized as a dimension but without the equivalent parameters of length, width, and depth used to measure physical dimensions. The fourth dimension has only two known dimensions within itself, forward and backward. Perhaps other undiscovered dimensions within time might lead to a greater understanding of controlling its distortions. According to scientists, time in the universe may be compared to an elastic sheet. Any object with mass warps the first four dimensions around it. Although it is not recommended to look directly into the sun, sometimes this effect can be seen in the sun's rays when looking over the silhouette of a rounded edge of an object with the sun immediately behind it. To a very small extent, you can see the light rays bending around the object. The shape of a black hole in spacetime would look similar to the distortion made by placing a heavy ball on a stretched sheet of rubber; it would create a circular sinking effect. This distortion effect is discussed in Albert Einstein's theory of general relativity. It also suggests that spacetime is further distorted when objects are spinning, which would be portrayed by a spinning object twisting the sheet of elastic. This effect, first predicted in 1918, is called "frame dragging," and can be observed by the earth's mass affecting spacetime, with the orbiting satellites lagging by approximately 6 feet each year.

Cyclical Universe Theory

This idea of the universe changing before entropy has fully set in originates in the question of the existence of time and space prior to our current universe. Some theoretical physicists are investigating the cyclical universe theory: while time itself never actually loops—everyone knows that we can never live the same minute over again—what this theory proposes is that before the big bang, there could have been an infinite number of big bangs. Over an infinite amount of time, universes could have begun with a big bang, grown and lived out their life span, and collapsed in on themselves to a point where all the matter and energy converged so densely that it eventually issued forth in the next big bang when all the energy is released (of unthinkably monumental size). This cyclical universe theory puts us humans in the *current* era, not the only era of the universe. This theory ties in well with what cosmologists are saying about a black hole that could eventually grow so large as to engulf the entire universe.

A black hole is a region in space where matter becomes greatly condensed, to the point where the gravitational pull is so strong that no type of energy, not even light, can escape its draw. This force is present within a radiant distance on a flat plane surrounding the hole, called the *event horizon.* Over time, as a black hole pulls in more matter and energy, it grows not only in size but in force. This essentially creates small portions of the universe where time slows down immensely. Cosmologists have theorized that, upon a single black hole growing large enough, it will not only engulf other black holes, but eventually the entire universe. At that point, time in this universe as a whole will come to a near halt due to the overwhelming gravitational pull emitted by the gargantuan black hole. Following this chain of events, time in the universe will go from a near standstill to returning to normal "speed" upon the discharge of enormous amounts of energy in a massive release, which we would call the next big bang.

From this, we might conclude that there is no definitive beginning or end to time.

To date, however, modern physics has proven that in all physical actions and reactions there is no creation or destruction of matter or energy, but only transfers of both. This would suggest that since it is all the same energy and matter that is being condensed into the final massive black hole that swallows the current universe, that upon the next big bang it would create a somewhat identical universe with all the same properties, matter, and energy. However, theoretical physicists are not completely sure about this. There is a mysterious variable force deep in space that scientists are calling Lambda that seems to produce a force that helps the universe expand, much as dark matter does. Its properties are little understood, but what is known about it so far indicates that accepting its existence also admits the potential for the laws of physics and time, which dictate our immediate surroundings, are either null or different in other parts of the universe. This understanding gives way in turn to the scientific speculation that under the cyclical universe theory, new energy and matter are created about every trillion years, the amount of time estimated by Paul Steinhardt of Princeton University and Neil Turok of Cambridge University to be the probable duration of each universe cycle. However, there are still ways that the cyclical universe theory could be disproved.

Ekpyrotic Universe Model

We know of our own universe and the four dimensions we experience within it. But are there perhaps other dimensions, or even other universes currently existing? A very new and unproven theory introduced in 2001 gives insight into these possibilities. This ekpyrotic universe model contradicts the beginning of the big bang model of the universe. The distinction between the two is that the ekpyrotic model states that instead of there being an initial big bang coming from infinitely condensed matter and energy, the universe was instead originally very vacuous and contracted until our first three directional dimensions (stretched like an elastic sheet, a membrane, or "brane" for short) collided with another three-dimensional brane. This caused the two to combine and produce something similar to the big bang effect, creating the universe we now live in and also causing the universe to then start expanding with much more matter and energy within it. The venue for this collision was the fourth dimension (time) that the two branes were moving along. This adds yet another possibility for the creation of the big bang.

Paul Steinhardt also explains that the basis for the ekpyrotic universe model comes from what is called the superstring theory, which requires 10 different dimensions for most formulations. The additional 6 dimensions are suggested as being twisted up into a microscopic ball called the Calabi-Yau Manifold; this is too small to be experienced in our everyday life, which is why our initial perception of the universe is of only four dimensions. Further, the theory places our four-dimensional universe on a five-dimensional spacetime that derives from what is called the *heterotic M-theory.* The theory constrains the physical movement of particles to within only our first three-dimensional boundaries, but on either side of the extra (fifth) dimension. The reality we perceive around us is one side of it. It is proposed that gravitational energy would be the only way for matter or light to traverse to the other side of the fifth dimension. But where, exactly, is the other side of this fifth dimension? The theories creators explain that it is on the other side of what we see as the "edge" of the universe, suggesting that there is no actual boundary to our universe, just an expanding membrane in our portion of it, with physics different from our own. The heterotic M-theory does not include other universes, just alternate dimensions within our own.

Whether or not there was an actual beginning of time, the more pertinent question that remains is whether or not there will be a definitive end to time. There are some theories of how the universe will end billions or even trillions of years from now, giving rise to the question whether or not time will also be destroyed with them. But if time is neither a physical object nor energy, can it really be destroyed? If the universe were to collapse in on itself or shred apart according to the big rip theory, then would the universe simply become a vacuous space of endurance of nothing? Although some say that time would cease to subsist, since there is no actual way to create the physical existence of time, it would seem impossible to actually destroy it.

Other universes and other aspects of time beyond our imagination may always remain unknown.

Time Capsules

In the simplest terms, a time capsule is a receptacle containing objects chosen as representative of the current age and preserved for future discovery. Contents of time capsules should ideally provide a genuine sense of the time period represented. For that reason, written messages and items reflecting popular culture are often included. A well-conceived time capsule can effectively bridge the gap between the present and the future.

A distinction has been made between a "real" time capsule and other experiences that provide insight into earlier cultures. Specific examples include sunken ships, archaeological sites, libraries, and archives. Forerunners of modern time capsules can be found in artifacts discovered in building foundations in ancient Egypt and Mesopotamia and in cornerstone dedications such as the one that took place at the York Cathedral in 1361. By the late 19th century, it was common in the United States for organizations and businesses to include time capsules in local and national ceremonies.

Many time capsules have a target date for opening, making it important to use materials that will last, to find a secure place for storage, and to record the capsule's location. Just one of many examples of lost capsules is the George Washington Cornerstone, laid in 1793 by Washington at the dedication of the U.S. Capitol. A centennial time capsule was introduced during the 1876 U.S. International Centennial Philadelphia Exhibition. It was opened by President Gerald Ford in the 1976 Bicentennial year. Now called the Centennial Safe, it is available for public viewing through a glass door in the Capitol Building.

The term *time capsule* was not introduced until the 1939 New York World's Fair. Constructed of copper, chromium, and silver, it was intended to last until 6936. Its contents include fabrics, metals, plastics, art objects, microfilm describing contemporary events, and common items such as fountain pens. Even more ambitious are millennial time capsules. An example is the 2,000-cubic-foot Crypt of Civilization, conceived by Oglethorpe University's president, Thornwell Jacobs. Its contents were sealed in an exhibition room on May 28, 1940, with plans for opening on May 28, 8113. It includes thousands of items, ranging from newsreels to a Donald Duck doll.

Use of time capsules has become common enough to be applied in the classroom, encouraging children to reflect on their own lives and note changes that occur over time.

One example of applying time capsules in outer space is the golden recording placed by NASA on *Voyager 1* and *Voyager 2*. Its contents could conceivably portray the diversity of earthly life and culture to extraterrestrials. There are many possibilities for creating time capsules in cyberspace. An example was seen when MIT's Sloan School of Management encrypted digital samples to represent the online world in the year 1999.

Time capsules illustrate a belief in the importance of the present and optimism about the future. When a capsule is opened by a future generation, it could be described as having achieved a kind of time travel.

Time Dilation and Length Contraction

Until the beginning of the 20th century time was thought to have a constant unvarying flow. A minute in North America was the same as a minute in Africa and anywhere else in the universe. But Einstein's theory of relativity changed that notion. He had discovered a bizarre aspect of the universe that is still not fully understood. A second of time here is much different than a second of time on a fast-moving object. Clocks on fast-moving objects actually slow down as compared to clocks on stationary objects. This is known as time dilation.

Understanding time dilation takes us back to the Michelson and Morley experiments of 1887. At that time it was thought light waves behaved like cars on a freeway (to use a more contemporary analogy). If one used a radar gun to measure the speed of an approaching car one might find that it was traveling 50 miles per hour. But if you are driving toward the car at 50 miles per hour the measurement would be different. The measured speed would be 100 miles per hour, the sum of your motion and the motion of the approaching car. Likewise, following the car at the same speed would produce a measurement of zero miles per hour. It is obvious that placement of the radar gun will produce different measurement of the car's speed. And it is equally obvious that light should behave in the same way. That is what made the Michelson and Morley experiments so revolutionary. The speed of light remained constant regardless of the speed of the measuring equipment.

Einstein delved deeply into this apparent contradiction and established the speed of light as a universal constant. To formalize this idea he used mathematics developed by Hendrik Lorentz, who had made the following observation: The speed of light in a moving frame of reference would remain constant if lengths contract in the direction of motion. For example, from the point of view of a stationary observer, a spaceship traveling at 86.6% the speed of light would measure one half its length. This idea was developed from the field of electrodynamics, which showed that the distribution of charged particles put into high-speed motion would similarly contract.

Along with length contraction, Einstein discovered that time was not equal between moving frames of reference. With each increment of speed, moving clocks slow down in relation to stationary clocks. This aspect of time has been firmly established by experiment. Though the time intervals are extremely small at our speeds, atomic clocks have become so accurate that time dilation has been measured. The observed slowing of clocks with speed conforms to the predictions of special relativity.

However, length contraction and the slowing of the clocks is what the stationary observer sees. Within moving vehicles, time and lengths appear to remain the same as they always were. Changes in length and time can only be inferred from knowledge about one's speed with respect to light. Further, it is a premise of special relativity that the view from within a moving vehicle is equivalent to all other views.

In a way, the calculations and impressions that emerge from the constancy of the speed of light and special relativity are an outlandish intellectual funhouse that annihilates our intuitive views of how the universe should and must behave.

For example, imagine you are in a spaceship traveling at 86.6% the speed of light. (You calculate this from the Doppler shift of the cosmic background radiation.) You decide to measure the speed of light entering the front of the ship and the back of the ship, doubting that light has a constant speed. It stands to reason that light coming in the back will take more time to reach the measuring point because the measuring device is moving away from the light source. Once again, that is not what happens. Light speed remains constant.

Now you measure the speed of light coming in the front. Light traveling in that direction will have less distance to travel since the measuring device is moving toward it. So, intuitively, the speed of light in that direction should measure at about twice the speed of the light. Of course this is a foolish experiment because we already know the outcome. Relativity tells us the measured speed of light coming in the front will be the same as light coming in the back, which was 300,000 kilometers/second.

However, this experiment may not be so foolish after all. Alterations of space and time with respect to the forward and backward directions within a speeding rocket have seldom been examined.

So how could light coming in the front have the same speed as light coming in the back? The Lorentz transformations tell us that light coming in the back is traveling over a shorter distance and that the clock has slowed way down. For a ship traveling at 86.6% the speed of light, the clock has slowed to half its duration compared to a stationary clock. This makes sense because for light to catch up with the measuring device it must travel over both a shorter distance and a longer time interval if the speed of light is to remain constant.

But these requirements are exactly opposite those for measuring the speed of light coming in the front. In that direction light must travel over a longer distance and/or a shorter time interval for the speed of light to remain constant. So you conclude the clock rate must have increased but you quickly realize this is not possible since you know exactly how fast the ship is traveling and that the clock must be ticking at half the rate of a stationary clock. Clock rate in any given speed frame is a constant determined exactly by the Lorentz transformations.

You would also know that the forward direction cannot contract because a shorter distance of travel combined with a slow clock would produce a speed measurement that would exceed the universal constant speed of light. Therefore you know that the light coming in the front of the ship must be traveling over a much longer distance, at least twice as long as the back. Of course you would not see that the distance is longer than the back. Nevertheless, the measurement of the speed of light leaves but one conclusion: The ship has become longer. As the velocity of the ship gets closer to the speed of light, your clock would slow down to practically a dead stop. Because of your knowledge about special relativity you know that for the speed of light to remain constant in both directions, the back of the ship must be shrinking dramatically and the front of the ship must be lengthening dramatically.

Relativity has not discussed a length expansion, but the thought experiment presented above suggests it must take place. Admittedly the writer is not an Einstein; nevertheless, the thought experiment conforms to the axioms of relativity and offers what may be the first relativistic explanation for why no experiment has shown that a physical length contraction takes place. It also suggests that no physical experiment will demonstrate the existence of a length contraction because simultaneous with that contraction is a length expansion that exactly cancels the effect.

Imagine now that you are inside the ship and flying at an infinitesimally small speed less than that of light. From your measurements you conclude the length of the front of the ship must be reaching toward infinity while the back of the ship must be contracting to nothing. This simultaneous stretching and compression of lengths takes human intuition beyond the warped reflections in fun-house mirrors and indicates that the relativistic world may be even more bizarre than generally thought.

Timelines

A timeline is a visual sequence of related events arranged in chronological order and displayed on a vertical or horizontal line. Graphing events on a line in the order of occurrence shows the relationship between the events. Timelines might also include dates, visual illustrations, and written commentary. History is the subject most often addressed by a timeline, but timelines might also be used as a scheduling tool to estimate the time needed for the completion of a project or task.

The emergence of modern publishing technologies enables the use of visual enhancements to display on a line graph the same information that might first have been recorded in an ancient or medieval chronicle. In contemporary culture, the use of the Internet and self-publishing software enables the creation of online and digital timelines that go well beyond the traditional historical subject matter covering a broad range of topics that can include all aspects of modern life such as science, religion, culture, and politics.

Closely related to the science of chronology, timelines are used to show a sequence of events that occur in orderly succession from the past to the present and possibly into the future. Two broad categories of information appear in chronologies and on timelines. Relative events that are temporal address the organic evolution of the earth and human experiences. Absolute events, such as the origin of the universe and cosmic history, can also be represented on a timeline or in a chronology. Although the words *timeline* and *chronology* are often used interchangeably, the visual component of a timeline sets it apart from a chronology. Both timelines and chronologies locate historical events in time but, perhaps because of the visual component, timelines lend themselves more readily to popular use and expression than chronologies. Chronologies, making almost exclusive use of written text to list events with the accompanying dates, often become the basis for writing scholarly history.

Chronologies have existed since ancient times in the form of king lists that predate written history. Two of the best-known king lists are from Egypt and Samaria. Other well-known chronicles come from medieval England. These ancient and medieval chronicles have been incorporated into modern accounts of ancient and medieval history. For purposes of understanding and teaching history, timelines are a recent development. The construction and assembly of historical information on a timeline, although useful for communication and learning, is not typically thought of as scientific research.

The concept of placing events on a line graph to show their order of occurrence is based on a worldview that is closer to Newton's than to Einstein's. That might explain why timelines are more often used in the discipline of history than in physics. Although the concept of time is derived from the study of physics, the visual representation of time on a linear continuum is more closely related to the efforts made by historians to assemble chronologies that place events in the order of their occurrence with no attempt to measure the duration of events. Physics concerns itself with duration, the measure of time between two repeating events. Establishing the most accurate time measurement requires the use of Einstein's relativity theory. Timelines assume, as Newton did, that there is a single universal time order to events and that all events have a unique chronological order. Physics as a discipline refers to timescales rather than to timelines when presenting the succession of epochs from the past. In everyday life it is still possible and useful to assume a Newtonian view of the world, making timelines an important tool for communication and teaching.

Time Machine

The vision of being able to travel through time much like traveling through space became popular in science fiction in the late 19th century. Since then, many different ways of time travel have been envisioned, such as by the means of drugs, mind power, dreams, hypnosis, godlike superpowers, cryogenic freezing, or time machines. The modern notion of devices for traveling through time was introduced by the writer H. G. Wells. In his 1895 novel *The Time Machine* he described a motionless machine that allows its operator to go forward and backward to any point in time. Time traveling is described as a continuous movement that is experienced by the time traveler as an accelerated passing of time. Wells's vision of a time machine has since become a model in science fiction. Yet, the descriptions of time travel using time machines vary. For instance, in the film trilogy *Back to the Future* by Robert Zemeckis, a modified car serves as a time machine that enables movement through time in jumps whereby the time traveler experiences a sudden and abrupt shift from one point in time to another.

Not only in science fiction but in physics as well, the theme of time machines became an intriguing and seriously debated issue in the late 20th century. According to current technological possibilities, the construction of a time machine is not possible, yet its theoretical possibility has been avidly discussed over the past decades. It is widely accepted that, according to Albert Einstein's special theory of relativity, time travel to the future is in principle possible. This is explained by the phenomenon of time dilation that occurs at speeds close to the speed of light. A vehicle capable of moving this fast would serve as a time machine to the future. Furthermore, according to special theory of relativity, traveling faster than the speed of light would result in a reversal of causality; that is, events that happen in the future would have effects on the past. However, Einstein's theory also states that it would take an infinite amount of energy for an object to accelerate to a speed faster than light and thus rules out the possibility of time travel to the past. The question of whether a machine could be built that nevertheless enables time travel into the past is a contentious issue in today's physics. With reference to Einstein's general theory of relativity, proponents of time travel brought forth various possibilities of how a time machine to the past could work in theory. Skeptics claim, however, that the laws of physics prohibit time travel into the past.

General relativity gives another explanation for travel into the future. The theory predicts that gravity slows down time. This phenomenon has been put into practice in creating the Global Positioning System (GPS). Moreover, general relativity explains travel into the past. Kurt Gödel was the first to propose a solution to Einstein's field equations that implies this possibility. He showed that spacetime can form a loop; this became known as a closed timelike curve (ctlc). By traveling along such a ctlc one can proceed to an earlier point in spacetime, namely where the two ends of the timelike curve meet. Even though it is conceivable that ctlcs appear naturally in the universe, it is disputed whether a spacetime structure that would serve as such a pathway to the past could be created artificially by a time machine. Yet, one of the restrictions of time travel utilizing ctlcs is that one cannot travel to all points in time. Thus, it is impossible to reach a time before the closed curve was established.

The first hypothetical model of a time machine was suggested by Frank J. Tipler in 1974. With reference to a solution of Einstein's field equations found by Willem Jacob van Stockum in 1936, Tipler showed that the construction of a large rotating cylinder would produce a ctlc and therefore create a time machine. A spaceship flying on a spiral path around a so-called Tipler cylinder could travel backward and forward in time. However, it has been shown that this is not a realizable model for a time machine because the cylinder would have to be infinite in length in order to create a ctlc. A more viable model for a time machine was proposed in 1988 by Kip S. Thorne, Michael Morris, and Ulvi Yurtsever that makes use of a two-way traversable wormhole, which is a topological feature of spacetime that establishes a shortcut through spacetime. Although no evidence of existing wormholes so far has been found, its theoretical possibility according to general relativity lead Thorne and his coauthors to the thesis that a future generation capable of creating and maintaining a traversable wormhole could transform it into a time machine. For that, a time shift between the two ends of the wormhole has to be induced, caused either by special relativistic time dilation or general relativistic time dilation. The two ends of the wormhole then exist in different times and hence one could travel forth and back in time by passing through it. Manifold objections have been raised against the possibility of creating a time machine by establishing ctlcs by physicists as well as philosophers. Most notably, Stephen Hawking formulated in 1990 a chronology protection conjecture, stating that the laws of physics prohibit the actual existence of ctlcs and hence dismissed the idea of time travel to the past altogether.

Time Management

The concept of time management applies in several different domains. In the sense of the scheduling of goods transport capacities, time management, with the goal of minimizing transportation costs, plays an important role for transportation companies. Time management in the coordination of timetables is highly important for railway companies because railway systems are often characterized by high-traffic density and heterogeneous traffic that is sensitive to disturbances.

The concept of time management also applies to the careful scheduling of manufacturing processes. This is especially important for companies that use a just-in-time approach to reduce inventories. Here the necessary parts for the following production step are produced and delivered right before they are needed; a mistake in scheduling can be quite expensive.

The concept of time management can be used in other areas, for example, to describe the organization of work time on the social level. Usually, however, the term is applied in the context of the individual use of time. A steadily growing number of books, articles, and seminars deal with this form of time management, and many companies spend huge amounts of money to improve time management by their employees.

Definition

An analysis of the concept of time management requires a closer examination of the separate concepts of management and of time. The word *manage* stems from the Italian word *maneggiare* (meaning to handle), which in turn originates from the Latin word *manus,* which again signifies "hand." Time management is most often used to describe the professional leading or supervising of a defined unit such as an organization or a business operation.

By knowing which options are available for achieving a specific goal, management can be better able to meet its objectives through planning, organization, and coordination of necessary resources, leading coworkers, and controlling results. In other words, management can be defined as the planning, organizing, directing, and controlling of everything necessary to achieve an intended goal.

But is the analogy to other kinds of management correct? There are different things that can be managed in the given sense: staff, money, natural resources, and many more. The question is whether time can be managed like natural resources. As the hundreds of entries in this encyclopedia testify, "time" is of philosophical interest as well as the subject of scientific investigation; furthermore, there is no simple definition of time. What can be said is that we experience the world in a way that allows us to differentiate between space and time.

Whereas process philosophers agree that the flow of time is a fact, philosophers of the manifold think that our experience of the flow of time is an illusion. Even though this question cannot be solved, it is a fact that time serves as an important reference quantity when thinking and communicating about different experiences during our lifetimes. In addition, a shared conception of time—whether time is real or constructed—allows us to coordinate our actions.

Yet at the same time it is important to note that we cannot save time in the sense of saving money or resources. We cannot store it and use it when needed. As individuals we cannot change the course of time.

Because we are not able to control time, we cannot manage it in the usual sense and the definition given above seems to make no sense. We have just the option of acting in a certain way with respect to the flow of time. In that sense, time management can be only the conscious planning, organizing, and controlling of one's own activities with respect to the flow of time.

History of Time Management

Historical Foundation

In premodern times, the understanding of time was strongly influenced by natural cycles and by religious beliefs and practices. Social interactions were organized based on the cycles that can be observed in nature, such as the phases of the moon.

Mainly as a consequence of the development of new instruments for the measurement of time, and in the course of the Industrial Revolution with its growing need for the coordination of economic activities, another understanding of time developed. With the evolution of large and automated factories, the usage rate of expensive machines became a crucial factor for business success, and the willingness to work on these machines at a specific time was an important factor for employment. In addition, the development of artificial light resulted in the extension of working time.

Even though there have also been attempts to set aside certain times as work-free—for example, in many countries Sunday as just a day of rest—more and more businesses also work then; for example, railroad companies, theaters, and restaurants.

As a tool and a symbol of this new understanding of time, clocks became common in every home in the second half of the 19th century. The standardization of time and the abandoning of "local times" orientated to the specific conditions of a particular place were other steps toward the easier use of time within the production process.

In an increasingly industrialized world it became more and more important to know the time and to be on time. To find time-saving work patterns was crucial for business success, and the corresponding scientific management approach of Frederick W. Taylor played an important role in maximizing profits. The mentality of finding the fastest way to finish a given task transferred to work that was done at home. As the 20th century progressed, more and more people began to wear wristwatches, and it became still easier to tell time and to organize life on the basis of the clock.

Origins of Modern Time Management

As a pioneer of modern time management, in the sense of planning and controlling one's own activities with the help of professional methods, Peter Drucker is among the most influential contemporary management authors. In his management book *The Effective Executive,* published in 1967, he allocates an important role to time management as one of the five talents that he identifies as essential for executives. As a basis for good time management, Drucker recommends the manager discover where his time actually goes and cut back on unproductive demands. In addition, he stresses the role of setting priorities. At the end of the book, Drucker discusses the art of making effective decisions. These topics are still important in modern time management.

Popularization and Development

In the following years a number of writers carried the subject forward. In the English-speaking countries, authors like Alec R. Mackenzie and Steven R. Covey gathered new ideas for the professional planning and controlling of one's own activities. In German-speaking countries, writers such as Lothar Seiwert published new books and articles.

At the same time, the subject grew in popularity. Covey sold more than 15 million copies of his book *The 7 Habits of Highly Effective People,* from the first publication in 1990 until now. In 1996, *Time* magazine named him one of the 25 most influential Americans. Seiwert sold more than 2 million copies of his books in 20 different languages and trained more than 100,000 people in time management.

Many organizations in the industrialized countries invested a lot of money to train their employees in the efficient use of time. In the year 2000 in Germany alone there were more than 30,000 people in the time management business, and more than 200 different books on the subject have been on the market with a revenue of about 5 billion euros.

In their publications, the new proponents of time management declared different aspects as being important for the sensible use of time. Two publications symbolize milestones in the development of contemporary time management and are discussed below.

In his 1972 book *The Time Trap: Managing Your Way Out,* Mackenzie gives a comprehensive idea of time management and discusses many methods to help managers to save time and be more efficient. The two factors that he sees as most important for the efficient use of time are: the management of oneself and the management of the work environment.

For the first task he recommends a "realistic self-appraisal," the use of a "time log," and the setting of realistic deadlines. For overcoming procrastination he refers to Norman Vincent Peale and recommends training oneself in the habits of making decisions on the first suitable occasion and of doing one thing at a time. Mackenzie also illustrates the importance of planning in the work process. The setting of priorities is explained with the help of the Pareto principle. In this context, Mackenzie stresses the importance of saying "no" to many of the projects offered as a key to effective time management. Some of his other suggestions include training in speed reading and avoiding the excessive use of memos. Along with stressing that delegation is an important organizing tool, Mackenzie also emphasizes the importance of being cautious in the use of the time of one's subordinates.

For the second task—the management of the working environment—Mackenzie develops different methods for preventing interruptions, such as the effective placement of one's secretary or executive assistant. Other aspects covered are the arrangement of the office, the establishment of a filing system, and the use of dictating equipment.

Nearly two decades later, in 1990, Covey published his influential book *The 7 Habits of Highly Effective People*. In contrast to Mackenzie, Covey concentrates on certain habits that he holds important for being effective. His key idea is that executives have to take care of their own habits before they can be good leaders and that their habits determine their effectiveness in the first place.

The first habit Covey recommends is learning to make a conscious choice of response to given circumstances ("Be Proactive"). A second important habit is having a clear idea of what one wants to achieve ("Begin With the End in Mind"). The third habit he recommends is to set one's priorities and act accordingly ("Put First Things First"). The fourth habit he stresses is the habit of thinking and acting cooperatively ("Win-Win"). As a fifth habit, Covey points out that an effective person needs to try to understand the standpoint of other people ("Seek First to Understand, Then to Be Understood"). Habit 6 grows out of the last two and is called "Synergize." According to Covey, the success of this habit is based on the two preceding ones. It rests on the idea that the creative atmosphere engendered by these habits allows far better results when people work together to solve a problem than when they work solo. As the final important habit for effectiveness, Covey recommends constantly preserving and improving one's own capacities ("Sharpen the Saw").

The development in time management was not limited to North America. An author especially important for the advancement of time management in Europe is Lothar Seiwert. In his 1984 book *Mehr Zeit für das Wesentliche* (*More Time for the Essentials*), Seiwert describes certain factors and techniques that he holds important for business success. These are the analysis of one's own strengths and weaknesses, having a clear plan for one's career, optimizing one's communication, and, finally, good time management.

In his book *The 1 × 1 of Time Management* (1989), Seiwert deals with factors that waste time (e.g., certain types of meetings); the use and methods of goal setting, and the use and tools of planning (e.g., follow-up charts); the advantage and the methods of prioritizing (e.g., ABC analysis); the optimal utilization of the output curve and of breaks; how to create productive hours; the value and rules of delegation; the optimization of the beginning and the end of the day; and the importance of self-discipline.

Until the middle of the 1990s the target group of time management literature and seminars was mainly executives. The authors in this period applied it mostly to work life. As shown in the examples, time management was understood primarily as a set of tools or habits to help executives to achieve business success in a shorter amount of time.

Time Management Today

In recent decades, time management advanced further. Time management today is not applied just to work, but to all of an individual's life. The target group of the corresponding literature and seminars broadened. Regular employees were included along with executives. Seiwert's publications show this change. In his book *Life Leadership* (2001), Seiwert distinguishes four areas of life (family and friends; work and achievement; body and health; meaning and culture). According to Seiwert, all of them need to be integrated into the new form of time management.

A closer look at the recent publications of major authors in the area of time management shows another change that went beyond adding new ideas. It was a change in perspective. Examples of this important transformation are demonstrated by American author Steven R. Covey and European author Lothar Seiwert.

In his book *More Time for the Essentials,* Seiwert focused on the persistent planning of time and the maximization of success in the field of business. Well-being was not considered or was just a small aspect. A decade later, in his 1998 book *When You're in a Hurry, Go Slowly,* Seiwert focused mainly on quality of life. Not acceleration but deceleration seems to him the key to this goal. He stresses the importance of a balance between work and free time. In his book *Don't Hurry, Be Happy* (2003) he goes a step farther. The book can be interpreted as an ode to idleness. Time management becomes a tool for maximizing well-being.

Stephen R. Covey's books show a similar development. As we have seen, his focus in *The 7 Habits of Highly Effective People* was on taking responsibility for being effective. In *First Things First* (1995) Covey stresses the importance of having a clear idea of what is important and what is not. In this book his focus is not on effectiveness but on well-being and life satisfaction. He asks, "How many people on their deathbed wish they'd spent more time at the office?"

In his 2004 publication, *The 8th Habit: From Effectiveness to Greatness,*" Covey extends this idea. In Covey's view, a new dimension is needed to deal with the challenges of the new knowledge-worker age. For Covey this dimension consists mainly of "finding of one's one sense/task of life." Finding it gives greater meaning to everything one does and makes a person more effective at the same time.

The Science of Time Management

As pointed out, time management is the subject of many publications and seminars. On the other hand, it must be said that the scientific basis of time management is small. Nevertheless, some studies investigate the subject, and Gary S. Becker's "A Theory of the Allocation of Time" (1965) builds an early theoretical framework for understanding the allocation of time in the modern world.

Several kinds of empirical studies on the subject of time management have been conducted: The first and most common type investigates the work and time management behavior of employees—especially in the field of management. One of the first studies, conducted in 1951, explored the working behavior of Swedish managers. The data show long work hours and little uninterrupted time for executives. Other studies examine a number of hypotheses; for example, based on behavioral decision theory and exploring the idea that people discount the consequences of their time management decisions. This assumption has been supported by research.

A second type of study explores the need for time management in specific areas, for instance in the field of health care. These studies explore and compare the need for time management competencies and the existing knowledge of time management, usually with the help of questionnaires. A third kind of study investigates the current use of different time management methods and the arrangement of time management training in specific contexts, such as in companies. A fourth type tries to discover important aspects of successful time management in the work environment.

A fifth type of empirical study tries to prove or disprove the efficiency of time management methods. These studies show different results.

A last type of empirical study tries to illuminate the relationship between the use of time management methods and certain human characteristics. A 1991 study examined the relationship between college grades and student use of time management methods. Time management was shown to be a better predictor than Scholastic Aptitude Test scores. Studies have also investigated relationships between time management, control, work–family conflict, and stress. Research on the interrelationship of academic stress, anxiety, time management, and leisure satisfaction has led investigators to conclude that adding time management to measures for anxiety reduction and leisure activities could be an effective strategy in reducing academic stress for college students.

Time Management in the 21st Century

Is professional time management useful in the 21st century? Five of the most common criticisms of time management are summarized here.

First, critics claim that some time management approaches pay little attention to human nature and that planning time in the ways proposed is neither possible nor useful. A closely related criticism is that the concept of time management perceives people as resources.

A second major criticism of time management is that it has the wrong goal—to encourage doing many things rather than focusing on one task—and that it therefore creates the problems it tries to solve. This critique is related to the claim that time management is for people who fear missing something. This leads back mainly to either the troubled relationship our society has with death, the attempt to escape from oneself, or the longing for a state of timelessness.

A third critique is that the concepts of time management are focused on the wrong thing. In this view, the new challenges caused by a dramatic change in work life cannot be mastered by individuals through the use of individual time management. What is needed is a change in the structuring of time on a societal level. Time management is accused of underestimating this need and of overcharging the individual.

A fourth criticism is that time management conceals a normative life concept. Even though it seems to be neutral, it actually defines certain goals of life, like business success, and it propagates a particular way of life.

A fifth line of criticism argues that time management doesn't keep its promise: "Who controls his time, has time." Karlheinz Geissler, one of the mayor critics of time management, gives four main reasons for this claim: First, that we cannot possess time; time does not vanish, we do. In his view, time management ignores or at least underestimates the use of the useless. Second, he argues that since we cannot posses or control time, attempting to do so results in controlling oneself. Time management training is nothing but a course in self-control. People become precision instruments, policemen of themselves. His third reason that time management doesn't keep its promise is that permanent time planning wastes time. Geissler's final reason points out that when using time management, planned spare time isn't free time—it has the touch of business.

What can be said in response to these points about time management? The critique that time management pays little attention to human nature makes an important point by saying that the planning of time should be limited by natural needs and cycles. The new concepts of time management take these points into consideration and the criticism is no longer valid. These new approaches try to incorporate research results about biorhythm, sleep, and recreation.

The second critique, that time management has the wrong goal—doing several things instead of focusing on one task—and that it creates the problems it tries to solve seems to be no longer a serious criticism. Recent books by Covey and Seiwert showed that doing many things is no longer the focus of time management. Yet it should also be said that some people do use time management for this purpose. The reasons may vary: from a disturbing relationship with death to an escape from oneself. But it is an incorrect use of time management that creates such problems, not time management itself.

The third criticism is that the concepts of time management are focused on the wrong things. The observation that many problems cannot be solved merely on the individual level is true, but it seems wrong to make this a criticism of individual time management. Although attempting to change the management of time on a societal the (e.g., through legislation) can be useful for the individual, it means interfering with the freedom to choose. In contrast to time management on a societal level, individual time management is a useful tool for dealing with the challenges of the 21st century without losing the freedom to choose (e.g., the freedom to decide when to work).

The fourth critique is that time management carries a hidden agenda in terms of promoting a normative life concept. To some extent this is normal since authors and speakers nearly always convey part of their own convictions along with their subject. But especially with the new developments in time management, these tendencies need to be looked at more carefully. Time management specialists should not automatically assume the stature of gurus who have answers to all of life's questions. But this is also true of a lot of advisory literature. When time management advice and methods are handled with care, they can offer useful tools for one's own life.

The important implication of the fifth criticism of time management, that it doesn't keep its promise of controlling time, is that time management does not claim to offer the total control of time. Time cannot be possessed. At the same time, life is not consistent and there will always be changes. Nevertheless, it seems useful to have a clear idea of one's own priorities and tasks. Without some kind of time management it would be even more difficult to act in a changing world.

Normal life offers new tasks every day. This can be buying food or clothing, but especially earning the money to purchase what we need and want. In the workplace there are even more responsibilities—be it participation in meetings or the preparation of reports. All of these tasks are directly or indirectly linked to human needs. We need to purchase food to satisfy our hunger; we want to be successful in the job to win acceptance or love.

While dealing with our tasks we must also respect the plans of others. This is especially true in the workplace. In that sense we need a basic planning of our tasks and our time to be able to fulfill them and to satisfy our needs.

Today certain reasons seem to make it even more necessary to plan and control our own activities and the use of our time. The first is the acceleration of life. A number of indicators show this development. In industry, product cycles are becoming shorter; even old movies are remade nearly twice as fast as the original film was produced. Tasks have to be done more quickly than before and speed is now an important factor for personal success.

A second reason is the tight social network that we are part of. We live in a highly interdependent working environment. To fulfill our responsibilities, we need preliminary work from others and we do preliminary work for others. The private lives of most people are highly interdependent as well.

A third reason for a growing need for personal time management is an ongoing time deregulation. The given time structure of our society vanishes. For the sake of jobs in a globalized world, more and more flexibility is demanded. Shift work has became normal and store hours extended. As a consequence, opportunities for activities with friends and family have decreased and coordination has become more difficult.

A fourth reason is a strong need for freedom of choice. Living in a democratic market economy means having many options. Many different political decisions can be voted on, countless activities can be done, and numerous products can be purchased. As a consequence, many options compete for the available amount of time.

A fifth reason for the growing importance of time management is that many people have started their own small businesses, and an increasing number of people are working from home (telecommuting). This development means workers are forced to be their own managers and to plan and control their own activities.

In addition, various empirical studies show negative side effects from a poor use of time. A majority of employees say that they have the impression that they need more time and that their health is impaired by time pressure.

According to the empirical evidence, it is still too early to know whether the effectiveness of different time management methods is proved or disproved. Overall, the studies seem to show that at least some forms of time management can be quite valuable. More research is needed, especially in regard to the efficiency of the different time management methods. Considering the number of negative consequences of the poor use of time, for example, the burnout syndrome, these studies seem to be worthwhile.

Timepieces

The term *timepiece* can refer to any device used for measuring time, including watches, clocks, and earlier devices such as the hourglass and the sundial. An amazing variety of timepieces have been produced throughout the ages, reflecting the ever-increasing importance of time and its measurement to humans in many different cultures.

Timepieces have long been recognized for their practical application. They have also been prized for their historical and artistic value, as can be noted by the preservation of antique timepieces in museums and their appeal as collectables. Early clocks—mostly affordable only by the wealthy—were often constructed of valuable materials and sometimes had unusual features such as animation.

But the concept of time, as well as the need to measure it, was likely not recognized by prehistoric humans. They relied on natural changes that they could observe—daylight and dark and seasonal changes—adjusting to them to ensure their survival. In that sense the celestial clock can be described as the initial natural timekeeper.

The first commonly used artificial timepiece was the sundial, which enabled the measurement of time by the sun's movements. Its use began as early as 3500 BCE, with the invention of the gnomon, angled so that a shadow would be cast on a base marked with the hours.

An increased emphasis on accurate time measurement can be traced to the Renaissance period, and that emphasis appears to be tied very closely to the social, business, and scientific advancements seen during that time. The earliest known clocks were turret clocks in towers, striking only the hour. An example can still be seen in Britain's Salisbury Cathedral clock. In the 15th century, clocks driven by springs were developed, enabling more portability. The mid-17th century marked the first use of the pendulum, the concept of which has been attributed to Galileo Galilei.

In 1840, the spring and pendulum were still in use when the first battery electric clock was invented. A completely battery-driven clock was developed in 1906, and domestic use became common. The first use of the quartz crystal in 1929 allowed for even greater accuracy, and it is still used in most clocks and watches today.

Eventually it was commonly agreed that there needed to be some standardization of time so that it could be accurately measured over all the parts of the globe. The system of Greenwich mean time, dividing the world into 24 time zones, was agreed upon as an international standard in 1884. Coordinated Universal Time (UTC) has been used for scientific purpose since 1972. The most accurate clocks in existence today are the atomic clocks used by the United States Naval Observatory.

For most of mankind's existence, time has been the main measurement that people make on a regular basis. The ability to keep track of time accurately in today's fast-paced world with its increasingly international connections has become even more important. As new timepieces continue to be invented, human beings will continue to acquire them. At the same time, it's not surprising that historical timepieces generate considerable interest.

Time Poverty

In recent decades, scholars from a range of disciplines including economics, sociology, psychology, and leisure studies have been exploring the question of how Americans spend their time. How much time do we devote to paid labor, over the course of a year and over the course of a life? How much time do we have for leisure? How much time do we spend with our children, or in our families? How much time do people devote to community service? And how have the amounts of time devoted to these activities changed over time? Of late, activist organizations and movements have sprung up to combat what many define as a crisis of *time poverty* in America—that is, not having enough time to do all the things one wants to do. More specifically, many scholars define time poverty as a shortage of leisure time or as a shortage of time "to care"—for personal health and spirituality, families, community, and the environment.

This entry provides an overview of definitional and measurement issues related to social scientific studies of time, presents empirical data on uses of time across place and time, and explores consequences of time poverty, overwork, overscheduling, and time pressure on health, relationships, children, communities, and the environment. The conclusion contains an examination of old and new approaches to combat time poverty, including work by labor unions and activist organizations like the Simplicity Movement, the Slow Living Movement, and the "Take Back Your Time" Day organization.

Overview

Accompanying societal shifts in Western countries from industrial to service economies is a shift in how much time people spend in paid labor. In both Europe and the United States, scholars have drawn attention to rising hours in paid labor resulting in the social problem of time poverty, also referred to as time deprivation, time scarcity, time famine, the time crunch, and the time squeeze.

Although the issue is prominent in Europe, evidence suggests that American workers have long clocked more hours of paid labor than their European counterparts, and the gap is widening. Juliet Schor started a national conversation with her book, *The Overworked American,* in which she documents increasing work hours for Americans since the 1960s. More recently, she uses Current Population Survey (CPS) data to present a striking trend: Between 1973 and 2000, the average American worker added an additional 199 hours to his or her annual paid labor schedule (2003). This translates into 5 additional weeks of work per year if one assumes a 40-hour workweek. Not all scholars agree with Schor's measurement of work time. Some scholars argue that leisure time has increased for individuals. However, recent evidence suggests that when households are the unit of analysis, a rising time squeeze is evident. More households are headed by single parents, primarily women, and dual-earner couples; hence, overall time available for activities outside of work has grown more scarce.

Why are Americans working longer hours in recent decades? Juliet Schor's work points to demands of greedy work institutions and rising consumerism. Other scholars suggest only some Americans are overworked, primarily those employed in large firms, those with high levels of education, and those working on the highest rungs of the occupational ladder. Quantitative data analyses suggest a bifurcated workforce with overworked employees and underemployed workers. In the past two decades, the number of people working more than 50 hours per week increased, while the number working less than 30 hours also increased. In short, the economy and employers benefit if some workers have high demands and excessively long days, while other workers have jobs that fail to provide enough time on the job and money to meet workers' needs. The rise of part-time work is troublesome if employees are working part-time because of the lack of full-time jobs. Employers reap major advantages by having a high percentage of employees in part-time work, including having a larger reserve workforce, paying lower hourly wages, and providing fewer benefits. However, for some workers it takes two or more part-time positions, some not captured in official statistics, to make ends meet. For those workers, a full-time position with benefits may be more desirable but less attainable in the current economic landscape.

Beyond daily or weekly work hours, scholars have measured time spent at work over the course of a year. The United States is the only industrialized country without guaranteed vacation time. Hence, the Bureau of Labor Statistics reveals that Americans average 8.1 days of vacation after 1 year on the job, and 10.2 days after 3 years. Approximately 26% of American workers take no vacations at all. Workers in several European nations, in contrast, are guaranteed 4–5 weeks of paid vacation each year (and sometimes more with collective agreements).

What does time poverty look like if we compare women and men, lower-class workers and upper-class workers, or racial/ethnic minorities and whites? In her now classic work, *The Second Shift,* Arlie Hochschild calculated that if paid labor and unpaid labor in the home were combined, women worked an extra month of 24-hour days per year when compared with men. More recent evidence suggests that the gender gap in leisure persists. In part because of continuing inequities in the gendered division of labor in the home, men have far more hours of "free time" than do women. In addition, gender differences exist in the experience of free time. Women's leisure time or "free time" is often contaminated by household chores and interrupted by children's needs.

Given their location in the secondary labor market and informal economy, poor and minority Americans are least likely to have protections against overwork, and least likely to have paid leave options. The "contingent" workforce, composed of part-time and temporary workers, includes 30% of all U.S. workers and consists primarily of women and people of color. In addition, those at the lower end of the socioeconomic hierarchy are less likely to have flexible or elastic time on the job. For example, executives can have secretaries reschedule appointments so they can attend a child's soccer game. Those secretaries, or factory workers punching a time clock, are less able to rearrange work time for children's activities, doctor's appointments, or parent–teacher conferences.

Beyond Work Hours: Perception and Experience of Time

While data on changes over time in relative hours devoted to work, family, and leisure are compelling, of equal interest is the perception of overwork, which also leads to the experience of time poverty or time famine. Recent studies show one in three workers is chronically overworked, but a higher percentage, more than 54%, feel overwhelmed by how much work they must complete. The perception of being overwhelmed is a critical new area of study. Beyond analyses of time poverty is scholarship on how we experience time in a fast-paced, global, 24/7 economy full of electronic gadgets, commercial products, and more "stuff" in general. One skill workers must possess to survive in this environment is multitasking, which also contributes to feeling overworked and overwhelmed. Many people perceive a decreased sense of time, even if actual time spent in an activity, for example, leisure, is unchanged. The question of how to measure quality time is an important one for time scholars in the future.

New concepts that capture quality of time are evolving. Some suggest we are experiencing more "dead" time or time spent in an activity not inherently fulfilling or satisfying or pleasurable. In particular, the Internet and proliferation of electronic gadgets and media are viewed as compromising the amount of "live" time we have. *Time estrangement* refers to the absence of meaningful activity. Work along these lines concerns itself not with how much time we spend at various activities, but rather with how often we are engaged in activities that allow us to be fully and deeply engaged in life. *Time thievery* refers to unpaid hidden work, like commuting, phone solicitations, tax preparations, conflicts with insurance companies, and arguing with children over homework. These are often viewed as unnecessary activities that erode our experience of quality time.

Consequences

Consequences of time poverty are far-reaching, influencing productivity, personal health, personal relationships, children's well-being, and the strength of neighborhoods and community organizations. Ironically, the more hours people clock at work over the course of the year, the less productive they are likely to be. In an interesting experiment at SAS, a private computer software company in an industry notorious for long work hours, employers began limiting weekly work hours. Starting with CEOs and eventually incorporating all employees, they reduced hours to 40 per week, then 35. The company switchboard was turned off at 5:00 p.m. and the gates locked at 6:00 p.m. In consequence, there were fewer programming errors, programmers were more alert, and millions of dollars were saved because of low employee turnover. Other examples exist, both historical and contemporary, of shorter workweeks leading to increased productivity.

In general, overwork contributes to a range of health problems for Americans, including obesity induced by lack of time for exercise and proper diet, high stress levels, and sleep deprivation. Evidence suggests that annual vacations reduce the risk of heart attacks in men and cut women's risk of death from heart disease in half. In particular, a sense of "time urgency" or time pressure leads to burnout, stress, and a range of mental health problems including anxiety and depression. Given this situation, perhaps it is not surprising that economist David Korten refers to our high-consumption, fast-paced economy as a "suicide" economy. The World Health Organization reports that by 2020, clinical depression is expected to outrank cancer and follow only heart disease as the second greatest cause of death and disability worldwide. Since those experiencing overwork are far more likely to exhibit symptoms of depression than other employees, solving the problem of overwork is necessary for improving the health of employees.

Arlie Hochschild's work on the second shift documented relationship problems experienced by couples who must conform to a job culture in which time for relationships and families are secondary. In particular, much evidence exists to highlight how stresses related to time poverty can have negative influences on children's health and wellbeing. Beyond the impact caused by the time famine for parents is the separate issue of time famine for children. In the last three decades, children have lost about 12 hours per week of "free time." Play as an activity has declined 25% overall among children, and 50% for unstructured outdoor activities. A trend in overscheduling, especially for middle-class and upper-class children, has reshaped the landscape of childhood. Of particular concern is the loss of sleep experienced by children, and especially teens, in the past three decades. Consequences of a speeded-up, heavily structured environment include stress, anxiety, and sleep deprivation.

For the past two decades, social critics have decried the decline in civic engagement. In his book *Bowling Alone,* Robert Putnam presents evidence of a trend toward less involvement in community and civic causes such as the PTA or NAACP. Whether the hard numbers exist to back up Putnam's assertion is unclear. What is clear, however, is the extent to which, at a local level, community organizations are competing with workplaces, families, and electronic media (e.g., television, the Internet, video games) for a share of increasingly scarce time needed to keep their organizations afloat.

Finally, time poverty has repercussions for the environment. Busy Americans have less time to recycle, less time to shop in local markets, and are more likely to consume fast food, buy processed foods, use disposable "convenience" items, and engage in online ordering. All of these practices have major environmental consequences and contribute to higher rates of pollution, full landfills, contaminated water, and perhaps even global warming. In short, those who spend fewer hours at work report behaving in more ecologically sustainable ways. In addition, certain forms of convenient transportation, like automobiles, have replaced public transportation, bike riding, and walking in a time-poor society. Environmental consequences include air, noise, and water pollution, along with solid waste from abandoned cars.

Solutions

Proposed solutions for time poverty exist at both micro and macro levels, from individual-level coping strategies to community activism to changes in public policy and the economy. At an individual level, a self-help industry has emerged to help people become more "efficient" with their time and to manage competing demands better. Grassroots organizations have sprung up worldwide to support advocates of slow living. The Slow Food Movement began in Italy, and now claims 80,000 members worldwide. Other organizations connected to a "slow" movement champion slow travel, slow schools, and slow cities. The United States is ground zero for the Simple Living Network and the Voluntary Simplicity Movement. While these initiatives can raise awareness of time poverty and provide support for alternative ways of living, larger structural-level solutions are also proposed to solve time poverty.

Currently, the push to rein in time on the job seems to come from activist citizens more than labor organizations. However, a look back in time proves illustrative for understanding what is possible. Peoples in industrial nations, led by the United States, long viewed one accomplishment of capitalism and industrialization as more money and more time. In effect, higher wages and fewer hours on the job were viewed as a mark of progress and a worthy goal. Aristotle wrote, "We work in order to have leisure," and throughout the 19th century, his vision was prominent in certain circles. In 1926, the American Federation of Labor made a commitment to shortening hours of labor—first to an 8-hour, 5-day week; next to a 6-hour, 4-day week. In 1930, W. K. Kellogg implemented a 6-hour day, allowing workers more time with family and in the community. Leisure infrastructures began to form, and public facilities (e.g., parks, community centers) flourished. In part because of the Great Depression, legislation was introduced into the U.S. Congress to set the workweek at 30 hours, with "penalties" for overtime.

This bill, the Black-Connery Bill, was passed in the Senate in 1933 but failed in the House. Fast-forward 75 years. Today, the push for shorter workweeks and improved quality of time is limited to smaller segments of labor and comes largely from people and organizations outside of labor and government. In terms of labor, the AFL-CIO has been at the forefront of pushing for family-friendly legislation. High rates of burnout in certain professions, like nursing, have influenced unions to fight unchecked escalating work hours in the health care industry, especially mandatory overtime for nurses. The service industry is not exempt from problems of overwork, especially with the rise of a 24/7 economy in which service providers are expected to work around the clock. In 2000, 37,000 telecommunications workers went on strike to protest required overtime. Certainly, the passage of the Family and Medical Leave Act in 1993 was a step in the right direction. But with only 12 weeks of unpaid leave guaranteed for new parents or a health crisis, the U.S. policy falls dead last in terms of provisions when compared with other industrialized (and some nonindustrialized) nations. All other industrialized countries provide some form of paid leave, and generally for longer periods of time. Of course, Sweden's policy is the crème de la crème, and provides a stark contrast to the inadequacy of U.S. policy. Swedish parents are entitled to 18 months of paid leave (with at least 3 months mandatory time for Dads, although couples can split it any way they like), and shorter workweeks until children are 8 years old. Even tiny Estonia manages to provide 18 months of paid leave, while Bulgaria provides 2 years of paid leave and an additional year of unpaid leave.

For the most part, the business sector has resisted efforts to rein in work hours or provide more leave time for workers. Hence, major changes at the level of political economy might ultimately prove most valuable. Former Harvard and Stanford Business School professor David Korten argues that Americans have forgotten the purpose of an economy. In his view, the purpose of an economy is to help us live fully and well. Time poverty results from a corporate global economy centered on a global financial system. In this system, government policies that speculators and businesses view as unfriendly to their interests, such as living wages, environmental protections, and reduced work hours, are resisted. In his view, combating time poverty and its debilitating consequences requires a shift in ideology, from economic decisions based purely on financial values to those based on life values. This involves changing the rules of the marketplace to honor full cost pricing and eliminate market-distorting subsidies that promote financial gain but are bad for worker health, relationships, child well-being, communities, and the environment.

While a shift in ideology and change in labor market practices may seem impossible to accomplish, the tide is turning as activist organizations press for change. John de Graaf reports on a new agenda for free time called It's About Time. Several organizations, including Take Back Your Time, Work to Live, and Mothers Ought to Have Equal Rights, have formed a coalition to push for public policies that provide time to care. In addition to paid parental leave and sick leave for workers, the coalition lobbies for more paid vacation, including an election day holiday, limits to compulsory overtime, better part-time work options with prorated benefits, and living wages. De Graaf recalls the great strike of 1912 by the women textile workers of Lawrence, Massachusetts. The overworked, underpaid women carried signs that read "We Want Bread, and Roses Too." More Americans are actively resisting time poverty. They want bread, the symbol for enough money to live, but also roses and the time to enjoy them.

Time-Release Medications

Time-release (also *timed-release*) medications are designed to increase the duration of the drug's action. "Time-release" is commonly understood to mean medication that delivers constant amounts of the drug that it contains over an extended period of time, or that releases its ingredients gradually to produce a sustained effect; for example, a capsule in which the casing dissolves in sections, releasing dosages at predetermined intervals. In other words, time-release medications are formulations that control the rate and period of drug delivery. Although there are many drug delivery devices or drug forms that deliver medication over an extended period of time (e.g., skin implants, patches), the term *time-release* is generally used to describe orally administered medication. The most direct effect of time-release medication is that instead of having to take several doses per day to get the therapeutic effect, one can take a time-release medication once a day, every 3 days, or even once every few months. Being able to take a pill once a day instead of four times or more, for example, can certainly improve a patient's compliance with a drug regimen. That is, it's often easier to remember to take fewer doses of medication. Examples of such medications include time-release pills that reduce the number of doses required for pain relievers and antidepressants.

Rationale for Time-Release Medication

Some drugs are inherently long lasting and require only once-a-day oral dosing to maintain adequate drug blood levels and the desired therapeutic effect. Many other medications, however, are not inherently long lasting and require multiple daily dosing to achieve the desired therapeutic results. Multiple daily doses are inconvenient for the patient and can result in missed doses, made-up doses, and noncompliance with the medication's regimen.

Almost all medications marketed today are initially in what is called "immediate-release" or "rapid-release" preparations. These are medications that disintegrate and dissolve in 5 or 10 minutes. Immediate-release medications produce a relatively rapid and high concentration of the drug in the body (a burst), followed by an exponential decline in levels of the drug in the blood, a peak and valley (trough) effect. So when conventional immediate-release medications are taken on schedule, using more than one daily, they cause sequential drug blood-level peaks and troughs associated with the taking of each dose. When the doses are not taken on schedule, the resulting peaks and troughs produce less than optimal drug therapy. For example, if doses are administered too frequently, minimum toxic concentrations of the medication may be reached. If, on the other hand, doses are missed, periods of subtherapeutic drug blood levels (those below the minimum effective concentration) may result, with no benefit.

On the other hand, a typical time-release medication provides an immediate release of the drug that promptly provides the desired therapeutic effect followed by gradual release of additional amounts of the drug to maintain this effect over a predetermined period of time. Many of these medications are formulated in such a way that the active material is coated with some relatively insoluble material or film. So when we take them, the upper coating or film releases very slowly in the body with the slow release of active material over a period of time. Thus, the advantages of time-release medications include less fluctuation in drug blood levels, less frequent dosing, enhanced convenience and compliance, reduction of adverse side effects, and reduction in overall health care costs. The potential disadvantages include the possible toxicity or nonbiocompatibility of the materials used to enable the time-release properties of the medication, undesirable by-products of degradation of those materials, lack of control of dosage once ingested (once ingested, time-release medications deliver treatment continuously, rather than providing relief of symptoms and protection from adverse events solely when necessary), dangers of high drug-delivery levels, and toxicity resulting from any loss of integrity of the release characteristics of the medication.

Terminology

Over the years many terms and abbreviations have been used to refer to medications designed to release their drugs in the body at a predetermined, rate, duration, and/or location to achieve and maintain optimal therapeutic drug blood levels. These include: controlled-release (CR), continuous-release (CR), delayed action, delayed-release, extended-release (ER, XR, XL), prolonged-release, prolonged-action, slow-release (SR), and sustained-release (SR). It is common for these terms to be used interchangeably, sometimes resulting in confusion about their exact meaning and whether there are differences among them. There are indeed technical differences. For example, "extended-release" refers to medication that allows at least a twofold reduction in dosing frequency as compared with conventional drugs; "delayed-release" medications are those that release the therapeutic drug at a time other than promptly after administration.

The United States Pharmacopeia (USP) recognizes the use of the term "modified-release" to embody the terms in common use today (controlled-release, extended-release, time-release, etc.) and defines modified-release medication as any medication or other dosage form having drug-release features based on time and/or location that are designed to accomplish therapeutic convenience objectives not offered by conventional or immediate-release dosage forms.

History

Development of time-release technologies began many years ago. In fact, in 1952, SmithKline and French introduced the first time-release medication, Dexedrine (dextroamphetamine sulfate) Spansule (a time-release capsule prepared so that an initial dose is released promptly and the remaining medication is released gradually over a prolonged period). Since then, several modified-release products based on different technologies and processing techniques have been developed that can be administered via different routes, namely, oral, transdermal (absorbed through the skin), ocular, parenteral (injectable), vaginal, and so on. Different mechanisms of release have also been suggested and explored.

Some highlights of modified-release (time-release) oral solid medication developed in the pre-1970s are:

- The Spansule (coated/uncoated drug beads in a capsule) in 1945
- Lontab (tablets by Ciba) in 1950
- Duplex (film coated tablet between the core and external layer) in 1959
- Duretter (plastic matrix dosage form) in 1959
- Controlled-release systems (1970–present)

Many early pioneers worked on the development of early time-release medication. One such pioneer in the 1950s was Hans Lowey. He developed a so-called slow-release medication, which was a salt tablet for troops in the Korean War. The troops, who were taking salt to retain water, often became ill by taking large doses at one time. Lowey enclosed salt granules in cellulose pellets, and compressed them into tablets that dissolved over 10 to 12 hours. In 1953, Mr. Lowey used the same principle to enclose nitroglycerine, a drug used to treat angina attacks. By releasing small quantities of the drug into the bloodstream over a sustained period, instead of in one large dose, the new tablets made it possible to use nitroglycerine as a preventive treatment.

Another pioneer in the field of time-release or modified-release medications was Alejandro Zaffaroni, who coined the term *therapeutic system* to designate pharmaceuticals that delivered their drug at a specified rate in the human body for a specified period of time. He founded the firm called the ALZA Corporation, in 1968, where he developed various types of controlled-release drug delivery systems (e.g., Glucotrol, for non-insulin-dependent diabetes; Duragesic, for severe chronic pain; NicoDerm CQ, for smoking cessation).

In recent years, controlled drug-delivery formulations and the materials used in these have become much more sophisticated, with the ability to do more than simply extend the effective release period for a particular drug. For example, some controlled-release systems can respond to changes in the biological environment and release medication based on these changes. In addition, materials have been developed that could lead to targeted delivery systems, in which a particular medication can be directed to the specific cell, tissue, or site in the body where the drug it contains is most needed. For example, nanotechnology can be used to provide controlled release of drugs (e.g., to the eye to treat diseases such as glaucoma) by combining biodegradable nanoparticles with the drug. Work has been done on the development of an implanted microchip device and wireless technology to actively control the release of drugs in the body over a prolonged period of time.

Examples of Time-Release Medication

Most time-release medications are tablets and capsules designed to deliver drugs to the circulating blood over an extended time period. For example, aspirin extended-release tablets dissolve, after ingestion, at the following rate:

Time (hrs)	Amount Dissolved
1.0	15%–40%
2.0	25%–60%
4.0	25%–75%
8.0	not less than 70%

Some other examples of time-release (extended-release) medication are:

- Compazine (prochlorperazine paleate) Spansule capsules, which consist of coated pellets formulated to release the initial dose promptly with additional drug for prolonged release. This has been used to treat nausea and vomiting.
- Desoxyn (methamphetamine hydrochloride) Gradumet tablets, which consist of the drug impregnated in an inert, porous, plastic matrix. The drug leaches out as it passes slowly through the gastrointestinal tract. The expended matrix is secreted in stool. This has been used for treating Attention Deficit Disorder (ADD).
- Naprelan (naproxen sodium) Controlled-Release tablets; this is a rapidly disintegrating tablet system combining an immediate-release component (released within 30 minutes) and a sustained-release component of microparticles that are widely dispersed, allowing absorption of the active ingredient and maintaining blood levels of the drug over 24 hours. This has been used for the management of mild to moderate pain, fever, and inflammation.
- Toprol-XL (metoprolol succinate salt) tablets consisting of drug pellets coated with cellulose polymers compressed into tablets; used for high blood pressure, angina, and heart failure.
- Quinidex Extentabs (quinidine sulfate) tablets produce extended release of medication by using a hydrophilic matrix that swells and slowly erodes. This drug has been used as an antiarrhythmic.

Chronotherapy-Release Medication

Closely related to time-release medications are the relatively newly developed chronotherapy-release medications. Until recently, it was thought that it did not matter when medications were taken, as long as they were taken. As is well known now, the human body has an internal biological clock, and its biochemistry can vary according to the time of day, month, or year, as well as the phases of the sleep cycle. Studies are starting to show that medication can be more effective if it is taken following these rhythms. Indeed, heart attacks, asthma, and joint pain from rheumatoid arthritis are all more likely to strike in the early hours of the morning because of circadian rhythms (the daily internal timing system that affects the bodily functions). Pharmaceutical companies have started developing medication to work with our biological clocks. Such drugs are called chronotherapy-release medication. These vary the dose released according to the time of day (or night) when it is most needed. For example, a medication called InnoPran XL (propanolol hydrochloride) is designed to be taken at bedtime but starts working in the morning when the blood pressure is highest. Also, two chronotherapy-release medications that are taken to control high blood pressure (Covera-HS and Verelan-PM) delay release after they are taken at bedtime for 4 to 5 hours and then have an extended release for 18 hours.

Timescales, Physical

The science of physics encompasses many orders of magnitude. This fact is witnessed impressively by the three most central entities of physical law—length, mass, and time. For example, the *length* or *size* of objects covered by experimental physics ranges approximately from 10^{-5} meter = 1 *Fermi,* the distance between two elementary particles in the atomic nuclei, to 3×10^{25} meters (m), the diameter of the universe. Flanked by these cornerstones one finds characteristic lengths such as the distance between two atoms in a solid (a few 10^{-10} m), the average distance between two air molecules at normal pressure and room temperature (1 µm = 10^{-6} m), and the thickness of a human hair, which is typically about 60 µm = 6×10^{-5} meter. In comparison, the diameter of the earth is about 13,000 kilometers (km), or 1.3×10^{7} m; the distance to the sun measures 150 million km (1.5×10^{11} m), and the distance to the next star, Proxima Centauri, is 4×10^{16} m.

The concept of *mass* comprehends an even wider scope: Between the mass of an electron (9×10^{-31} kg) and the estimated mass of the universe (10^{-42} kg), there is an incomprehensible gap of 72 orders of magnitude. For example, a protein molecule weighs about 10^{-21} kilograms (kg), and a bacterium amounts roughly to 5×10^{-16} kg. One cubic centimeter of air at normal pressure and room temperature weighs 1 milligram (10^{-6} kg). Of course, the laws of motion also apply to very heavy objects such as airplanes (100 tons = 10^{-5} kg), or for the revolution of the earth (6×10^{24} kg) around the sun (2×10^{30} kg).

The range of the third fundamental entity of physics, *time,* is the subject of this article. Similar to length and mass, the concept of time obeys many orders of magnitude, or *timescales,* varying from the rapid electron dynamics in the atom (10^{-18} s) to the slow dynamics of cosmology (10^{-17} s). The 35 orders of magnitude in between—a factor of one hundred million billion billion billions!—host the full variety of microscopic and macroscopic phenomena.

The diversity of physical timescales is like that of physics itself. It cannot be the aim of this entry to describe every possible temporal dependency of physical interactions, as this would imply reducing the whole of physics to a few pages. Instead, it presents an overview of a selected number of characteristic timescales in the form of a viewgraph (Figure 1), where each time is representative of certain classes of physical events (e.g., the cosmological scale or the mechanical scale). Following the time arrow in Figure 1 from the very slow to the very fast, every timescale is specified by important examples governed by physical law. This entry will furthermore explain how our perception of time is related to the perception of other physical entities, which allows us, for example, the use of the spatial coordinates of the clock's hands as a measure for time. Particular attention will be paid to the occurrence of periodic events in nature, which are the basis of any type of time measurement. It will turn out that our human definition and classification of time is in fact the natural result of our limited senses, determined by the physical conditions we are encountering on earth.

Time Mapping and Periodicity

Time measurements are at the heart of physical experiment. In order to characterize the temporal evolution of a physical state, it is necessary to know the time during which the observed change occurs. Humans, however, do not possess a specific organ for the measurement of time flow—time cannot be measured directly. If we want to know how much time has passed, it is necessary to refer to other entities that are quantitatively more accessible to us, such as the position of an object. When we move, for instance, we cross a certain distance within a certain interval of time. This relation is captured by the physical definition of velocity and its unit: meter per seconds, or kilometers per hour. At a constant velocity, the crossed distance is directly proportional to the passed time, which implies that the physical entity *length* can be used as a measure for the entity *time*. In fact, whenever we observe moving objects, say, a train passing us with a constant velocity, or a cup falling off the table, or the hands of our watch moving with respect to the marks and numbers on its face, we compare the change of the spatial coordinates with the flow of time. This mapping also works in the opposite direction; for example, we conveniently denote distance in terms of traveling time when we say, "Montreal is about 5 hours away from Toronto."

In our daily experience, the flow of time is linear, meaning that it passes constantly and independently of our recognition. It shall be but mentioned here that neither the linearity of time flow, nor the linear relation between time and velocity holds for very fast objects—a rather counterintuitive result owed to the theory of relativity. The speed of light can in principle not be exceeded by any object, and in fact for objects moving with a velocity close to the speed of light, time passes more slowly. Also, if a velocity is not constant but changes with time, the observation of time flow via spatial measurements becomes more complicated, if not impossible. The relation between space, time, and velocity is then arbitrated by the mathematical operation of integration, and the velocity as the quotient of "distance per time" applies to average velocities only. Nonetheless, it is clear that the physical timescales are closely related to a discussion of motions and velocities, which will play an important role later in the discussion.

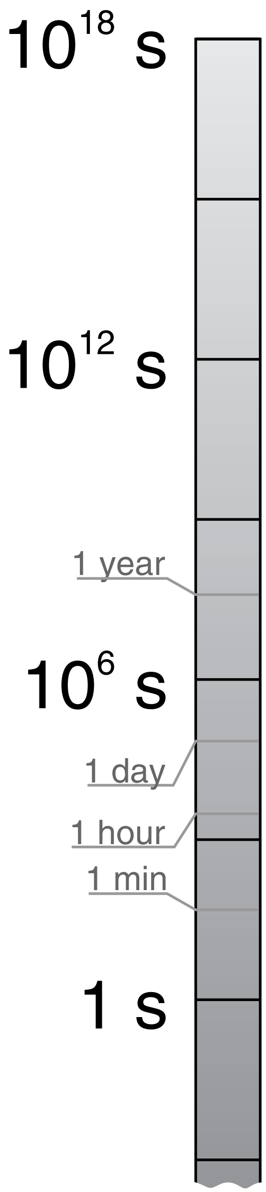
Although our normal temporal experience is linear, time is often measured against periodic events or motions, such as the oscillation of a pendulum or the rotation of the hands of a clock, the vibration of a resonantly excited quartz crystal, or the frequency of an electromagnetic wave emitted from an atom. The analysis of physical timescales is thus also strongly correlated to the discussion of frequencies, the unit of frequency being *1 Hertz* (1Hz) = 1/s (one oscillation per second). The favorability of periodicity for the measurement of time is owed to two facts. First, many events in nature do in fact occur in a regular, repetitive manner—from the very small (e.g., the oscillation of an electron around the atomic nucleus) to the very large (e.g., the revolution of celestial bodies). Two very important cycles both for biological evolution on earth as well as human history are the rotation period of the earth and the duration of the earth's revolution around the sun. The corresponding time intervals, one day and one year, have been synchronized against each other by, for example, the Julian calendar and more complex concepts like *sidereal time* and *universal time*.

Secondly, periodic events in nature represent the most stable known time measurement standards, and thus represent a reliable source for the definition of temporal units. For example, in the atomic clock, the energy difference between two atomic states of the cesium atom (the hyperfine states $F = 4$ and $F = 3$ at $m_F = 0$) corresponds to a certain frequency that is converted to the clock rate of a reference clock with the help of a microwave resonator. The relative standard deviation of this clock rate is better than 10^{-13}, which results in an inaccuracy of 1 second in 300,000 years. In fact, time can be measured with much higher accuracy than masses and lengths. For this reason, the unit "meter" was redefined in 1983 using the constant speed of light as "the distance that light travels within the time interval of 1/299,792,458 seconds."

The "Conditio Humanae" of Temporal Perception

The discussion of physical orders of magnitude at the beginning of this entry evidences a very anthropocentric perspective: It is striking that the units for measurement of the three entities match human proportions closely: One meter is about half the size of a man and comparable to the length of one step; multiples of one kilogram are appropriate measures of how much we can carry and how much we weigh; and one second resembles for example our heartbeat, our walking frequency, and the time it takes for us to walk one meter. This is not too surprising, for the discovery and measurement of the world started with immediate human perception. Conversely, human dimensions and senses are the result of billions of years of biological evolution and are almost perfectly suited to the physical conditions we are encountering on earth. For example, the visual sense is adjusted to the motions of mechanical objects in our vicinity—that is, close to the earth's surface—which in turn is determined by the gravitational acceleration of $g = 9.81$ m/s^2. The somewhat odd unit m/s^2 is better understood as m/s per second, which means that a body initially at rest will have a velocity of roughly 10 m/s = 36 km/h after one second of free fall—an easily conceivable and observable speed. Thereby, our visual sense processes information at the rate of roughly 20 times per second, which—for a velocity of 10 m/s—corresponds to an update of the object's position every half meter. This perfect accommodation of the visual sense to conditions on earth becomes even clearer if one compares the above values to other stellar objects. On the sun's surface, the acceleration is 274 m/s^2 = 1 km/h per second, which would be impossible to follow by eye for even 1 second. On the other hand, acceleration on the moon happens at 1.6 m/s^2, which would prevent the detection of motion from a greater distance.

Strictly speaking, however, the visual sense is not limited to this tiny temporal window of observing kinematics. Visual information is inseparably bound



astronomical scale

Age of the universe (13.7 billion years)
Age of the sun (4.6 billion years)
Age of the earth (4.5 billion years)
Earliest life on earth (3.5 billion years)

Earliest mammals (200 million years)

Earliest great apes (33 million years)

Homo sapiens (130,000 years)

The slowest physically relevant timescale is that of astronomical events, starting with the formation of the universe about 13.7 billion years ago. Although this vast age seems incomprehensible in comparison to a human lifetime, we do have a direct means of access to it: telescopes. Since light travels at the finite speed of 299,792 km/h, the light from a distant star takes a certain time before it reaches us. The information obtained through a telescope is thus that of the star at an earlier age, and the more remote an object is, the further we look into the past. Light from the sun takes about 8 minutes to reach the earth. The light from closest star beyond our sun, Proxima Centauri, has travelled already 4.2 years when we observe it, and the next galaxy, Andromeda nebula, is about 2.7 million light-years away. Probably the oldest object observed so far is a very faint and distant galaxy behind the massive galaxy cluster Abell 2218, with an approximate age of 13.4 billion years — just a few hundred million years younger than our universe.

solar scale

Revolution period of Neptune (165 years)
Tectonic motion (~1 cm/year)

Revolution period of the Earth

Revolution period of Mercury (87 days)

Rotation period of the Earth

macrobiological scale

Oldest living tree,
a bristlecone pine (4,800 years)

Lifetime of a human (80 years)

Lifetime of an erythrocyte (100 days)

microbiological scale

Aerobe ATP synthesis within citric acid cycle (< 90 min)
Cation exchange in the cell (min - hours)

Round trip time of blood in human body (1 min)

pH-equilibrium in cells (~ 1s)
Rotation and emission period of a pulsar (1 ms - 10 s)

AC frequency (50/60 Hz)
Speed of nerval impulse (10 - 100 m/s)
Water exchange in cells (~0.01 s)

mechanical scale

Electron transport in conductor (0.1 m/s)

Photographic exposure time
(1/1,000s of a second - 10s of seconds)
Speed of car (130 km/h)

Tennis Ball, Baseball (200 km/h)
Hurricanes (300 km/h)
Car engine (5,000 rot/min)

half life times of radio isotopes

Tellurium (^{128}Te) - 7 x 10^{24} years
Bismuth(^{209}Bi) - 2 x 10^{19} years
Thorium (^{232}Th) - 14 x 10^{9} years
Uranium (^{238}U) - 4.5 x 10^{9} years
Uranium (^{235}U) - 704 x 10^{6} years

A physical phenomenon that occurs on every timescale is radioactivity, i.e. the decay of atomic cores under the emission of radiation. One can distinguish between α (helium cores), β- (electrons or positrons) and γ-radiation (photons). Radioactivity is a statistical process, which means that it cannot be predicted when exactly an individual core will decay. However, for a large number of particles one can determine a certain time after which half of the particles will have decayed — the half life time ($\tau_{1/2}$).

Plutonium (^{239}Pu) - 24,110 years
Radium (^{226}Ra) - 1,602 years

Cesium (^{137}Cs) - 30,2 years

Sulfur (^{35}S) - 87.5 days

Radon (^{222}Rn) - 3.8 days

PET isotopes for cancer diagnostics:
Fluorine (^{18}F) - 109.3 min
Carbon (^{11}C) - 20.3 min
Nitrogen (^{13}N) - 10.0 min
Oxygen (^{15}O) - 2.1 min

Lifetime of a free neutron (15 min)

Thorium (^{223}Th) - 0.6 s

Polonium (^{215}Po) - 1.7 ms

Notes: This viewgraph represents an overview of selected characteristic timescales of physics, each of which is representative for certain classes of physical events. The time arrow is given in logarithmic units, that is, each tick denotes a factor of 1,000 in duration.

to a second, much shorter timescale: the frequency of optical waves. Light propagates through space as an *electromagnetic wave,* a wave where an electric and a magnetic field reproduce each other with a certain frequency (predicted by Maxwell in 1865, experimentally confirmed by Hertz in 1880). From the full spectrum of electromagnetic waves, only waves with frequencies of $\nu = 3.3 \ldots 7.7 \times 10^{14}$Hz are visible to the human eye, which corresponds to the "optical" wavelengths between 780 nm (red light) and 390 nm (violet light; note also that this part of the visual sense is optimized to our surroundings, that is, to the spectral emission maximum of the sun at 500 nm). Although we are not able to resolve such rapid oscillations directly, we nonetheless use the information encoded in the frequency—the color—and in the incidence position of the wave to form our visual impression. For that, we make use of the fact that every frequency ν corresponds to an energy $E(\nu)$ determined by the famous equation $E = h\nu$, where h is Planck's quantum of action. That is, we measure the frequency of a wave by measuring its energy! This energy is absorbed by certain types of dye molecules (e.g., rhodopsin) in the uvula and rods of the retina, where it triggers within picoseconds a certain photochemical reaction (stereoisomeration) to change the configuration of the molecule. This alteration affects other proteins that control the ion transport of the cell, that is, the cell potential, and through that the intercellular signal transmission. A signal is thus passed on onto deeper-sited ganglion cells, the axons of which form the optical nerve and connect the eye to the brain.

The human body is also sensitive to other types of electromagnetic radiation. For example, the storage and transfer of heat in a solid can be physically described as the excitation of lattice vibrations, or *phonons.* Such atomic vibrations act at 10^{13} Hz and can be aroused by infrared and microwave radiation. The corresponding heat is measured by our body with the help of specific thermosensory receptors in our skin, which "fire" at a specific rate of a few Hertz according to the surrounding temperature.

Finally, humans are also capable of detecting nonelectromagnetic waves such as mechanical *sound waves.* Sound waves propagate from their source to our ear through an acoustic medium such as air or water. This medium performs periodic density modulations and hence pressure oscillations, which are translated by our eardrum into mechanical oscillations of the ossicle and consequently transmitted to the inner ear and converted into nerve impulses. Our acoustic sense covers timescales from tenths to tenths of thousands of seconds, that is, 10s to 10,000s of Hz. It is evident that human perception is indeed a very complex compound system of different detection mechanisms acting on very different timescales, which makes it thoroughly ambiguous to speak of one "humanlike perception."

Relevance of Different Timescales in Physical Description: Time Hierarchies of Complex Systems

For the mathematical treatment of complex physical systems, the existence of different timescales is of crucial importance, because entities varying slowly with respect to the ones of interest can often be considered quasi-constant—they are *separable,* which reduces the complexity of the problem significantly.

In many cases, the different processes form a whole temporal hierarchy. For example, an erythrocyte cell has a lifetime of about 100 days. During its aging process, it changes several properties, including certain average ion concentrations in the cell plasma. However, the ion concentration can also vary on a shorter timescale according to momentary needs of the cell. Part of the short-term ion exchange is mediated by active ion pumps like the sodium-potassium pump (Na^+/K^+-ATPase), which can create ion gradients on a minute to hour scale, during which the overall lifetime variations are negligible. The formation of a pH-equilibrium within the cell happens on account of the much quicker H^+ (proton) transport on a second scale, so that in turn the sodium–potassium distribution appears quasi-static. Finally, proton and ion fluctuations have an effect on the concentration gradients and the electrochemical potential between the cell interior and exterior, which is compensated by the osmotic pressure difference created by water fluxes. Since water can permeate the cell membranes freely, this compensation happens within hundredths of a second.

Viewed from the opposite direction, the existence of a time hierarchy implies that all subsystems follow the slower higher-level changes instantaneously. For example, to any variation in the ion concentration, the osmotic pressure adjusts instantaneously, so that—on an ion timescale—the cell is always in a steady state, which has led to the coining of the term *quasi-stationary state.*

The foregoing biophysical example simplifies matters to a certain degree, but nonetheless gives the right feeling for the separability of timescales in a complex system. Other typical examples include the different response times of electrons and heavy ions in electric fields as known from (for example) plasma physics, the Slowly Varying Envelope Approximation used to separate the rapidly oscillating electromagnetic waves from, say, the comparably long overall Gaussian shape of a laser pulse, or the thermodynamic net production of entropy while increasing the local degree of complexity.

Concluding Remarks

It is fascinating that the conceptual basis of physics holds for so many orders of magnitude, and that in most regimes physics is successful in predicting events ahead of time. Although generally presupposed, this coherence is neither trivial nor a necessity—it is the result of a centuries-long attempt to unify distinct physical theories and phenomena, whereby faster and slower regimes of motion were conquered successively. During this process, the concept of time had to be refined many times, leading sometimes to the border of comprehension. For example, the theory of the great and the massive, Einstein's general relativity, has taught us that time is neither absolute nor linear, but only one dimension of an inseparable four-dimensional spacetime, which is furthermore curved due to the existence of masses.

The search for a conclusive concept of time is not yet finished. Contemporary physics still struggles with inherited inconsistencies, for example regarding the use of time in quantum mechanics. Quantum mechanics, the theory of the very small, does not treat time as a regular physical observable, but has granted it an "exceptional status" (*Ausnahmestellung*), as Erwin Schrödinger once put it. Strangely, it is the only variable that is assumed not to be influenced by measurement, contrary to all other variables. This conceptual difference continues to pose difficulties for the positioning of quantum mechanics with respect to other physical theories. It is thus to be expected that any unified theory must provide a new, unified physical definition of time.

TIMETABLES

An essential tool of modern life, the timetable is thought to be an inheritance from medieval monastic communities. Usually created in tabular format, these documents help us organize and plan what is to occur and at what time. Without them, parents would not know when to send their children to school, passengers would not know when to catch their buses, and planes and trains would risk colliding. It could be said that the timetable provided the essential foundation for the globalization of travel, communications, and economics.

Timetables require a standardized unit of time together with a standard system of references to time. In order to have meaning, statements such as "your flight leaves in one hour" or "two weeks ago I borrowed a book" must be universally understood and accepted. Societal acceptance of what time is, its divisions, as well as a common understanding of what constitutes the past, present, and future, are the basis of a shared civilization. Conventions such as time zones and the international date line clearly play an important role in forming this shared social understanding. The international date line separates two consecutive calendar days. By international agreement, the eastern hemisphere, located to the left of the line, is always one day ahead of the western hemisphere. Requiring travelers who cross the date line to change their watches upon arrival brings them "into synch" with others at their destination. Convenience and the politics of local government interests have relocated the line several times, as happened in 1995 when Kiribati, an island in the Pacific Ocean, moved a large segment of the international date line so that the entire nation would be on the same time zone.

Standard time refers to the division of the earth into 24 time zones, each corresponding to 1 hour of time, and set to the same local time within each particular zone. When travel was limited to short distances, time zones were not needed. However, with the development of great railway systems, standardization of time became an issue debated and discussed by businessmen, politicians, engineers, and vacationers. The development of the 24-hour clock was the work of the Canadian Pacific Railway. Prior to the establishment of standard time zones, railroads picked their own standard of time. An 1870s issue of the *Traveler's Official Guide* illustrates the problems with this method: 12:02 Baltimore time was 12:12 in New York, 12:24 in Boston, and 11:52 in Buffalo. Municipal variations in departure and arrival timetables caused considerable frustration and confusion for travelers. Safety was an overriding issue, as different time references increased the risk of trains meeting head-on. Through the work of Sir Sandford Fleming, a Canadian railway engineer, Standard Railway Time was established in 1883 following a 19-nation meeting. To Fleming, the lack of standardization impeded industrialization and the modernization of society. The earlier efforts of Charles Dowd, an educator from Madison, Connecticut, and William Allen, an official of the American Railroad Association, contributed to this significant event.

Timetables establish rhythms—the observance of holidays, the start of the school year, occupation-based work schedules—around which our lives, our everyday comings and goings, are formed. Today, sophisticated computations are applied to urban bus networks, rail and air travel, classroom and exam scheduling, and shift work and just-in-time delivery systems. Scheduling timetables must be efficient, robust, and flexible enough to adjust to external influences, such as the grounding of a plane or the cancellation of midterm exams due to inclement weather. Heuristic algorithms are frequently applied in order to maximize the use of limited resources, and to coordinate and synchronize numerous and varied parameters. (A heuristic is a rule used to find a feasible solution that is close to the optimal solution.)

Timetables are published as books, booklets, posters, back-lit displays, on the Internet, and via text messaging. Early rail timetables were haphazard in format, cluttered as they were with advertisements, footnotes, and tiny type, and they were not always specific about whether times were morning or afternoon. Travelers now enjoy access to rail, bus, ship, and air travel timetables from any device with Internet access, and can receive up-to-the-minute status reports on arrivals and departures.

Time Travel

Long before time travel was embraced by science, the subject captured the imaginations of shamans, mystics, and science fiction writers. In his novel *The Time Machine,* H. G. Wells depicted a world where the past, present, and future coexist all at the same time. The distant future was a terrifying realm where murky, subterranean beings cannibalized the people who lived above ground. And returning to the past was as simple as making a

U-turn on the highway of time. For centuries, perhaps thousands of years, time travel to both the past and the future has been a persistent dream.

In 1905 Albert Einstein brought time travel into scientific discussion with his special theory of relativity. In a "thought experiment," Einstein demonstrated that a clock moving through space will tick more and more slowly the faster it travels, until it stops completely at the speed of light. (A clock could never actually attain the speed of light, however, because its mass would become infinite at that speed.) Ever since Einstein, it has been assumed that because the tick of a mechanical or atomic clock slowed with increasing speed, a way to travel into the future had been discovered. This widely accepted theory of time travel is explained by the so-called twins story.

Imagine that spaceships in the future are capable of traveling near the speed of light. A twin decides to journey to another solar system 15 light years distant while his brother stays home. Because the traveling twin is moving at high speed, his clock slows and from his perspective the trip lasts just 1 year. However, the clock of the twin who stays home ticks off 30 years while his brother is away. When the traveling twin arrives back home, he finds that his brother has aged 30 years.

Most theoretical explanations of time travel assume that a highly advanced civilization could overcome the insurmountable technological problems of designing spacecraft that could fly at near the velocity of light, where time dilation is most pronounced. Science fiction accounts, therefore, have time travelers hurtling through space at nearly the speed of light; in some cases their journeys last billions of earth years.

But do we live in a universe where such travel is actually possible? Are the clocks in living cells like mechanical clocks, and will they slow down at high speeds?

Travel to the Future

The interactions of life processes are complex and interdependent. Quantum mechanics describes how chemicals form bonds, and these reactions are the basis of the electron transport chain of metabolic machinery, which is the basis of biological clocks. An often-heard interpretation of special relativity is that relativistic speed will slow down each cellular part, exactly proportionally, so that delicately balanced chemical reactions of oxygen transfer, electron transport, protein synthesis, and diffusion of chemicals across cell membranes will precisely intermesh. But is this an accurate understanding of relativity?

Cellular processes are not like the gears of a clock. They depend upon a bath of chemicals in a constant and rapid motion called Brownian motion. This motion takes place in all directions over very short distances where the molecules behave like mass in a particle accelerator. This has unexpected effects for the molecules moving in the direction of travel. Approaching the speed of light, much more energy is needed to accelerate them faster. Inside the cell this means that the molecules bouncing forward travel at a slower speed and shorter distances than those bouncing in the other directions. And this effect is greater for the faster molecules than for the slower ones. At high relativistic speeds this anisotropy concerning acceleration would cause molecules to move more easily in any direction but the direction of travel. This disrupts the normal pattern of Brownian motion as well as the distribution and concentration of ions within the cell. Particularly mobile molecules would tend to accumulate on cellular partitions away from the direction of motion, thereby disrupting all cellular processes. Any disruption of the pattern of Brownian motion would cause cell death.

The technology does not exist to accelerate life to high speeds, and given the sensitivity of cell processes negative effects would begin to be felt at around 14% of the speed of light. This corresponds to a relativistic mass increase of about 1%. A speed limit, slower than one would expect, is indicated by the laws of special relativity.

The existence of a low bio-relativistic speed limit has far-reaching theoretical consequences. To return to the traveling twin, let us arbitrarily place the speed limit at 30% of the speed of light. The round trip to a solar system 15 light-years distant would take about 30 years. The space traveler who began his trip at the age of 20 would be 48.5 when he returned, whereas his homebound sibling would be 50 years old. The age difference is hardly worth mentioning. All travel into the future requires much faster speeds, which would likely lead to cell death.

When Einstein proposed his theory of special relativity, little was known about our speed through the universe. Now we know, as a result of the discovery of the cosmological background radiation (the radiation left over from the big bang), that we are moving through space at around 380 kilometers per second. In comparison to the speed of light, which is about 300,000 kilometers per second, our speed is practically a dead stop. This seems odd, since other galaxies are traveling at very high speeds. One must then wonder if our extremely slow speed is a requirement for the evolution of life.

When trying to make sense of life in the universe, theorists are wary of claiming humans are unique. So the accepted philosophical argument assumes that life on Earth is not unique. This implies that the conditions of our evolution are shared by life in the universe; otherwise we would be a rare exception. It follows then that other intelligent life also probably evolved on slow-moving planetary systems. A bio-relativistic speed limit would likely exist for them as well.

The existence of a bio-relativistic speed limit greatly restricts the radius of possible space exploration. Assuming that our life span remains at around 70 years, the maximum radius an individual could travel away from Earth, without sophisticated methods of suspended animation, may be about 25 light-years. At this time, only travel within our solar system appears possible, although no attractive destination exists.

Putting the speed limit aside, there are other reasons time travel is primarily a subject of science fiction.

Travel to the Past

General relativity, Einstein's subsequent theory, opened a door to travel into the opposite direction—the past. The mathematical grid-work of gravitational fields in general relativity theory maps the movement of matter. The formulas have predicted some of the most exotic phenomena in the universe, such as black holes, as well as the bending of light by gravitation.

Kurt Gödel, a friend of Einstein's known for his incompleteness theorem, used Einstein's formulas to pave a soul-preserving path into the past. Gödel's universe is perhaps an ideal laboratory for understanding time and the motion of matter. That universe was a carefully designed mathematical description of a spinning cloud of dust. The dust of astrophysics, however, is not ordinary dust. The universe is so vast and galaxies so numerous that an entire galaxy is treated as a single dust grain. His solutions showed that spinning, galactic specks could produce a closed, timelike curve (ctlc), where the axis of time bends back on itself. Presence of ctlcs is widely believed to indicate the possibility of travel into the past. At least Gödel thought so, and he claimed a powerful spaceship flying at relativistic speeds could carry a traveler into the future, to arrive at the past. Ctlcs appear in other solutions of the general theory; however, few theorists seem to have understood the implications for life that might get caught in these warped regions of spacetime.

When we hear that travel to the future can lead to the past we naturally wonder what would transpire during such a journey. If we could find Earth in Gödel's universe it would not be the planet we know. The return to the past of our Earth would not be a process of reversal, where all the molecules and atoms would stop their forward motion and begin moving in the reverse direction. That would be contrary to the laws of physics that made Gödel's universe tick.

For a while on Gödel's Earth, perhaps mountains would grow and erode, but then something strange would happen at a future date. Inexplicably, each particle, atom, light wave, fractured atomic nucleus, exploded cosmic ray, everything would have to follow a new set of physical laws that would cause Gödel's Earth to reconstitute itself—returning to exactly the same conditions, positions, temperatures, masses, energies, and velocities as an earlier time. Migration to an earlier energy state is contrary to the laws of physics.

This, of course, would require new physics, since such patterns are contrary to the second law of thermodynamics. This law states that everything tends toward increasing randomness and entropy, which is the opposite of what was taking place in Gödel's universe.

Some theorists object, stating that the second law of thermodynamics is statistical and does not preclude unusual chance events. For example, the law does not prohibit an ice cube that has just melted from forming again into an ice cube, which would produce an apparent reversal in time. It states only that that event is unlikely to take place. However, the mathematical chance of rewinding the whole universe is infinitesimally small.

These same theorists claim that if one chance exists in an infinite number of possibilities, then given enough time that event becomes probable. It must be noted that this exact argument for what is possible is applicable to crying statues, staffs that turn into serpents, parting oceans, water changing to wine, and the inside of a whale being a safe location for human travel. Such speculations are beyond the realm of science.

On Gödel's Earth, time moved toward the future and arrived at the past. There winds had to blow in exactly the same manner and the sun could never run out of fuel. Galaxies and stars didn't collide and black holes were not gobbling up matter. The birth and death of stars, even life itself, played no role.

Although we can't draw the multidimensional spacetime Gödel contrived, a simple model represents how his universe was designed. Think of matter in the Gödel universe as moving like cogs on a wheel, and think of the wheel itself as spacetime. Gödel's universe moved into the future a cog at a time, moment by moment, until matter eventually arrived back at an initial cog position. Each dust particle had a simplistic, mechanistic movement. Gödel's universe was a spacetime cosmological clock that expressed the basic mechanistic properties of the formulas of the general theory of relativity. The clock ticked, the hands went around, but no one was there to notice that the new times were identical to the old times. In Gödel's universe the past was the future and the future the past. All times were the same time. Time itself had ceased to exist. Gödel's world does not exist, but it offers a tantalizing mathematical hint that travel into the past might be possible.

Wormholes

Wormholes, known as Einstein–Rosen bridges, are another mathematical construction of the general theory that offer the theoretical possibility for travel into the past. Think of spacetime as a two-dimensional piece of paper folded over but with its sides not touching. These bridges connect the flat portions of the folded sheet, representing a rapid shortcut between two distant regions of the universe. Under normal cosmological conditions, wormholes, if they could exist, would slam shut before a spaceship could pass through. Many books and articles and Internet pages espouse modified wormholes that can stay open as a possible means of time travel. A great deal of thought has gone into the physics necessary to build a wormhole-based time machine. They are plagued by many theoretical problems besides the fact that they require relativistic speeds, which would kill life. Setting that aside, major theoretical obstacles exist for making and operating a "time machine," not least of which is that the fundamental physics of time is uncertain.

To travel back in time using a wormhole time machine means that one would be able to shake hands with oneself. Inexplicably, theorists are mute about that astounding event but are almost universally worried about a paradox: What happens when someone goes back in time and kills oneself? Obviously, if you killed yourself you would not exist, so you couldn't then go back in time to kill yourself.

The physically interesting problem, however, is that shaking one's own hand defies at least one law of physics: the conservation of matter and energy. Few ask this simple question: Where would the matter, nervous system, and memory come from to manufacture a duplicate self? Theorists, many of them physicists, offer no physical explanation for when, where, and how the clone is produced. We are only told duplication magically happens and then we are distracted in the next breath when it is claimed that the duplication of matter does not defy the laws of physics. A little-advertised consequence of travel to the past is that once such a mysterious process were started, it would continue operating into infinity in the past. The present would appear to become flooded with an infinite wave of clones that would cause the universe to collapse into a massive black hole.

The belief in time travel rests completely upon one's definition of time. Most discussions see time as a type of spatial dimension, but this is not a physical fact. The time used by science, general relativity, special relativity, and Newtonian physics is not a spatial dimension, it is a measurement of motion. Time helps us measure the positions of matter as thay move through the universe. The clock ticks differently from place to place and is a full-blown mathematical dimension, but no past travel destination exists within that dimension. The known universe of time is the ephemeral ticks themselves, and nothing more.

Thus, the idea that time travel is possible rests upon an incomplete understanding of relativistic law. Our cells are not simplistic mechanical clocks. They are rapidly moving particles that have altered trajectories at high relativistic speeds. At such speeds these clocks do not just slow down, they die. Accordingly, despite the closed timelike curves that pop up in various solutions of the formulas of general relativity, the prospect of traveling to the past to meet one's younger self remains the stuff of dreams.

Time Warps

Time warps have been a favorite topic in science fiction literature from H. G. Wells's *The Time Machine* (1895) to the present-day *StarTrek* series. According to these stories humans can jump throughout history to change or observe events in the past or future, and spaceships can travel quicker than the speed of light in order to travel to other galaxies, but what exactly is the scientific basis behind this phenomenon?

A time warp is defined as the slowing down or speeding up of time. This is a relatively recent concept in the history of science. In 1905 Einstein showed that space and time were relative rather than absolute, and in 1912 he showed that space and time were related ("spacetime" as it came to be known), stating that it was actually curved instead of a straight line as had previously been thought. Since the 17th century, Newtonian physics had stated that space and time were absolutes. Einstein concluded that space and time are warped by matter and energy and thereby elastic and relative. His *special theory of relativity* states that time is elastic and as a result can be stretched and shrunk.

What are the methods by which time can be warped? Speed is one tool. In order to test this theory, physicists Joe Hafele and Richard Keating put highly accurate atomic clocks into airplanes and flew them around the world in 1971. They compared the readings of these clocks with identical clocks they had left in the laboratory. The result was that time ran more slowly in the airplanes. The airborne clocks were 59 nanoseconds slower relative to the clocks that were kept in the laboratory.

This is a small difference; to get a really dramatic effect one must move very fast. Speed will distort time based on how fast an object is moving. The closer you get to the speed of light (300,000 kilometers per second) as you travel, the bigger the time warp gets. The time warp becomes infinite when the speed of light is reached.

Speed is only one method of warping time. Another method is gravity. The earth's gravitational pull causes clocks to lose one microsecond every 300 years. Because of the lack of gravity in space, it would make sense that time would run faster in space. It is not that noticeable, though; one would gain just a couple of milliseconds by spending 6 months aboard the International Space Station. Stephen Hawking, one of the modern leading experts on the relationship between space and time, has suggested that spacetime is nearly flat on Earth, so the curvature resulting from gravity makes very little difference in our everyday life, making us oblivious to the time warp phenomenon.

Contemporary physicists are researching recent developments such as string theory, which may provide greater insight into time and space and the relationship between the two.

Time Zones

A time zone is one of 24 mostly equal divisions of the earth, created in an effort to standardize time worldwide. For the most part, a time zone is equal to 15 degrees of longitude and operates at exactly 1 hour plus or minus its eastern and western neighboring zones. In any time zone, the zone immediately to its east is 1 hour ahead, and to its west, 1 hour behind.

It was 1879 when Sir Sandford Fleming proposed the use of time zones, which were officially adopted in 1884 at a conference held in Washington, D.C. Prior to the use of time zones, localities kept their own central, or civil time. Usually, towns would set their clocks to noon once the sun reached its high point. The method was not exact and even neighboring cities and towns saw great variation in time within their own boundaries. Some towns had residents who would travel the town every week with watches in hand for people to set their own watches, in order to try to keep a uniform time within the town.

This system worked as well as it needed to and had strong ties to the days when sundials were used to tell time. The sun reaches different points across different places of the earth, so local times were very different, but with relatively sedentary communities, there was no need to keep standardized times. Although travel between towns was not uncommon, there was little inconvenience in resetting one's clock based on the locale.

With the onset of faster modes of transportation, those needs changed. Railroads were being built and used extensively, and the increase of travel and people being transported across greater distances in shorter times posed a great problem to scheduling and timekeeping. Fleming, a Canadian engineer and surveyor, played a major role in the development of the rail system throughout Canada and the United States. He quickly realized that the need for more accurate scheduling demanded a standardized time.

Fleming used simple mathematics to determine the size of each time zone: with the world comprising 360 degrees, and a day consisting of 24 hours, each zone should equal 15 degrees of longitude—1/24 of the world's circumference. He presented his plan at numerous conferences until a version was adopted at the International Meridian Conference of 1884. Despite Fleming's assertions that time zones allowed for use of local time, the conference rejected the use of time zones. It was, however, agreed that the use of the meridian of Greenwich as the prime meridian made sense, as the majority of maps and charts at this time had already been using it as such.

The United States and Canada adopted the use of their time zones on November 18, 1883, also known as "The Day of Two Noons." Within 30 years, Coordinated Universal Time (abbreviated UTC) and time zones were being used by all major countries. There have been some changes to each zone's size based on local and political considerations, allowing countries and states to remain within a given zone. For example, China, which should span five zones, uses just one, and in the United States, most states are within its own zone, despite geographical boundaries.

Toffler, Alvin (1928–)

Alvin Toffler, American author and futurologist, is noted for his contributions to the analysis of social change and the human condition. Taking a psychological and sociological approach to the impact of technology, Toffler presents a unique perspective on the dynamics of the human condition as society rapidly progresses from industrialism to a quasi-Marxist state. Although not concerned directly with time as such, he does concentrate on the rate of change that is relative to previous periods of history and the effects that are seen today. Toffler is known for his major works *Future Shock* (1970), *The Third Wave* (1980), and *Powershift* (1990).

Toffler depicts the dynamics of human life and the development and restructuring of societies. As humankind expanded its intellectual horizon and implemented newly developed technologies, the rate of change increased dramatically within a social framework. Increases in population (dispersion), extent or degree of individualism, social relationships, and economic development and restructuring (e.g., the decline of industrialism and technocracy) are critical points in the attempt to create a new society. In times of shifting power, corporate downsizing, and multitasking, individual longevity and identity are depicted as being psychologically transferred and expressed in social relationships; for example, modular relationships and maladaptive actions and reactions. From clearly defined economic (employment) and social (family) structures to the development of a continual transient state found at all levels, humankind is depicted as grappling with and attempting to adapt to this new environment. When vast changes within a short time created stress and distortion beyond the adaptive capabilities of our species, Toffler acknowledged the phenomena with his term *future shock*. Essentially, it is almost a *Twilight Zone* scenario: surreal perceptions of dynamic change with real consequences.

The affluence and materialistic nature of modern society is well documented. This fact regarding modern society, along with Toffler's conception of future shock, can push humankind's physiological and psychological resources to the limits. In response to this condition, Toffler identified maladaptive psychological conditions seen in the attempt to adjust. This adjustment entails forms of denial, specialization, obsessive reversion, and super-simplification. Although Toffler does not offer direct solutions for this predicament, he does hold that education and educational environments may have a critical and essential place in directing the future of society. Education, for Toffler, must be dynamic and ever-changing to meet the expectations found in the evolution of modern society. Education must keep pace and mimic in structure the concepts and rates of change seen within society. This open-ended process of changing the mind-sets of youth, via individual focus, can be seen as a unique adaptation to prepare for the future.

Toffler's account of social problems, along with the theoretical underpinnings, exposes the serious problems that are seen within modern societies. Rapid technological advancements, changing complexion of family structures, changes in business strategies and structures, and political and social upheaval all denote the rapid changes experienced in society. Future shock, similar to Marx's concept of alienation, depicts the experience of disconnection that individuals experience directly from the mode of production, for example, as seen in both *Future Shock* and *Powershift,* and its perceived reflection of the individual's identity and self-worth. In the attempt to offset the implications of radical change, no single individual can correctly predict or solidify the future of humankind. The rate of change, similar to the behaviors of individuals, is beyond the control of a preplanned structured society. In the endeavor to construct the future, to adapt at the very least, humankind must guard itself from pseudoscience, hidden political agendas, and the rising tide of fundamentalism. Change, as seen in both biological and cultural evolution, is an integral and constituted part of our species and its related humanity. Toffler's works expose the difficulty experienced during periods of rapid change and the effects it has on society. How successfully our species will adapt to the future remains to be seen.

Tolkien, J. R. R. (1892–1973)

J. R. R. (John Ronald Reuel) Tolkien was a storyteller in the truest sense, generating tales infused with contemporary concerns, classic themes, and ancient traditions. *The Lord of the Rings* trilogy, arguably his greatest work, certainly exemplified this reality. Yet, for all the grandeur of Tolkien's imagination and careful intertwining of reality, myth, and fiction, it is the complexity of Tolkien's view and utilization of time that truly make his work so masterful.

Pursuing the scholar's life, Tolkien ultimately became an eminent philologist whose academic career included appointments at Oxford, where he guided students and colleagues alike toward a better understanding of and appreciation for languages, both modern and ancient. Aside from his academic efforts, Tolkien was an imaginative writer whose fondness for mythology and Arthurian romances led to his translation of classic works such as "Sir Orfeo" and "Sir Gawain and the Green Knight," as well as creating original fiction, including his *Lord of the Rings* trilogy. It was within this latter work and associated writings that Tolkien thoroughly developed his concepts of time, particularly the concept of immortality.

Tolkien's elves, ever valiant, graceful, and dignified, anchored his perception of immortality and timelessness. Wherever elves dwelled, they lived eternally. While mortal weapons could slay them, Tolkien's elves remained impervious to the normal ravages of time, including aging and disease. Tolkien treated this conditioning as a blessing and a curse, with elves living endlessly but watching all else fade to memory. Yet, this duality did not diminish or limit Tolkien's conceived notion of time and eternal life.

In addition to the immortality of the elves, Tolkien viewed immortality from the perspective of themes that are timeless, ever cycling through the ethos of societies. Good versus evil and nature versus technology were two of the key themes that surfaced through Tolkien's writings. His works reflect the notion of such themes, continually resurfacing as time passes, making such conflicting viewpoints seem as immortal as the elves themselves. Time, consequently, becomes an echo of the very themes that play out in both Tolkien's Middle-earth and our own reality.

Immortality, as a temporal theme within Tolkien's writings on Middle-earth, was offset by the opposing premise of life being finite, time thereby having an end. Yet, the finality of an individual's life varied considerably among the creatures of Middle-earth. The wizards Gandalf and Saruman were far more ancient than they appeared to be. Notwithstanding the centuries they endured, they must have appeared relatively youthful. Likewise, the Ents, great trees that often walked about the forests of Fangorn, suffered through the encroachment of humanoids for ages, making Treebeard and his brethren early occupants of Middle-earth. Yet, for both the wizards and the Ents, time was not endless. Their time was not relegated to immortality. The Ents, in particular, seem caught in a state of decline as the Entwives were lost, making future procreation questionable; their time was consequently fading.

Humanity itself faced a variety of projected life spans in Tolkien's writings. While most humans lived less than a century, the descendants of Númenor lived for centuries, as did Aragorn, before succumbing to death. Regardless of ancestry, though, all humans were as mortal as the dwarves and hobbits that shared Middle-earth with them. No matter their ancestry, all humans would ultimately suffer defeat at the hands of time. Collectively, the mortal creatures of Tolkien's Middle-earth brought realism to this fantastic epic. While some, such as the bearers of the Ring of Power, could postpone aging, ultimately they too would surrender to time, effectively balancing those who would witness time's control of life.

The temporal nuances found throughout Tolkien's masterpiece, *The Lord of the Rings,* reflect the storyteller's deep understanding of tradition, myth, and history. These iconic and immortalized images—the immortality of the elves, the longevity of the heirs of Númenor, or even the endurance of Gandalf and his nemesis, Saruman—among others, continue to provide readers with a multifaceted understanding of time, while simultaneously granting J. R. R. Tolkien himself a bit of immortality.

Tolstoy, Leo Nikolaevich (1828–1910)

Leo Nikolaevich Tolstoy was a Russian writer, essayist, spiritualist, and philosopher. Born to a noble family, he received a university education and served in the army during the Crimean War, which Russia launched against Turkey, England, and France. He traveled throughout Europe and later embarked on philanthropic missions to assist peasant children and serfs. *War and Peace* (1865–1869) and *Anna Karenina* (1875–1877) were the novels that established him as a world-renowned author. While *War and Peace* was a historical account that spanned 15 years, *Anna Karenina* focused on the personal struggles in an individual's life.

War and Peace is praised for its complex characters and is considered one of the greatest technical literary accomplishments in the history of Western novels. The story was set in a turbulent historic time when the French leader Napoleon Bonaparte launched the military campaigns of the Napoleonic Wars at the beginning of the 19th century. The lives of more than 500 characters are examined in the course of the novel; the book spans 15 years and the generational changes that naturally occur with the passing of such time. The novel tells of historical events, great romance, and family issues as it follows the turbulent events of the period and traces the changes as generations grow from children into adults.

Anna Karenina highlights the meaning and purpose in human existence, dealing with the common themes of love, marriage, family, and fidelity. It is the story of a woman who leaves her older, politically savvy husband, their young son, and a loveless marriage for an enticing, younger military officer. She strives to overcome her guilt and find love and peace in this relationship. She and the young officer have a child together. Still, her guilt overrides her potential for happiness and she ends her life by jumping in front of a moving train.

Tolstoy writes of universal problems and timeless issues such as childhood, youth, and death in *Three Deaths* (1859), love and marriage in *Family Happiness* (1859), and class relations in *Polikushka* (1859). Love, living naturally, and generational conflicts were themes in *Two Hussars* (1856) and *The Cossacks* (1852–1863). The timelessness of these literary themes and his approach created a body of literature whose appeal is universal.

Generations of readers and critics continue to read, study, and discuss Tolstoy's work. His output as a writer spans 45 volumes of fiction and an equal number of volumes containing essays, correspondence, and diaries, signifying an enormous cultural impact.

In addition to his stature as a literary figure, Tolstoy was a man of principle, regarded in his lifetime as a profoundly moral authority, particularly after he had released from bondage the serfs who by heredity and tradition had long been attached to his ancestral estate. Many thinkers were influenced by his viewpoints on religion and the duty of civil disobedience. But today his reputation rests primarily on the enduring body of literature he created.

Totem Poles

From the Totempolar Region, the mountain-bordered coastline from southeast Alaska to coastal Washington, the indigenous Northwest Peoples—the Tlingit, Haida, Tsimshian, Kwakwaka'wakw, Bella Coola, Salish, and others—carved their legacies in columned sculptures of cedar. The iconographic symbols of their sophisticated abstract art, later to be known as "form line," were visual documentations, a primal form of "written" language for communicating significant cultural and historical events. It is factual that songs, dances, oratory, painted and woven clothing, house fronts, ceremonial utensils, canoes, and other *at.óow* (Tlingit clan identity) were also records of history to these West Coastal Tribes. Nevertheless, it is the totems standing majestically, bearing witness through the ages that these coastal people have for the most part identified with; and those of other cultures have recognized as symbols of the Northwest culture.

The Northwest Peoples' intricate hierarchical civilizations were divided into clans and caste systems, and were contingent on the knowledge of tribal and family lineage as the foundation of their status, and on the right of proclamation of certain crests to be displayed artistically in songs, dances, and narrative accounts. Witnesses were required to authenticate the claims; wealth would be accumulated to pay these witnesses in the ceremony known as a potlatch, the vehicle employed to establish this worldview. It is surmised that house posts and memorial poles were predecessors of the totem poles, for the first explorers noted external totems in small numbers. The availability of metal tools in abundance revolutionized totem art, as the wealth from the fur trade with Europeans established the means for the various clan chiefs to commission totems for their potlatches, thereby launching an artistic renaissance in totem art.

Totem poles have been categorized as follows:

- Some totem poles *celebrate clan history.* Legends belonging to a clan could tell how the clan came to be. Some totem legends deal with the seasons, such as "Fog Woman," who is a symbolic representation of the fog that arrives in the summer with the salmon run, signifying the beginning of the Tlingit New Year. Also within the Potlatch oratory the locations of where the clan had settled are given. The symbols on the totems then remind the witnesses of the chronological order of history concerning the clan.

- Some totems served as *memorials to the deceased.* Chiefs and other high-caste clan members had the means to accumulate the wealth required to honor their deceased with a memorial pole; this in itself was a record in time of the numbers of high-caste members honored within a tribe, as well as a testament to the clan's wealth. Illustrated upon the poles are the clan's *at.óow* (crests); through the years a clan might add a crest, perhaps through marriage. Older poles would therefore lack that crest, and the newer pole would thereby bear witness to the advent of the acquired crest; or in the case of shamans, the representation of spirit helpers, for example, the owl memorial totem at Saxman, Alaska.

• Some totem poles serve to *commemorate historic deeds or events.* When an extraordinary event occurred, such as the advent of the Europeans, which is represented on a Kasaan totem with a man in European garb standing on the water from whence he arrived, a totem would be commissioned with the crest of the chief who was active during the event and with symbols of the event or deed, thereby giving a date for this occurrence.

• Some totem poles convey *ridicule, shame, or revenge.* The ridicule pole concerns an unpaid debt due a person or clan. A totem is a costly item, so the debt due the clan would likely be a huge amount in order to warrant the pole's commission. The magnificently sculpted Three-Frog Pole in Wrangell, Alaska, is such a totem; there is a shroud of mystery over the payment, so when a replica was commissioned by the Civilian Conservation Corps (CCC) for Wrangell Park, there was outrage in the Native community that this debt was being resurrected. The shaming pole is usually interchangeable with the ridicule pole since the commissioning clan intends to shame the debtor into remuneration; except in cases where shame is the primary objective, such as the lewd pole once placed in front of the longhouse that used prostitution as the means to support their potlatches; this occurred during early colonization. Finally, the balancing in righting a wrong was complex in these societies; for instance, should one of low caste slay a high-caste person of another clan, the person blamed for the murder would not be required to die, but one of his high-caste kinsmen had to balance the loss. A former grave post at Kake, Alaska, illustrated a European man on top, a Native man second down, with pertinent crest and other symbols below them. This totem is a testimonial representation of a requisite due for the slaying of their clansman; the fact that a totem was commissioned may presume that a European of the clansman's caste is required for the "eye for an eye" judgment. Whether a ridicule, shaming, or revenge totem, a public record was required to give substance to the case and to remain for all time, or until the situation was settled.

In the 20th century a growing concern arose over the limited time left to gather tribal knowledge from dwindling numbers of elders, and to save the tribal languages that were dying. The efforts in this fight against time resulted in today's Northwest Natives experiencing a resurgence of their cultural identity and arts. Today, restorations of older totems are being administered, such as at the Klawock Totem Park in Alaska; also the Repatriation Act of 1990 initiated more totems being returned to the Native Peoples and replicas being carved; for instance, the Burke Museum's return of two "Kats the Bear Hunter" house posts

Exxon Ridicule Pole and carver Mike Webber. This modern-style ridicule pole was commissioned by the Eyak Tribal Council for the multibillion dollars owed by Exxon Mobil for the 1994 court judgment (overturned in 2008) to the oil spill victims of 1989.

Source: Photo by Ross Mullins. Used with permission: http://www.alaskacarving.com to the Tongass Tribe, for which master carver Nathan Jackson and son Stephen each carved a replacement pole to be displayed at the Burke. In addition, new totems are also being carved, such as the commemorative poles of Liberty and Freedom at Washington, D.C., by Salish carver Jewell "Praying Wolf" James for the victims of the attacks of September 11, 2001. And, in 2007, at Cordova, Alaska, Alutiiq/Tlingit carver Mike Webber sculpted a shaming pole for the 1989 *Exxon Valdez* oil spill and the damages that resulted.

The art of totem pole carving, which once neared extinction because of missionary fervor during the colonization of the Northwest Territory by Europeans and Americans, has returned. Totem poles continue to function as symbols of Native cultures and records of time.

Transhumanism

Transhumanism is a philosophical movement that affirms the technological enhancement of the human species and the coming about of transhumans and posthumans. Like the Christian religion or Marxism, it sets its hopes on the future. In contrast to the other movements, it is a dynamic worldview that does not expect a final perfect state. For transhumanists, human beings are a work in progress, a species to be overcome, and whose qualities need to be enhanced. In contrast to traditional evolution, one transhumanist goal is that human evolution will be directed and regulated by human beings so that their intellectual, psychological, and physiological capacities become improved. Some technologies that are relevant in that respect are bioetechnology, nanotechnology, information technology, and artificial intelligence.

Transhumanism sees itself as compatible with traditional liberalism; it is in accordance with one's own values or those of one's parents which capacities are supposed to be developed. Thus, transhumanists distance themselves from the eugenics movement. Yet in doing so they employ a restricted notion of "eugenics," one that refers to state regulated eugenics only. Other types of eugenics, like liberal eugenics and autonomous eugenics, on the other hand, are exactly what transhumanists are in favor of.

Past and Present

The first intellectual who employed the notion of transhumanism was the biologist, philosopher, and writer Sir Julian Sorell Huxley, who is the half-brother of the writer Aldous Huxley, author of the famous novel *Brave New World* (1932). However, the word *transhumanism* could already be found in a 19th-century English translation of the Paradiso section of Dante's *Divine Comedy,* and it consists of two Latin words: lat. *trans*—beyond, lat. *humanus*—human. The Iranian American futurist Fereidoun M. Esfandiary (1930–2000), who admitted to having "a deep nostalgia for the future," enabled the transhumanist movement to be connected with some well-developed philosophical ideas by means of his 1989 book, *Are You a Transhuman?* He published this book under his new name FM-2030, which refers to the year in which he believed that he would celebrate his 100th birthday. Meanwhile, the University of Oxford, in England, is one of the institutions in which some particularly influential transhumanists teach and discuss their worldviews. Particularly noteworthy is the philosopher Nick Bostrom (1973–), who cofounded (with David Pearce) the World Transhumanist Association in 1998. Since 2005, he has been director of the Oxford Future of Humanity Institute.

Transhumans and Posthumans

The concepts of transhuman and posthuman are particularly important for most thinkers in that movement. Yet there is no generally accepted understanding of what they mean. If we compare Esfandiary's and Bostrom's meaning of the concept *posthuman,* the vast number of meanings of that word that one can hold as a transhumanist becomes clear. Esfandiary distinguishes between the notion of the *transhuman* and that of the *posthuman.* Transhumans are transitory human beings who still belong to the human species but have technologically enhanced capacities, which is why they represent the evolutionary link to posthumans. Posthumans no longer belong to the human species. They are members of a new, enhanced species. The similarities between Esfandiary's concepts and some of Nietzsche's concepts are striking. Esfandiary's concept of transhumans resembles that of Nietzsche's higher humans, and Esfandiary's concept of posthumans seems to have a lot in common with Nietzsche's concept of the overhuman. Bostrom, on the other hand, holds that posthumans belong to the human species but have capacities that cannot be found in current human beings. He also holds that at the present time we might not even be able to imagine which qualities these might be.

Pro and Con

The transhumanist movement does not include philosophers only. Especially in the field of literature, quite a few adherents can be found, such as the French author Michel Houellebecq (*Les particules élémentaires,* 1998). A number of public intellectuals, however, are highly critical of the transhumanist movement. The political scientist Francis Fukuyama is a vehement critic who fears that this movement could undermine the basis of liberal democracies, something he points out in detail in his bestselling book *Our Posthuman Future.* The philosopher Jürgen Habermas, in a 2001 book on liberal eugenics, made critical remarks concerning the transhumanism movement.

TRANSPORTATION

Transportation is the act of transporting or conveying. Throughout history, transportation has developed into increasingly efficient means. The most basic yet most enduring form of human transportation is, of course, walking. Since the beginning of the species, humans have powered their own bodies, one foot in front of the other.

Even at the onset of what many feel to be a major advance in transportation—the wheel, around 3500 BCE—people still had to walk in order to use the wheel, which was set below pull carts. Even the early chariots were pulled by people. It was not until much later that humans were able to step off their own feet and onto a nonhuman powered, wheel-based device. This came in the way of the horse-drawn chariot around 2000 BCE.

Around the same time the wheel was being put to its first uses in carts and human-drawn chariots, the first boats were entering the water. These were used in river travel and again were powered by people through the use of oars, and later by the capture of wind power through the use of sails.

Only in the modern era was a major advance made in the development of boats, with the advent of the steam engine. This was an extremely slow process, as the first steam-powered paddle boat was demonstrated around 1783, with its first practical appearance 4 years later. The steam engine was adapted for use on land nearly 20 years later, with the invention of a primitive, not very practical steam-powered locomotive intended for use on roadways.

Meanwhile, some other variations of travel had emerged. Primitive oar-powered submarines were first used around 1620. Iron horseshoes had dramatically improved the ability of horses to pull carriages, carts, and buses by 1662. And hot-air balloons first took flight in 1783.

Except for wheelbarrows and simple carts, many of the primitive sources of transportation have been replaced. Again, walking remains the most primitive and to some extent the most popular mode of transport even in contemporary times. The wheel, ironically, came full circle more than 5,000 years after its invention. It was 1790 when the bicycle was invented. The first bicycles were powered simply by pedals that turned a larger wheel to create motion. Today there are many varieties, mostly chain-driven and many with multiple gear speeds.

By the end of the 18th century the steam engine had been perfected, and the first steam-powered passenger boat was introduced by Robert Fulton. A few years later, the first practical locomotive was designed, this time intended for use on rails.

The first rumblings of a gasoline-powered automobile were heard in the mid-1800s from Jean Lenoir. Karl Benz improved the idea and put the first practical automobile, equipped with a combustion engine, on the road in 1885.

Henry Ford would advance the science of automobiles, particularly their manufacture. He is well-known for the design of his Model T automobile, but in fact it was the assembly line from which the Model T was manufactured that made the automobile much cheaper to make and thus more affordable for individuals to own. The first Model T rolled off the line in 1908.

The turn of the 20th century was an exciting time for travel and transport, with Ford's mass production of cars and the Wright brothers taking flight in the first engine-powered airplane in 1903. The rest of that century witnessed explosive growth and development in transportation, with the birth of jet planes, helicopters, motorcycles, and rockets.

Not only has the passing of time seen greater advances in modes of transportation, the modes of transportation have themselves affected humanity's experience of time. In general, as time passed and new transportation vehicles were invented, less time was required for travel. Today, automobiles, commercial airplanes, trains, and ships have developed into some of the quickest modes of transportation. Automobiles themselves have seen great change over time, with the first automobiles traveling at speeds of only a few miles per hour. Now, privately owned automobiles (excluding customized racing models) have the capacity to travel at speeds greater then 100 miles per hour.

The average commuter train travels at speeds of about 25 miles per hour, and while personal automobiles may have the capacity to travel more quickly, the infrastructures differ greatly, allowing trains to travel their tracks virtually undisturbed, while autos must obey myriad traffic signals and stoppages.

Airplanes have developed into the fastest mode of transportation. A commercial airliner travels at an average speed of about 600 miles per hour, a far cry from the 42-mile-per-hour world record set by Orville Wright in the early 1900s.

The first rocket to be successfully launched was in Germany in 1942. Within 20 years, the first human to enter space aboard a rocket ship was the Soviet Union's Yuri Gargarin inside *Vostok 1* in 1961, when he made one orbit around the earth. Eight years later, the American astronaut Neil Armstrong was the first to walk on the moon. Space travel has been evolving ever since. Satellites, space stations, and exploration missions continue to be announced and developed. Missions studying Mars are underway, with plans for the further study of Venus and other planets. With the continued development of space travel and the ability to travel longer distances in shorter periods, the planets and beyond are not unreasonable targets for future exploration.

TREES

The most common understanding of the term *tree* is that of its botanical meaning. Most botanists define trees as perennial woody plants with a single stem (trunk), normally greater than 13 to 16 feet (4 to 5 meters) in height. Trees are also important in dating objects and sites, and in commemorating both historical events and specific individuals.

Worldwide, the number of tree species is estimated to be more than 80,000. Yet, on average, 5% of tree species in any country are estimated to be threatened or endangered. Generally, a tree is differentiated from other living plants by its relatively large size and its structure (having a single stem or trunk). Some species of trees can be very large: giant sequoias, coast redwoods, Douglas firs, and some eucalyptus grow 300 feet tall or more and have trunks 30 feet across. Some species also have very long life spans. One of the bristlecone pines of the White Mountains of California in the United States, nicknamed Methuselah, is the world's oldest known living tree, with an age exceeding 4,700 years.

Particular trees are considered historic because of their age, size, or cultural significance. For example, the plane tree of Hippocrates on the Greek island of Kos is thought to be the largest tree in Europe. Hippocrates, the famous Greek physician who lived around 400 BCE and who originated the well-known Hippocratic Oath, is believed to have planted this tree. One of the most famous banyan trees, of the species known as the sacred fig or bo tree, is the Sri Maha Bodhi tree in Sri Lanka that is believed to have grown from a cutting from the tree under which the Buddha became enlightened in the 6th century BCE.

Because of the longevity of trees, it has been the practice to use them as markers to aid in the location of places. For example, a popular tourist attraction in Sherwood Forest in Nottinghamshire in the United Kingdom is a tree called the Major Oak. This is purported to be the tree where the legendary Robin Hood and his Merry Men met to hatch their plots. In the eastern United States, the locations of old graveyards can sometimes be determined by the cedars that were planted there.

Also, because of the longevity of many trees, it has been commonplace throughout history to plant trees as memorials (lasting tributes to people or events) or to commemorate significant events such as the birth of a child, the completion of a new house, the opening of a building, and the visit of a dignitary or other special person. As the tree grows, it is a reminder of the event or significant people or the passage of time since the occurrence of the event.

Tree Timepiece

A tree was probably the very first timepiece, indicating the passage of time during a day by its casting of a shifting shadow. Early humans would have noticed that, in the early morning, a tall tree had a long shadow pointing to the west. As the sun rose in the sky, they would have noticed that the tree's shadow became shorter. Then, in the afternoon, the shadow moved to the other side of the tree and pointed east. Gradually, the tree's shadow became longer as the sun set in the west. Thus, by looking at the changing shadow of a significant tree, early humans were able to count the passage of time, and it was probably this practice that led to the development of the first instrument for measuring time, the sundial.

As it grows, a tree incorporates some of nature's most accurate evidence of the past. Each year, a tree increases its girth or the size of its trunk. This growth is recorded as concentric rings in a cross-section of its trunk. These tree rings have been shown to record evidence of floods, droughts, attacks by pests, lightning strikes, fires, and even earthquakes, thus making trees some of nature's most accurate timekeepers. For example, Chinese pine trees (*Pinus tabulaeformis*) have been used to reconstruct total January–July precipitation in

Central China from 1775 to 1998! Indeed, a completely new scientific field, called dendrochronology, has arisen that involves the analysis and description of tree-ring data in order to date and interpret past events, such as climatic changes.

Trees have been important to humankind's continued existence. We are all familiar with the use of wood from trees as a common building material. Trees and other plants release the oxygen that we breathe; prevent soil erosion; provide food and shelter; and provide material for human use, such as paper, medicine, tools, weapons, and even toys. Trees also play an important role in many of the world's cultures and mythologies.

Tree Parts

The basic parts of a tree are the roots, trunk(s), branches, twigs, and leaves. The roots of a tree are generally embedded in the earth, providing support for the tree and absorbing water and nutrients from the soil. Not all trees have the same plant parts. For example, most palm trees are not branched, and the saguaro cactus (*Carnegia gigantea*) of North America has no functioning leaves. Yet, based on their general shape and size, these are both also generally regarded as trees.

Several different terms are used to refer to groups of trees growing together, depending on the density of the trees and the extent of the space occupied. A small group of trees growing together is called a grove or copse, and a large area covered by a dense growth of trees is called a forest. A landscape of trees scattered or spaced across a grassland is called a savanna.

Dendrochronology

The term *dendrochronology* is derived from the Greek terms *dendron* (tree), *chronos* (time), and *logos,* meaning "science of," and so refers to the science or study of time by using trees. Dendrochronology, often called tree-ring dating, is the method of scientific dating based on the analysis of tree-ring growth patterns. Andrew Ellicott Douglass of the University of Arizona pioneered dendrochronology in the early 20th century. It is based on his observation that wide growth rings of certain species of trees were produced during wet years and, conversely, narrow rings during dry seasons. Therefore, over a long period of time, examination of some tree trunks reveal a sequence of tree rings with a pattern of wider and narrower rings indicating climatic conditions like droughts, cold summers, and so on. Thus, the annual growth rings of a tree reveal not only its age (by counting the rings), but also the changing environmental conditions during its lifetime.

Until relatively recently, radiocarbon dating was the only method known for dating wooden objects; that is, determining their age or the length of time since they were built or constructed. Dendrochronology is much more precise than radiocarbon dating, being accurate to a single year. Thus, the use of tree-ring data makes possible the establishment of precise dates for wooden objects, structures, and prehistoric events.

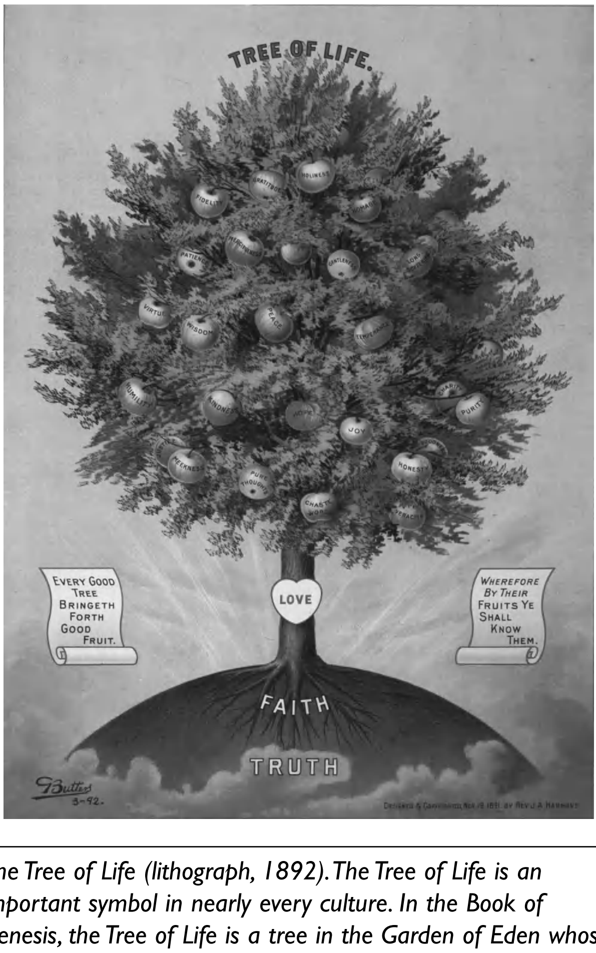
Cornell University researchers have used applied dendrochronology not only to determine the age of old houses in northeastern New York state, but also to date wood buried beneath the volcanic ash of the famous Santorini volcanic eruption, one of the largest in the last 10,000 years. They showed that this eruption occurred most likely in the late 17th century BCE, 100 years earlier than previously believed. Researchers at the University of Arizona have also used tree-ring data to examine the increases in levels of heavy metals (tungsten) over time in the small town of Fallon, Nevada, in the United States, that was the site of a cluster of childhood leukemia cases. Dendrochronology has also been used to date a previously unvalued portrait of Mary Queen of Scots in the National Portrait Gallery in London. Interestingly, it had been dismissed as an 18th-century copy, but dendrochronology established that the panel on which it was painted was from between 1560 and 1592, thus making it an authentic original portrait.

Trees in Mythology, Culture, and Religion

Trees exist as an element in many legends and myths worldwide. Trees have also become incorporated in symbolism and are used to convey messages connected to the qualities that certain trees are thought to possess. For example, trees are often used as a symbol for life. Pre-Christian

Europeans and many others associated trees with longevity and fertility. The tree also appears in religions worldwide, where it is worshipped directly or used as a place around which to worship. For example, the Druids frequently worshipped and practiced their rites in oak groves, whereas some ancient pagans worshipped the trees themselves. The tree also forms an important part of Christian scriptures. One notable scripture makes reference to two trees in the Garden of Eden (the Tree of Life and the Tree of the Knowledge of Good and Evil). *Etz Chaim,* Hebrew for Tree of Life, is a common expression in Judaism.

In Norse mythology, Yggdrasil is the giant ash tree located at the center of the universe that links and shelters the nine worlds of Norse cosmology. Yggdrasil has three main branches and roots, and was believed to have sprung from the beginning of time. Its roots are believed to represent all time (i.e., past, present, and future).



The Tree of Life (lithograph, 1892). The Tree of Life is an important symbol in nearly every culture. In the Book of Genesis, the Tree of Life is a tree in the Garden of Eden whose fruit gives immortality.

Source: Library of Congress, Prints & Photographs Division.

The Greeks, Romans, Celts, Slavs, and Teutonic tribes venerated the oak tree. In each case, it was associated with their supreme god, as oak was sacred to Zeus, Jupiter, Dagda, Perun, and Thor, respectively. In Indian culture there is a sacred tree called the Manorathadayaka that is believed to grant human wishes. Generally, in Asia, ancient trees are associated with temples, pagodas, and shrines. In North America, Native Americans have a special regard for trees, using these in many of their ceremonies and ritualistic dances (often using cottonwood trees).

Record-Breaking Trees

One can rate the world's record-breaking trees based on several factors, namely height, trunk diameter or girth, total size (volume), and age. The world's record for the tallest tree is a coast redwood (*Sequoia sempervirens*) that is 379.1 feet (115.55 m) tall and is located in Redwood National Park, California. The stoutest living single-trunk tree species in diameter (excluding baobabs, which store large amounts of water in their trunks, making accurate measurement difficult), is a Montezuma cypress (*Taxodium mucronatum*) named El Árbol del Tule (Spanish for "the Tule Tree") located in the Mexican state of Oaxaca. Its diameter is 38.1 feet (11.62 m). The largest tree in total volume (tall and of large diameter) is a giant sequoia (*Sequoiadendron giganteum*) known as the General Sherman tree; it has a volume of 55,040 cubic feet (1,489 m^3) and is found in Sequoia National Park in California.

Other Meanings

The term *tree* is also used to refer to any representation of hierarchical relationships that uses the analogy of trunk, stem, and branches, such as a decision tree, genealogy or family tree, or binary tree. In computer studies, a *tree* is a group of domains that have the same domain name server (DNS) name; for example, *def.com* (the top domain), and *sales.def.com* and *techsupport.def.com* (the child domains).

The Tree of Life Web Project is a collaborative effort of biologists from around the world. Its Web pages are linked to one another hierarchically in the form of the so-called evolutionary tree of life. On more than 9,000 World Wide Web pages, the project disseminates information about the diversity of organisms on Earth, their evolutionary history, and their characteristics. It starts with the "Root of All Life on Earth" and moves out along diverging "branches" to individual species.

Although hierarchical structures or trees often represent subordinate relationships or ranks, these trees can also represent an order of precedence and so sometimes characterize the time at which events or processes occur in relation to others in the tree. The term *tree* is also used to represent physical objects that contain branches like a tree (e.g., the hat and coat tree, with pegs on which to hang things).

Trilobites

The trilobites are a remarkable group of extinct arthropods that lived in the seas of the Paleozoic era (542–251 million years ago [mya]) and went extinct before dinosaurs dominated the earth. Trilobites were early arthropods with a hard, segmented exoskeleton, and therefore easily fossilizable. Although all share a similar body plan, there was a great diversity of size and form. They are grouped in the extinct class Trilobita, which is subdivided into 10 orders, over 150 families, about 5,000 genera, and more than 17,000 described species. With such a diversity of species, it is very probable that the ecological role of trilobites was very extensive. They surely included planktonic, swimming, and crawling forms as well as a varied set of trophic niches (mostly detritivores, carnivores, and scavengers). Because of their great diversity and abundance in the fossil record, trilobites are important key taxa in Paleozoic biostratigraphy, chronostratigraphy, paleoenvironmental reconstruction, paleogeography, and even plate tectonics.

The body plan of all trilobites consists of three main body parts: a cephalon (head), a segmented thorax, and a pygidium (tail). Its name "trilobite" means "three lobed," but this term does not refer to these three body parts. Instead it points to the fact that they have a long central axial lobe flanked on each side by right and left pleural lobes. Their exoskeleton was composed of calcite and calcium phosphate minerals in a protein lattice of chitin. Many trilobites had compound eyes, in addition to antennae used perhaps for taste and smell.

Trilobites first appeared during the early Cambrian, and flourished throughout the lower Paleozoic. When they first occur in the Cambrian fossil record, they are already highly diverse and geographically dispersed, suggesting a previous evolutionary origin. It is reasonable to assume that the trilobites shared a common ancestor with other arthropods before the Cambrian period. Trilobites have been often included within subphylum Chelicerata, which groups the arachnids (spiders, scorpions, etc.), xiphosurans (horseshoe crabs), eurypterids (sea scorpions), and pynogonids (sea spiders). All of them together with the trilobites seem to share a pre-Cambrian common ancestor, forming the taxon called Arachnomorpha. The ancestors of the trilobites are probably to be found in the arthropod-like, segmented animals called trilobitomorphs, which lived during the Ediacaran period of the Neoproterozoic era, more than 550 mya. They include fossil taxa like *Spriggina* and *Parvancorina* found in the Ediacara Hills (South Australia). These taxa have been classified as vendobionts, annelids, or arthropods, but their morphology bears a striking resemblance to that of trilobites, and they therefore may be excellent candidates for ancestors of trilobites.

Except perhaps for the order Phacopida, whose first record occurs in Ordovician sediments, all trilobite orders appeared during the Cambrian period. The nine trilobite orders and some of their main genera are: Agnostida (e.g., *Agnostus, Condylopige*), Redlichiida (e.g., *Redlichia, Paradoxides*), Corynexochida (e.g., *Corynexochus, Illaenus, Leiostegium*), Lichida (e.g., *Lichas, Odontopleura, Damesella*), Phacopida (e.g., *Phacops, Calymene, Dalmanites, Cheirurus*), Proetida (e.g., *Proetus, Phillipsia, Cyphaspis, Bathyurus*), Asaphida (e.g., *Asaphus, Ampyx, Dikelocephalus, Cyclopyge, Ramopleurides*), Harpetida (e.g., *Entomaspis, Harpes*), and Ptychopariida (e.g., *Ellipsocephalus, Ptychoparopsis, Conocoryphe, Elrathia*). The first true trilobite is probably contained in the order Redlichiida. The olenellids of the order Redlichiida include some of the most primitive trilobites, such as *Olenellus* and *Fallotaspis*. The orders Corynexochida, Lichida, and Ptychopariida evolved from Redlichiida during the Middle Cambrian. The rest of the orders (Asaphida, Harpetida, Proetida, and probably Phacopida) evolved from Ptychopariida during the Middle and Late Cambrian. There are doubts concerning the origin of the order Agnostida. The systematic position of this order within the class Trilobita remains uncertain since ontogenetic evidence suggests they descended separately from crustaceans. However, other specialists support the hypothesis that the agnostids evolved from some group of ptychopariids. In spite of the doubts about their true origin and the phylogenetic relationships among their orders, trilobites have become an essential group for estimating the rate of speciation during the evolutionary radiation known as the Cambrian explosion, since they are the most diverse fossil group during this so-significant period of life history.

The exact reason for the extinction of the trilobites is not clear. Before the end of Devonian, their species richness began to decrease, perhaps due to the arrival of the first sharks, efficient predators of trilobites and other marine animals. Trilobites declined strongly after the great Late Devonian extinction event 374 mya. All trilobite orders disappeared in that event except for some species of the order Proetida. The last members of this order were extinguished in the Permian–Triassic boundary mass extinction event 251 mya. Horseshoe crabs may be the closest extant relatives of trilobites.

Twins Paradox

The supposition that time differences between events are not absolute in reality was first expressed by Einstein in his famous work of 1905. He deduced from the equation for the dilation of time that the relation between the time data $\Delta\tau$, Δt of clocks situated at the equator and at the pole, respectively, will be the result of the rotation of the earth with the circumferential velocity $u \approx 0.465$ km/s ($c \approx 300{,}000$ km/s is the speed of light):

$$\Delta\tau = \sqrt{1 - u^2/c^2}\ \Delta t. \tag{1}$$

Thus a clock at the equator should be delayed approximately 8/100 microseconds per day with respect to the clock at the pole.

Equation (1) determines the *proper time* of a moving clock in the inertial system of reference. In the case of time-dependent velocity $u(t)$ it is necessary to take it as a differential equation and integrate it. Equation (1) represents a special case of the conclusion of the relativity theory that the actual time is (apart from the constant multiplying factor) equal to the length of a section of the world line between the events (spacetime points) P and Q:

$$\tau = \frac{1}{c}\int_{P}^{Q} \sqrt{g^{ik}dx^{i}dx^{k}} \ . \tag{2}$$

The *clock paradox* in its broadest sense means the existence of a difference between the actual times measured by the clocks moved in different directions between two meetings. From the geometrical point of view, this means different lengths of appropriate parts of world lines in spacetime. In the case of long and rapid motions, this difference will be reflected also in the biological age of organisms (according to A. Eddington, our faces represent clocks indicating passing years). Thus it is especially impressive when speaking about the *twins paradox*.

The most common and most often discussed form of the paradox is the following: One of two identical twins will remain on the earth while the second makes a cosmic flight proceeding with the constant velocity u close to the speed of light. In the vicinity of a distant star the wandering twin will change the direction of his flight in a very short time interval compared to the total duration of the flight, and he will return to Earth. When the twins meet, the difference in their respective ages, corresponding to equation (1), will be immediately apparent.

The word *paradox* as used here refers primarily to the strangeness of the conclusion, whose theoretical and experimental legitimacy is beyond doubt. Nevertheless, even now (and sometimes even in physics publications) opinions are offered that the contradiction is real. They are based on the *relativity of time*. From the point of view of the wandering twin, motionless in his own system Σ, it is the earth-bound twin (at rest in the system S) who recedes and then again approaches with the velocity u. Could not the comparison of times give the opposite result for him?

The standard answer claims that the systems S and Σ are not equivalent. Only system S is inertial for the whole time (no regard is taken of negligible effects connected with the motions and gravity of the earth and the sun). In order to return to the earth, the wandering twin changed the direction of his flight and felt great inertial forces in connection with this. His system is not permanently inertial and the use of equation (1) is consequently justified only in system S.

Although this answer is in principle correct, it is not quite sufficient to overcome objections. The accelerated period of the astronaut's flight could be negligibly short with respect to the duration of flight that had a constant velocity. Moreover, the astronaut could be accompanied on his route away from Earth by a friend in another rocket. After the astronaut reaches velocity u, his friend turns his flight in the same way the wanderer will do after reaching the distant star. So he will experience the same periods of accelerated motion as the astronaut before landing back on Earth. Nevertheless, the difference between the respective ages of the earth-bound twin and of the attendant friend will be negligible according to equation (1).

There are at least three apparently different explanations, which in fact do not exclude but rather complement each other.

Four-Dimensional Geometry

Let us compare the lengths of world lines of the twins (see Figure 1). The world line of the earth-bound twin (a) is depicted in the middle; the world line of the wanderer twin (b) and the world line of his attendant friend (c) are on the right; and the extreme case (d), where the direction of the flight in the same direction changes in an infinitely short moment, is on the left. In Euclidean geometry, the broken line, is longer than the direct joining of two points. But in Minkowski geometry, the set of points at equal distances from the beginning is not a circle, but an equiaxial hyperbole. Thus the case is opposite: the broken line is shorter as the direct join of points over the quantity ΔT depicted in bold in the figure. In both geometries the difference of lengths is created by mere existence of the "corner," not by some length adherent to the corner. The noninertial (curved) parts of world lines do not essentially contribute to their lengths, but the existence of a break on the distant place will influence the length significantly.

Potentials in Noninertial Systems

Let us write equation (2) in noninertial systems with the help of components of metrics ($g_{\alpha\beta}$ are space components, $g_{\alpha 0}$ mixed components, g_{00} time components). Thus we obtain

$$d\tau = \sqrt{1 + \frac{2\varphi}{c^2} + \frac{2\gamma_\alpha u^\alpha}{c} - \frac{u^2}{c^2}}\, dt \tag{3}$$

where

$$g_{00} = 1 + 2\varphi/c^2, g_{\alpha 0} = \gamma_\alpha, u^2 = -g_{\alpha\beta}u^\alpha u^\beta, u^\alpha = dx^\alpha/dt. \tag{4}$$

So in addition to the velocity *u,* the scalar potential φ and the vector potential γ increase in the equation connecting the element of the actual time *d*τ and of the coordinate time *dt*. These potentials express the influence of the force fields in the noninertial system on the flow of time. The relationship between the finite sections of proper and of coordinate times can be obtained by the integration of equation (3). Let us note that in the case of nonsynchronized time (nonzero mixed components of metrics), other definitions of velocity and vector potential also can be found in the literature, leading to more complicated equations.

At the point when the astronaut's flight changes direction, the force field with the scalar potential φ increases in his reference system Σ. This field (from the point of view of Σ) turns the direction of motion of the earth with its twin. The potential on the earth increases with the distance from the astronaut and with the rate of his acceleration, and thus its influence does not vanish even in the case of the nearly zero duration of the turn. According to equation (3), this potential causes a faster flow of time on Earth during the astronaut's turn, which overbalances its slower flow due to the velocity. In this way, the calculation performed in the noninertial system will affirm the younger age of the astronaut in the moment of meeting.

In the case of the zero velocity of the clock, equation (3) reduces to

$$d\tau = \sqrt{1 + \frac{2\varphi}{c^2}}\, dt \tag{5}$$

and expresses the influence of the potential on the flow of time. According to general relativity, this potential could be produced not only by the accelerated motions of the reference system in flat spacetime, but also by the gravity of matter. Einstein's conclusion on the difference between the data of clocks at the pole and at the equator was made before the advent of general relativity. So the earth was considered to be like a traffic circle, and not influenced by its own gravity. In fact, however, the potential φ on Earth is influenced by its mass and the surface of the rotating Earth at the equipotential level (the earth is an oblate spheroid). Consequently, clocks in different places on the earth's surface with the same potential (e.g., at sea level) run at the same rate, contrary to Einstein's original opinion.

Contemporary standards for precise measurement allow testing the clock paradox by using airplanes. The influence of velocity as well as the influence of potential in different altitudes has been convincingly confirmed by these experiments. These results are at present given practical application by the GPS system.

Mutual Observations

Suppose that the twins are able to perform mutual optical observations during the flight. Their observations will be influenced not only by the dilation of time (1), but also by the usual Doppler effect caused by the receding or approaching of the observers. The resulting *relativistic Doppler effect* consists of the relationship between the frequency f_O recorded by the observer and the frequency f_S emitted by the source (the relative velocity u is taken as positive when receding and negative when approaching):

$$f_o = \sqrt{\frac{1-\frac{u}{c}}{1+\frac{u}{c}}} fs \quad . \qquad (6)$$

Consequently, each twin sees his fellow twin grow older more slowly while the twin is receding—he sees the delay of his clock and the red shift of his colors. While his twin is approaching, the opposite is true—both see their twin's clock speed up and a blue shift in his colors. The observations are completely symmetric and the duration of the astronaut's accelerated flight can be (even from the observer's point of view) negligibly short. Why, then, is the reason asymmetrical?

It is essential to realize that the astronaut sees the change of red shift to blue shift in half of his flight when he uses the rocket's engine to turn toward Earth. In contrast, the twin on Earth will see the blue shift together with the turning of his brother's rocket because in this moment the signum of u in formula (6) is changed. So he sees it in the moment, where the astronaut is long ago on his way to Earth (as a consequence of the finiteness of the speed of light). Consequently, the faster aging of astronauts endures in the earthly observation much shorter as the slower aging. The calculation again affirms the results obtained by other methods.

Tylor, Edward Burnett (1832–1917)

Edward Burnett Tylor, often considered the founder of cultural anthropology as a field of study, made enormous contributions to the development of the discipline as it has come to be known. He was a contemporary of other important contributors to the field, such as Herbert Spencer, Charles Darwin, Sir James Frazer, and Lewis Henry Morgan, among others. It was in Tylor's definitive work, *Primitive Culture* (1871), where his greatest contribution would be made to anthropology, in particular through advancing the idea of sociocultural evolution, a process of change in human societies that occurs over time.

Tylor was born in Camberwell, London, England, on October 2, 1832. His parents, Joseph Tylor and Harriet Skipper, were Quakers. Being brought up in a household dominated by the Society of Friends, along with being educated at a local Quaker school in Tottenham, was no doubt influential on his life and later works, where his focus was on religion and its evolution, one of the key features of *Primitive Culture.*

Tylor worked a while in his father's business, a brass foundry. Around the age of 20, however, he showed signs of tuberculosis and was forced into an early retirement. It was during this time that he was granted a chance to embark on an overseas trip to the United States, which he toured extensively in 1855 and 1856.

In Cuba, he met the famed British ethnographer and archaeologist Henry Christy, also a Quaker. The two embarked on a journey to Mexico, which resulted in the production in 1861 of Tylor's first published work, *Anahuac,* a memoir of the trip containing relevant anthropological notes on the people he had encountered.

Tylor returned to England and married, then published his *Researches Into the Early History of Mankind* in 1865. This publication would prove the foundation for his grand opus, *Primitive Culture: Researches Into the Development of Mythology, Philosophy, Religion, Art, and Custom* in 1871. Following this work was the also-popular *Anthropology: An Introduction to the Study of Man and Civilization* in 1881.

Tylor was awarded many titles throughout his career. Beginning in 1871, he became a Fellow of the Royal Society, received a Doctor of Civil Laws degree from Oxford in 1875, Reader in Anthropology (1884), and then became first Professor of Anthropology at Oxford in 1896, the first academic post in the field of anthropology. In recognition of his achievements, Tylor was knighted in 1912, only 5 years before his death.

Tylor's contributions to the field of ethnology and cultural anthropology are monumental. He is well known for his ideas of sociocultural evolution and work with animism (a "primitive" religion whose beliefs include spiritual beings, as well as attributing life in terms of a soul to inanimate objects in nature, e.g., rocks and water). Tylor claimed that religion followed a unilinear track of evolution from simple animism, through polytheism, to complex monotheism. A contemporary of Charles Darwin, Tylor was influenced heavily by Darwin's works. In fact, the two maintained a close correspondence, with Tylor offering the opportunity for one of Darwin's sons to help him with *Anthropology*.

Tylor believed that cultures evolved in a manner similar to biological evolution, in a unilinear fashion. Eventually the small-scale societies (tribal) would reach the goal of large-scale civilization. Like Morgan's, Tylor's idea of cultural evolution involved stages, beginning with "primitive or savage" through "barbarism" to "civilization." Progress is marked by rationality, and all societies will eventually reach the point of "civilization," though it will be at their own rate.

Another key feature of Tylor's work is the idea of "cultural survivals" or cultural ideas and materials that withstand the test of time. One of these survivals can be found within religion. Tylor illustrates this by comparing notions of the afterlife in animistic religions to ones found within monotheism. Monotheism in itself is a cultural survival, a product of progression from earlier animistic and polytheistic religions from belief in the Many to belief in the One.

Tylor's death in 1917 was preceded by a slow progressive dementia. In spite of this, his passion for anthropology remained lively until his death. As a key figure in cultural anthropology he influenced other scholars of the late 19th and early 20th centuries, including Sir James Frazer and later Leslie A. White. Since then many of his ideas have been reworked, but they remain a cultural survival.

U

Unamuno y Jugo, Miguel de (1864–1936)

Taking the Darwinian perspective seriously, the Basque philosopher, writer, and poet Miguel de Unamuno y Jugo grappled with the stark implications of evolution and time for understanding and appreciating all life forms (particularly our own species). Giving preference to feelings and emotions rather than to science and reason, he longed for immortality despite the fact of personal death and species extinction. He lamented the existential condition of the human predicament, but gazed into the starry vastness of changing reality for a solution to the cosmic fact of pervasive finitude. Critical of Darwinism, Unamuno rejected both its mechanism and materialism. He developed an interpretation of evolution that is essentially mystical. His speculations extended far beyond the confines of this planet in order to embrace sidereal time and the entire universe.

Unamuno was not content with those evolutionary ideas that were espoused by Charles Darwin, Thomas Huxley, Ernst Haeckel, and Herbert Spencer; his own process interpretation of the world did not give priority to science and reason. Instead, Unamuno's passion for life caused him to have a deep sympathy for the finite existence of all living beings on the earth. No doubt, it pained him to see organisms perish, never to return to the realm of the living. Likewise, stars and planets appear in the universe, only to vanish into cosmic oblivion. Even so, Unamuno intuited that something everlasting would eventually emerge out of the ongoing struggle in, and pervasive suffering of, the organic world. He was especially concerned about the destiny of our own species. Unamuno focused intensely on human consciousness, which he hoped would never return to the silent nothingness from which it had once emerged. His longing for personal immortality caused him to adopt a mystical view of evolutionary time and its final goal.

Unamuno presented his unique worldview in his major work, *The Tragic Sense of Life* (1912). This book is a radical departure from those established scientific facts and those traditional religious beliefs that pervaded the end of the 19th century. Its basic theme is the quest for eternal life: the overcoming of finality through the attainment of the personal immortality of the human soul. The result is a remarkable vision of the future in terms of an organismic view of this dynamic universe. Unamuno saw the evolving cosmos as an emerging organism analogous to a developing person. He envisioned the whole universe as a totality that is evolving into a single cosmic entity. Just as cells make up organs and organs make up an organism, stars make up galaxies and galaxies make up this universe. Through extensive extrapolation, Unamuno saw this evolving universe preparing itself for the emergence of God in the distant future.

For Unamuno, the entire world will never be extinguished. The end of cosmic evolution will be the formation of God as a Supreme Being. This cosmic entity will emerge when all the finite beings of this universe converge, creating a single collective consciousness. Since personal consciousness emerges in a human being as the result of the interaction of innumerable cells, so a center of cosmic consciousness will emerge in this universe as a result of the interaction of countless galaxies. The end result will be the appearance of God, in which everything is preserved forever in the eternal memory of this supreme consciousness. Consequently, immortality is achieved throughout all future time as a result of the eternal God sustaining everything as endless consciousness in God's own supreme consciousness.

UNIFORMITARIANISM

Uniformitarianism, a term introduced by William Whewell in the mid-19th century, refers to a cornerstone of geology. Uniformitarianism is based on the premise that present-day processes have operated throughout geological time. Although the earth is in a dynamic state of change and has been so ever since it was formed, the processes that operate today are the same that shaped it in the past. The expression, "The present is the key to the past" is commonly used to summarize uniformitarianism. Therefore, in order to understand and interpret geological events from evidence preserved in rocks, we must first understand present-day processes and their results. Thus, the earth's past is available to us through understanding the current processes and interpreting them in the strata.

James Hutton (1726–1797) was the precursor of the uniformitarian principle. In his *Theory of the Earth* he believed that "the past history of our globe must be explained by what can be seen to be happening now" and concluded that "the Earth must be millions of years old." Unfortunately, Hutton's ideas were not widely disseminated or accepted, so catastrophism, more easily associated with religious doctrines, continued to be the prevailing geological idea well into the 1800s. It was Charles Lyell (1797–1875) who became the principal advocate and interpreter of uniformitarianism after his *Principles of Geology* was first published in 1830–1833. In this book, one of the most renowned scientific texts ever written, Lyell put forward this principle clearly and concisely, and applied it to the study of the earth's crust. Lyell recognized the tremendous cumulative effect that could have resulted from small, imperceptible changes brought about by still-active geological processes over long periods of time. Not only did Lyell effectively reintroduce and establish the concept of unlimited geological time, but he also discredited catastrophism as a viable explanation of geological phenomena. To model the mountains and valleys, it was not necessary to resort to cataclysms that in a short time would have produced great changes, as catastrophists claimed; weaker forces, acting slowly over long periods of time, were sufficient to explain them. The uniformitarian principle became the underlying philosophy of geology because it provided a much simpler explanation for observed geological phenomena than catastrophism. Philosophers call it the principle of simplicity, or "Occam's razor": one should not invent unknown or extraordinary causes if the usual known procedures are sufficient.

Although Lyell in his development of uniformitarianism surely did a great deal to further the science of geology, he also misrepresented other contemporary theories and mixed together under the banner of uniformity a variety of disparate claims, some of which have been politely ignored so as to avoid embarrassing a key founder of modern geology. Lyell's concept of uniformitarianism should be separated into two different meanings: *methodological uniformitarianism* (of the laws and processes of nature) and s*ubstantive uniformitarism* (of the intensity of the processes and the state of the earth). Stephen Jay Gould, paleontologist, evolutionary theorist, and dialectical biologist, claimed that substantive uniformitarianism is false while methodological uniformitarianism is now a superfluous term that is best confined to the past history of geology.

The assertion that only processes that can be observed to operate in the present should be used to explain events in the past is today, as it was then, a somewhat more controversial claim. This methodological principle is a way of expressing "the uniformity of the laws of Nature throughout time," a postulate or "the rules of the game" put forward by Isaac Newton in the late 17th century. The uniformity of the laws of nature is a self-evident proposition, so it is known to be true by understanding its meaning without any demonstration or proof. The uniformity of the processes is a consequence of this postulate. It is important to note that while English-speaking geologists always use the term *uniformity,* continental Europeans prefer the use of the term *actualism* (because in romance languages the words derive from the Latin *actualis* meaning present, present-day). In fact, "the uniformity of laws" is an application in natural sciences of philosophical actualism, the ontological view that stands in opposition to possibilism and denies that anything not actual (real and existing as a fact) can be said to exist. Thus, the idea of uniformity is a necessary condition for starting even any scientific task, so the principle turns out to be close to a commonsense rule.

Uniformity in the intensity of the processes or gradualism is not a methodological rule, but a theory that must be demonstrated. The argument as to whether the rhythm, velocity, and intensity of the geological processes have been variable or constant throughout the history of Earth, and to what degree, is a debate that continues today. Scientists generally agree on a preference for invoking presently observable processes to explain the past, but some scholars suggest that certain past events (such as mass extinctions) require the inference of causes that are no longer acting or are now acting at markedly lower rates or intensity. We know that in the history of the earth there have been times of calm and times of crisis. Some crises affected only a region, while others were global. This assertion of Lyell's that the rate of geological change was uniformly "slow, gradual, and steady, not cataclysmic or paroxysmal" surely provided the basis for Darwin's gradualism. An appreciation of the immensity of geological time was central to understanding the evolution of Earth and its biota. The recognition of virtually limitless time was also instrumental in the acceptance of Darwin's theory of evolution. Lyell's uniformitarianism and gradualism and Darwin's theory of organic evolution would dominate the earth sciences for nearly 150 years.

Lyell has also been criticized for his supposition of the uniformity of state or antiprogressism. In his effort to refute catastrophism, he assumed that in the history of the earth everything occurred at a slow and uniform pace, in a succession of cycles that repeat themselves indefinitely without advancing in any direction. This supposes that there is no vector of progress and that, although details are modified, nothing really changes. In other words, the earth is effectively in a dynamic steady state. In this claim, Lyell found it hard to accept that throughout the history of life on Earth, substitutions and renovations of species of animals and plants had taken place. It took years before Lyell was finally convinced of organic evolution. This is the component of Lyell's uniformitarianism that is most typically ignored by modern geologists, because a large body of evidence indicates that the earth has changed dramatically over its history. In the past few decades new theories have developed in the geoscience community recognizing that both major catastrophic events and rhythmic environmental cycles play significant roles in geological processes and the evolution of life.

Universe, Age of

In 1926 the American astronomer Edwin P. Hubble discovered that all distant galaxies are rapidly moving away from us. This pioneering observation was (and still is) broadly interpreted as a global expansion of the universe. Hubble's discovery, together with the cosmological Friedmann-Lemaitre-standard model, led to the general insight that the universe should have a temporal origin, which, since the 1950s, has been called the big bang. The hot big bang picture received what is considered final confirmation in the mid-60s when the cosmic microwave background radiation (CMBR) was first observed. The CMBR is broadly considered as a leftover of an early hot and dense universe. We define the age of the universe by the time t_0 that has elapsed since the big bang.

After his observations, Hubble estimated the universe to be expanding with a current rate of $H_0 \approx 500$ kilometers/second/Mpc (1 Mpc = 3.26 million light-years = 30,840,000,000,000,000,000 km). In cosmology, H_0 is called the Hubble parameter. If we could assume the cosmic expansion to be constant over the whole history of the universe, we could simply determine its age as the inverse Hubble parameter $1/H_0$. According to Hubble's first estimate, t_0 would obtain a value of 2 billion years, in contrast to what we know about the lifetimes of our earth and many other celestial objects. During the following decades, until the 1970s, the value of H_0 was dropping to a range of 50 . . . 100 km/sec/Mpc due to major advances in our knowledge of stellar populations and more sophisticated measuring methods. Accordingly the estimates of t_0 were increasing to about 10–20 billion years.

Certainly the cosmic expansion has not proceeded at a constant rate throughout its history. Thus one has to keep in mind that the $1/H_0$ estimate can be only a very rough approximation for the age of the universe.

Other independent methods of age determination are thus in great demand. For a start, it is possible to extract a lower t_0 limit from *geochronology,* that is, from the determination of our planet's age. One can access reliable radiometric methods for this purpose. It has been known for a century that uranium-235 is decaying to the stable lead-207 with a half-life-period $t_{1/2} \approx 700$ million years. For uranium-238, on the other hand, it takes 4.5 billion years to (finally) decay to lead-206 by 50%. In order to determine the age of rock, one has to measure the mass fractions of such long-living radioactive elements as well as their stable decay products. Once knowing the "mother"- and "daughter"-elements' mass ratio, it is simple to reliably calculate the ages of the earth's crust's oldest rocks, as well as those of meteorites and the moon. By this method one could assign the age of 4.6 billion years to the earth and the solar system.

From stellar evolution theories, anyway, it is known that there must have been existing earlier generations of stars before the sun. One can tell from the solar metal content. Heavy elements (or *metals,* as denoted by astronomers) are formed over millions and billions of years in the inner regions of massive stars and admixed to the interstellar medium during nova- and supernova explosions. If the sun were a first-generation star, it should contain heavy elements in much lower amounts than observed.

Among the oldest objects within the universe are so-called globular clusters (GCs). These are stellar aggregations of spherical shape and high density, located predominantly in the periphery, or halo, of our galaxy (and other galaxies as well). The up to 10 million stars in a GC are widely assumed to have formed coevally, more or less. We know about the old ages of GCs from their comparable low metallicities (i.e., the abundance of heavy elements) on the one hand and from their stellar population composition on the other: According to our present knowledge, stars change their temperature-luminosity relationship after the end of a certain life cycle (the main sequence cycle), the duration of which is strongly correlated with the mass of the star. If one is plotting the temperatures of GC stars against their luminosities in a so-called color-magnitude diagram, most of the data points will be located along a narrow straight line, the main sequence. Color-magnitude diagrams of GCs show a common feature: the straight main sequence line does not continue above a certain temperature but experiences a sharp bend. At this location, stars are assembling whose main-sequence evolution is just ending. One can tell the age of particular GCs from the position of this "knee" by applying stellar-evolution theories.

Independently, one can make use of so-called white dwarfs (WDs) to determine the age of stellar systems. WDs represent the final stage of low-mass stars (m < 1.4 M), cooling down without any further energy production over billions of years. The current temperature together with its mass allows one to calculate the age of a white dwarf. The analysis of numerous of GCs' stellar populations finally yields ages of 11–13 billion years. Following the theories of early cosmological structure and star formation, the universe has to evolve for at least some hundreds of millions of years before the appearance of the first stars. Finally this suggests the universe has an age of 12–14 billion years.

Since the beginning of the new millennium the NASA space probe WMAP (Wilkinson Microwave Anisotropy Probe) has been sending data from cosmic microwave radiation measurements down to earth. WMAP provides the opportunity to measure and analyze the tiniest variations within the otherwise homogeneous microwave background. These fluctuations represent the birth sites of the billions of galaxies we observe today, but moreover, the detailed distribution of these fluctuations is closely connected to the values of the fundamental cosmological parameters like the density parameter Ω, the cosmological constant Λ, or the Hubble parameter H_0. A statistical analysis of the background fluctuations therefore allows the accurate calculation of these parameters and hence the reconstruction of the detailed expansion history and age of the universe. From the most current WMAP data, cosmologists calculated an age of $t_0 \approx 13.7$ billion years, in excellent concordance with the stellar evolution results.

Universe, Closed or Open

The density parameter, a ratio of the real density of matter in the universe to a specified critical density, describes the shape of our universe. The shape of the universe will determine its ultimate fate. A closed universe would have a density value greater than the critical density value of 1, while an open universe, a value less than 1. Critical density, at 1, is the point where just enough matter exists to maintain a balance between collapse and infinite expansion. A closed universe is of finite size and matter cannot spread far enough apart to cease having a gravitational effect on neighboring matter during expansion. The result is eventual collapse, the big crunch. In an open, unbounded universe expansion is infinite and matter, spread ever thinner, has a decreasing gravitational effect on other matter.

The shape of the universe may also be described by the geometry of its curvature. Relativity describes gravity as the curvature of spacetime by an object's mass, the whole universe curved by the total content of its mass. There are three possible curvatures. All take into account an assumption about the way matter is distributed and how gravity works, along with the manner in which the universe first appeared in the big bang.

A positively curved universe, a sphere, is closed and finite. The angles of a triangle in this universe would add up to more than 180 degrees. The density of its mass would cause an eventual halt and reversal of expansion, followed by collapse. A negatively curved, hyperbolic universe, imagined as saddle-shaped, is infinite and unbounded. The angles of its triangles add up to less than 180 degrees, its negative critical density causing it to expand forever. A third possibility exists, that of a flat universe, where the balance is just enough to enable the expansion to approach zero, yet not support collapse. A flat universe conforms to Euclidean geometry, where the angles add up to 180 degrees. Today, scientists generally regard our universe as flat, although the exact amount of mass present has not yet been determined. Most of the universe seems to be composed of little-understood invisible dark matter and dark energy.

Observations of temperature and other variables in the cosmic microwave background radiation, the afterglow of the big bang, have yielded more information about the likely geometry of space. These measures suggest a flat universe. A recent study, using information from the Sloan Digital Sky Survey, looked at the distribution of a great number of giant elliptical galaxies sufficiently distant to measure the evolution of these galaxies over the past 5 billion years. The resulting yardstick for measuring cosmic expansion again led to the conclusion that the universe is flat.

Universe, Contracting or Expanding

In the 1920s the physicists Alexander A. Friedmann (1888–1925) and George Lemaître (1894–1966) succeeded in describing the global dynamics of the universe by simplifying the field equations of the general theory of relativity with the help of symmetry assumptions. The equations they found do not allow for a stable, static universe. This result led Albert Einstein to add a so-called cosmological constant to his equations in order to achieve an equilibrium state for the universe. In 1926, however, the American astronomer Edwin P. Hubble (1889–1953) observed all distant galaxies as moving away from the earth, the more distant stars receding the fastest. After this discovery, the expansion of the universe was considered a fact, and even Einstein finally removed the cosmological constant from his field equations. There are nevertheless local deviations from the global expansion, if the gravity between close-by objects manages to overcome the global Hubble drag. For example, the Milky Way and the Andromeda galaxy are approaching each other at the rate of some dozen miles per second to merge in 2 to 4 billion years.

It is generally thought that right after the big bang, the beginning of space and time, the universe ran through a very short period of extremely fast expansion called *inflation.* This very enormous expansion passed over to the moderate one still taking place today. One usually assumes a phase transition of a spatial homogenous scalar quantum field that exerts a negative pressure as a reason for inflation. The detailed origin and course of inflation is still a matter of speculation.

Based on numerous observations, especially by the NASA space probe WMAP, cosmologists are today in a position to characterize the state of the universe via just a few parameters. The most important of these are the mean cosmic density Ω; the Hubble parameter H_0, characterizing the current expansion rate; and finally the cosmological constant, which is, along with the mean density Ω, crucial for the future of the cosmic expansion. Depending on the values of these numbers we live in a universe that either will bring its expansion to a halt and maybe even convert it to contraction in a far distant future–or that will expand forever. The connection between H_0, Ω, and Λ on the one hand and the history and fate of the universe on the other is given in a simple way by the Friedmann-Lemaître equations. Following the parameters, it is widely assumed today that out universe will even *accelerate* its expansion in the future, instead of slowing it down.

This knowledge makes any philosophical speculation needless concerning the so-called arrow of time. In his most famous book, *A Brief History of Time,* astrophysicist Stephen Hawking speculates about the direction of time and a decrease of entropy in a contracting universe. The possibility of a time inversion is, however, generally not accepted. Rather, the "cosmological arrow of time" is interpreted in a way that the particular size of an exclusively expanding universe allows us to distinguish both globally and uniquely between the past and the future.

Universe, End of

The end of the universe is a concept that has been used to define timelessness itself. Something lasting to the end of the universe used to be synonymous with eternity. Using the latest cosmology theories, contemplating the end of the universe is still considering some of the largest spans of time in human imagination. At this moment in the lifespan of the universe we are standing a short way down a long road with an uncertain ending. Three current possible ends are: an endless expansion, a big crunch, or a big rip of everything in the universe.

Until the early 1900s the universe was thought to be static and eternal. Ideas about the beginning and end of the universe were in the philosophic realm. Although astronomers understood that the stars in the sky were other suns, no one imagined that the hundreds of billions of suns in our galaxy were only a tiny proportion of the suns found in hundreds of billions of galaxies. When Albert Einstein developed his theory of relativity in 1912 he suggested that matter and energy were interchangeable under the right conditions. Calculating the total matter and energy in the universe combined with astronomical observations gives a defined beginning and end.

Researchers have agreed that the universe began as a "big bang" around 14 billion years ago when all matter and energy were collected together in an infinitesimally small point. From that beginning, it suddenly expanded out in all directions. Initially extremely high temperatures dominated it, so that atoms and matter could form only when it had cooled down. That matter then formed into stars and galaxies, and that expansion continues today.

The question of the ultimate fate of the universe is dependent on whether it is open or closed. Either the amount of matter and energy in the universe will allow it to expand forever in all directions from its single point of origin, or the universe has enough matter and energy in it that after expanding a while, it will slow its expansion and gravity will draw everything back into a single infinitesimal point. It is also possible that we do not know enough yet to eliminate other possibilities, such as dark energy ripping the universe apart.

Collapse as a Final Fate

Current theory still suggests that the universe is open and that the universe will not collapse into a single point. However, the discovery of the possibility of dark energy has led to a theory known as the big crunch. If this theory is true, its effects would not be noticeable for billions of years. The big crunch predicts it will be 12–14 billion (10^{10}) years before the universe collapses again into a single point. It is theorized that dark energy could change in character as the universe ages from a force that opposes gravity to a force that increases the power of gravity. This change would result in the expanding universe eventually stopping and beginning to contract.

If a collapse does happen, the first effect would be a slowing of the stars' and galaxies' tendency to spread apart. The stars would slow until for a brief time they would not move apart at all. At that point, billions of years in the future, stars will be very far apart and they will have aged. The lifespan of a star like ours is about 10^{10} (10 billion) years. Star formation will have slowed as the universe ages and matter for condensation into new stars (in the form of exploded stars) will be more diffuse.

As matter begins to be gathered back together, matter for star formation will be easier to find again as everything becomes closer together. An observer in space with sufficient lifespan would see the sky fill again with stars, growing over billions of years to become crowded. Also, because of the shrinking closed universe, rays of light would be able to cross the universe and come back from the opposite directions. The sky would fill with "ghosts" of galaxies and stars that have burned out although their light continues.

As the stars become even more crowded and the universe becomes one thousandth of its present size, the background stellar radiation would interfere with the planets until they became uninhabitable. Eventually the stars themselves would begin to tear each other apart through gravitational interactions. Suns would form out of the debris, only to be destroyed again. The last few million years before the end, the universe would be a fiery, lethal place as matter rushes into multiple black holes and those black holes begin to combine with each other into one final black hole. The final second of the universe would be instantaneous as all light and matter disappear behind the black hole event horizon into a single dimensionless singularity. What would happen beyond that singularity is still unknown.

Infinite Expansion

If the universe continues to expand, the end of the universe will be very similar to the famous line from T. S. Eliot's 1925 poem "The Hollow Men": "This is the way the world ends—not with a bang but a whimper."

Scientists currently believe that the universe is expanding and even accelerating as it flies apart. As the eons pass, the universe will get thinner, colder, and darker. As stars go through their life cycles, more and more stars will go out. Even low-mass long-lived stars, like white dwarfs, will gradually burn their fuel and cool down, pulsars will gradually lose their spin, and black holes will continue to add to their masses.

For an imaginary observer where the earth currently exists, 3 trillion (3×10^{12}) years from now the nearest galaxies will have receded beyond the cosmic light horizon. The galaxies will appear to be dark and difficult to observe. As the energy of the universe runs down, visible light will shift to lower-energy infrared light. This process of dimming will continue as galaxy and star formation stops as the universe reaches the age of 100 trillion (10^{14}) years.

An observer at the end of the life of the universe would see a long quiet time as all matter in the universe becomes either part of super-massive black holes or scattered stellar debris. The universe would slowly change until all the matter outside of black holes experiences proton decay at around 10^{40} years. The final stages of the universe may last for 10^{100} years when the black holes themselves evaporate into photons (via Hawking radiation). After that, all matter in the universe may consist only of photons and leptons as the universe winds down to the ultimate low-energy state.

Other Ends

Another end that has been contemplated involves dark energy behaving in a different way. The idea is that of a big rip, where increasing dark energy gradually opposes gravity and dominates the universe. It has been speculated that if the dark energy–driven expansion of the universe fed back on itself, expansion could trigger a growth of dark energy resulting in an increasing strength of the dark energy, making the expansion accelerate even more rapidly. If this were true, the universe would end violently in 21 billion years, as all material objects in the universe were ripped apart into subatomic elementary particles.

Universe, Evolving

The general theory of relativity by Albert Einstein (1879–1955) forms the basis of any discussion about the fate and the evolution of the universe. The theory's principal feature is a system of differential equations that connects the cosmic matter content with the intrinsic geometry of spacetime: A massive particle curves the space in its vicinity, and the deformed space exerts influence on the motion of another particle. The Einstein system of equations reduces to only two independent equations if applied to the universe as a whole. This is due to the assumption that the universe is homogenous and isotropic on very large scales (e.g., above a 100 million light-years). The remaining two equations describe the course of cosmic expansion via three free parameters (the expansion rate H_0, the mean energy density Ω, and the cosmological constant Λ). The time dependence of the expansion also determines the behavior of the global temperature, which (together with matter and radiation density) again defines the conditions for any physical process in the early universe.

Today it is widely accepted that the universe was brought into existence 13.7 billion years ago in a very hot and dense state. The current temperature of the universe is 2.7 Kelvin, or 2.7° Celsius above absolute zero. Right after the big bang (BB) the temperature is believed to have been some 10^{32} K. It is assumed that under such conditions the four fundamental forces (gravitation, weak, strong, and electromagnetic interaction) were unified as a single force, described by a hypothetical *theory of everything* (TOE), which has not yet been put forth. In the course of the (initially very rapid) cooling, the fundamental forces we know today separated from the unified interaction one after another. Coevally the first elementary particles could freeze out of the high energetic matter/radiation mixture: Following quantum field theory, particle/antiparticle (*P/AP*) pairs can form from radiation and decay instantaneously again, while the Einstein relation $E = mc^2$ is preserved. Here E is the energy of the radiation quantum, that is, the photon; m the P/AP mass; and c the speed of light. Due to a not completely understood asymmetry during the *grand unification* (of strong, weak, and electromagnetic force) epoch, there was a tiny excess of matter compared to antimatter (1,000,000,001: 1,000,000,000). So, after the decay of all P/AP pairs there was some extremely small amount of matter left over, which provides the substantial content of the universe today.

Quarks and antiquarks were the first particles to freeze out 10^{-33} seconds after the BB. Their high energies prevented them from forming bound states with each other. They instead constitute a so-called quark-gluon-plasma consisting of free (anti)quarks and gluons, the mediator particles of the strong interaction. Via permanent crashes most quark-antiquark pairs annihilated each other instantaneously, producing radiation until the one-billionth-excess was finally left over. After a millionth second, the temperature had dropped enough to allow for bound states of various quark species (*flavors*), the best known of which we know as protons and neutrons. After about one second all electron-positron (= *anti-electron*) pairs also annihilated except for the above-quoted excess, so that the substantial basis of the "normal" matter we know today (in contrast to *dark matter*) was provided.

Subsequently, the next hierarchical level of matter was formed in a 3-minute-process called *nucleosynthesis*—the assembling of atomic nuclei, consisting of various proton/neutron combinations: helium (2 protons + 2 neutrons), deuterium (1p+1n), as well as tiny amounts of helium-3, lithium, and beryllium were brought into existence during this epoch. The hydrogen cores, the lightest of all, had already been in existence in the form of single protons. At that time electrons could not become bound to the positively charged nuclei via electromagnetic forces, because of the still enormous cosmic temperature. In fact, such electron-nucleus bonds could happen at any time, but due to a permanent barrage of high-energy photons, those were extremely short lived. Thus, a few minutes after the BB, all the *baryonic* matter in the universe (basically protons, neutrons, nuclei, and electrons) was provided in the form of a highly ionized plasma, standing in thermal equilibrium with radiation.

For the next 10,000 years the universe evolved without any outstanding events. The expansion simply continued, as temperature and matter density dropped accordingly. And so did the energy density of radiation, in a particular manner: First, the number density of the photon reduces as R^{-3}, where R is the cosmic *scale parameter,* that is, the *"diameter"* of the universe. In addition, electromagnetic radiation suffers a so-called *redshift:* the wave trains are simply being stretched while they float through an expanding space. This leads to a further loss of energy, known as R^{-1}. Thus radiation, the dominant energy component in the early universe, is losing its energy density much faster than matter (R^{-4} and R^{-3}, respectively). After approximately 10,000 years, matter becomes predominant in the cosmic energy budget. By today radiation has lost any relevance for cosmic evolution.

It took almost 400,000 years for the next milestone of cosmic history to occur. By then the photons had lost such a large amount of energy that they were no longer able to destroy the bonds between electrons and nuclei as they had done earlier. Within a very short period a substantial amount of the universe transformed from an ionized state to a neutral hot gas. This brought the permanent photon scattering to an end, since it is not possible for photons to interact with electrically neutral particles. After this event of *decoupling,* radiation for the first time was able to drift freely through space without any deflection. The universe has been transparent since that time. The radiation released then is still detectable as *cosmic microwave background radiation* and provides one of the fundamental supporting pillars for the hot BB picture.

Once matter and radiation were decoupled, the formation of large structures in the universe was possible. Prior to the decoupling event, structure formation was prevented by ongoing matter-radiation interactions. Within a few hundred millions of years the tiny density fluctuations, which must have been present right after the BB, were amplified sufficiently to collapse locally through the influence of their self-gravity. This allowed the first galaxies and stars to form. These first stars had to get by on the available elements hydrogen and helium, present at that early epoch of the universe. Presumably they were quite massive and accordingly very short lived. They were thus able to enrich the interstellar matter quickly with progressively heavier elements up to iron, which had been created by the stellar interior fusion processes. Only from these heavy elements was it possible for (terrestrial) planets to form, together with stars of later generations. After the onset, star formation experienced a continuous boom and reached a maximum after 3 billion years to decline again later on. Stars form within larger structures, the so-called *dark halos,* which also accommodate massive galaxies like our Milky Way or the Andromeda galaxy. The very first dark halos, some hundreds of millions of years after decoupling, had comparable small masses of some million solar masses (M_{sol}). In the course of time, near flybys and mergers between smaller halos happened, causing larger and larger structures to form in the universe. Today one can find enormous accumulations, herds of galaxies, so-called *superclusters* with masses up to 10^{15} M_{sol}.

In the future we can expect further growth of the largest structures due to ongoing merger events. As shown by observations in 1998, the universe has been expanding at a slightly increasing rate for about the past 5 billion years. In fact, this acceleration seems to increase continually. This is expected to counteract structure formation more and more in a far distant future.

UNIVERSE, ORIGIN OF

In the last two decades of the 20th century, observational cosmology grew from a crude science to one of exquisite precision. Observations made from Earth and from space uniformly confirm a picture of a visible universe composed of a hundred billion or so galaxies, each containing typically a hundred billion or so stars, flying away from one another as if from an explosion that is dubbed the *big bang*. According to current best estimates, the big bang began 13.7 ± 0.2 billion years ago.

Hubble Expansion and Inflation

The expansion of the universe was discovered by Edwin Hubble in 1929 and until recently has appeared to be linear; that is, the average recessional speed of galaxies from Earth was proportional to their distance. In 1998, two independent research groups made the surprising discovery, since confirmed by further independent observations, that the expansion is actually accelerating. The universe is falling up!

The latest data also strongly support a model proposed in the early 1980s called *inflation,* in which the Hubble expansion was preceded by an exponential expansion lasting only about 10^{-35} seconds during which the universe increased in size by hundreds of orders of magnitude. This implies that by far the greatest portion of the universe that exploded from the same source lies beyond our visible horizon, the farthest distance we can see given the finite propagation speed of light. This rapid expansion flattened out the geometry of the universe analogous to the surface of a large balloon and further implied that the energy density of the universe is very close to what it should be if the universe began with zero total energy. That is, no energy from outside was required to produce the universe. The birth of the universe did not violate the law of *conservation of energy* or any other basic principle of physics.

Various models of inflation predict the existence of other universes besides our own, each appearing by the same process. Although we have no way of empirically verifying these universes, neither do we have a way of ruling them out. While some people have contended that science should not consider objects that cannot be directly observed, this argument is refuted by the fact that science has done so many times with great success, such as with the theory of atoms in the 19th century.

Dark Matter, Dark Energy, and Quintessence

Today visible matter, which constitutes all stars and galaxies seen with the most powerful optical telescopes, comprises only 0.5% of the mass of the universe. In fact, normal atomic matter, including that which is nonluminous, such as the matter in planets or dead stars, totals only 4%. The remainder of the universe is composed of some yet-unidentified substance called *dark matter,* comprising 26% of the mass of the universe, and an even more mysterious *dark energy* that is the largest component, fully 70% of the universe's mass. The dark energy is responsible for the repulsive gravity that drives the accelerated expansion. Furthermore, it is expected that this acceleration will continue to increase with time so that the universe is destined to become more and more dilute.

Although gravity is normally thought of as purely attractive, Einstein's 1916 *general theory of relativity,* the modern theory of gravity, predicted repulsive gravity for matter with sufficiently negative pressure or if empty space has positive curvature described by a term in Einstein's equations called the *cosmological constant.* Current observations tend to favor the cosmological constant option, but have not totally ruled out the possibility that dark energy is composed of a yet-unidentified material field that has been dubbed *quintessence.*

It should be mentioned that cosmologists are still studying various alternatives to the picture presented above, which remains the current consensus.

Order, Chaos, and "Nothing"

While electromagnetic radiation, composed of the photons in the *cosmic microwave background,* makes only a tiny contribution to the total energy of the universe, the number of photons outnumbers the number of atoms in normal matter by a factor of a billion. These photons move around almost completely randomly with a thermal blackbody energy spectrum characterized by an average temperature of 2.7 degrees on the absolute Kelvin scale. Their deviation from randomness is only one part in one hundred thousand. The common but mistaken belief that the universe is very orderly is a bias based on humanity's location on Earth, a tiny speck of order in a vast sea of disorder.

According to current cosmological models based on both general relativity and quantum mechanics, inflation originated from a tiny region of space on the order of 10^{-33} centimeter across that is indistinguishable from a primordial black hole. This implies that the universe as we know it started from a state of maximum entropy, that is, maximum disorder. It began in total chaos. This chaos, being without structure, is about the closest we can come to describing a state of nature that we can label as *nothing*. The structure of the universe evolved as the universe exploded out of the initial chaos. Because of the expansion of the universe, there is increasing room for order to evolve as time goes on.

For three decades, the *standard model of particles and forces* has successfully described all empirical data from both laboratory and astronomical instruments. This model utilizes the methods of relativistic quantum field theory. A relativistic quantum field consists of particles called quanta, and every elementary particle is the quantum of a field. Within the mathematical formalism, annihilation and creation operators are used to add or subtract quanta from a field. When the annihilation operators are applied a sufficient number of times, we are left with a perfectly well-defined quantum state of zero particles we can identify as "nothing." The basic laws of physics still apply in this state.

One objection that might be raised is that if this region of chaos we call "nothing" still can be described by the laws of physics, then it is something with structure and not "nothing." However, it must be recognized that the laws of physics are human inventions and not to be viewed as structural properties of the system being described by physical models.

When we perform the annihilation process on the particles of the universe in its current state of matter, the vacuum that we get when all particles are removed still has a net *zero-point energy* and so is not quite "nothing." However, the very early universe is expected to be *supersymmetric,* that is, equally balanced between the two kinds of elementary particles: *bosons,* which are characterized by integer spin (spin is the intrinsic angular momentum of a particle) and *fermions,* which are characterized by half-integer spin. In that situation, the zero-point energies exactly cancel and we have zero particles and zero energy.

The state of "nothing" is related to the well-studied situation in quantum mechanics where particles can tunnel through barriers that will not permit particle transmission according to classical mechanics. Quantum theory allows for the wave function of an external particle to pass through the barrier. This is called *quantum tunneling*. The region inside the barrier is termed "unphysical" because the momentum of the particle is an imaginary number (that is, its momentum contains the factor $\sqrt{-1}$). Such a particle is unmeasurable but still describable mathematically. The theory of quantum tunneling has been verified empirically and used to explain the radioactive *alpha decay* of nuclei with great precision. The s*canning tunneling microscope,* which can be used to view objects as small as atoms, is based on quantum tunneling.

In a crude sense, quantum tunneling can be viewed as a process by which the energy of a particle undergoes a spontaneous fluctuation, which is allowed by the *Heisenberg uncertainty principle,* one of the basic principles of quantum mechanics. Momentarily, the particle has sufficient energy to surmount the barrier. It is as if a dog confined to a yard by a fence too high for him to jump, gets a boost from nowhere enabling him to go over the fence. Many scenarios for the spontaneous origin of the universe are vaguely described as "quantum fluctuations." However, the tunneling phenomenon is well established and can be fully described mathematically.

Reputable physicists have published in peer-reviewed journals a number of proposals for the formation of the universe by natural means from an initial state of "nothingness" or chaos. While none of these can be proven to represent the precise manner in which the universe appeared, the fact that all these scenarios are consistent with existing knowledge and violate no known laws of physics suffices to demonstrate that no nonnatural forces were necessary to bring the universe into existence.

Assuming an isotropic universe, Einstein's theory of general relativity leads to the *Friedmann equation* that, in turn, can be used to derive a simplified form of the *Wheeler-DeWitt equation.*

That equation, in this case, is mathematically equivalent to the nonrelativistic *Schrödinger equation* for a particle of mass equal to half the Planck mass (and zero energy moving in one dimension within a specific potential energy field). Solving this equation gives the "wave function of the universe."

At least two solutions have been proposed. A solution proposed by Alexander Vilenkin has the universe tunneling out the chaos described above and thus "coming from nothing." A solution proposed by James Hartle and Stephen Hawking has no boundary conditions but describes a universe, existing before the chaos, that tunnels through that chaos to produce our universe. From our point of view that prior universe undergoes a contraction and deflation that is the opposite of our inflation and expansion. However, in this other universe the arrow of time is reversed from ours. Thus, from the point of view of an observer in that universe, inflation and expansion such as ours also takes place—just in the opposite direction of time. However, since so many spontaneous (random) phenomena are responsible for the evolution of structure in both universes, they are not expected to be exact mirrors of one another.

Again it must be emphasized that the origin of the universe cannot be proven to have taken place in exactly the fashion of either of the two scenarios presented; they can simply be viewed as plausible ways that the universe could have arisen from nothing by natural means, demonstrating that no supernatural input was required.

Finally, it should be noted that the state of "nothing," that is, the unphysical state that we have labeled chaos where the quantum wave function does not describe measurable particles, is actually less probable than the physics state that describes real particles. Many physical systems undergo spontaneous phase transitions from simpler, more symmetric states to more complex states with less symmetry and more structure. The most familiar example is the way water vapor turns to liquid and then ice. While the reverse processes also happen, they require the input of heat energy. Take away that heat and the natural progress is from simplicity to complexity. Since nothing is simpler and more symmetric than "nothing," the state of matter in which there is something rather than nothing is more natural. The reason we have something rather than nothing is that nothing is unstable.

UNIVERSES, BABY

The term *baby universe* can be applied to any newly formed universe, including the initial stages of our own universe. More commonly, the term has been applied in speculation about the existence of other universes that could have developed before or after our own universe came into being—universes that have existed, are existing, or will exist outside of the framework of our own cosmos. Since such universes would inhabit a different time and space, we are unable to verify or observe them.

The popularization of the term baby universe apparently had its genesis in astrophysicist Stephen Hawking's lecture "Black Holes and Baby Universes," presented at the University of

California, Berkeley, in 1988. The contents of that lecture were later included in a collection of his essays with the same name.

A black hole has generally been defined as a region in space and time with such a strong gravitational field that nothing can escape from it. Hawking, however, speculated that there could be an exception because the uncertainty principle would allow particles and radiation to travel faster than light for a very short distance. These emissions would eventually result in the loss of mass, with the black hole completely disappearing. Nothing coming out of a black hole would resemble what fell into it, though it would retain the same energy. A separate intriguing question is what would happen to the objects that fell into the black hole. Hawking suggested that they might enter a baby universe of their own that would branch off from our own part of the universe. If the baby universe was ever able to rejoin our region, it would appear as another black hole.

The idea of the existence of other universes has led to some speculation in the past about time travel. But Hawking added the important qualification that the baby universes would occur in imaginary time, defined as existing at right angles to real time. Though imaginary time is a well-established scientific concept and an important one for the understanding of quantum mechanics and the uncertainty principle, it in no way resembles our own subjective view of time. If human beings fell into a black hole, their history in real time would come to an end, and they would be torn apart by gravitational forces. In imaginary time, the changed particles would enter a baby universe and come out again from another black hole. Because of the small size of baby universes, we are unable to observe them or to predict their numbers or patterns. However, Hawking thought that their existence might help explain such values as the cosmological constant, which gives the universe its natural tendency to expand or contract.

In 2004, Hawking surprised some cosmologists by stating that he now considered himself wrong about the existence of baby universes that branched off from our own. He now claims that as a black hole begins to die it simply sends its contents back out into the universe in a transformed state. Other cosmologists, however, continue to speculate about the possible existence of baby universes and/or multiple universes, sometimes referred to as the multiverse.

Cosmologist Alan Guth is credited with introducing the theory of inflation, which allowed the universe to grow from only about an ounce of primordial material. Guth further concluded that the idea of the existence of multiple universes is a logical consequence of inflation. Furthermore, cosmologist Lee Smolin speculates that black holes created after the explosion of a star might give birth to other universes by a process sometimes referred to as a "bounce." The more black holes a universe has, the more it could eventually produce. The laws of physics would likely evolve to encourage this process.

A new universe could possibly develop into one similar to ours, with intelligent beings. The concept of time in this different region of space and time would probably seem as real to those observing it as our definition of time is to us. In our own universe, we have defined time as having its beginnings following the big bang, which we now believe occurred about 14 billion years ago. Observers have made considerable efforts to measure the passage of time in a uniform way.

Dave Shiga reported on a model whereby the universe might shatter into pieces, each of which would grow into a new universe. This theory could explain why our own universe began in such a well-ordered state, with the natural process of entropy, or disorder, increasing through time as the universe inflated. Moreover, cosmologist Sean Carroll suggested that our being part of a large group of universes might also explain why entropy has not occurred as rapidly as might be expected.

Physicists have investigated the possibilities of scientists actually being able to produce baby universes in their laboratories. The big bang involved the production of a new spacetime in a very tiny space. That conclusion led to the speculation that if energy could be concentrated to a high enough degree, it might reproduce the same process in a laboratory. An example is seen in the 2006 work by Nobuyuki Sakai and colleagues at Japan's Yamagata University. They hoped to create a baby universe using the Higgs field, which would ensure that the density of energy inside bubbles of a false vacuum would remain constant. If successful, then the baby universe would presumably break off into a spacetime of its own. It would have no direct effect on our own universe and even be hard to verify as having taken place. Despite inherent problems and doubts, interested physicists are not likely to abandon such efforts.

There may be no reason to think that baby universes will ever serve as a means of time travel or as a means of escape in the event that our own universe would become uninhabitable. But scientists and laypersons alike should be interested in what further observation and testing might tell us about the real or theoretical possibilities of their existence, including the implications regarding the origin of our own universe and our concepts of time and space.

Ur

Ur was a Sumerian city in southern Mesopotamia, located near the mouth of the Euphrates River. The site is significantly inland in present-day Iraq, but in ancient times the Persian Gulf extended much farther north, making Ur a seaport on busy land and sea trade routes. The city was both historically and culturally significant for over 2,000 years.

The city of Ur was founded in the 5th millennium BCE, during the Ubaid period. By 2800 BCE, Ur had become one of the most prosperous Sumerian city-states. Over time, Ur had three dynasties of rulers who extended their control over all of Sumer. Ur is referred to in the Bible as Ur of the Chaldees, birthplace of the Prophet Abraham. Chaldeans settled the area about 900 BCE, placing the city of Ur and the Bible in the same historical context.

The founder of the First Dynasty of Ur was the conqueror and temple builder Mesanepada, who reigned about 2670 BCE. The city was a leading urban center, with control over much of Sumer. The First Dynasty is known best through the extraordinary collection of grave goods found in the royal tombs excavated by Sir Leonard Woolley of the British Museum and the University of Pennsylvania Museum in the 1920s. The elaborate jewelry and personal items were made of many precious and semiprecious materials imported from as far away as Afghanistan and Pakistan, an indicator of the extensiveness of trade in the region.

Ur was captured about 2340 BCE by King Sargon of Akkad. This Akkadian period marked an important time in the blending of Sumerian and Semitic cultures. After this dynasty, there is a long gap in the historical record where practically nothing is known except that a second dynasty rose and fell.

Ur-Nammu, the first king of the Third Dynasty of Ur, reigned from 2113–2095 BCE. He revived the empire of Sumer and Akkad, and by controlling the outlet to the sea, made Ur the wealthiest city in Mesopotamia. This was an important time of political expansion in the area. His reign also marked the beginning of a renaissance of Sumerian art and literature. He wrote the first law in recorded history and built great walls around the city. His son and successor built a monumental ziggurat to worship the Sumerian moon god Nanna. The massive ziggurat, one of the best preserved in Iraq and most recognized monuments in the world, still looms more than 20 meters over the desert today. Many other iconic buildings were constructed during this neo-Sumerian period.

The descendants of Ur-Nammu held power for more than a century, until just before 2000 BCE, when the Elamites captured the current king and destroyed the city. Rebuilt shortly after, the city was eventually assimilated into Babylonia. Ur remained a provincial capital and an important religious center throughout the period of Assyrian rule in Babylonia.

King Nebuchadnezzar II of Babylonia initiated another period of intense building at Ur. Temples were remodeled and the great ziggurat was increased to a height of seven levels, making an imposing landmark that rivaled other buildings of the time.

Ur began to decline after Persia gained control of the region. By the 4th century BCE, the city was uninhabited. The relatively quick decline was probably due to a combination of factors, including drought in the region, the Euphrates changing its course, and the silting of the outlet to the Persian Gulf.

The architectural history of Ur documents the city's continuous historical, cultural, and political significance for a span of over 2000 years. It was an economic and religious center for most of its history. It remains one of the best preserved Sumerian cities in Mesopotamia today. Ur documents a lengthy time period of achievements by Sumerian society.

Utopia and Dystopia

Generally, a utopia is an imaginary perfect place in space or time, in particular a not or not yet attainable type of society. Within literature, fictions emphasizing the social, political, and moral aspects of an ideal community constitute the utopian genre. Utopia, in its various expressions, is the conception of a successful life and living together and thus the denunciation of existing conditions. Literary utopias can be separated into utopias of time and utopias of space. In addition to a positive and optimistic understanding of utopia, there are concepts that subvert the utopian ideals: The so-called dystopia or anti-utopia is a negative utopia that proceeds from the assumption of a selfish and imperious human nature. As a negation of idealistic romance, dystopias emphasize the dark side of mankind and the consequent worst state of society.

Definition

The term *utopia* is a made-up word from the Greek words *ou* (no) and *topos* (place) that means "no place" or "nowhere." Its first verifiable mention is in the Latin title of the novel *Utopia* (1516) by Sir Thomas More, which was originally published as *De Optimo Reipublicae Statu, deque Nova Insula Utopia* ("Concerning the best state of the republic and the new island Utopia"). The very antithesis of More's humanistic ideas is the thinking of his contemporary Niccoló Machiavelli, who developed in his dystopia *The Prince* (1513) a society ruled by pure power.

With the increasing use of the term *utopia* in 17th-century European literature, it soon became part of the everyday language. In its metaphoric meaning, utopia described a nonexisting albeit cogitable place of a commonwealth superior to the existing one. The contradiction of this place was related to its impossibility and for this reason utopia turned into a pejorative term referring to an unrealistic or naïve idea. During the 19th century the significance of utopia changed to more temporal aspects, and perfection was created in the future. The ambiguity of utopian ideas expressed in the criticism and hope of progress persisted into the 20th century. In recent times, utopia is often used as a term for economic, political, historical, religious, scientific, and technological improvements.

Temporalization of Utopia

Until the end of the 18th century, *utopia* referred to an imaginary country, often supposed to be situated in an isolated or undiscovered territory on Earth. Utopias of place assume a succeeding model of socialization in the present within an unreachable or unknown spatial distance. Due to the discovery of the world it became more and more difficult to create an earthly place of perfection. Even though More and his contemporaries wrote in the century of great voyages of discovery, they refused the idea of a fully mapped world.

With Louis Sébastien Mercier's novel *The Year 2440: A Dream If Ever There Was One* (1771) the concept changed from utopias of place to utopias of time. Utopia became an ideal place in the future, and the anywhere was substituted by an anytime. The essential new element was the optimistic way in which time was used. Within the classical understanding of time, the ideal society on earth existed only in the past; all events in the present and in the future will be inferior to former times. Already in the *Republic,* Plato referred to a special conception of time by creating a society that can reach the perfection of the world of ideas only in retrospection. Similar conceptions of time can be traced in the utopian writings of the European Renaissance. Various philosophers and authors believed in the myth of a past or current golden age that could be followed only by a worsening situation. Despite the introduction of a prospective view, the 18th century remained a period of transition from space to time.

The first novel demonstrating a social development from present to future is *Looking Backward: 2000 to 1887* (1888) by Edward Bellamy. It is a primary utopia of time in the proper sense of illustrating successive and plausible moral and technical improvements. Instead of caricaturing the existing deteriorated conditions by outlining a better state, Bellamy offered practical solutions to reach a reform. Due to the progress in science and the advanced philosophy of history, the revaluation of the future enabled the temporalization of the literary utopia. In particular, the developments in modern science caused the hope of a better life in the future.

Utopia and Dystopia in Literature

Utopia and dystopia are strongly connected with the ambiguity of satire, which is often concealed in utopian writings. Consequently, anti-utopian satires can also be read as utopias. Already in early Greek writings utopian thoughts are articulated, and the conception of an ideal state of society as a normative model goes back to Plato's *Republic* (c. 380 BCE). The visionary theocratic thinking in the Middle Ages is expressed in, for example, *The City of God* by Saint Augustine of Hippo. Important utopias in the 16th century were written by Thomas More, Françoise Rabelais, and Michel de Montaigne. The most popular literary utopias since More are *Christianapolis* (1619) by Johann Valentin Andreae, *The City of the Sun* (1623) by Tommaso Campanella, and Francis Bacon's *The New Atlantis* (1626), as well as those of Joseph Hall, Cerrard Winstanley, Margaret Cavendish, and James Harrington. A great writing of the 17th century is the satire *Gulliver's Travels* (1726) by Jonathan Swift. Nineteenth-century utopias concerning idealistic communism are works in the tradition of Karl Marx and Friedrich Engels. Examples of political and economic utopias are found in the writings of Samuel Butler, Edward Bellamy, William Morris, and Theodor Hertzka. Notable 20th-century authors include H. G. Wells, Charlotte Perkins Gilman, Yvgeni Zamiatin, and B. F. Skinner. Pure dystopias are George Orwell's *Nineteen Eighty-Four* (1949) or *Brave New World* (1932) by Aldous Huxley.

V

Values and Time

The term *value* has many meanings. It can have a purely economic meaning regarding monetary worth (i.e., shareholder value), an epistemological meaning of coherency and simplicity, an aesthetic meaning as in the beautiful, or it can carry an ethical meaning. Common to all these meanings, however, is that humans consider that which has "value" to be something worth striving for. This is the case even if there is no consensus about which specific things are properly considered to have value. This problem is intensified by the time dimension. Values that were formerly esteemed may fall from high regard while other values rise to take their place. The crucial question is, therefore: Are there any values that are universal, or are all values subjective? Similarly, are there any criteria that can establish an objective validity for values? Does it mean that there are values that are timeless? Or is another relation to time possible if there exists an objective validity for values?

The Concept "Value" in History

Plato (427–347 BCE) argued that values possessed an objective validity. They are eternal and universal, and thus they remain valid for all times and all places. His basic understanding can be described in the following way: There exists an objective realm of the ideas, and values such as the True and the Good belong to this realm. Plato sought to demonstrate his philosophy by separating the true ideas from the "shadows" that dim human perception. Using the now-famous Analogy of the Cave, he argued that human understanding can be freed from the shadows, but it involves a laborious process. Christianity incorporated much of Plato's philosophy, including that on the nature of the True and the Good.

Christians consider that Jesus Christ, as the revelation of God, is the incarnation of true value. This belief, which is the central Christian mystery, entails that value is to be known in the person of Jesus, as revealed in Christian scriptures. As such, value is considered to be personal and at the same time transcendent and immanent. God is the epitome of truth and goodness, whose holiness is worth striving for. In the Gospel of John, for example, Jesus says about himself: "I am the way, the truth and the life."

The savagery of religious wars in Europe and elsewhere, however, has in modern times led to an ethical reevaluation. No longer are the Good and Value in the foreground. They have been replaced in ethical and political thought by contractually secured rights. The philosopher Thomas Hobbes (1588–1679) developed a new ethic to ensure domestic and international peace and security. He passed over the ethics of values in favor of an ethical contract theory. It is true that his work continued to emphasize values, namely the values of property and "commodious living," but the contract theory emphasized the value of security above all. The social contract ensures that the one essential right, the right to life, is secure.

Immanuel Kant's (1724–1804) highly rational obligation ethics also belongs here. It is not objective values, or God as an absolute objective value, that is worth striving for as a value. On the contrary, according to Kant's ethical principle, the categorical imperative, one has the duty to act according to those maxims that can be universalized by a general legislation. Kant moved away from the "natural law" theories of value, and strove for objectivity by constructing a system based upon reason. Just as pure reason is not affected by time, the dimension of time does not play a role in Kant's ethics. The categorical imperative is therefore eternally and universally valid. That said, Kant did acknowledge the importance of appreciating value in the area of aesthetics.

Rejecting this form of ethics, Max Scheler (1874–1928) introduced a substantial values ethics system. According to Scheler, objective values exist and they are discovered in the human affect, that is, feelings. These values justify themselves according to their own form. As values, they differ from rules or duties. On the contrary, humans are drawn to follow them automatically. They are just as objective as logical thinking. Ethical relativism is unthinkable for Scheler, as is the dependence of value upon temporal circumstances. Nevertheless, values are dependent upon time because humans are temporal beings and are dependent upon values for personal fulfillment. In the course of a lifetime, humans develop according to a regimen of values. Persons mature by discovering values and, in freedom, using them to guide their lives. By living according to these true values, they show themselves to be loving, and thereby share in the love of God, who is the ground of all value.

In this way, authentic humans discover and experience the true order of values. Accordingly, lust is the lowest value. Higher on the order are the biological values, then aesthetic values that recognize the beautiful and what is ugly, and then personal values that know what is moral and good. Finally, the highest value is the value of holiness, namely the value of God. In a way, Scheler returns full circle to Platonic-Christian convictions.

Genesis of Values

These convictions of Christian values and the sacredness of values in general were already under criticism a generation before Scheler. The most notable of these critics, Friedrich Nietzsche (1844–1900), formulated a fundamentally different view from that of Christianity: Values have no objective validity, but are simply the product of particular points of view. He ascribed Christian values to a slave mentality—and its morality resulted from its resentment against its former masters. Priests were the ones responsible for inculcating those "slave" values. According to Nietzsche, this explains the genesis of such values as "good" and "evil." And with the passage of time, the slave values became internalized, especially values of so-called altruism, Christian charity, and sacrificing love.

Nietzsche argues for a reevaluation of these notions—a devaluing of values. Rather than eternal, they are to be found precisely in space and time. Values do not belong to a realm of ideas, but are concrete and should be understood as affirmations of life. For Nietzsche, accordingly, what most affirms life is the will to power. This value is realized precisely within time, by humans exercising their fullest powers first to overcome the self, and thereby to assert the human will generally. Such notions as justice and generosity dissipate the will, and therefore are countervalues. Principles of Christian slave morality cannot be affirmations of life, but rather the opposite. These antivalues have the effect of making people servile to those few who are able to assert their will to power.

At the same time that Nietzsche systematically challenged the Christian understanding of values, one of the founders of modern sociology, Max Weber (1864–1920), developed a perspective on values that had far-reaching implications. Weber studied human interaction from what was to become known as a sociological perspective, from a "meta-level," and provided a descriptive analysis of values. Refraining from value judgments himself, his descriptive analysis began from a framework where values are temporal and subjective. The term itself, *value,* corresponds to those concepts that his subjects valued, as determined through careful and neutral observation. Corresponding Platonic and Christian ideas of Value and the Good can be compared because the systems share similar philosophical methodologies. It is also relatively easy to see how they frame analogical notions of eternal truths. However, as soon as the notion of an objective truth is, per methodology, excluded as a possibility, the notion of value is necessarily considered subjectively.

Weber's project was not to find Truth or the Good, both metaphysical ideas; it was to find what societies found to be true and what they held to be relatively valuable. Relevant for his system, therefore, is the dichotomy between fact and value. Circumstances (facts) are stable, and values result from subjective valuations. Creation stories, for example, are interesting because they reveal a culture's subjective account of values to sociologists, ethnologists, and philosophers. Natural scientists, on the contrary, study the "facts" or what can be objectively quantified or explained.

Yet this strict separation between objective and subjective sciences was found to be unsustainable—between the study of objective circumstances, accessible to an objective science, and the study of subjective values, which can at best be scientifically described. The classical pragmatists (Charles Sanders Peirce, William James, John Dewey, George Herbert Mead) already held that values permeate all our experiments. Already by the 1960s, philosophers of science had demonstrated that all descriptions of circumstances are affected by valuations (epistemic and ethical values). We see through the lenses of those values. Naturally, this especially applies to the descriptions of ethical situations, such as the "circumstances" of human interactions in social situations. Cultural anthropology expressed this with the following conviction: Ethical values are culturally embedded.

Historically Emergent Values

Is it possible to develop a set of values that are not subjective, dependent upon time, and culturally determined? Stated differently: Do all values come into being and pass again from existence in the flow of time? Are they all dependent upon specific cultures? If this were the case, then a universalistic ethics would be possible only on the level of rights, if at all. Or would it be possible to return to Plato's realm of the ideas, if we wanted to establish universally valid values? If that were the case, however, we would have to deal with all the problems of Platonic philosophy.

The great philosophers of pragmatism, James, Dewey, and Mead, and their successors such as Hans Joas have suggested an alternative: Though values are bound in time, and develop with the times, they also retain validity over the course of time. The term *emergence* describes a concept with a meaning that lies somewhat in between the concepts of "construction" and "discovery." On the one hand, the term *discovery* conveys a meaning that values preexist—as in an objectively given realm. On the other hand, *construction* conveys the sense of a voluntary creation, such that a created value has only a voluntary appeal.

By describing values as "emergent," there is a recognition that they are indeed historical innovations. Yet many products of distinct social periods, such as human rights, can be shown to be values that will stand the test of time. They have sticking power because they represent stable and defensible social values. The metaphor of a birth, as described by Michel Foucault or J. Bottéro, helps illustrate this process of a historically emergent concept whose validity is acknowledged once it has been formed and generally recognized. This birth metaphor demonstrates the importance of hermeneutics for understanding: Just as the birth of a human child, in a certain sense, is the emergence of an unknown nature, so also with a value; its emergence continues to require interpretation as it matures and takes on a specific role and meaning in society. A value can develop through the course of history and even take on new ethical dimensions and meanings.

We can take, as an example, Saint Thomas Aquinas's (1224–1274) concept "human dignity" that many centuries later continues to be developed. For Kant, human dignity is expressed by the insistence that humans never be used as means, but are always ends in themselves. Certainly, Aquinas would not characterize human dignity in this way, and yet there are important continuities between the philosophers. For both, the killing of an innocent person is a violation of human dignity, whereas capital punishment in the case of a person who is a danger to society can be morally justified. Perhaps today there has been further development such that the killing of any person, even a dangerous criminal, is forbidden because it is a violation of human dignity.

The historical tragedies of the 20th century, with its wars, genocides, and political crimes, provide the context for the emergence of an understanding of human dignity in the world community. With the development of universal human rights there was a recognition that humans are fundamentally equal and worthy of protection, care, and political freedoms. This development emerged as a general rejection of, for instance, Nazi principles that declared: (1) some humans can have no worth, and are therefore expendable, and (2) human worth and moral status can be judged on the basis of racist criteria. The Nazis' history of violence forced the world community to discern and declare the value of human dignity in the concrete formulas of the United Nations's Declaration of Human Rights.

New debates continue to focus understanding of human dignity. One example is the debate regarding the use of torture for political reasons, such as spawned by the U.S. actions in the U.S. military base in Guantanamo, Cuba. Related are questions about whether innocent civilians may be killed to prevent greater evils, whether the death penalty is justifiable and other questions. Ideally, at least, this process of continual debate should result in deeper understanding and consensus. Yet important questions remain unresolved regarding the extension and application of moral dignity. Social consensus does not exist regarding the moral status of human fetuses, for example. It is therefore difficult to grasp how society can provide guidelines regarding their protection. Similar questions emerge at the end of life, with debates surrounding organ donation. If with "brain death" a patient is no longer considered a human being, then the implications and protections of human dignity no longer apply, and bodily organs can be ethically harvested for medical reasons.

In a new and developing context, in which the value of human dignity is continually reconsidered in terms of its emergence from a 20th-century context of violence, the question of euthanasia takes on an interesting dimension. How is human dignity to be understood in this context? Advocates of euthanasia argue that allowing a patient to make a considered decision to end his or her life is consistent with human dignity. Opponents, however, demand a recognition that every human life is inviolable, and thus euthanasia is contrary to human dignity.

Possible Timeless Dimension of Historically Emergent Values

The example of the value of human dignity can further the discussion regarding the expansion of values. What is meant by the epistemological value of "simplicity"? What is meant by the aesthetic value of "beauty"? What is the precise meaning of such values as "truth," "love," and the like? Assuming at this point that all values develop in time within specific historical circumstances, it is possible to propose that the meaning of these values can never be exhausted. Is a timeless dimension of values then possible?

In order to answer this question, several distinctions must be made: first, regarding the emergence of values; second, regarding the exact meaning of values; and third, regarding the distinction between values. The emergence of values is always timebound. Their validity is not simply a given, but rather they develop in the course of history. Therefore, they are not carved in stone, so to speak, and, as such, are valid for all time; instead, their meaningful content continues to be dependent upon time. Because the intelligible content of values is related to historical experiences, the possibility exists that their meaning can develop with time—and that they can pass into oblivion. Values depend on historical events, on the genius of certain personalities, on nature, and on cultural and scientific discoveries. Nevertheless, a fundamental meaning can be found that emerges in time but is nevertheless not relativistic. Rather, it can be argued that it maintains a validity that is independent of time.

The best example to illustrate this is the historical condemnation of slavery and the value of human freedom. Aristotle as well as many Christian philosophers and historical figures had no moral qualms concerning the institution of slavery. They assumed that for some persons, the exercise and enjoyment of liberty was not appropriate or necessary. Rather, the fact that some people are born into a state of slavery was seen to be consistent with justice. The value of a fundamental freedom of every person, such that slavery was inherently unjust, became generally recognized only in the period of the Enlightenment. Yet, despite its historical emergence, this insight is valid universally, such that there is no place on earth where slavery is justly permitted.

This argument regarding the value of freedom applies as well to aesthetic value. By way of example, we can point to the historically composed great musical works of art. Created "in time," the music remains timelessly valuable. This is the case even if, in the future, there comes a time when no one appreciates the music. Finally, regarding the epistemological values of, for example, simplicity and coherence, they share this timeless and universal validity even though being discovered in the course of time.

The Continuing Importance of Time

The recognition of universally valid ethical, aesthetic, and epistemological values can be seen as important historical achievements of human culture. Unlike Platonic philosophy, they do not depend upon an objective and eternal world of value. And, in contrast to philosophies that neglect the temporal emergence of values, the position presented here recognizes how important insights regarding human values emerged historically. Time was necessary for their emergence, but there is no time in the future when these values would be invalid. In this sense, therefore, we can speak of them as having achieved a status of universality and timelessness.

Vampires

In contemporary popular culture, vampires are fictitious immortal creatures of the night who sustain themselves by drinking the blood of the living. These undead creatures might be the unsettled souls of criminals or suicide victims. They may have been victims of other vampires, as those who are attacked by vampires are fated to become vampires themselves.

By convention, vampires are often depicted as aristocratic; male vampires are tall, handsome, and dressed in a black cape draped over formal attire. Women vampires are most often subordinate to male vampires, and they may be called brides or sisters of the patriarchal vampire. Regardless of the gender, male and female vampires have compelling seductive power over their victims. Modern vampires have a hypnotic stare that captivates the victim. Their canine teeth become prominent and their eyes turn blood red as they prepare or are compelled to feed. The teeth are used to penetrate the flesh of a victim's neck, from which the blood is then drawn.

Vampires have no shadows, and cannot cast a reflection in any mirror or reflective surface. They walk most often in the cover of darkness but can walk about in daylight. They sleep in unhallowed ground or in earth that is taken from their native lands. They are immortal, unaffected by mortal wounds, disease, or old age.

Repelling a vampire is difficult, but they are uncomfortable with garlic and religious icons. Their ability to withstand these items strengthens, however, as they age. That is to say, a new vampire is more susceptible to suffering ill effects from being in contact with holy water and is repelled by a crucifix, a consecrated communion host, or other religious icon. Vampires can travel as mist or fog. They must be invited to enter a home where they seek to take a victim; they cannot enter except by invitation.

Vampires such as the notorious Count Dracula, created by Bram Stoker in 1897, are believed to be almost invincible. They can easily move in daylight, but with diminished powers. They control and transform into beasts such as wolves and bats. They can control the minds of even the strongest character, and enslave them into their power. Stoker's vampire is based on the historic 15th-century Prince Vlad Tepes (the Impaler) of Wallachia and other long-standing folklore legends.

In vampire folklore, it was commonly believed that vampires could come from those born between Christmas and the Epiphany. If one was the seventh son of the seventh son, or was born with a harelip or with teeth, vampirism was suspected. Evidence that the mania spread is revealed by the exhumation of graves 3 or more years after the death of a child. Most believed the vampire treatise: Vampires need not feed every night; victims might linger for days before death; and that in death they become the undead.

According to legend, vampire hunters would cut off the creature's head, fill its mouth with garlic, drive a wooden stake through its heart, and cut out the heart and burn it. When the evil vampire is killed, all evil that it created also dies.

Verne, Jules (1828–1905)

Jules Gabriel Verne was born on February 8, 1828, in Île Feydeau, in the city of Nantes, France. He was the first of five children born from the marriage between his father Pierre, a Parisian attorney who came from a lineage of jurists from Provence, and Sophie Allotte de la Fuÿe, of Breton and Scottish origin. Verne began the study of law in Paris but chose instead to pursue his passion for literature and the theater. When Pierre Verne realized his son's ambitions no longer included jurisprudence, he withdrew all financial support. Verne never practiced law, but his writings, which explored the themes of time and the future, would earn him a secure place in world literature.

During the 1850s Verne attempted to survive financially as a playwright and published several works, including *Blindman's Bluff.* In 1856, Honorine Deviane, a widow with two children, was introduced to Verne at a friend's wedding. Eight months later, on January 10, 1857, the two were married. At some point after their introduction Jules became a stockbroker and it is speculated he made this career change in order to provide for his family. Four years later, on the August 3, 1861, the couple's first and only child, Michel, was born.

"De la Terre a la Lune" ("From the Earth to the Moon," 1865). Here the space travelers board the moon-projectile in Jules Verne's account of space travel.

In January 1863, when Verne was 30, his first novel, *Five Weeks in a Balloon,* was published. The text described a futuristic hot-air balloon adventure set in Africa, an area relatively unknown to Europeans. Although his work had both geographical and scientific flaws, Verne's book was ahead of its time. *Five Weeks in a Balloon* proved to be the first in a series of novels that described technology that did not yet exist or was in only the earliest stages of development.

From 1862 to 1886, Verne lived in Amiens with his family but traveled to the United States to visit New York City and Niagara Falls. During this period he also visited many European countries and gained both worldwide fame and a modest fortune.

On March 9, 1886, Verne's mentally unstable nephew, Gaston, shot him with a pistol. A bullet entered Verne's left shin, giving him an incurable limp. Gaston was judged to be mentally ill and spent the rest of his life in an asylum. The time of the shooting coincided with the deaths of Jules Verne's mother and his longtime friend and publisher Pierre-Jules Hetzel.

Following Verne's death on March 24, 1905, his son Michel began to publish his works after substantial revision; the revised works began to appear in 1919.

Four of Jules Verne's best-known novels include *Journey to the Center of the Earth* (1864), *From the Earth to the Moon* (1865), *Twenty Thousand Leagues Under the Sea* (1870), and *Around the World in Eighty Days* (1873). From oceanographers in submarines to space walks on the moon, the author sparked the imaginations of millions. Prophetically, descriptions of such later developments as television, automobiles, skyscrapers, high-speed trains, and many other modern technologies resonate throughout his novels. It is not an exaggeration to state that Verne's ideas produced a greater interest in technological advancement and influenced modern-day society.

As one of the pioneers of the science fiction genre, along with others such as H. G. Wells, Jules Verne led the way for others to dream and create. In the 20th century Verne's novels were translated into 140 different languages and were the basis for a number of popular movies.

Virtual Reality

The term *virtual reality* is used to describe a variety of computer-generated environments, experiences, and activities that range from existing technologies like computer games to futuristic visions as pictured in popular movies like *The Matrix*. A virtual reality (VR) is created by specific technologies that enable the user to perceive and interact with virtual objects in an artificial environment that has its own spacetime continuum and follows its own laws that are implemented as the properties of the virtual objects. The development of powerful microcomputers, head-mounted displays (HMD), datagloves, and the CAVE (Cave Automatic Virtual Reality) laid the foundations for VR. Since then, the ability to create and experience virtual worlds has drawn much attention in the humanities and in public discourse. Current VR technologies allow a primarily audiovisual experience of the virtual environment. Future technologies are expected to include the other senses as well. Along with spatial properties, VRs can also be provided with temporality. Online VRs, such as Second Life or World of Warcraft, have introduced their own virtual time, which passes whether the user is logged into the virtual world or not. Yet, the characteristics of virtual time can significantly differ from those of real time; for example, virtual time can be made reversible.

Jaron Lanier, one of the pioneers in developing VR technologies, is widely recognized as having coined the term *virtual reality* in the 1980s. It is notable that this term superseded other proposals like Artificial Reality, which was suggested by Myron W. Krueger, and Phantomology as the writer Stanisław Lem proposed—even though the term is paradoxical. The English word *virtual* (lat. virtus: manliness, excellence, character, worth, courage) stands for "practically" and "as good as" as well as "almost" and "nearly, but not completely," whereas the term *reality* refers to the way things really are in contrast to their mere appearance. Taken literally, a VR is something that appears to be real and that is practically as good as the real thing but is not entirely real. In a driving simulation game one can steer a virtual car looking and acting like a real one, yet crashing the virtual car of course does not have the same effects as in real life.

Various attempts have been made to define VR more thoroughly. In the early years, technology based definitions were prevalent. This understanding proved to be insufficient to grasp the characteristic features of VR. In an attempt to find a more appropriate understanding, the focus shifted from the technologies at hand to the specific modes of experience a VR creates. Thus, VR is mainly understood as a medium to create an experience that can be characterized as an immersive simulation, which is artificial, interactive, and communicative, and that creates the experience of telepresence. An experience is immersive when the user becomes absorbed in the sensations of the VR. This might lead to the impression of being present in the artificially created environment, which is called telepresence. Immersion in a virtual environment is a gradual experience. One can feel immersed into a game played on a desktop computer with a regular computer screen. Technologies like the HMD, which was developed in 1968 by Ivan Sutherland and Bob Sproull, are even more immersive because they cut off all visual sensations of the outside world. Stereoscopic images are shown on two displays that are placed right in front of the eyes. Furthermore, the movement of the head is traced by the HMD, and based on head movement the corresponding visual information is given. Another approach to creating immersive virtual environments is the CAVE that was developed in 1991 by Carolina Cruz-Neira, Dan Sandin, and Tom DeFanti. The user is placed in a cube (approximately 3 by 3 by 3 meters in size), and the virtual environment is projected onto the transparent walls of the cube by rear projection. A regular keyboard or mouse can be used to interact with virtual objects. Again, to give the user a more realistic impression other devices like the dataglove were invented. This glove-like interface, developed by Thomas G. Zimmerman and Lanier, allows the user to grab and modify a virtual object almost like a real object. Elaborate datagloves give a haptic feedback when touching a virtual object and thereby create an even more realistic impression.

Today's existing technologies allow the user to immerse and interact in virtual environments. However, unlike as envisioned in science fiction, they have not yet become indistinguishable from the real world. Still, the idea that technological progress will render this development possible has become an intriguing thought for the humanities as well as the social sciences. But even though this futuristic vision has become something like a yardstick in the assessment of virtual environments, the current technological possibilities raise questions about the social, ethical, ontological, and economical effects of virtual reality. To address this problem one could ask for the status of actions in virtual environments. Theoretically, events that happen in a virtual environment do not have an effect on the real world. A person killed in a war game is not really dead outside the virtual world. Furthermore, it is in principle possible to undo actions, and thus time is reversible. A virtual game can be played over and over again. It is for this reason that VR applications are used in the training of soldiers. Yet this fundamental openness can be undermined technologically and socially. Every implementation of a virtual world codifies certain rules about how objects in a virtual environment react. Virtual objects are subject to their own laws that determine their behavior. By adjusting the physics of virtual worlds to the actual laws of physics, real-world behavior of objects can be simulated and predictions can be made, like in simulations of crash tests. In addition to that, social rules can be established in VRs. Virtual communities, that is, communities in VR such as Second Life, have their own rules for social interaction. Nevertheless, it is the subject of ethical and juridical discussions how virtual crimes should be treated in real life. The moral implications of VR are considered to pose a serious challenge for ethics.

Voodoo

An African-based religion, voodoo's ancestral roots extend into the remote past. Three African groups had the strongest influence on voodoo: The Yoruba of present-day Nigeria, the Fon of Dahomey (Benin), and the Kongo of present-day Zaire and Angola. Voodoo consists of complex rituals, duties, and symbolic actions that are carried out by its practitioners. The word *voodoo* means "spirit" or "deity" in the Fon language and traces back to the West African Yoruba people living in Dahomey as late as the 18th and 19th centuries.

History

The religion of voodoo originated on the sugar plantations of Haiti. Some of the voodoo prayers and invocations hold fragments of West African languages; however, Haitian Creole is the primary language of voodoo. Creole is the only language spoken by 80% of contemporary Haitians. Its grammatical structure is strongly influenced by West African languages, and it uses a largely French vocabulary. Although many of the names of voodoo deities can be traced back to their African origins, these spiritual beings were transformed and adapted to a new land and sociocultural context; interactions among slaves created this amalgamation of beliefs, deities, and ritual practices. Voodoo arrived in North America when the first Africans landed in Jamestown in 1619 as indentured servants. As the number of indentured servants and, later, slaves increased through the West Indies and into North America, voodoo worshippers became most prevalent in Haiti and New Orleans. Unfortunately, little is known about the formation period of voodoo in Haiti.

Voodoo and Popular Culture

Sensationalized in novels and in Hollywood films, many misconceptions about voodoo have come about in the minds of Westerners over the years. Voodoo has been portrayed as sorcery or evil magic involving orgies, human sacrifices, and cannibalism. A sensational novel written in 1884 by S. Saint John, *The Black Republic,* described voodoo as a profoundly evil religion and was responsible for most of the misunderstandings. These misconceptions have been portrayed in Hollywood films since the 1930s and continue today. Since voodoo involves divination, manipulation, and herbalism, it gives the appearance of magic rather than religion. It was seen as something to be feared and was actively suppressed during the U.S. colonial period when many priests were killed or imprisoned. Such practices can be attributed to the prejudices and fears of blacks by slave owners faced with the ever-present threat of rebellion. Haiti's independence was attained relatively early, around 1804, at a time when most other countries in the western hemisphere were still heavily dependent on slave labor. In fact, the organizing of the slaves' revolt is important as its role is apparent in the downfall of President Jean-Claude Duvalier in February 1986. In addition, "antisuperstition campaigns" carried out in the 1940s aimed to alleviate some of the persecution carried out by the Catholic Church. Currently, there is an uneasy peace between the Catholic Church and voodoo.

Catholic Influences of Voodoo

Despite their obvious differences, voodoo was heavily influenced by Catholicism. Because the French slaveholders were Catholics, they made baptism mandatory. Consequently, many voodoo practitioners hid their beliefs and rituals but continued to practice them under the guise of Catholicism. Among slaves, Catholicism was viewed as a way to continue and expand their religion at the level of rite and image rather than theology.

Syncretism With Voodoo Deities and Catholic Saints

Over the years, parallels have developed between voodoo spirits and Catholic saints. For example, Dambala, the snake god of the Fon peoples, is worshipped along with Saint Patrick whose Irish legend also involves snakes. The ancestral homeland of Africa is a powerful concept in voodoo. Haitians call to the spirits as *frangine* or "frank Guinea," meaning truly African, to convey that the spirit is good, ancient, and proper. Voodoo spirits go by several names: *Iwa* (from the Yoruba word for "spirit" or "mystery"), *sint* ("saints"), *envizil* ("invisible"). In the countryside, the spirits are grouped into *nanchon* ("nations"). The names of the voodoo nations refer to peoples and places in Africa. For example, Wangol stand for Angola and Mondon for Mandingo.

In voodoo, the person consists of various parts: the body or the physical being and after death, the soul, which can consist of two to four souls, the most common being the *gro bonanj* and the *ti bonanj*. *Gro bonanj* is related to consciousness or personality while the *ti bonanj* or "little guardian angel" is regarded as spiritual energy. A person's spirit is connected to certain *Iwas,* and a person who venerates particular spirits can petition for help from those spirits and the qualities and powers that they possess, linking humans with the divine.

Voodoo is an inseparable part of Haitian art, literature, music, and film. Hymns are played on the radio and voodoo ceremonies are broadcast on television along with Christian services. Music and dance are key elements to voodoo ceremonies. The purpose of the dancing ritual is an expression of spiritually to connect with the spirits. Gifts and animal sacrifices are offered to gain favor. People petition the spirits for an abundance of food, to have a better standard of life, for love, and for good health. Ceremonies also serve to build community ties and reinforce history and traditions. Participants come before the priest to ask for spiritual guidance and advice. The priest or priestess offers aid in the form of knowledge, herbs, medicines, or healing through faith. Voodoo also teaches respect for the natural world.

Voodoo in the 21st Century

Today voodoo survives as a legitimate religion and millions of people practice voodoo worldwide. The struggle to survive as a religion has endured for 3 centuries. Religions that are similar to voodoo are found in the Caribbean and South America: Quimbanda, Candomblé, Santería, and Umbanda.

W

Wagner, Richard (1813–1883)

In the history of the arts, liberal activist Richard Wagner looms as an extraordinary genius whose prodigious creativity produced 10 remarkable music-dramas that deal with time. For subject matter, he used both legends and myths from the Germanic, Icelandic, and Scandinavian worlds of objects, characters, emotions, and events. Throughout his work resounds the theme of the search for one's identity, or the longing for one's salvation. As such, Wagner's symphonic operas reflect both psychological and philosophical issues ranging from the lust for power to the existence of evil. The concept of time is especially relevant in his epic tetralogy *Der Ring des Nibelungen* and sacred work *Parsifal*.

In Wagner's three early music-dramas, the finitude of human time is essential to the legend. *Der Fliegende Holländer* (1843) is the tale of a brash Norwegian captain who, after making a conceited claim, is condemned by the devil to sail endlessly around the world on his phantom ship. This seaman is doomed until he meets a maiden who will sacrifice her life, through faithful love unto death, in order to bring salvation to his accursed existence. Similarly, in *Tannhäuser* (1845), the main character seeks forgiveness and redemption from sin through his long journey from the valley of the Wartburg to Rome and back; not having received forgiveness from the Pope, only the death of Elisabeth releases Tannhäuser from his guilt-ridden anguish for having once preferred the physical passion of Venus rather than her spiritual love for him. In *Lohengrin* (1850), the identity of a mysterious visitor to Antwerp remains a secret until Elsa begs to learn from him his name and place of birth; upon revealing his identity, Lohengrin must now return to Monsalvat, never again to visit this kingdom. Finite time gives a dramatic element of anticipation to each of these three operas.

Wagner's *Tristan und Isolde* (1865) focuses, however, on eternity. Because the two star-crossed lovers longed to be united forever in the darkness of night, only in death will they become free from the separating realm of earthly daylight as well as the brute reality of time and change. But, in *Die Meistersinger von Nürnberg* (1868), the medieval plot stresses the transition from a rigid style of singing with its old-fashioned restrictions, to a new mode of vocal expression with loftier aspirations and creative innovations. The two opposing orientations are each represented by a singer: One sings a traditional song according to established rules, while the other offers a beautiful love-inspired song that clearly breaks from the past. Thereby, to the delight of the wise shoemaker Hans Sachs, this unique prize song announces the dawn of a new age of enlightenment.

Nevertheless, it is in Wagner's massive four-opera masterpiece *Der Ring des Nibelungen* (1876) that the composer reveals the significance of time for comprehending both the evolution of characters and the passing of events. The saga spans a complex sequence of dramatic situations, from the origin of the world, through the emergence of diverse individuals and pivotal circumstances, to the end of the godly domain. The flux of reality is best represented by the flowing Rhine River, raging storms, and magic fire.

In this tetralogy, Wagner's use of the leitmotif technique is particularly important. Musical themes represent objects, characters, emotions, and events. By using, modifying, and developing these leitmotifs, the symphonic musical web allows the listener to move backward and forward through time; during a performance of the *Ring* cycle, the listener is reminded of past situations and can even anticipate future circumstances. Musical themes also allow the listener to know the subjective intentions of a character, particularly if the words being sung differ from what the audience recognizes in the music to be what is actually being thought by the same individual. Thus, the fluidity and diversity of the music complements and intensifies both the flow and complexity of the drama.

Wagner instructed that his *Ring* cycle be presented over the course of an evening and three days. Concerning time, however, the tetralogy itself actually spans many years. Furthermore, over time, conflicts emerge between duty and inclination, as well as between compassion and selfishness. The beginning of *Das Rheingold,* the first opera of this series, is a musical representation of the origin and unfolding of this universe in general, and our evolving Earth in particular. The age of this planet is indeterminate, but its recent history consists of a sequence of events that alter the living world. The inhabitants of this three-tiered Earth include the dwarfs who exist in Nibelheim deep under the ground, the giants who live in Riesenheim on the planet's surface, and the immortal gods and goddesses who rule from Valhalla (a castle stronghold high in the towering mountains). The epic story focuses on a magic ring that was fashioned by Alberich, the Nibelung, out of reddish gold from the Rhine River where it had been enjoyed by three beautiful Rhine maidens. Whoever possesses this ring becomes master of the universe. Along with the Rhine River, this magic ring endures throughout the four music-dramas as a symbol of eternity. However, this twice-cursed ring brings certain death to its loveless owner. Nevertheless, over time, the ring passes through the hands of several characters who lust after its awesome power—Alberich the ugly dwarf, Wotan the insecure god, Fafner the stupid giant, and Hagen the evil Gibichung.

In *Die Walküre,* human beings emerge and Siegfried, the naïve hero of this saga, will be born from the sister-brother union of Sigmund and Sieglinde. It is now the intention of Wotan, the head of the gods and goddesses, that this hero, free of the cursed magic ring, will eventually save their world from its forecast doom, prophesied by Erda the eternal earth mother. Next, in *Siegfried,* the hero comes into possession of the ring after killing Fafner (who had changed himself into a dragon). Upon finding the now-mortal Brünnhilde, Wotan's favorite daughter, Siegfried proclaims his love for her but leaves the mountain-top Valkyrie rock for adventurous undertakings.

In *Götterdammerung,* the three Norns weave the future into their rope of time, but the cord of destiny breaks, symbolizing that the end of the old order of gods and goddesses is imminent. Although ignorant of its awesome power, Siegfried refuses to return the ring to the Rhine maidens. Unfortunately, he is later murdered by the treacherous Hagen, who fails to gain possession of the magic ring. Brünnhilde secures the ring and sets the great hall of the Gibichungs on fire; the roaring flames spread to and consume Valhalla. Thus, after many years, this fatalistic cycle ends. A new era now dawns to replace the old order, and the evil of the ring has temporarily vanished from the world. It may be argued that, quintessentially, the existence of ugliness (personified by Alberich) in this imperfect world set the story of the *Ring* cycle on its tragic trajectory. Interestingly enough, one wonders if this dwarf did in fact die at the end of this tetralogy. Perhaps there were previous cycles. In time, ongoing events may even generate an endless sequence of the same or similar cosmic cycles.

In *Parsifal,* the search for one's identity and the longing for one's salvation meet in a medieval, mystical legend where time itself may be said to dominate the opera. Home of the Holy Grail and Sacred Spear, the Gothic temple of Monsalvat in Spain seems to be removed from the ravages of change; even its inhabitants seem to be in a state of quasi-suspended animation beyond the natural world. Throughout this opera, time is relative; some events happen gradually, while others occur instantaneously. Parsifal is the naïve seeker who, after years of wandering and avoiding sensuous temptations, discovers himself to be the savior of a sanctified knighthood. Parsifal thereby redeems both himself and those who have suffered from evil in the world, and he becomes the new king at Monsalvat. Furthermore, the Holy Grail itself endures as the metaphysical focus of changeless eternity.

Time pervades Wagner's operas, whether it is manifested in changing characters, altering situations, or developing events. No doubt, while working on *Der Ring des Nibelungen* over 28 years, Wagner must have imagined himself living among the diverse characters of this epic saga. He was able to transcend both his severe critics and public situations, immersing himself in a mythological realm of incredible events. One may also argue that his own genius reflected each of the characters in this cycle. Nevertheless, in *Parsifal* Wagner gave to the world of opera a timeless story of human salvation. In doing so, he transcended even his own personal shortcomings by stressing the eternal value of selfless compassion.

Wahhābism

Wahhābism is an Islamic religious sect that first arose on the Arabian Peninsula in the 18th century. The sect was founded by Muhammad ibn 'Abd al-Wahhāb (1703–1787), who wanted to preserve the purity of Islam. Adherents of this religion are called Wahhābīs or *Muwahhidūn* ("Unitarians"), a name that reflects their extreme approach to monotheism. Wahhābism is a revivalist or puritanical interpretation of Islam that requires its followers and other Muslims strictly to observe the traditional duties and observances of Islam, including using the Islamic or *Hijri* calendar, which has 354 days in a year, divided into 12 lunar months of either 29 or 30 days (29.5 days is the time taken by the moon to complete a full circle around the earth). This calendar is used both to date events and as a way for devout Muslims to track the observance of Islamic holy days.

History

Born in 'Uyaynah in Arabia, Ibn 'Abd al-Wahhāb preached a very austere interpretation of Islamic doctrine that attempted to return Islam to its original form by forbidding some of the practices and customs (such as Sufism) that had crept in over time and that did not have their basis in the Qur'an or *sunnah* (those religious practices that were instituted by Muhammad or his companions). Adherence to traditional means of marking the passage of time and the celebration of religious holidays was instituted as a mandatory practice for all Wahhābīs, who follow the *Umm al-Qura* calendar (based on precise observations of the new crescent moon in Riyād), whereby Islamic months begin at sunset of the day when the *hilāl* or lunar crescent is first visually sighted.

The Ibn 'Abd al-Wahhāb considered those who disagreed with his teachings, including the dating of religious observances and holidays, to be heretics, and justified the use of force in imposing his doctrine on others through the concept of *jihād,* or "holy war." He eventually settled in the Nejd desert, and through an alliance with the ruling Sa'ūd family clan, was able to resist the suppression of the Ottoman emperors and those Muslims who resisted his extremist views. The Sa'ūdis rapidly expanded their territory during the 18th and 19th centuries, establishing a new capital in Riyād and founding the present-day Kingdom of Saudi Arabia, and adopting Wahhābī doctrines and practices as the official state religion.

Beliefs

Wahhābism is a monotheistic religion that is founded upon the principle of *tawhīd,* a belief in the Divine Oneness. Tracking and observing religious events at the times ordained by the Qur'an is an important element of Wahhābism, since it both reflects and reinforces the centrality of God in everyday life. Wahhābīs follow only the teachings and writings of the Prophet Muhammad and his companions and those of the generation immediately following, and consider any Islamic customs and practices that were introduced by the generations that came after the prophet as *bid'ah* (innovations) that are forbidden to Wahhābī followers—such practices include any use of modern or Westernized means of tracking time or calculating the placement of religious holidays (such as the Gregorian or Julian calendars). Adherence to Wahhābī and Islamic doctrinal practices is enforced by the *muṭawwi'ū* or religious police ("enforcers of obedience"), who monitor private as well as public observance of Islamic and Wahhābī doctrine. Wahhābīs emphasize the simplicity of Islam, including traditional ways of observing the passage of time, believing that religious observance must inform every part of public and private life in order to create a just and holy society.

WATCHES

The watch has long been an integral part of everyday life for many people. Throughout the years of its development, the basic definition of the watch has remained the same—a portable timepiece, usually encased, and small enough to be carried or worn. The first watches appeared in the 15th century through the efforts of clock-making centers established in Italy, France, Germany, and England. By the late 16th century, Geneva had become an important center of watchmaking. Early American watches were produced mainly by mechanization, a process that achieved success by the middle of the 19th century.

Because clocks were weight-driven, they remained mainly stationary until the invention of the coiled mainspring made portable versions possible. Producing miniaturized versions was a natural development, also demanding greater accuracy in craftsmanship.

Early mechanical watches had only one hand and were inaccurate because they ran more slowly as they wound down. By 1700, improvements had been made so that watches normally lost only 5 to 10 minutes each day. A minute hand was also added.

The portability of the watch served as a symbol of progress and individualism. Early watches were generally worn hung from the neck or belt or carried in a pocket. Wristwatches did not become common until the 19th century and were worn mainly by women. World War I saw a major increase in their use by those engaged in the war effort. Wristwatches were eventually commonly worn by both sexes.

In 1891, the importance of accuracy was dramatized by a head-on collision of trains at Kipton, Ohio. That catastrophe led to a system organized to standardize and inspect railroad watches, which were expected to vary less than 30 seconds within a 2-week period.

The use of electricity in clocks had already occurred by the 19th century, and, by 1929, the use of the quartz crystal had improved the accuracy of clocks. With the development of high-energy batteries it became possible to apply both electricity and quartz vibrations to watches. The first commercial versions were introduced by Seiko in Japan in 1969 and by Hamilton in America in the early 1970s. While the Swiss, noted for their careful craftsmanship, used quartz crystal, they continued to produce mostly mechanical watches.

Efforts were made to further miniaturize the components of electric watches. Electric watches now feature integrated circuits, or chips, so that time can be read digitally.

Anyone wanting to acquire a new watch today can find a wide variety of styles and price levels to choose from. Watchmakers naturally have some reason to be anxious about the future of the industry. Some people, particularly members of the younger generation, express the opinion that watches are no longer necessary because of the advent of cell phones and various electronic devices. Nevertheless, positive news about sales continues to be reported. Accuracy has always been a crucial measure of the worth of a watch, but its decorative value has not lagged far behind. Collectable watches are a big business, ranging from antique and uniquely designed watches to formerly mass-produced watches, such as Rolex sports watches.

Watchmaker, God as

The identification of God as a supernatural watchmaker, a being equated with the Creator in the Book of Genesis 1–2, remains one of the most famous analogies in the history of religious thought, especially in ongoing discussions about creation and the beginning of time. Though other scholars like Robert Boyle had compared the universe to a clock, William Paley (1743–1805), the English clergyman, theologian, and Christian apologist, popularized this particular analogy in the opening paragraph of his 1802 classic work, *Natural Theology; or, Evidences of the Existence and Attributes of the Deity, Collected From the Appearances of Nature.* In Paley's scenario, a thoughtful person finds a watch while crossing a heath; the walker notes the difference between the watch's complex mechanism, as opposed to a simple stone on the path. Paley suggested that this observer might well assume that the watch did not assemble itself or come together by accident. Instead, he said that the watch reflected design and function. Paley closed his argument by pointing to an inevitable inference: The watch's structure was no accident, and it must have had an intelligent maker, an artificer (or artificers) who designed and created it for a purpose.

This watchmaker analogy reflects Paley's background and special interest in "Christian apologetics" or "Christian evidences"—the title of another of his famous books, published earlier in 1794. The book also illustrates the Enlightenment tension between orthodox faith, materialism, and various forms of Deism, all of which found support for their positions in the work of Newton and other scientists and philosophers of that day. When William Paley wrote *Natural Theology,* he took his place in a long tradition of scholars (e.g., John Ray, William Derham) who acknowledged two kinds of revelation—that is, the printed word/scripture and nature. In this "Watchmaker Analogy," which is actually a parable about the Creator, he reflected the spirit of Psalm 19:1 and related biblical texts: "The heavens declare the glory of God; and the firmament sheweth his handywork" (King James Version, as read and quoted in Paley's era). Archdeacon Paley listed many examples of complex designs in the realms of biology and astronomy and, especially, anatomy (e.g., the eye, ear, heart, hand) and argued that such evidence points to the existence of a purposeful and good God. A reasonable observer accepts this inevitable inference, said Paley, because the amazing phenomena discussed in *Natural History* reflect far more complexity in form and function than the relatively simple mechanism of a watch. He argued like a lawyer as he enumerated example after example, though Paley claimed that the mechanism of human vision alone made the case for God's existence. Of course, a naturalistic explanation for the eyeball's gradual evolution became a cause célèbre for those who rejected supernatural intervention (e.g., Charles Darwin, and later, Richard Dawkins).

From the time of its original publication in 1802, Paley's version of the argument from design or the teleological argument for the existence of god met with various reactions—from skeptics who found the analogy weak and unconvincing to believers who found the evidence reasonable and compelling. Students of Paley's metaphor must consider the critical questions raised by the earlier writings of Hume and the later conclusions reached by Darwin, most of whose teachers at Cambridge accepted the watchmaker analogy. Surprisingly, both Darwin and, more recently, Dawkins have praised Paley's literary style and logical method. Dawkins prefers Paley's willingness to propose answers to fundamental questions over Hume's skepticism. Even though Dawkins rejects Paley's watchmaker analogy, he appreciates the archdeacon's attempt to explain the way things work, while Hume merely criticized other points of view but proposed no alternative.

Some critics claim that the watchmaker analogy is flawed from the start, insisting that Paley's comparison between a watch and the world "compares apples with oranges." Others object to Paley's analogy by pointing to flaws and suffering in nature that neutralize any talk about a careful, beneficent Designer. Still other critics have accused Paley of "begging the question"—of making a facile leap from whatever kind of creative agent his argument from design might reasonably require to the Judeo-Christian God, a reflection of Paley's parochial background and education. In other words, Paley and his ilk assume the existence of God who created all things "in the beginning," but the argument from design in itself cannot prove that this deity exists. In a series of popular books and public appearances, Dawkins—who has assumed Huxley's role as "Darwin's bulldog"—argues against the conscious designer theory and insists that natural selection is a purposeless "blind watchmaker." Though he admires William Paley's work in some ways, Dawkins claims that what Paley and others interpret as a beneficent, planned creation is just an illusion. So, in the terminology of William Paley's analogy, Darwin and Dawkins (and many other scientists) say that the gradual evolutionary changes by natural selection provide the only "design" needed in the "living watches" of the biological realm.

Paley's watchmaker analogy has made a comeback in the modern controversy over origins and in the latest round of debates over creation and evolution. For many, naturalism or scientific materialism, based on the laws of physics and chemistry, offer a convincing explanation as to the origin of all things. Others find this worldview inadequate and insist that an impersonal and purposeless process of natural selection strains credulity and cannot answer fundamental questions (e.g., the "irreducible complexity" of biochemical systems). In the most general terms, there is not much difference between Paley's simple watchmaker analogy and the so-called anthropic principle, since both depend upon a "finely-tuned universe." In courts of law, opponents of the intelligent design movement, the most recent form of creationism, regularly encounter Paleyian arguments. Of course, Paley's 1802 classic analogy represents a modern version of the argument from design taught by Greek philosophers (e.g., Plato) and medieval European theologians (e.g., Thomas Aquinas). In fact, the Judeo-Christian tradition has no monopoly on the teleological argument, and representatives from a number of religious and philosophical systems advocate something akin to Paley's simple premise and attribute order and complexity to a Designer.

WEAPONS

A weapon is a device or instrument used as an aid in fighting. It can be an object or device but may also include psychological tactics, diplomacy, or any other means that destroys, defeats, or forces an adversary into submission or compliance. Weapons developed over time as humanity gained knowledge in metallurgy and other technologies as well as tactics and strategies, and eventually the sciences of physics and chemistry.

Early Weapons

The earliest weapons were most likely sticks and stones. Paleolithic cave drawings suggest that the club—a shaped piece of wood—was the first fabricated weapon. From this the mace was developed by the addition of a weight, such as a stone or metal head, to the end of the club. The addition of blades led to the development of the battle-axe. By the 5th century CE, such axes had been refined and developed into the throwing axe.

From observation early humans learned that round stones flew straighter than flat ones. The invention of the sling added accuracy and distance to thrown stones. Split stones were used as crude knives, then later as tips for spears and arrows. The Sumerians were the first people known to use copper, a metal with a relatively low melting point, for knives and blades early in the Third millennium BCE. Bronze quickly replaced copper because this alloy of copper and tin had a superior hardness. Iron, which requires higher temperatures to be worked, replaced bronze by the first millennium BCE. As metal became the common material for weapon making, the knife became larger and developed into the sword.

The swords of Sultan Mehmed (II), Sultan Selim (I), Bayezid (II), and Constantine kept in the Imperial Treasury. The sword became the primary weapon for close-quarter fighting and remained so up to the 16th century CE. Even today, the sword remains a common symbol of the warrior as some modern militaries still wear swords with formal dress uniforms.
Source: Library of Congress, Prints & Photographs Division.

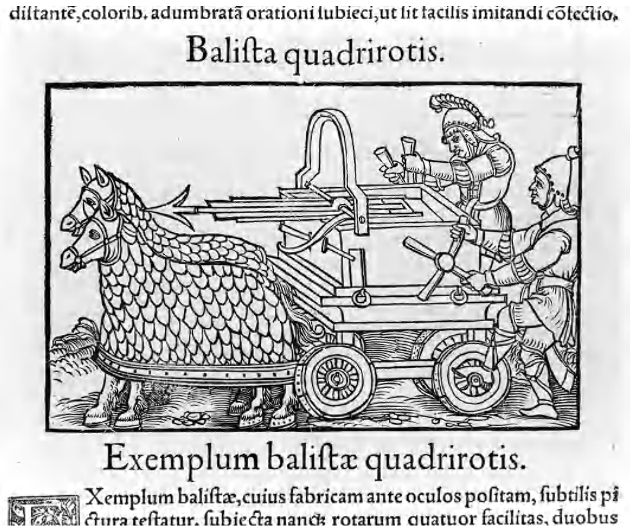
Early weapon development included the arrow, a small version of the spear that could be shot from a bow. Bows and arrows added distance, accuracy, and quantity since many arrows could be carried. By 8000 BCE, people throughout the world were using the bow and arrow and it remained a primary weapon of many cultures until the end of the 16th century CE. Western Pacific and South American cultures developed the blowpipe and dart, a weapon based upon human lung power. The blowpipe usually was made of a hollow reed and varied in length from a few inches up to 15 feet. Darts varied in size from 3 to 18 inches.

As nations formed armies and carried out warfare, weapons developed to give superiority on the battlefield. The chariot was developed in the mid-second millennium BCE. The chariot was highly effective against infantry on flat terrain because it provided maneuverability and a raised platform from which to employ weapons. The Chaldeans began using cavalry, a new development in tactics, around 1000 BCE.

With every weapon came a defense against it. The first known depiction of shields is found in Egyptian paintings from around 4000 BCE. Helmets appear around 2500 BCE, and scale armor made of small metal plates appears about 1000 years later. Around 300 BCE, the Celts invented chain mail, a fabric made of interlocking metal rings. The Romans used both chain mail and leather for armor.

By the Second millennium BCE, cities began to build enclosure walls in order to defend against invading armies. The Assyrians were the first people to build siege engines to counter wall defenses. By the 800s BCE, they had developed the battering ram, a wheeled engine designed to wedge between and pry out stones in a defensive wall. The Romans developed the catapult, a device capable of throwing a heavy object a great distance with good velocity and accuracy against or over a city wall. They also developed a ballista, an oversized bow that was capable of shooting very large arrows.

The ancient Egyptians, Phoenicians, and Greeks used specially designed ships in warfare. Most of these people fought from the ships using methods similar to those of land warfare or hand-to-hand combat. However, the Greeks developed ships with a bronze ram on the bow that could be used to puncture an enemy vessel.



Print from 1552 shows two Roman soldiers with a horse-drawn ballista. The device, mounted on a wagon, is manipulated like a crossbow, shooting large arrows at enemy fortifications. The horses are well covered with armor.

Source: Library of Congress, Prints & Photographs Division.

Medieval Weapons

Most medieval weapons simply tended to be improved versions of ancient weapons. The first leap in weapons technology came with the Chinese invention of gunpowder in the 800s CE. The Chinese used gunpowder to make incendiary bombs, which they tossed by catapult. They also used gunpowder to propel rockets. In the latter half of the 13th century, the Chinese invented the cannon, which fired projectiles from metal barrels. The first projectiles were arrows; later, shot began to be used. By the late 14th century, cannons reached Europe and became common weapons in warfare.

The oldest known handgun was found in Tannenberg (East Prussia) and dates to the second half of the 14th century. This gun was simply a small version of the cannon, measuring 12.5 inches long and weighing 2.5 pounds. It was fired by touching a lit match to its rear vent. Because the gunner held the gun under one arm and had to look at the match to fire it, aiming was difficult.

The first long arms were long versions of the handgun and appeared early in the 15th century. By the 1500s, improvements led to the mechanical firing gun, which could be aimed easier. The stock, wood attached to the barrel, began to be shaped to fit into the shoulder in order to absorb the recoil and to allow aiming the weapon with some precision. These developments led to the first flintlock muskets, which appeared in 1547 in Spain. By the mid-19th century, improvements such as rifled barrels, breech-loading cartridges, and the cylindro-conoidal bullet made the long gun both more accurate and faster to operate.

The "Little Boy" bomb was the first nuclear weapon used in warfare. It was delivered by the B-29 Enola Gay, *which is on display at the Smithsonian Institution's National Air and Space Museum. The bomb was detonated at an altitude of 1,800 feet over Hiroshima, Japan, on August 6, 1945. It weighed about 9,000 pounds and had an explosive force (yield) equal to about 20,000 tons of TNT.*

Source: U.S. Air Force.

The Venetians were the first to place cannons on ships. These were small in caliber and were used against personnel. By the mid-16th century, iron cannons were commonly mounted on heavy merchant ships. Nations soon learned that heavy merchant ships were not the best choice for warships, which needed to be light and fast. This led to the development of the specialized naval warship and professional navies.

Modern Weapons

Many modern weapons are improved versions of older weapons; however, several new weapons emerged with the 19th- and 20th-century technology explosion. Airplanes, tanks, machine guns, land mines, torpedo-firing submarines, and chemical weapons were introduced in World War I. World War II ushered in the use of rockets and the atomic bomb, which began the nuclear age. During the arms race of the cold war (1950s and 1960s), humankind became capable of total self-annihilation for the first time in history with the proliferation of nuclear-armed strategic missiles. Later 20th- and 21st-century testing includes space-based weapons, lasers, particle beams, and other sophisticated weapons.

Weber, Max (1864–1920)

Maximilian Carl Emil Weber was a German sociologist, political economist, lawyer, and politician. His early study of the sociology of religion, *The Protestant Ethic and the Spirit of Capitalism* (1904/1905, revised 1919/1920) is still regarded as one of his most influential works. In this book, Weber points to a new conception of time that emerges with the development of modern capitalism. Time becomes an economic quantity, a factor of human action, and an object of rationalization.

From 1882 to 1886, Weber had studied law, political economy, philosophy, and history in Heidelberg, Berlin, and Göttingen. After 1892, he held posts as a professor of economics at Freiburg, Heidelberg, Vienna, and Munich. He was politically active, and served as a member of the German delegation to the Peace Conference that concluded the Treaty of Versailles. Weber is considered to be one of the founding fathers of modern sociology and an influential analyst of modern society. Weberian concepts, such as those of the freedom from value-judgment (*Werturteilsfreiheit*), ideal types, and *Verstehen* (understanding), provided an important contribution to the methodology of the social sciences. At the center of this work is the question of the origins of modern capitalism. For Weber, the fundamental quality of capitalism is economic rationalism. The economy is determined by strict mathematical calculation aimed at the maximization of profit.

The thesis of Weber's investigation is that there is an intrinsic relationship between characteristics of the Protestant spirit and modern capitalism. Both share an ethic that sees acquisition as an end in itself, and not a means to the satisfaction of needs. Historically important for the formation of this ethic was the development of an idiosyncratic concept of vocation (*Beruf*) in the Reformation. Vocation is understood in the sense of a divine calling (*Berufung*). The fulfillment of this calling becomes an end in itself, a duty to be fulfilled in order to live a godly life. Worldly work thus experiences a positive revaluation in contrast to the Roman Catholic conception.

According to Weber, particularly responsible for the development of the modern capitalist spirit are the characteristics of ascetic Protestantism, such as Calvinism. The doctrine of predestination held here presents the psychological drive for the development of this particular ethic. According to the doctrine of predestination, one part of humanity has been predestined by God to eternal salvation, and the other to damnation. The fate of each person is therefore determined by God and not by one's own deeds. There is therefore no way to ensure or to attain the salvation of one's soul. This resulted in religious doubt and inner loneliness of the individual. In order to bear this doctrine, believers made it a duty to regard themselves as chosen and found, in unceasing work, a remedy against their doubts. Even though one's works could not lead to blessedness, they were a sign of chosenness. This drive for self-assurance led to a rational ethical way of life, a "worldly ascetism." Belief is preserved not in monasteries, but rather in worldly life, and belief finds expression in professional activity. The striving for profit is thereby regarded as intended by God, while the ascetic aspects of the movement work against the enjoyment of possessions. Vocational performance and wealth become mere ends in themselves. Finally, with the fading of its religious roots, the ethic described by Weber experiences its full economic effect. It is reflected in the bourgeois professional ethic and is an essential constituent of the modern capitalist spirit.

The demand for an ascetic and rationalized lifestyle affects the modern understanding of time. Weber shows how time is given a special place, particularly in Puritan doctrine. Only the continual exercise of vocational work accords with the will of God. Wasting time and resting content with one's property are, on the other hand, considered serious sins. Every lost hour is an hour lost to the labor that serves the glory of God.

This doctrine is reflected in the spirit of capitalism, which Weber illustrates with the example of Benjamin Franklin. Time is understood by Franklin to be equivalent to money. Wasting even just small amounts of time can mean a considerable reduction of capital in the long run, and prudence speaks against it. An adherence to deadlines demonstrates a constant creditworthiness. Time becomes a decisive factor in economic thinking. In contrast to the traditionalist, who aims at the mere satisfaction of his basic needs, the modern capitalist strives for a rationalization of time in order to increase production and accumulate capital. Time itself becomes a limited resource and therefore gains economic value.

Wegener, Alfred (1880–1930)

Alfred Lothar Wegener, a brilliant interdisciplinary scientist born in Berlin (Germany), was a meteorologist, geophysicist, and Arctic explorer who proposed the theory of "continental displacement," or what later was called "continental drift." According to this theory, the continents were once united into a single protocontinent, which he called Pangea. Over time Pangea broke up, and the pieces drifted apart into their present positions. Wegener died in 1930 when he was lost in a blizzard during an expedition to the Greenland icecap.

Alfred Wegener studied the natural sciences at the University of Berlin. He became interested in climatology and joined the 1906–1908 expedition to Greenland to study polar air circulation. In 1911 he published *Thermodynamik der Atmosphäre,* a standard textbook dedicated to the science of weather, and in 1926 he accepted a professorship in meteorology at the University of Graz (Austria). Although most of Wegener's life was spent in the study of the climates of the present and the past, his most notable scientific contribution was his hypothesis of continental drift. In 1915, after his participation in World War I, he published his continental drift theory in *Die Entstehung der Kontinente und Ozeane,* translated into English in 1924 as *The Origin of Continents and Oceans.*

Early 20th-century geologists viewed continents as fixed features that could rise and fall, but not move sideways. Given the difference in density between continents and the deep-sea floor, Wegener proposed that the continents floated somewhat like icebergs in the water. He believed that Pangea originated near the South Pole, and the centrifugal force of the earth's rotation caused its breakup 300 million years ago and the drifting of the resulting fragments toward the equator. The idea of a primitive Pangea arose with Wegener's observation that most of the continents seem to fit together like a jigsaw puzzle. For example, the West African coastline and the east coast of South America provide good evidence of that hypothesis. Searching for further evidence, Wegener found many similarities between the fossil record and paleoclimate between Africa and Brazil; Europe and North America; and Madagascar and India, today separated by oceans but previously united in the Pangea supercontinent.

The continental drift theory remained controversial until the 1960s, when the geologist Harry Hess proposed that the movement of the continents was a result of the existence of mantle convection currents. Geologists now call this process the plate tectonic theory. According to this view, the plates are composed of continents and ocean floor, and float on the asthenosphere. The oceanic ridges are divergent plate boundaries where the rising of magma has created new crust. At the areas where plates have collided, great mountain ranges such as the Himalayas and the Andes are formed.

Wegener's hypothesis was incorrect in certain aspects. For example, today we know that the continents are attached to the plates and do not move independently of them, and that mantle convection is responsible for the breaking and dispersal of these plates. Nevertheless, the continental drift theory can be regarded as a forerunner of modern and paradigmatic plate tectonics theory, and Wegener as an earth science visionary.

Wells, H. G. (1866–1946)

As a novelist, prophet, and gadfly, Herbert George Wells was one of the 20th-century's most multitalented writers. Born on September 21, 1866, in modest circumstances in Bromley, Kent, Wells narrowly avoided a life of penury and obscurity in the drapery trade his mother planned for him. He studied at the Normal School of Science at South Kensington (now the Royal College of Science and part of the University of London) under T. H. Huxley (1825–1895), and taught for a while before being able to earn a living as a writer. Wells's importance as a thinker has long been disputed, but few would deny his influence. Central to his thought was the seriousness with which he took evolutionary time and its implications for all living beings, including *Homo sapiens.* Indeed, Wells's work can be seen as the development of his understanding as to just how deeply and totally all living beings are determined by evolutionary time. His first published writing was a series of what were then known as scientific romances, now known as science fiction. The best of these works, *The Time Machine* (1895), *The*

Island of Dr. Moreau (1896), *The Invisible Man* (1897), and *The War of the Worlds* (1898) remain classics in their field to this day.

Common wisdom says that these works represent Wells at his best, but his writing career lasted another 45 years and included some very significant books. After the scientific romances, Wells moved on to novels about life, the best of which were *Kipps* (1905), *Ann Veronica, Tono-Bungay* (both 1909), *The History of Mr. Polly* (1910), and *The New Machiavelli* (1911). These novels can be read as insightful stories about human interaction and for their specific insights into the mores of Edwardian England. Wells then moved on to what he later called his prig novels: *Marriage* (1912), *The Passionate Friends* (1913), and *The Wife of Sir Isaac Harman* (1913). Less successful as novels, these books revolved around ideas of social reform and personal commitment to living one's life fully and in the public interest.

As it did for most people of his generation, the onset of the First World War produced a new range of conflicts that Wells felt the need to explore. While being suspicious of patriotism, Wells deeply loved England, and his wartime books, both fiction and nonfiction, reflected this tension. The best of his wartime works were *Mr. Britling Sees It Through* (1916) and *The Undying Fire* (1919). The war also brought on a short phase of quasi-mystical religiosity, expounded in *God the Invisible King* (1917), although Wells soon tired of that approach and returned to what he called in his autobiography "the sturdy atheism of my youth."

After the war, Wells embarked on a series of what have been called textbooks for the world. They were the hugely popular *Outline of History* (1920), *The Science of Life* (1931), and *The Work, Wealth, and Happiness of Mankind* (1932). Each of these was very influential despite a generally disdainful reception from the academic community. In each of these works Wells was concerned to place humanity in its natural setting and subject to the same evolutionary pressures of change and development as all other living things. He downplayed the role of great men in history and was suspicious of climactic events and turning points and other historical devices designed, in his mind, to flatter the so-called great men. Wells hoped these books would become tools by which people took control of their destiny and worked cooperatively toward a new planetary humanism.

Largely in the service of this vision, Wells produced a steady stream of novels. The most outstanding works from the interwar years were *Christina Alberta's Daughter* (1925), a study of the dangers of succumbing to transcendental fantasies; *Mr. Blettsworthy on Rampole Island* (1928), a black-humored dystopia about the breakdown of the Edwardian consensus about progress; and *The Bulpington of Blup* (1932), a comic look at human pretensions. *Mr. Blettsworthy,* in particular, deserves much more recognition than it has received, not least because it anticipated better-known dystopias like Aldous Huxley's *Brave New World* (1932).

Wells also became known in his capacity as a prophet of the modern age. He foresaw, for instance, trends such as the abolition of distance, nuclear war, suburbia, committed relationships outside marriage, even the Internet. He was also a strong proponent of the conservation of natural resources half a century before this became part of the cultural mainstream. Against this, as late as 1927, he was oddly unable to see much future for radio.

It is often claimed by Wells's detractors that he ended his days deeply disillusioned with the scientific rationalism he had spent his life advocating. His last work, *Mind at the End of Its Tether* (1945), is usually cited in this respect. This claim, however, is unjustified, because Wells was never the uncritical rationalist his critics make him out to be. Since his earliest scientific romances, Wells had been ambivalent about the power of science and notions of easy, unlimited progress that were commonly said to be the by-product of science. Indeed, the strength of those works lies largely in his powerful articulation of this tension. Wells's career was an ongoing reflection on humankind's capacity to use responsibly the power that science was handing it. This underlies the lasting appeal of his science fiction, and reappears periodically, as in *Mr. Blettsworthy.* What the reader gets in *Mind at the End of Its Tether* is Wells's pessimistic and realistic strands interweaving with each other, and his more optimistic strand playing second fiddle.

Wells continued to produce engaging work until the last years of his life, highlights being *The Brothers* (1938), *The Outlook for Homo Sapiens* (1939), and *You Can't Be Too Careful* (1941), his last novel. During the Second World War, he was instrumental in composing a Universal Declaration of Human Rights, which exerted an influence on Eleanor Roosevelt's work to formulate the United Nations's Declaration of Human Rights. Wells died on August 13, 1946.

Werewolves

The legend of the werewolf is a legend that transcends cultures and speaks to a perpetual human fascination with shape-shifting, lycanthropy, and the personal battle framed in terms of good versus evil. According to the tradition, werewolves are human beings who shape-shift into bestial wolf form. Although these transformations can be intentional and purposeful, common legend holds that werewolves are under a spell or curse caused by the bite of another werewolf. The modern werewolf story, derived from legendary sources, has changed significantly over the centuries.

The word *werewolf,* traced to its 11th-century Anglo-Saxon origin, means "man wolf." One of the oldest references was captured by the Roman poet Virgil who, in his eighth *Eclogue* (42–37 BCE), tells a story of voluntary transformations of humans into wolves, achieved by means other than being bitten by another werewolf. In Ovid's *Metamorphosis* (8 CE), the god Jove punished King Lycanon of Arcadia with bestial transformation. Later still, in the *Satyricon* by Petronius (27–66 CE) we read of a werewolf that sustains bodily wounds that remain even after the transformation back to human is complete.

Over time, as is typical of legends, the characteristics of werewolves have changed; modern writers have created new creatures that resemble but are in varying degrees different from the earliest described werewolves. The werewolf was popularized in the 1941 film *The Wolf Man;* writer Robert Siodmak reduced centuries of myth and folklore to represent what are now popular cultural beliefs. In his rendition, the werewolf was an innocent victim who was cursed through a werewolf attack. Other beliefs include the following: Werewolves change shape from human to a wolf at the coming of each full moon; in the werewolf state, the human is unaware of his or her actions and loses consciousness of time; in this condition the werewolf enacts the hunt and slaughter of innocent humans, whether for sport or for sustenance. Injuries that a werewolf sustains while in wolf form linger even in human form. A werewolf is repelled by wolfsbane, which is an attractive but poisonous perennial herb of the buttercup family. Werewolves can live eternally. Silver bullets kill werewolves, who then return to human form upon death.

White, Leslie A. (1900–1975)

Leslie A. White was an American anthropologist well-known for his theories of sociocultural evolution, studies of the Pueblo peoples, and his neoevolutionary stance. He revived and expanded the theory of evolution in anthropology, especially in terms of the origin and development of sociocultural aspects during the emergence of our species over millions of years. In doing so, his sweeping temporal orientation supplemented the merely structural and functional approaches to cultural anthropology that were offered during the first half of the 20th century. It was no coincidence that White's major work, *The Evolution of Culture,* was published in 1959, the year that celebrated the centennial of the appearance of Charles Darwin's *On the Origin of Species*. White's own cultural perspective encompassed a technological focus that spanned from the Stone Age, through the coming of agriculture, to the emergence of civilization and the Fall of Rome.

Born in Salida, Colorado, on January 19, 1900, White grew up in rural farming communities in Kansas and Louisiana and joined the U.S. Navy in 1918. Initially interested in the physical sciences, White was affected deeply by his involvement in World War I, and began studying psychology at the University of Louisiana and then later at Columbia University in New York where he earned his BA (1923) and MA (1924). Coincidentally, this was the same university where Franz Boas, his foremost opponent, was teaching, and it would be under one of Boas's pupils that White's interest in anthropology would be nurtured.

White earned his Ph.D. in sociology/anthropology from the University of Chicago in 1927; during this time he was able to spend some time among the native peoples of America such as the Menominee, Winnebago, and finally the Pueblo. Afterward, White taught at the University of Buffalo, N.Y. until 1929, then the University of Michigan, where he taught until 1970. His remaining years were spent at the University of California at Santa Barbara until his death on March 31, 1975, in Lone Pine, California.

Though he initially wrote in the Boasian tradition, White became enamored of the works of Lewis Henry Morgan, Herbert Spencer, and Sir Edward Burnett Tylor. These three writers all appealed to White's own views of sociocultural evolution. White would write some of his later works specifically on Lewis Henry Morgan, including *Excerpts From the European Travel Journal of Lewis Henry Morgan* (1937) and *Pioneers in American Anthropology: The Bandelier-Morgan Letters* (1940), which earned him a reputation as one of the world's leading scholars on Morgan. At the time, these were not the most popular anthropologists for students of the Boasian tradition because of their reliance on assumptions and judgments made without benefit of measurable information. White revitalized their ideas into what was characteristic of a neo-evolutionist.

His theory of sociocultural evolution relies on the importance of technology. Without technology, there would be no social systems. In fact, White measured progress not by the level of technology that was being used, but rather by the amount of energy per capita that was being produced by the technology. In this way, White was not merely echoing the evolutionists of the 19th century, but rather updating them.

The formula that White used to represent this theory was "$C = E \times T$," where C is equal to the level of cultural development, E is equal to the amount of energy consumed per capita per year, and T is equal to the efficiency of the technology being utilized. Simply put, the progression of a culture relies upon the increase of energy employed, or by the increase in efficiency of the technology.

Like Morgan, White was quick to point out stages of technology that indicate development. On the lowest level are energy and power provided by one's own muscles. The next step up is the use of domesticated animals to help provide energy. The third stage is marked by the use of plants (i.e., agriculture). After this stage is the one White believed the current populace was in: the use of natural resources (i.e., coal, gas, oil). The next step, which White thought was only a matter of time, was the use of nuclear energy.

Because he placed his emphasis on technology and not on areas important to other cultural evolutionists, White was constantly criticized. This emphasis upon materialism led many to believe that White was ignoring other aspects of culture. Culture, though, was a general phenomenon to White, and it operated as a superorganic entity, as it did in Spencer's ideology. Furthermore, culture rested on technology and, in turn, ruled over both the sociological and ideological spheres he had further divided culture into. In response to his critics, White underlined the importance of technology again and laid out quite simply its importance for survival and its ability to help harness energy for human needs. Logically, he concluded that those who harness more energy are at an advantage over other societies, and that must mean they are more advanced in terms of evolution.

White considered himself to be a culturologist (a scientist dedicated to observing and studying culture), rather than what he termed the other two remaining scientists: biologists and physicists. His major works, *The* Science of Culture (1949) and *The Evolution of Culture: The Development of Civilization to the Fall of Rome* (1959), remain classics in the field. It is in *The Science of Culture* that White first introduced the relationship that exists between culture and technology. *The Evolution of Culture* posited White's belief that culture is still evolving, and that cultural development continues to rest on both the technological and the material adjustments of humans to the natural world. His last work, *The Concept of Culture* (1973), was published during his stay at the University of Santa Barbara, and reiterates the inseparability of culture from both human evolution and human sociability.

White's revolutionary counter viewpoints on Boasian tradition in cultural anthropology earned him both reverence and contempt from colleagues. Further outbursts from White, including his acceptance of socialism, scorn for theism, and praise of the former Soviet Union as being more technologically advanced than the United States, severely limited any hopes of advancement for his career. However, his works were the precursor of future studies to be performed in biophysics, and also ecological economics that would develop in the late 20th century. His works would also serve as the backdrop for further expansion by Gerhard Lenski, a sociologist famed for his contributions to ecological-evolutionary social theory.

Leslie A. White's thought and theory have influenced generations of anthropologists. The current emphasis on emerging technology makes his ideas particularly relevant.

WHITEHEAD, ALFRED NORTH (1861–1947)

Alfred North Whitehead was born in 1861 in Ramsgate, England. He was a professor of mathematics in Cambridge (U.K.) and London until his 63rd birthday. In 1924 he accepted a chair in philosophy at Harvard University. In the following years, until his retirement in 1937, he developed one of the most impressive philosophical cosmologies of the 20th century. Whitehead's main philosophical work, *Process and Reality,* forms the basis of process philosophy. His academic career can be divided into two distinct periods: his natural-scientific philosophical period and then his metaphysical period. Whitehead died in Cambridge, Massachusetts, in 1947.

Bifurcations

The natural sciences are concerned only with nature, that is, with the object of perceptual knowledge, and not with the synthesis of the knower with the known. The sciences are not concerned with reasons of knowledge but rather with a coherent explanation of nature. This point of fact led to the bifurcation of reality. Whitehead delivers two similar formulations of such bifurcations, both of which he rejects categorically: (1) The distinction between events of nature and events as they are formulated in scientific theories, and (2) the distinction between events of nature as they exist by themselves and as they appear to us.

The first concept maintains a purely conceptual existence of physical entities, such as atoms and electrons. On the one hand, there were phenomena, and on the other hand, logical terms of scientific formulae. For Whitehead, scientific concepts are derived, by way of logical abstraction, from nature. He argues against the bifurcation of reality into the mathematical world and the apparent world. Concepts, as far as they are true, refer directly to facts of reality.

The second formulation of bifurcation is a direct consequence of the first one. Historically, after separating the realm of apparent nature from the realm of its physical description, John Locke asked how both realms could be connected. Isaac Newton developed a kinetic theory of atoms but did not explain how unperceivable atoms in absolute space and time are connected with our spacetime experiences. Locke realized that moving particles can only set other particles into motion, and that they do not produce the quality of redness. Therefore, he thought that there are secondary qualities not in the things themselves but that are, rather, psychological additions of a mental substance. In addition to the first bifurcation between scientific object and sensory perception, a second bifurcation appears between sensory perception and reality itself. This results in the banishing of the observer from nature. Thus, the observer can have knowledge only of his sensory impressions but not of the objects that produced them. The knowledge of reality now requires a theory.

Perception

To avoid these bifurcations, one has to consider the origin of every possible source of knowledge. Whitehead regards this origin as being in everyone's daily experiences and these experiences are the direct starting point for the British empiricists: First, every experience has its origin in perceptions. Second, the primary ideas of perception join secondary ideas deduced by reflection in order to put the sense data into an order. In addition to these two starting points of the British empiricists, Whitehead integrates psychic impressions like emotions, beauty, love, and satisfaction, among others.

If Whitehead had restricted himself to the theory of perception of the British empiricists, he would be subjected to the false conclusion that reality is constituted out of static and isolated substances. But relations do not fit into a substance philosophy. Whitehead can do justice to relations in sensory perception due to the broadening of the theory of perception by the mode of causal efficacy. He realized that sensory perceptions take place only in symbolic reference and that the two modes of sensory perception, presentational immediacy and causal efficacy, are abstractions from symbolic reference. Perceptions in presentational immediacy depend on the spatial relationships between the perceiver and the sense data, while temporal aspects are totally ignored. If all knowledge is traced back to perception at a moment, one cannot have empirical knowledge of relations, nor of the continuum of reality. Contrary to David Hume and Immanuel Kant, Whitehead finds evidence for causal connections and temporal continuity in sensory perception. He asserts that one can perceive them directly. He tacitly assumes the experience of temporal and spatial extension. Temporally adjacent events are perceived directly in a temporal window of perception: the "specious present" (William James). It is perceivable that later events confirm earlier ones. We have knowledge of an extensive continuum of reality because of our perception of spacetime relations. The specious present contains not only immediately observed events; it also includes the immediate past. The presence of immediate past events shows that present and future events have to confirm earlier events in the same way that immediate past events had to confirm more distant past events. Causality in Whitehead's philosophy means that we never perceive a series of events alone, but that later events must emerge from earlier events in the specious present. Perceptions in causal efficacy contain the temporal aspects of the process of reality.

Sensory perception takes place only in the complex mode of symbolic reference connecting the pure modes of presentational immediacy and causal efficacy. As a result of the fusion of the two pure modes of perception, perception in symbolic reference causes errors and misinterpretations. Normally, the pure modes of perception are not identically illustratable in terms of each other. Symbolic reference is an active synthetic element of the perceiver, producing emotions, convictions, and beliefs concerning other elements of reality.

Time

Within each period of his philosophical development, Whitehead expresses the idea that space and time do not exist independently. Spacetime cannot in reality be considered as a self-subsistent entity. It is an abstraction whose explanation requires reference to that from which it has been abstracted. In his natural philosophy, the real world is an extended, continuously flowing process. Later, in his metaphysical period, space and time are seen as abstractions from extended events and are to be experienced empirically.

Time in Whitehead's Natural Philosophy (1914–1925)

An entity is an abstraction from the totality of the continuously flowing process of reality. Temporally extended events do not exist independently. They are parts of an extended nature and have the duration of the specious present of a perceiver. What scientists accept as elements or parts of the whole are actually abstractions. In reality, the elements exist and have meaning only by virtue of the whole and vice versa. Therefore, time does not have any reality in nature but is the property of a perceiver. The reality is characterized by an extensive spacetime continuum. Durations are arbitrary elements that are simplified by abstraction. Any duration is part of other durations; thus, every duration has other durations that are parts of it. Accordingly, there are no maximum or minimum durations. Therefore, there is no atomic structure of durations, and the perfect definition of a duration is an arbitrary postulate of thought. Sensory awareness posits durations as factors in nature, but events in nature do not have any reality independent of a consciousness and do not have definite temporal extensions. Time relations are an expression of an ordering relation by a perceiver. Spacetime is nothing other than a system for the pulling together of assemblages into unities. Physical time deals only with certain formal, relational aspects of our changing human experience. Relative to other abstractions, space and time offer a comparatively simple structure, which is suitable as a basis for objective distinctions in reality. This simplicity is probably the reason why thought chooses them as the permanent ground for objective distinction.

During the specious present one perceives a unit already separated into its parts by the activity of the perceiver. The parts entertain certain characteristics, of which time and space are examples. The common structure of spacetime conforms to the uniform experiences of sensory perception. But the unity of sensory perceptions does not exist without problems. It is not clear how one can proceed from individual experiences to a uniform spacetime structure. Whitehead confesses that what he has termed the "uniformity of the texture of experience" is a mere illusion. This uniformity does not belong to the immediate relations of the crude data of experience but rather is the result of substituting for them more refined logical entities. This process of lifting the uniform time and space of the physical world into the status of logical abstractions takes the extremely fragmentary nature of all direct individual conscious experience into account as well. All speculation must start with individual experiences as its sole data. It is untrue that we are directly aware of a smoothly running world. If Whitehead accepts that reality is a continuously flowing process, then he will have made no progress in his natural philosophy concerning Kant's concept of time. Temporality of perception is not sufficient to account for causality and time as real properties of nature.

The Epochal Theory of Time (1925)

The transition from momentary events to extended actual occasions is initiated not only by the knowledge that perception takes place in the specious present and that causal interactions are directly perceivable. It is also a result of logical difficulties within physical theories and metaphysical outlines. Physical descriptions of dynamic processes like impulse, velocity, and tension and the descriptions of simple physical structures like atoms, or biological organisms, presuppose the existence of temporal events. In addition, becoming is possible only if reality is constituted out of temporal, atomic events. Becoming and continuity are incompatible, according to Zeno of Elea. Here, Whitehead shows that momentary events can be deduced out of extensional events by means of the method of extensive abstraction, one of his central ideas. All these points forced him to conclude that reality is not founded on momentary events, but rather on temporal, extended events.

Despite the fact that Whitehead probably never became acquainted with the post-1924 development of quantum theory, first results motivated him to transfer the new knowledge of philosophy and psychology to all events of reality. In particular, Bohr's model of the atom in 1913 and de Broglie's wave theory in 1924 resulted in a critical examination of his natural-philosophical starting point.

From now on, the particles of reality are no longer material, static forms but spatiotemporal extended events. The change from materialism to Whitehead´s organic realism is characterized by the displacement of the notion of static stuff by the notion of fluid energy. Such energy has its structure from action and flowing and is also conditioned by quantum requirements. Whitehead got his inspiration from scientific discoveries, without necessarily going into their specific formalism. His doctrine of the epochal character of time depends on the analysis of the intrinsic character of an event, considered to be the most concrete, finite entity, which he calls the "actual occasion." But to avoid any bifurcations, a perceiving consciousness may no longer be an exception outside nature. Whitehead's metaphysics is a consequent transition of the internal experiences of human beings to all entities of nature. Every actual occasion has to be a factor equal to other factors residing within the fact of nature. Therefore, they present a physical and a mental pole. This means that an actual occasion shares in the character of being both a physical and a mental occasion. Every internal aspect of time has an external time aspect as an equivalent. In the epochal theory of time, Whitehead unifies four different time aspects one finds in the experience of an actual occasion. There are two internal and two external aspects. The internal time aspects are the passage of thought (becoming and perishing, retentions), and the experience of extension (unlimited act, inner time consciousness, retentions, and protentions). The external time aspects are the potential physical time (extensive continuum), and the actual physical time (passage of nature, becoming and perishing). Experience of extension corresponds to potential physical time; and the passage of mind corresponds to the passage of nature.

The physical concept of time unifies the experience of an extensive continuum and the perception of concrete, actual occasions. It unifies the discontinuity and continuity of the external world into one concept. The physical pole is extended over the whole spacetime continuum and can be divided. The spacetime continuum is derived from this coordinate divisibility.

In contrast, the mental pole does not share in the divisibility of the physical pole. The mental pole has its equivalent in a thought of the mind. It is an act of attention that has the duration of the specious present. The passage of mind is confronted with the experience of an unlimited temporal act in the internal time concept.

An actual occasion is the product of the interplay of the physical pole with the mental pole. In this way, potentiality passes into actuality, and extensive relations mold qualitative content and objectifications of other particulars into a coherent, finite experience. Every actual occasion is a spatiotemporal unit possessing an indivisible volume and time quantum. Coordinate divisibility shows that each actual occasion is composed of a number of subordinated actual occasions. Actual occasions express the uniform spacetime structure of the universe because their external relations fit them into superordinate actual occasions, and their internal relations, the coordinate divisibility into subordinate actual occasions, merge them into an extensive continuum. The spatiotemporal extensive continuum is the general structure to which all actual occasions must conform.

If one takes into account that the actual world is built up of actual occasions that have different temporal extensions that overlap each other, and that one perceives this world in the specious present, one is able to perceive causal connections directly. One can recognize the development of actual occasions on their historical routes and realize how an actual occasion passes and a new one becomes.

Physical time, physical space, and creative advance are abstractions that presuppose the more general relationship of extension. The extensiveness of space is really the spatialization of extension; the extensiveness of time is really the temporalization of extension. Physical time expresses the reflection of genetic divisibility into coordinate divisibility.

The assignment of the different time aspects to the final units of reality becomes possible through the transformation of the natural philosophical concept of momentary events into actual occasions. While in Whitehead's natural philosophy the events still depend on the activity of a perceiver, actual occasions are in his metaphysics the final units of reality. They are the real things of the world and have their own being. They are not momentary cuts through reality but rather forms that have the properties of spatiotemporal extension and creativity. The temporality of the actual occasions determines what time is. Physical time is an abstraction from this temporality.

White Holes

White holes are the theoretical time-reversal opposites of the astronomical bodies known as black holes. In 1916, Karl Schwarzschild used Einstein's general theory of relativity to derive the first model of a black hole. The negative square root solution of the Schwarzschild model of the spacetime continuum provided for the existence of white holes. Since general relativity is time symmetric, the purest definition of a white hole is a black hole running backward in time. The complete Schwarzschild model includes a black hole, a white hole, and two universes connected at their horizons by a wormhole.

The time reversal action of white holes provides for a difference in behavior from black holes. Black holes are known for their high gravitational forces that prevent any matter from escaping the pull of the forces. Because white holes are understood as black holes running backward in time, white holes will repel matter while black holes make matter disappear. In astrophysics, a white hole is postulated to be a celestial body that spews out matter, perhaps because the white hole is a collapsed area of space that is expanding, thus putting matter back into space as it expands. Other researchers theorize that white holes eject matter from the event horizon while black holes absorb matter at the event horizon. However, this behavior is not affected by the time reversal of the entities so it is theorized that both white and black holes attract matter, with the difference in action occurring at the event horizon. Physicists who specialize in relativity generally agree that white holes are essentially time-reversed black holes from which particles must exit but cannot enter. Following on this, a black hole can become a white hole with negative time when the direction of time is reversed. Using the theory of general relativity, one can hypothesize that a rotating black hole in a specific part of the spacetime continuum can be attached to the same hole in another part of the spacetime continuum where, depending on the observer's location, it can appear as a white hole. The existence of white holes expelling matter provides a response to the question of where the matter that is sucked into a black hole ends up. If black holes take in matter, their corresponding white holes expel matter.

In 1962, John Wheeler theorized the Einstein-Rosen bridge as spacetime-matter metric, which involves a wormhole acting as a bridge to connect two universes. The wormhole acts as a shortcut through space and time to allow travel between the two universes. This occurs in areas of space located in the center of a black hole and a white hole. The Schwarzschild model discussed above supports this theory.

White holes are highly theoretical, however, because they cannot be observed, and black holes are difficult to locate because they absorb all light. In addition, white holes violate the second law of thermodynamics, which states that heat moves naturally to a region of low temperature from a region of high temperature, but white holes, by their definition, do not run out of heat or mass. Opening our minds to the possibilities of other universes allows us to consider universes that operate differently than ours. Perhaps the second law of thermodynamics does not apply beyond our universe; thus white holes could indeed exist.

William of Conches (1080–1154)

William of Conches (Guillelmus de Conchis), a commentator on the philosophical works known to the first half of the 12th century, is one of the major figures in the circle around the famous school of Chartres. On the topics of time and eternity, William is interested in fine distinctions. Thus, he discusses the different meanings of *eternal* (*aeternum*), *sempiternal* (*sempiternum*), and *perpetual* (*perpetuum*). According to him, the first expression designates something without a beginning and without an end (i.e., God), the second something with a beginning before time but without an end (i.e., the world), the third something without an end but with a temporal beginning (i.e., the human soul). The last two definitions show problems typical of a Christian Platonist, whereas his ancient pagan predecessors had no need of such a distinction because of their assumption of the eternity of the world and of human souls, which migrate from one body to the next one.

While commenting on Plato's *Timaeus* 37c–38b, William defines eternity and gives no fewer than three definitions of time: Eternity, "the presential state of everything what is, what was and what will be," is reserved to God alone, such that he had to create an image of that eternity when creating the material world. This image, time, can be defined in a general way as "the dimension of duration and movement of the changeable things." This definition, which is borrowed verbatim from John Scotus Eriugena, is "general" (*generalis*), according to William, because it designates time both as a whole and regarding its parts. The second definition is "time is that space which has begun with the world and will end with the world." This definition, which William ascribes to the *Timaeus,* is "total" (*totalis*), because it concerns only time as a whole (*totum*). The definition in Cicero's *De inventione,* "time is a certain part of eternity, i.e., of that large space, with the signification of the certain space of a day, a night or a month" (which is discussed also by William's contemporary Peter Abelard) designates, according to William, only the parts of time that in his mind, however, exist in reality (and not only in human language, as Abelard puts it). The difference between eternity and its image, that is, time, is precisely that time consists of a succession of moments, whereas in eternity everything is comprehended at one time (*comprehendetur simul*). By distinguishing two meanings of "day," William attempts to eliminate the difficulty that time is created, according to Plato, at the moment of the creation of the world, while the Bible presupposes that there were already days when God started the process of creation: According to William, the Book of Genesis meant by "day" the span of 24 hours, while Plato meant the determination of the day as the span of time between sunrise and sunset. William can be regarded as one of the first representatives of Christian Platonism in the Scholastic period; similar ideas can be found in many Christian philosophers with a Platonic standpoint up to Nicholas of Cusa (Cusanus).

William of Ockham (c. 1288–1347)

William of Ockham was an English Franciscan friar and philosopher who argued that only individuals exist, not essences or forms, which have no existence apart from the human mind. Ockham's theory of time is an application of his general principle that entities should not be multiplied unnecessarily. Thus, the soundest argument is one that rests on the fewest assumptions, factors, variables, or causes; this principle is still commonly referred to as "Ockham's razor." According to this principle, Ockham acknowledges only a nominal definition (*definitio quid nominis*) of time, not a real one. That is, the word *time* does not signify a particular thing, but just the continuous movement of the heavens. Insofar as that movement can be measured, time also signifies (*consignificat*) the human mind and its activity of ordering things as occurring earlier or later.

Ockham stresses that in order to recognize time, it does not suffice just to be aware of some change; rather, change has to be understood as motion (*motus*), as a continuous process in which the particular instances of change happen. Thus, directly (*in recto*), "time" signifies a processual, continuous motion, and indirectly (*in obliquo*) the awareness of that motion in the human mind. By identifying in this way time and motion, which are distinguished only by activity of the mind, Ockham leads the medieval predilection for defining time via movement as an equivalent of time to its ultimate consequence: While most thinkers before him identified the "matter" of time with motion but granted to it a form of its own as did Albert the Great, Ockham denied that time even had a separate existence in this restricted sense. Consequently, he also denies that the sentence "time is a thing being (*tempus est ens)*" is true in the sense of "time exists"; rather, it is true only by virtue of the truth of other sentences concerning the existence of past time, of present time, and of future time. In reality, however, only the actual moment (*instans*) exists. All prior moments no longer exist, and all future moments do not yet exist; they are "a pure nothing" (*purum nihil*). Because of this, an activity of the mind is necessary to bring about that successive motion that we call time: Our mind is able to recognize things that it itself imports (*importat*) into the world, such that they exist in a certain way outside of the mind (*extra animam*), but due only to the mind's activity. This holds true for past and future moments of time, which do not exist in themselves but whose potential existence as moments that have been and moments that will be can be actualized by our cognition, such that we grasp the continuous succession of such moments, which we call time, though all but one of its elements actually do not exist and especially not apart from things in the process of change. This interpretation of Aristotle's statements in the fourth book of his *Physics* relies heavily on Averroes's interpretation of the same texts, which are quoted frequently in William of Ockham's treatise on time.

WINE

Throughout the ages, wine has served a variety of purposes. From religious ritual to everyday consumption, this fermented liquid has been a mainstay in various cultures, primarily in the Mediterranean region of the world. Not only does the production and consumption of wine have a long history, but time is also a key factor in improving the quality of wines.

Origin

The beverage wine was most likely stumbled upon by accident and not intent, given that the end product is just a specific point in the natural cycle of grape spoilage. Grape cultivation for the purpose of wine creation began no later than 4000 BCE, and perhaps as early as 8500 BCE, during the Neolithic period. The first activity of this kind is known to have taken place around the Caspian Sea, near the modern-day nation of Iran.

Basic Necessity

Wine has been produced in one capacity or another for well over 6,000 years. Since its discovery, wine has served as a delectable beverage with all the attributes associated with liquids that are alcoholic in nature. Throughout most of that time, however, wine has also been considered a basic necessity for the survival of various peoples. In regions with tainted or unreliable sources of water, the stored product of fermented grapes provided a stable and untainted source of hydration. In addition to serving as a necessary means of hydration, wine has also provided those who consume it with beneficial polyphenolic flavonoids, more commonly known as antioxidants. Wine is also laden with sugars, and therefore calories, making it nutritionally beneficial as a source of energy. In addition, moderate quantities of alcohol have recently been proven to benefit the cardiovascular system and enhance blood circulation.

Religious Connection

For thousands of years, wine has served a variety of cultures and religions in their divine worship. Greek libations to their gods often involved the pouring of wine. In Judaism, a kiddush blessing on Shabbat is required to be spoken over wine, if possible. Similarly, it is customary to drink four cups of wine during the course of the Jewish celebration of Passover.

All Christians use wine for similar yet markedly different reasons, depending on their denomination or sect. Roman Catholics believe the wine to be changed, literally, into the blood of Christ during the weekly rite of the Eucharist, while most Protestant denominations hold wine as an important, more symbolic link to their Creator. Until the mid-19th century, all Protestant groups relied on wine, much like their fellow Christians. Thomas Bramwell Welch, a Methodist minister, applied pasteurization techniques to stop the naturally occurring fermentation of grape juice into wine. Since then, most Protestant churches in the United States have switched to rites held with grape juice, keeping the "wine" name in accordance to scriptural reference. During America's prohibition days of the early 20th century, wine was allowed to be produced and used in the Mass and also domestically for religious ceremonies. Islamic law prohibits the usage of alcoholic beverages. As a result, wine is forbidden to Muslims.

History

From its earliest origins through the present, the uses of wine have varied in keeping with the nature of the society and the times. Little is known of the societal implications of wine for those in the Caspian Sea and Mesopotamian region about 4000 BCE and before. However, during the late Uruk period within Mesopotamia (ca. 3500–3100 BCE), it is known that the upper classes were enjoying this aromatic and palatable drink.

Wild grapevines never grew in ancient Egypt. Yet by the beginning of the Old Kingdom period (c. 2700 BCE) several wines found themselves on a canonical set of provisions for the afterlife of rulers and the elite. In an era when the afterlife was more tangible than spiritual or ceremonial, wine was seen not as an all-powerful magical elixir, but rather as a staple on the "menu" of nutritionally sound consumable goods necessary for one's existence in eternity.

Around 1000 BCE, the Romans began to make substantial contributions to viniculture by applying an empirical method to their harvest. Romans began to observe and take note of the characteristics associated with the ripening of grapes, as well as classifying the grapes into different colors and varietals. Equally as important, they began to identify diseases associated with the cultivation of grapes, and also recognize the types of soil in which the specific varietals thrived or withered. To increase their yield, Romans also began to prune their vines so as to eliminate potential threats from within, while simultaneously initiating irrigation and fertilization techniques. In addition, during this era of Greco-Roman influence, wine storage began to shift from clay jars and animal hides to glass bottles, this serving to increase the life expectancy of a batch of wine.

Points of Reference

The oldest written account of viniculture is referenced in the Hebrew Bible, with Noah planting a vineyard for the purpose of producing wine. In Europe, wine often takes the name of the region in which it is grown; for example, Burgundy, Chianti, Bordeaux, and Champagne. Varietal (specific grape type) names are often associated with New World producers, or with vineyards in countries outside of Europe. Examples of varietal names include Riesling, Merlot, Cabernet Sauvignon, and Sangiovese.

"Sometimes wines" can be produced from the fermentation of fruit other than grapes (e.g., plum, strawberry). They often cannot be specifically referred to as simply a wine, since the word *wine* can often legally refer only to beverages made from the fermentation of grapes.

The cuisine being served is often taken into consideration when pairing wine with a meal. As a general rule, white wines are served with lighter entrees such as seafood or chicken, in order to complement and not overwhelm the meal. Given the generally hearty and robust characteristics associated with red wine, it is often paired with stronger tasting red meats, such as beef. Thomas Bramwell Welch, a staunch prohibitionist in the United States, introduced pasteurization to grape juice so that it did not naturally transform to wine. He is also a founder of the Welch Grape Juice Company, one of the largest fruit juice producers in the world.

Wine is often erroneously stored beyond its peak. More than 80% of wine sold worldwide is meant to be consumed within 1 to 2 years of its corking, so as to prevent overmaturation. Only a select few wines, such as a port, are suitable for aging decades or even longer. Today, rare and prestigious vintage wines are among the most expensive consumable products available. A bottle dating to the late 18th century sold for $160,000 in 1985, and it is not uncommon for some premium vintages to fetch above $10,000 per bottle.

Given the relatively new trend in collecting wine, the temptation to engage in the business of wine falsification and deceit has proved irresistible, and lucrative, for an unscrupulous few. Incidents have been reported of master forgers creating or altering wine labels and even bottle contents so that they are nearly identical to ultra-rare vintages, the result being an overvalued falsity.

Witching Hour

The phrase "the witching hour" refers to the general time of night when, according to popular lore and superstition, spirits of the dead, as well as a variety of other supernatural beings ranging from ghouls to witches, are said to wander the earth and are at the peak of their fiendish strength and devilish effectiveness.

The term may be found in both an 1831 introduction to Mary Shelley's classic novel *Frankenstein* (1818) and Washington Irving's famous tale *The Legend of Sleepy Hollow* (1820) before Ichabod Crane has his fateful encounter with the spectral Headless Horseman. In other forms, the term can be traced to Shakespeare, who uses the phrase "the witching time of night" as a means to set the spooky scene for Hamlet's first attempt at the murder of the conniving King Claudius. Interestingly enough, Hamlet also meets with the ghost of his father at the hour of midnight, the predominant time the witching hour is said to begin.

Historically speaking, the idea of the witching hour, or perhaps as it was more suitably thought of, a time when the unnatural and unorthodox were given free rein, may have arisen from later Roman history when members of pagan cults were persecuted by newly Christianized Romans for carrying out their rituals under the cloak of night when most respectable Roman citizens would be fast asleep. In fact, many neopagans confirm that a true witching hour occurs only at midnight on a full moon. The reasoning behind this seems to stem from the belief that the aura that surrounds the moon is a harbinger of change, and also that the lunar aura carries an apogee of power when the moon is at its fullest. The moon goddess (in her Roman name, Diana) has long been associated with witchcraft and is still worshipped by practitioners of earth religions and other neopagans (or, as some people like to refer to them, witches, but more properly Wiccans) today.

Further speculation upon the correlation between witches and the witching hour would reveal that the typical witches' Sabbath time is around midnight. These particular scenes of the witches' gathering have often been shown in the theater to be at night, with conditions that meet the idea of the witching hour, usually depicting a full moon in the background. One excellent representation of this is in the film *The Crucible,* based upon Arthur Miller's play of the same name. Set at the time of the Salem witch trials, the opening act depicts a nighttime witches' Sabbath in which local teenager Abigail Williams kills a chicken as a sacrifice, aspiring to attain the happily married John Proctor's love through magic.

The temptation of Dr. Faust by Mephistopheles also occurs during the midnight hours, and elements of the witching hour are immortalized later during the Walpurgisnacht (the Witches' Night) scene in Johann Wolfgang von Goethe's *Faust* (1808). Walpurgis Night is the time, according to German folklore, when witches gather upon the Brocken summit of the Harz Mountains in northern Germany to celebrate the coming of spring; this holiday is held during the night of April 30. During the midnight hour of Walpurgis Night, similar to a belief in America (except the date is changed to Halloween), it is said that Satan himself is able to walk the earth due to a weakness in the barrier separating the living and the dead.

The exact time of night that the witching hour is said to begin varies, even though the witching hour is traditionally said to begin at midnight. Depending on how modern the interpretation, it can either begin later than this time, or simply begin at midnight and last until another particular time.

The 2005 movie, *The Exorcism of Emily Rose,* has popularized the witching hour as beginning at 3:00 a.m., when the titular character becomes possessed by demonic entities. In the film, the Catholic priest who is given the task of expelling the demons calls 3:00 a.m. the "demonic witching hour," and he explains that this particular time is a chance for the evil forces to ridicule the Holy Trinity, and also to play upon the traditionally accepted hour of Christ's death, the so-called miracle hour, or 3:00 p.m. Some paranormal investigators have reported that 3:00 a.m. is associated with an increase of phantasmal and psychic incidents, possibly attributable to the influence of the movie on the public imagination.

Woolf, Virginia (1882–1941)

Virginia Woolf is one of the major British writers of the 20th century. Mainly known for her novels, Woolf was also a proficient reviewer, essayist, diarist, and writer of letters as well as an influential publisher. Her novels and essays combine psychological, philosophical, and political insights with great literary craft and an experimental style. Although her themes often center around questions of feminine identity and woman's position in society, many of Woolf's writings are also concerned with the complex questions of the nature of reality and time. Her literary works are by now regarded as classics of the modernist canon.

Virginia Woolf was born Adeline Virginia Stephen into the upper-middle-class family of the Victorian man of letters and biographer Leslie Stephen in London on January 25, 1882. She was one of eight children (among them the painter Vanessa Bell) and suffered greatly from her mother's early death when she was only 13. She was educated mainly at home and began writing diaries and short prose pieces at an early age. Her first journalistic piece was published in 1904. She took up teaching female workers in 1905 and worked for the women's suffrage campaign in 1910. Her first novel, *The Voyage Out,* was published in 1915. Together with Leonard Woolf, whom she married in 1913, she started the Hogarth Press in 1917; it was to become an important publishing house for modernist literature, sociopolitical criticism, and psychoanalysis. Living in London and Rodmell (Sussex), they had many famous acquaintances in the fields of literature, music, psychology, economics, and politics of the time. Greatly concerned about German fascism and the ongoing war, and on the verge of another in a series of nervous breakdowns, Virginia Woolf committed suicide on March 28, 1941.

Major Novels and Essays

After having published her two early novels, *The Voyage Out* (1915) and *Night and Day* (1919), which both deal centrally, albeit in different ways, with the question of female identity in early 20th-century society, Virginia Woolf set out to experiment with prose forms in her short story "The Mark on the Wall" (1917) and with her third novel *Jacob's Room* (1920). While having already discursively posed the question of whether and how language, the arts, and science are able to represent reality in her early works, Woolf now started to focus more on the nature of perception and to develop techniques that transformed the philosophical questions of knowledge and representation into a literary experience.

Woolf's next novel, *Mrs. Dalloway* (1925), is not only one of her best-known works but also one in which the philosophical paradoxes of time are most prominently present. Started under the working title *The Hours* and set on one day in the postwar London of the early 1920s, *Mrs. Dalloway* juxtaposes the passing of objective, linear time, represented by the chimes of Big Ben, with the subjective temporal experience of its main characters, Mrs. Dalloway, an upper-class politician's wife, and the mentally disturbed war veteran Septimus Warren Smith. Their continuous movements between present perceptions and past experiences extends the temporal dimension of the novel, juxtaposing narrating and narrated time, while at the same time questioning the nature of what is real in terms not unlike Henri Bergson's distinction between *temps* and *durée.*

This contrast between subjective and objective time is also explored in *To the Lighthouse* (1927). While two of the three main sections of the novel deal with single days in the lives of a female painter, Lily Briscoe, and the Ramsay family, in 1910 and 1920, respectively, the much shorter middle section is about the 10 years that lie in between. Time here is represented as an impersonal theme of the events that happen—among them the death of two characters—indicating the cosmic but also indifferent nature of time's passing.

The passing of time, and the question of history, is also addressed in Woolf's mock-biography *Orlando* (1928). Mixing fact and fiction as well as going beyond the scope of serious historiography, it is about the life of an English aristocrat from the 16th century to the present who not only stays young but also changes sex halfway through the novel.

More earnest in tone, and experimental in style, is *The Waves* (1931) in which short lyrical passages following the diurnal passage of the sun are contrasted with the lives of six characters from early childhood to middle age, narrated in the form of soliloquies. Again, the cosmic dimension of time is set against—or rather: as a frame for—the individual experience of time and its subjective significance in a literary form that offers an extraordinary reading experience.

The title of Woolf's penultimate novel, *The Years* (1937), refers directly to time. Similar to *The Waves,* Woolf juxtaposes the cosmic time of nature—the seasons—with human time—history—in alternating pastoral and narrative passages that give an account of the Pargiter family from 1880 to "the present." More than in *The Waves,* however, Woolf's focus here is on a feminist critique of history. A similar political concern engaged with questions of history and individual agency is at the heart of Woolf's last novel, *Between the Acts,* which was published posthumously in 1941. Setting her novel against the background of the Second World War, Woolf poses the question of whether—and how—civilization might be preserved through artistic endeavors.

Through her work and her diaries—which she kept writing until near her death—Virginia Woolf can be seen as an author continuously engaged with the various dimensions of time—phenomenological, epistemological, historical, and political. By transforming these dimensions into an artistic form, Woolf makes "time" available for her readers as an aesthetic experience that at its best parallels, if not extends, philosophical reflection.

Worlds, Possible

By "a possible world" philosophers mean a total state of affairs in the conception of which no contradiction is involved. Our own world—the real world, the actual one—is just one of many possible worlds. Indeed, it is just one of infinitely many, since for any possible world containing, say, n atoms there is another logically possible world containing $n + 1$ atoms, and so on ad infinitum. All possible worlds other than the actual world we inhabit are nonactual.

A world the conception of which does involve a contradiction is said to be an impossible world. An impossible world, of course, is a nonactual one. There are many possible worlds in which you, the reader, exist; the actual world is one of them. And there are possible worlds in which you do not exist; any such world is nonactual. But there are none in which you both do and do not exist; any such world is an impossible one.

The Banality of Possible Worlds

Although the term *possible worlds* entered the philosophical lexicon only in the writings of Gottfried Leibniz (1646–1716), the fact is that we all think about them everyday, though not usually under that description. The idea of worlds different from the actual one is totally commonplace. One wonders what the world would have been like if one had done something different from what one in fact did: if one had chosen a different partner or profession, for instance. One wonders what history would have been like if Hitler had won the Second World War. Equally, one ponders whether one should do this or that, or something else, where each of the possibilities would make a difference in how the world, or one's little part of it, would then turn out. And one makes plans for the future hoping things will turn out one way though conscious of the fact that they may not.

The concept of possible worlds is implicit in all these ways of thinking. To imagine the past as having been different (even in the smallest respect) from the way it was, or the future (even in the smallest respect) as being different from what it will be, is to entertain the concept of different possible worlds branching out from the past (perhaps even from the beginning of the world), or from the present, or from the future.

Thus, there is nothing arcane about the notion of possible worlds, actual and nonactual alike. They feature in our dreams, our imaginings, our hopes and fears for the future, our regrets over past deeds and lost opportunities. We think about how the world *might* have been, and of how it *might* yet come to be.

They also feature in fiction, especially science-fiction novels and films in which we are invited in our imaginations to enter into worlds that often bear only the faintest resemblance to the real world that we in fact inhabit. Some are plausible. Some are not. And still others seem beyond the bounds of belief. Science-fiction stories involving time travel, in particular, often challenge our sense of what is possible and what is not. Are such stories internally consistent or is there a contradiction involved somewhere? Is time travel possible? Is it possible to change the past? Or the future, for that matter?

Theoretical Applications of the Concept

The concept of worlds, possible and impossible, actual and nonactual, can play a valuable role in clarifying our thinking about many issues. In philosophy, the concept has been used to give us a better grasp of matters of logic (leading eventually to the development of temporal logics), semantics, and issues in philosophy of religion, philosophy of science, ethics, and metaphysics. Some examples follow.

Possible Worlds and Logic

The aim of logic, as conceived by its founder, Aristotle (384–322 BCE), was to establish general principles for reasoning such that *if* we started from a set of true premises we could be guaranteed that we would finish with a true conclusion. These principles would ensure that the conclusion follows, as he put it, "of necessity" from the premises.

Leibniz claimed that these principles about what follows of necessity (the principles of logic) *are true in all possible worlds*. This insight has enabled subsequent philosophers to give illuminating accounts of the whole field of logic.

In terms of possible worlds, we can define many of the most basic concepts of logic as follows:

P implies Q	There is no possible world in which P is true and Q false
P is consistent with Q	There is a possible world in which both P and Q are true
P is inconsistent with Q	There is no possible world in which both P and Q are true
P contradicts Q	There is no possible world in which both P and Q are true and no possible world in which both P and Q are false
P is a contrary of Q	There is no possible world in which both P and Q are true but there is a possible world in which both P and Q are false
P is a subcontrary of Q	There is no possible world in which both P and Q are false but there is a possible world in which both P and Q are true

Consider the propositions:

1. The universe began more than 13 billion years ago.
2. The universe began less than 3 billion years ago.
3. The universe began at least 3 billion years ago.
4. The universe began no more than 13 billion years ago.

A little thought will suffice to show

- that (1) *implies* (3)
- that (1) and (4) are *contradictories* and hence, by definition, are *inconsistent* [ditto for (2) and (3)]
- that (1) and (2) are *contraries* (and hence, by definition, are *inconsistent*)
- that (3) and (4) are subcontraries (and hence, by definition, are *consistent*).

Moreover, we can define an argument as *valid* only when its premises imply its conclusion. Thus the simple two-premise argument:

5. Time began when the universe began.
6. The universe began on Sunday, October 23, 4004 BCE.

Therefore,

7. Time began on Sunday, October 23, 4004 BCE

is *valid* since there is no possible world in which its premises are true and its conclusion false. (Note that it would be *sound* only if it was not only valid but also had true premises, i.e., premises that are not only true in some possible world but also true in the actual world.)

The concept of possible worlds also enables us to define some important properties of propositions. Clearly, each of the propositions (1) through (7) is true in some possible worlds (and hence *possibly true*) and false in some others (and hence *possibly false*). Propositions having the property of being possibly true and possibly false have been described, ever since Aristotle, as *contingent*. By way of contrast, propositions such as

8. Not both P and not-P (the so-called law of noncontradiction)
9. 2 + 2 = 4 (a truth of mathematics)
10. If a thing is red then it is colored {a definitional or analytic truth)

are described as *noncontingent,* these all being instances of so-called *necessary truths* (propositions that are true in all possible worlds) while their contradictories

11. Both P and not-P
12. It is not the case that 2 + 2 = 4
13. Some red things have no color

are instances of *necessarily false* or *self-contradictory* propositions (not true in any possible world).

The properties of being necessarily true, necessarily false, or contingent are said to be *modal* properties. Aristotle sketched the foundations of a modal logic in which these properties play a vital role. Medieval logicians appealed to their logical intuitions to elaborate on Aristotle's findings. In 1918, C. I. Lewis developed axiomatic systems for various modal logics. In 1959, Saul Kripke provided some of these with a widely accepted semantic underpinning in what is called *possible world semantics,* and, about the same time, Arthur Prior extended modal logics in the form of *temporal logics* (sometimes known as *tense* logics).

Possible Worlds and Science

The aim of science is to determine which of many possible worlds is actual. Its method is to progressively eliminate from further consideration all those that experience and reason show to be inconsistent with what we already know (or have compelling evidence for believing) to be true of the actual world.

That, in a nutshell, is how Karl Popper (1902–1994) and his followers such as Peter Medawar (1915–1987) view science. On their account, a scientist has an idea of a *possible* world, that is, a way the world might be, and then tests it experimentally to see whether the *actual* world conforms with it. If it withstands the tests, it is accepted provisionally as the best account available to date. But if not, the scientist—if endowed with an open mind and intellectual integrity—will reject it as having been ruled out by experience of how the actual world works.

Consider propositions (1) through (7) again. All are contingent, that is, true in some possible worlds and false in others. But which, if any, is *actually* true?

Although Bishop Ussher (1581–1656) believed he had God's word, as revealed in the Bible, as his authority for claiming (6) to be true (that the universe began in 4004 BCE), only a few diehard biblical creationists would nowadays agree. Edwin Hubble (1884–1933) turned to science for an answer and calculated an age of about 2 billion years based on observations of the rate of expansion of the universe. That was in 1929. In 1947 George Gamow (1904–1968), with new evidence in hand, gave an estimate of 2 to 3 billion years. And current estimates, based on evidence produced by the Hubble Space Telescope among other things, are that the big bang began about 13.7 billion years ago, thereby asserting the truth of proposition (1), and thereby implying the falsity of its contradictory (4) and the falsity of its contraries (2) and (6).

Arguably, it is through a succession of such episodes of conjecture and refutation that the big bang theory of current physical cosmology has replaced Ussher's. We have come, through experiment, to realize that the possible worlds that Ussher, Hubble, and Gamow conceived are *nonactual* ones.

These advances were prompted by observation-based experiments. But not all experiments are observational ones. Some are made in "the laboratory of the mind," by conducting pure "thought experiments." The history of science, and of physics in particular, is replete with such cases. Notable examples range from Galileo's thought experiment refuting Aristotle's belief that heavier objects fall faster than lighter ones to Erwin Schrödinger's "Cat" critique of certain interpretations of quantum mechanics. And they include Einstein's thought-experiment in which he, at age 16, conceived of himself chasing a light-wave—a thought experiment that led him to formulate a new conception of physical time and space.

Possible Worlds in the Philosophy of Time

Thought experiments can help us get clear about how the concept of time relates to other concepts.

Is Time Travel Possible?

It is not just science-fiction writers who entertain the idea of traveling back in time. Some physicists do, too, on the grounds that certain concepts of traveling through time are consistent with both general relativity and quantum theory.

Yet some thinkers have rejected the notion outright. Many argued that time travel would make it possible for individuals to go back in time, kill their own paternal grandfather while they were still a child, and thereby ensure that they themselves were never born. Hence, the so-called grandfather paradox.

But where lies the contradiction? Not in supposing that the laws of nature (of genetics, in particular) would thereby be violated, for there is nothing contradictory involved in that part of the story. The paradox lies elsewhere.

It is tempting to think of traveling through time as akin to traveling through space to visit a place one hasn't been to before. This fosters the idea of visiting a place in the past, even though one hasn't been there before, and of leaving one's mark by changing things once one gets there. But this is where real paradoxes arise. For it is a logical truth—true in all possible worlds—that the past was what it was. It follows that you cannot go back to a previous time unless you have already been there. You can travel to the past only if you already *were* in the past. It follows, too, that you cannot *change* the past from what it was by, for example, killing your grandfather if the fact is that he wasn't killed. There is no possible world in which either can occur.

Some tellers of time-travel tales have been astute enough to avoid any paradox. Robert A. Heinlein is a case in point. His novel *Time Enough for Love* depicts a world that is self-consistent and hence possible.

Must Time Have Begun With the Big Bang?

Most physicists, following Stephen Hawking (b. 1942), would answer "Yes" on the grounds that the big bang model *defines* time that way. The argument is that since physicists can define time only in terms of its observational consequences, and events occurring "prior to" the big bang would have no such consequences, the concept of time prior to the big bang "makes no sense."

But this is conceptually confusing. It would seem to make the proposition

5. Time began when the universe began

true "by definition" and hence a necessary truth. Yet (5) is clearly contingent. We can easily, and without contradiction, conceive of worlds in which the big bang was preceded by phases of expansion and contraction. That is to say, there is no contradiction involved in the supposition that the oscillatory universe model is true. Or the steady state model for that matter. In fact, both models entail that neither the universe nor time had any beginning at all.

So what has gone wrong? There has been a failure to distinguish between *operational definitions* of time (definitions couched in terms of the operations by which time is measured) and the concept of time itself. The concept of time itself has a scope that is not restricted by any particular scientific theory or to any method of measurement used by that theory. Arguably, its ties with other concepts are more a matter of philosophical analysis than of empirical inquiry.

Could Time Pass Without Events Occurring?

It is obvious enough that a series of events (changes in objects or states of affairs) cannot occur without the passage of time. How about the converse? Could time pass if nothing was changing?

Few philosophers entertained this possibility until Sydney Shoemaker (b. 1931) argued for it. He told a possible worlds parable about a world with three parts, A, B, and C, each of which undergoes periodic "local freezes" of, say, one year's duration—periods during which nothing whatever occurs—such that the freezes for all three parts coincide at regular intervals. The inhabitants of each part, he argues, could even have observational evidence for the freezes occurring in the other parts, have evidence from inhabitants of other parts that their part also undergoes periodic freezes, and calculate the times when all the freezes occur at the same time.

It won't do to object that none of the inhabitants could, during the concurrent freezes, observe or measure the passage of time. That would be to appeal to the operational definition of time whose tenability is in question. It won't do to invoke Ockham's razor and say that it is much simpler to suppose that the supposedly concurrent freezes never occur. The principle of parsimony is not a logical one. Nor will it do to object that his scenario affords no causal mechanism by which the freezes of any of the three parts could come to an end. For the issue is not whether his possible-worlds scenario is physically possible. It has to do only with whether it is logically possible.

Unless a strictly logical contradiction can be found in the Shoemaker scenario, we have no option other than to allow the possibility of time passing in the absence of anything whatever occurring.

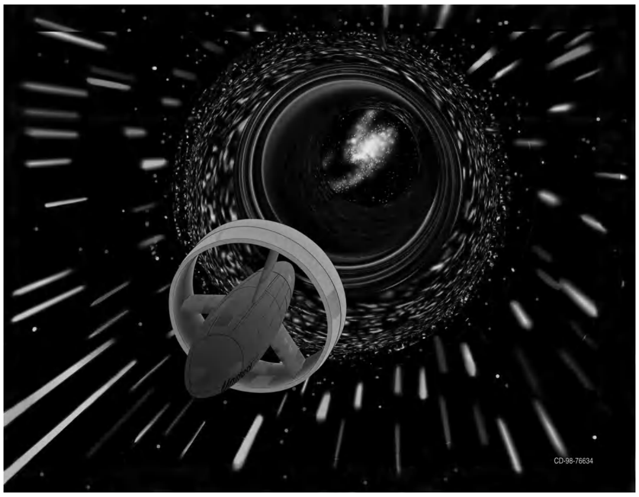
Wormholes

A wormhole is a theoretical connection, often referred to as a tunnel, between two black holes. The two black holes could be in two different locations in the same universe, or they could be located in two different universes. In the case of both the former and the latter, each black hole would necessarily be located in a different time, in keeping with the concept of spacetime as delineated in Albert Einstein's theory of general relativity.

In fact, it was Albert Einstein and Nathan Rosen who discovered the mathematical possibility of wormholes, but they called them "bridges" in 1935. These Einstein-Rosen bridges, as wormholes were first called, would not allow any object to pass through, they theorized, because the middle of the wormhole would twist or pinch until it separated, creating a singularity, a literal dead end.

A black hole is formed when the resulting matter from a supernova explosion collapses until all the matter is squashed into a point at which volume is zero and density, gravity, and the curvature of spacetime are infinite. That point is called the black hole's singularity. A wormhole connects two singularities.

Spacetime is a four-dimensional continuum that consists of three-dimensional space with the traditional x, y, and z axes plus a fourth coordinate—time—added to make four-dimensional spacetime. Einstein theorized that one could not know the location of an object independent of both its place (spatial coordinates) and instance (time coordinate) with respect to the observer or observers. For example, if person A in San Diego observes the location of the sun at time A, and person B in Cairo observes the same object at time B, then the sun exists in different places in spacetime. If one considers that a few time zones separate these observers, as opposed to light-years



Artist's illustration of a spacecraft passing through a wormhole to a distant galaxy. A wormhole is a hypothetical topological feature of spacetime that is essentially a shortcut through space and time. Assuming that general relativity is correct, wormholes may exist. There is no evidence, however, for anything like a wormhole in the observed universe.
Source: NASA.

between celestial objects, the importance of spacetime with respect to location and instance becomes more evident. Expanding the concept from the scale of the earth to the scale of the universe allows one to conclude that two black holes connected by a wormhole must exist in different times if they exist in different locations.

Thus, a wormhole would allow rapid time travel, cutting an interstellar trip from several millennia down to a few days or a few hours. There would be many possibilities for the direction of time travel. If the first black hole lies at point A in the past, and the second black hole lies at point B in the future, then a wormhole could take one forward in time, as well as backward. If, like the Einstein-Rosen bridges, the wormholes pinch, they could close, become attracted to a different singularity, and reopen an alternate pathway through spacetime.

Although the discovery of black holes and the behavior of visible matter that surrounds them lend support to wormholes' existence, the study of wormholes is still considered by most to be speculative in nature.

X

Xenophanes (c. 570–480 BCE)

Xenophanes, one of the Presocratic philosophers, lived in Colophon (in Ionia, Asia Minor) until about 546 BCE, when he left following a conquest of Ionia by the Medes and began to travel the known world widely. He may have spent time in Elea (southern Italy), and Aristotle reports that he was said to have been a teacher of Parmenides. He observed fossils of sea animals in mountainous regions and conjectured that the sea must have covered those mountains in earlier times. He also is said to have thought that everything comes to be from earth and water (mud), which is why the remains are found in dried mud. Worlds (or world orders) may come and go, perhaps in cycles. Thus there is change in the physical world over time, and the physical world and its inhabitants exist in time.

Xenophanes did not accept the traditional Greek conception of a pantheon of many gods who fought with one another, lied, seduced, and could be placated by gifts from mortals. In the course of his travels to many regions around the Mediterranean, he had observed many different religious beliefs. He wrote that the Ethiopians make their gods snub-nosed and black (like themselves), whereas the Thracians' gods are portrayed with red hair and gray eyes (characteristics of the Thracians themselves). Thus each human race creates an anthropomorphic god in its own image. Xenophanes thus concluded, as reported by Clement of Alexandria: "And if oxen and horses and lions had hands, and could draw with their hands and do what man can do, horses would draw the gods in the shape of horses, and oxen in the shape of oxen, each giving the gods bodies similar to their own." He is thus contemptuous of any such view of the gods, or god, as like any mortal being. There must be one god, concluded Xenophanes, not like any mortal creature in body or in mind. This god "sees all over, thinks all over, hears all over" (Sextus Empiricus), a precursor of the more modern view of a god who is omnipresent, all-powerful, all-knowing, and omnibenevolent. The god imagined by Xenophanes does not move or change (it would not befit a god to do so) but sets all things in motion by pure thought. This anticipates Aristotle's prime mover, Augustine's God, and the mathematician-god of Leibniz. Thus for Xenophanes, one god exists and is the source of the world. (Some conclude that his god is equivalent to the world, that Xenophanes was an early pantheist, like Spinoza, but this would not be consistent, equating a god that does not change with a world full of change.)

One of the problems with the traditional Greek gods of Homer and Hesiod was that they were too much like humans, with all the flaws of humans but in greater measure. Xenophanes seemed to believe that god must represent a kind of perfection, an ideal; thus such a god would have to be one, not many (as the many gods would have to differ from one another to be many and thus be better or worse, more or less strong, and the like, than one another, but god must be the best, the most perfect, and thus be only one). This god is eternal, does not change, does not come into being or pass away. Thus Xenophanes' god is timeless, or outside of time, or in all time.

Y

Yeats, William Butler (1865–1939)

William Butler Yeats, Irish playwright and poet, was brought up in Dublin and London and became among the foremost writers of the modernist movement in 20th-century literature. Deeply involved with the Irish literary revival, he took an active part in the creation of an Irish literary theater. Yeats was awarded the Nobel Prize in Literature in 1923. Well aware of the accelerating pace with which the world around him was changing and being a nationalist and a conservative, Yeats was known for his desire to maintain the traditional forms of society and government that he ardently supported.

One of his best-known poems, "The Second Coming," reveals Yeats's belief that history and time are cyclic. The poem describes the destruction of the ruling monarchy as part of an unavoidable collapse of the world order as he knew it. Describing chaos and violence as a product of the foreseen rift in ways of old, the piece concludes with a famous line conveying his belief that the disorder creeping across modern life would give birth to a new beginning, as with the times preceding the birth of Christianity: "And what rough beast, its hour come round at last, Slouches towards Bethlehem to be born?"

Yeats's poem "The Lake Isle of Inisfree" expresses the speaker's desire to abandon modern society with its hurried pace and retreat to a tranquil island. The poem's narrator uses this reflection on an uninhabited island as a stolen moment to escape the onrush of a quickly developing civilization. Describing his island refuge, Yeats writes, "And live alone in the bee-loud glade. And I shall have some peace there, for peace comes dropping slow." The speaker resolves that this quiet life is a mere musing and that such isolation is not something easily found. Writing "while I stand on the roadway, or on the pavements grey, I hear it in the deep heart's core," Yeats reminds readers of the ever-present asphalt world that surrounds us. Retreat to a state of isolation offers the promise of escape from a world that is growing and changing too fast.

Years after the poem's publication, Yeats reflected that the idea for "The Lake Isle of Inisfree" came to him as he paused on the sidewalk of a busy street. Peering into a shop window, he saw an advertisement meant to draw a rushed passerby's attention with a metal ball suspended on a jet of water in a fountain. The lazy trickle of water and simplicity of the attraction moved Yeats; time seemed to slow down, and the reverie he experienced inspired thoughts of a simpler time and place.

Yeats died in France in 1939, and 9 years later his remains were transported to his final resting place in Ireland. His headstone displays a short excerpt from one of his final poems, "Cast a cold eye on life, on death, horseman pass by!" Readers of his epitaph are advised to look on both life and death with equanimity, to continue on their way and not dwell on the end of life but rather go on living it.

YOUTH, FOUNTAIN OF

The Fountain of Youth is a legendary spring whose waters are alleged to have the ability to halt the ravages of time or even reverse the aging process. By drinking or bathing in it, one is supposed to experience the erasure of all signs of age. Legends of the magical spring as told to the early Spanish explorers also included tales of vast riches and precious metals lying alongside the pool, awaiting the discoverer.

Some Fountain of Youth fables have placed its location in eastern Asia, where it was sought after by Alexander the Great. According to other stories, the fountain is located in Hawai'i. The best-known location comes from the 15th and 16th centuries, when Spanish explorers first arrived in the New World. They were told by the natives of modern-day Cuba and Puerto Rico that the magical body of water was located in a land to the north, which they called Bimini (Florida). They told the Spanish of an Arawak (natives of current-day Haiti) chief named Sequene, who sailed north with a ship of men and never returned home. Their failure to reappear was seen not as a failure in which they were lost at sea, but rather as a success. It was believed by many that they did in fact find the supernatural water and stayed to enjoy their recaptured youth in a new land.

Juan Ponce de León (1460–1521) traveled with Columbus on his second voyage in 1493. The Spanish settled in the area, and in 1513, after a stint as the governor of Puerto Rico, de Leon financed his own expedition to travel north in search of the Fountain of Youth. The ship supposedly landed in

the vicinity of what is now St. Augustine, and he proposed that this land be called La Florida. It was in this area of St. Augustine where he claimed to have found the Fountain of Youth.

To some residents of this area of Florida, the Fountain of Youth is more than just a legend. The land containing the supposed spring is now a park where visitors can purchase glimpses of what is touted as the true fountain, on the basis of a landmark cross that was found adjacent to the spring. Discovered at the beginning of the 19th century, the cross is made of 27 coquina stones and is believed to have been placed there by Ponce de León. Authenticity of the cross having been laid by de León himself was verified in 1904 with the further discovery of a nearby salt cellar, which contained a signed parchment declaring a statement of witness to the laying of the stones in 1513. As for the local water itself, thorough testing has disclosed no rejuvenating properties.

Z

Zara Yacob (1599–1692)

The African thinker known as Zara Yacob was a rationalist who challenged the status quo by elevating reason over faith in the quest for truth. He did so within a deeply conservative context in which little or no tolerance was shown toward dissenting interpretations of religious writings. Although Zara Yacob lived in a tumultuous time of religious persecutions, he believed that there is no good or bad time as such; rather, it is humans' actions that make the times good or bad.

Zara Yacob was born in Aksum, Ethiopia, in 1599 to a farming family. He attended religious school for many years and later spent his career as a teacher, writer, and philosopher. According to Claude Sumner, a scholar of the life and works of Zara Yacob, Yacob is credited with formulating modern philosophy in Ethiopia at the same time that it was developing in Europe, particularly in England and France. He thus secured an important place in the history of African philosophy.

For Zara Yacob, God is revealed through reason. In working out his understandings of knowledge and human nature, Zara Yacob affirmed a belief in the power of reason, using it to examine the dogma of the Church. Zara Yacob's thoughts parallel the ideals of the European Enlightenment. As a realist, he strongly believed that people should trust the evidence that comes through senses and practical proofs rather than the dogmas of teachers, priests, or prophets. He believed everything must be critically examined and inspected before it is accepted as true. This approach to knowledge and the process of knowing put Zara Yacob at odds with the Church authorities. To escape persecution he took refuge in a cave, where in solitary exile he developed most of his philosophical ideas. During his time, the rift between Catholics and Protestants in Europe also had an impact on Africa. Missionaries of both denominations were working hard to disseminate their respective religious views in Africa, and Ethiopia was a target. The Portuguese were important allies of the then-politically weakened king of Ethiopia, known as Susnios, whose sovereignty was threatened by low-lander Islamic political forces. With the help of the Portuguese, the king won the battle and responded by converting to the Catholic Church. Those Ethiopian Christians who were Orthodox and who openly challenged the king's conversion were persecuted; many were killed. Zara Yacob was among those fortunate enough to survive.

With the benefit of his formal education, Zara Yacob used his time in solitude to critically examine the practices of his time in religious matters—both in Ethiopia and Europe. He had the chance to debate with the European missionaries of the time. Based on his in-depth meditation, Zara Yacob systematically formulated philosophical explanations to some of the perennial questions. In this regard, Zara Yacob's thought can be categorized into three areas of philosophical inquiries: These are the methods of knowing, human nature, and the obligations of humans.

Zara Yacob's method of knowing is called *Hassasa* or *Hatata*—which means to question, search, investigate, examine, or inspect. According to Teodoros Kiros, Zara Yacob's epistemological approach to knowledge and knowing involves discursive subjection and critical examination of truth through intelligence or natural reason. This extends to the acquisition of faith itself through a critical examination and rational reasoning. Thus, faith in God comes only after extensive reasoning. According to Zara Yacob, nothing should be taken for granted unless it is first subjected to critical examination by intelligence or natural reason. Such discursive method also applies to the faith in the conception of God. Meditation, according to Zara Yacob, is a method of thinking powerfully enough to explore the mystery of the notion of God, the principles of Christianity, human nature, and ways of life in general.

According to Zara Yacob, human weakness allows people to be lured by falsehood, wealth, status, and power. He suggests humans need the support from their creator—God. According to Kiros, he identifies two types of laws—the law of God and the law of humans. The law of God makes the law of humans complete. Overreliance on the human law leads to falsehood and deficiencies, whereas the use of the law of God enables humans to attain righteousness and make intelligent decisions. Zara Yacob argues that because humans suffer from falsity, errors, and poor choices, they need guidance from the laws of God. Humans should consult God in their choices and decisions for the reason that, according to Zara Yacob, truth cannot be discerned on the basis of human affairs alone.

Zara Yacob argues that the fundamental obligation of humans is to the service of God. God created humans with intelligence, and that intelligence should be used in turn to know God. It is only then that people can turn their energies to the service of their fellow humans. This involves, according to Zara Yacob, loving others as oneself.

Zara Yacob examined diverse areas of inquiry in his philosophical journey during his solitary life; these include matters of marriage and abstinence from sex, fasting, monastic life, controversies in the interpretation of religious materials, the roles of prophets, differences among various religions, and education. Zara Yacob strongly recommends married life and giving birth to children, as it is the will of the creator God. Thus, he openly challenged the then-monastic and celibate life advocated by the clergy, with the conviction that marriage benefits human society.

In regard to the notion of time, Zara Yacob understands time as a measure of events and actions of humans. He believes that everything needs to be done at the appropriate time. Thus, his notion of time is that there is time for everything. Patience to do things at their right time, in this regard, is considered to be the mark of wisdom. His influence on his disciple Wolde Hiwet is observed in the works of the latter, who continued to develop Zara Yacob's treatise after the latter's death. Accordingly, these thinkers believe that time is what we are and what we do. They reject the idea of celebrating the old days as good and condemning the present as bad. Every period, according to them, has its own goodness and badness. The kernel of the argument is the following: Be good and do good, then time will be good to you; if you do evil, the time also will be evil.

Zeitgeist

Zeitgeist is a term of German origin, meaning "spirit of the age," or "spirit of the times." In a formal context, zeitgeist presupposes that the time one speaks of has an essential relation to a governing idea or set of ideas, which in turn presupposes that time has a meaning. This idea is venerable. Ancient and medieval thinkers habitually thought of time as a succession of ages, most memorably recalled for us now in Shakespeare's *As You Like*

It (Act II; scene 7). At a more colloquial level, when in the 1950s the American painter Willem de Kooning (1904–1997) spoke of existentialism as "being in the air," he was speaking of zeitgeist.

The notion of zeitgeist is a secular descendant of these ideas. Zeitgeist is a secular concept because it recognizes that it is what people do that gives an age its determining characteristics. Traces of the older versions of the idea reappear when it is assumed that the determining characteristics of the age were also somehow inevitable.

Accounts differ as to the origin of the idea. Some claim it began with the German historian Johann Gottfried von Herder (1744–1803) in 1769 as a translation of the Latin phrase *genius seculi,* or "guardian spirit of the century." An important influence on German Romanticism, von Herder spoke of the *Volksgeist* as the spirit of each people. He also dreamed of the *Volksgeist* being encapsulated in a single individual, the great man who, by virtue of his capturing the needs of the day, can coerce the people to bend to his will.

The most significant philosopher to take up the zeitgeist idea was G. W. F. Hegel (1770–1831). According to Hegel, philosophy is nothing less than the age coming to understand itself. In this way, subscribing to a philosophy not indicative of the zeitgeist was a betrayal not only of the true philosophy but of oneself and one's place in time.

Many of the attempts by teleologically inclined historians to impose rigid periods in history work on the assumption of the power of the zeitgeist. Hegel saw history moving from what he called the Eastern phase, where freedom was held up for want of a coherent idea of individuality, to a Greek phase, where the ethical life was discovered. This was followed in turn by the Roman phase, where people were brought to heel by the rule of law. Only with the Germanic phase of history—the current zeitgeist—was it recognized that humans are free by definition.

Hegel's periodizing of history, each marked by its characteristic zeitgeist, has attracted many imitators. Historical thinkers as varied as Karl Marx (1818–1883), Oswald Spengler (1880–1936), and Arnold Toynbee (1889–1975) all theorized on the zeitgeist. Other thinkers have thought in terms of zeitgeist in different contexts. For example, the Spencerian evolutionist John Fiske (1842–1901) conceived of evolution as moving inexorably and approvingly to the form of laissez-faire capitalism in the United States at the time. The idea can also be put to pessimistic uses, as when Martin Heidegger (1889–1976) spoke of the contemporary zeitgeist in terms of the age of technological frenzy and the consequent dehumanizing of man. More recently, zeitgeist has become a fashionable word among the more popular commentators and apologists of postmodernism to indicate the ubiquity of the ideas they support.

One of the first people to question the teleologically determined zeitgeist was Johann Wolfgang von Goethe (1749–1832), who had Faust declare that the spirit of the times is nothing more than the combined spirit of the people who live through the times. Among philosophers the most thorough critic of the notion of zeitgeist in history was Karl Popper (1902–1994), particularly in *The Open Society and Its Enemies* and *The Poverty of Historicism.* Among historians the Dutchman Pieter Geyl (1887–1966) criticized the notion of zeitgeist in the context of his criticisms of historian Arnold Toynbee.

It is now generally conceded that history does not have an underlying meaning written into its fabric. Although it is true that an age can seem strongly tied up with one idea or another (the "swinging '60s" is an obvious example), it is false to see that particular age as necessarily and exclusively determined and characterized by that idea. Zeitgeist is best understood in the loose sense as the currently predominant, though not necessarily true, idea or family of ideas that can set the tone for the time.

Zeno of Elea (c. 490–c. 430 BCE)

Zeno of Elea (southern Italy) was a student of Parmenides, who argued that what is real is One, not many. A consequence of this rational position ("being is, non-being is not") is that motion, or change, is an illusion (the Way of Opinion, not the Way of Truth). The consequences of this view affect the possible views of space and time, since motion is generally considered as a change with regard to space over time. Zeno constructed a number of arguments in defense of his master Parmenides; some are measure paradoxes, directed against plurality. Probably his most famous paradoxes are four paradoxes of motion, which all argue that motion is impossible (at least given any accounts that had been put forward regarding the nature of space, time, and motion). Parmenides had come in for a great deal of criticism of his views on the One; Zeno is at least deflecting some of the attacks by drawing out the apparent consequences of opposing views and using Parmenides' own rational principle—that whatever leads to a contradiction must be false—against the attackers.

Zeno constructed four paradoxes of motion. At least two of them clearly examine the consequences of the suppositions that (a) space and time are both continuous, or (b) space and time are both discrete. One might wonder why Zeno put forward exactly *four* paradoxes. Because time can be either continuous or discrete, and space also can be either continuous or discrete, that can lead to four possible combinations: space and time both continuous, space continuous and time discrete, space discrete and time continuous, or both space and time discrete. The first and the fourth paradoxes clearly fit the first and fourth combination possibilities. This entry examines whether the middle two paradoxes might be construed as representing the other two options.

The Bisection Paradox

The bisection paradox (sometimes referred to as the "dichotomy") looks at the consequences if both space and time are viewed as continuous (infinitely divisible). Let us imagine that someone wants to travel from A to B. To get to B, first she must travel halfway; then to get from there to B, she must travel half the remaining distance; and so on ad infinitum. Thus she can never complete the journey from A to B because there is *always* half the remaining distance left to traverse. If one were in a football game, and the defense kept committing fouls that cost them penalties of half the remaining distance to the goal, the offense could never actually score on those penalties, no matter how many of them there were. The path from A to B is divided as follows:

A 1/2, 3/4, 7/8 15/16 . . . B.

To get from A to B is an infinite (endless task), because it amounts to passing through an infinite sequence of points (1/2, 3/4, 7/8, 15/16, . . .) for which there is no last point, so the "end" of the sequence can never be reached.

The Regressive Version

Our intrepid traveler wishes to go from A to B. To get to B, she must first go halfway; but to get to the halfway point, first she would have to travel half the distance to that (i.e., reach the 1/4 point). However, to get to the quarter-point she would first have to go 1/8 of the distance, and so on and so on. Thus we see the following dilemma:

A . . . 1/16 1/8 1/4 1/2 B.

Her task involves beginning an infinite sequence of points of which there is *no first point,* so she can never get off of A to begin the journey, as there is no first point at which to begin. Thus (concludes Zeno), motion is impossible.

The "Achilles"

The Greek athlete and hero Achilles is to be pitted in a race against a tortoise. Being a good sport, as he is the faster runner, Achilles gives the tortoise a head start. The paradox is that Achilles can never overtake or pass the tortoise, even though he is faster, because in the time it takes Achilles to reach the point where the tortoise was, the tortoise has advanced. Again, by the time Achilles gets to the next point at which the tortoise had been, the tortoise has moved on; this pattern continues on without end. Achilles must always get to the point where the tortoise was, but in this time, the tortoise has moved on. A diagram illustrates the dilemma:

$$T_0\, T_1\, T_2\, T_3\, T_4\, T_5 \ldots$$

$$A_0\, A_1\, A_2\, A_3\, A_4\, A_5\, A_6 \ldots .$$

The subscripts indicate starting time (0) and subsequent times (1, 2, 3 . . .) at which Achilles has reached the spot where the tortoise *was;* at time 1, for example, the tortoise has advanced to position T_1, whereas Achilles has only reached level with T_0, the place the tortoise started at but has now vacated. Thus Achilles can never overtake the tortoise.

This could possibly be interpreted as viewing space as discrete and time as continuous. Achilles must always move to a distinct place that the tortoise has left and, in the time (no matter how short) this has taken, the tortoise has moved ahead some distance. If space is discrete, then Achilles must always move from one spatial minimum location to another; if time is continuous (infinitely divisible), these successive spurts to the spots where the tortoise *was* can continue indefinitely, with the tortoise always moving to some new spot.

The Arrow

This paradox begins with the premise that an object is said to be at rest when it is in the place where it is. Thus, argues Zeno, if the arrow is to be moving, it is either moving in the place where it is or in the place where it is not. Clearly, it cannot move in the place where it is not. And if it is in the place where it is, it is at rest. Thus the "moving arrow" is at rest and cannot move. This could be interpreted as looking at discrete time instants (indivisible units), in which the arrow cannot be said to be moving (because it is in the place where it is), and so, even if space is continuous, the arrow cannot move to another spatial location; it must remain "in the place where it is."

The Stadium

This paradox deals with the assumption that space and time are discrete, that they are made up of "minims" (minimal units), which is a view (based on the limits of measurement) advocated recently in modern physics. Zeno looks at a stadium in which two sets of chariots (the A's and the C's) are going to race in opposite directions to each other. Let us also include a set of fixed columns (the B's) at the center of the stadium, to serve as reference points. So the initial starting configuration is

$$\leftarrow A_1\, A_2\, A_3$$

$$B_1\, B_2\, B_3\ t = 0$$

$$C_1\, C_2\, C_3 \rightarrow .$$

Let us assume that the chariots (in groups A and C) move at a speed of one spatial unit (spun) per temporal unit (tun), or speed = 1 spun/turn. After one time unit has elapsed, the positions of the chariots will be as indicated in the picture below:

$$A_1\, A_2\, A_3$$

$$B_1\, B_2\, B_3\ t = 1$$

$$C_1\, C_2\, C_3.$$

The big question here is "*When* did A_2 pass C_1?" and there seems to be no meaningful answer to this question. There seems to be no *time* at which they can be said to have passed one another, because in the minimum time of 1 turn they have *jumped* to their current location, without having passed each other at any specifiable time! If another unit of time passes, the configuration will look like the following:

$$A_1\, A_2\, A_3$$

$$B_1\, B_2\, B_3\ t = 2$$

$$C_1\, C_2\, C_3.$$

Aristotle says about this part of the paradox that "half the time is equal to its double" (*Physics*

VI, 9: 239b). Presumably, this is based on the fact that in t = 1, C_1 has passed *two* A's, but only one B; it takes C_1 *two* units of time to pass two B's. Thus it seems that half the time (1 time unit) to pass two A's is equal to its double (two time units, which it takes to pass two B's). This would seem to be a serious misunderstanding of relative motion (in one case relative to fixed bodies, and in the other relative to bodies that are also moving), one that Zeno would not have committed. The crucial objection seems to be the first one—that there is no time at which C_1 can be said to have passed A_2, and yet at t = 1, C_1 is one spatial unit to the east of (to the right of) A_2. How could this have happened?

Perhaps what Zeno's paradoxes tell us, over 2 millennia later, is that we still do not have a logically adequate account of space and time.

ZODIAC

The zodiac denotes a cycle of 12 zones in a belt along the ecliptic, an apparent path on which the sun travels each year through a series of 12 astrological constellations. The path extends 9° on either side of the ecliptic that encompasses the paths of all planets of the solar system, except Pluto. Each astrological constellation is an arrangement or configuration of stars that make up the astrological signs occupying 1/12 or 30° of the great circle. These planetary constellations were first observed and defined by ancient scholars who determined the dates of each zodiacal sign based on the time in which the sun was visible in its corresponding constellation. This is commonly referred to as a sun sign.

The signs and their corresponding dates include Aries, the Ram (March 21–April 20); Taurus, the Bull (April 21–May 21), Gemini, the Twins (May 22–June 21), Cancer, the Crab (June 22–July 22), Leo, the Lion (July 23–August 23), Virgo, the Virgin (August 24–September 23), Libra, the Scales (September 24–October 23), Scorpio, the Scorpion (October 24–November 22), Sagittarius, the Archer (November 23–December 21), Capricorn, the Goat (December 22–January 20), Aquarius, the Water Bearer (January 21–February 19), and Pisces, the Fish (February 20–March 20).

The ancient Mesopotamians were the first to arrange the constellations into an astronomical map according to zodiacal divisions. Developed around 450 BCE, this arrangement is a numerical scheme or system that divides the ecliptic into 12 equal regions by astrological signs. Modern scholars also note that Babylonian cuneiform tablets with ancient zodiacal signs are dated back to 412 BCE. Some Greek sources also show that the ecliptic was discovered in the late 5th century BCE. The ancient science of astrology, or the reading of the constellations and predicting the effect such movement of celestial bodies would have on earthly affairs, quickly spread in popularity from Mesopotamia to the Arabic world and into India, Europe, and the Orient.

Many ancient societies believed that the first day of the year was the vernal equinox or first day of spring, which astronomers identify as March 20 or 21 in the northern hemisphere. This also marked the first day of the zodiacal calendar. People have long recognized that the sun passes through a given constellation each month, thus explaining the 12 zodiacal signs and their correspondence to the 12 months of the year. At birth, one is assigned a sign of the zodiac, based on the original "tropical zodiac" arrangement of constellations and the path of the sun as determined by the ancients. In astrology, the configuration of the stars at the time of birth determines one's fate in life.

By reading the zodiac, ancient astrologers would interpret daily occurrences and predict future events; astrology was thus the science of the ancients. Astrologers have made many predictions, prophesized the coming of great kings and the fall of great leaders. They foretold pandemics, plagues, and natural disasters and sometimes predicted peace and prosperity. Modern skeptics have observed that most of the astrologers' predictions have fallen short of fulfillment. One of the most prominent criticisms of the zodiacal system relates to the phenomenon called the "precession of the equinoxes." *Precession* refers to the earth's movement, rotation, and revolution over time. The earth's axis swings around in a circle in space, completing a circle about once every 26,000 years, while the sun, moon, and other celestial bodies orbit in the same band of sky. With the passage of time, the earth's wobbling orbit causes it to shift and to point to different parts of the sky. Henceforth, even the lengths of each season of the year vary and are adjusted through the usage of adding a calendar day; a year in which a calendar day is added is called a "leap year." Astrologers do not account for this precession of the equinoxes, even though it has disrupted the location of the zodiacal signs by roughly 3 calendar weeks.

The 12 astrological signs no longer relate to the astronomical constellations in which the sun actually appears. Modern astrologers continue to follow the traditional "tropical zodiac" dates, which follow the vernal equinox observed by the ancient astrologers, so the tropical zodiac now relates more to the time of year than to the relative position of the sun to the constellations. Most modern astrologers ignore the actual positions and relativity of the sun and celestial bodies. A small number of astrologers use a sidereal zodiac, which makes adjustments for the 3-week constellation shift. An Aries in sidereal zodiac is born between April 13 and May 13, whereas in the traditional zodiac the birth occurs between March 21 and April 20.

Zoroaster

Zoroaster (Zarathustra) was a prophet and religious figure in the ancient Persian territory now known as Iran. The exact dates of his life are widely debated among scholars. He is said to have lived anywhere between 1800 and 600 BCE. He founded Zoroastrianism, which was practiced widely in the Persian Empire and is still practiced today in the Parsi community of India. The major text of this religion is the *Avestas,* which consists of small groups of hymns or poems. The *Gathas* are said to be the oldest and most important of these groups, because they are thought to be written by Zoroaster himself. The basic teachings of these texts are that there is one Supreme Being and a cosmic struggle between good and evil spirits. He is considered to be the earliest philosopher to discuss individual morals and the basic principles of right and wrong. If Zoroaster truly lived in 1200 BCE or earlier, then he is the founder of the first religion based on revealed scripture.

What is known about the life of Zoroaster comes from a collection of historical documents, including the *Gathas*. Pliny the Younger writes of him 9 times in his *Natural History.* He was married 3 times and had three sons and three daughters. He started his ministry at the age of 30. The first converts to his religion were his wife, his children, and one of his cousins. He converted the King Vishtaspa, who helped to spread his religion throughout the Persian Empire. He died at the age of 77 fighting in a holy war.

By the age of 40, Zoroaster had seven revelations, each one devoted to one of the seven attributes of the Godhead; these attributes are God the Eternal Light, the Good Mind, Righteousness, Dominion, Piety, Well-Being, and Immortality. He believed that the Supreme Being was a spirit and could not be represented in an image. These are the cornerstones of his faith. Zoroaster believed that there was a constant struggle between good and evil. He preached that humans were free to choose between right and wrong and that these decisions would affect their afterlife. In his teachings, people are seen as weak against temptation, but strong virtue makes it possible to overcome evil. Evil is said to be a delusion and an unawareness of the existence of good. Atheism is considered a great sin against God because it influences others away from the truth of God's goodness. In the *Gathas,* Zoroaster identifies good and bad actions primarily on their consequences for humanity in general. In doing so, he defined a code of ethics in writing for the first time.

Zoroastrianism long predates Judaism, Christianity, and Islam, and the influences are clear in the similarities. Each of these religions speaks of a Creation in 6 days, humans driven from paradise, immortality of the soul, an omnipotent god, and a great flood. Some scholars believe that the Jewish Pharisees come from the word *Parsi* and that this sect was influenced by Zoroaster's followers in ancient Babylon. Zoroastrianism was the religion of the Magi, mentioned in the New Testament as having visited the baby Jesus in Bethlehem.

Zurvan

During the past 2,600 years, the Indo-Iranian religious traditions have diverged along a number of different paths. In various times and places—and in a number of languages—several major systems of mythology and theology emerged, though similar concepts and the use of a common pool of divine names reflect the historical connections between these traditions. *Zurvanism,* an offshoot (or heresy) of Zoroastrianism that focuses on the principal deity Zurvan (sometimes spelled Zervan), represents one interesting lineage of this religious family. In the Zurvanite worldview, Zurvan was the god of fate and boundless time, the hypostasis of time itself. As a result, this tradition has special interest in cosmogony, eschatology, and predestination.

The exact origin and chronological development of Zurvanism remains uncertain and is still the subject of considerable debate (e.g., the views of religious historian Robert Charles Zaehner). Some scholars explain this emphasis on Zurvan by pointing to external influences on Zoroastrianism, from Babylonian astrology or Greek philosophy, for example. Zurvanism cannot be associated with a particular temple, ritual, priesthood, or image. Few ancient texts discuss this tradition in a cogent or consistent manner, and many of the references to Zurvanite beliefs come from Christian, anti-Zoroastrian sources. Although its roots go back to Zoroastrian thought of Achaemenian times (by at least the 5th century BCE), the Zurvanite system rose to prominence only under the Sassanid rulers (224–651 CE). By that time, it seems that a circle of devotees adopted a monistic view and accepted Zurvan as the supreme deity and creator—in reaction to the more dualistic outlook of Zoroastrianism (as seen, e.g., in the cosmic conflict between Ahura Mazda and Angra Mainyu). Though interest in Zurvan declined in later medieval Zoroastrian sources, Zurvanite concepts influenced Mithraism, Manichaeism, and Mandaeism.

References to Zurvan in early Avestan and Pahlavi sources identify this god as uncreated and eternal. According to one medieval version of the Zurvanite cosmogonic myth, the creation required 10,000 years. After the first millennium, twins were born to Zurvan—Ahriman (Angra Mainyu) and Ohrmazd (Ahura Mazda), the cosmic adversaries of Zoroastrianism. Zurvan allowed the former to rule for 9,000 years, after which Ohrmazd assumed control. Meanwhile, these two spirits created the world as a battleground between good and evil, though Zurvan had predetermined history's ultimate outcome.

In the Zurvanite perspective, Zurvan was the lord of both limitless time (eternity) and the time of long dominion (finite time). Devotees held that Zurvan presided over history, from creation to the eschaton, but they also maintained that the great god existed prior to the beginning and after the termination of historical time.
